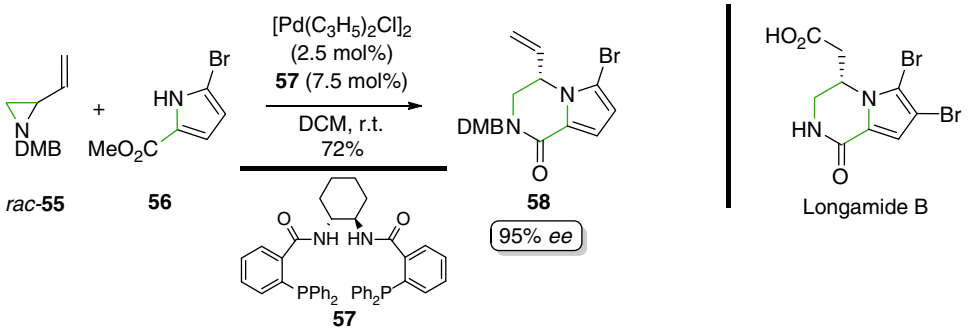
Interestingly, the C1-substituted derivative of **39** (C1 = Me) provides three products in the cycloaddition, which correspond to the cycloadduct having a methyl group at C4, C6, and C7 (3:20:77). Hence, this implies that the TMM intermediate is both highly fluxional and lacks chemoselectivity. However, in a related reaction involving nitrones as 1,3-dipoles, aryl TMM substitution leads to a highly stereoselective reaction with the aryl group proving critical to the stabilization of the TMM intermediate (**Scheme 10**). For example, the initial TMM complex **47**, generated from **46** with palladium(0), undergoes rapid isomerization to the more stable benzylic anion **48**, which affords **51** as the exclusive constitutional isomer (cf. **49** and **50**) with good diastero- (up to 8:1) and excellent enantioselectivity (up to 93% *ee*) with a chiral phosphoramidite.

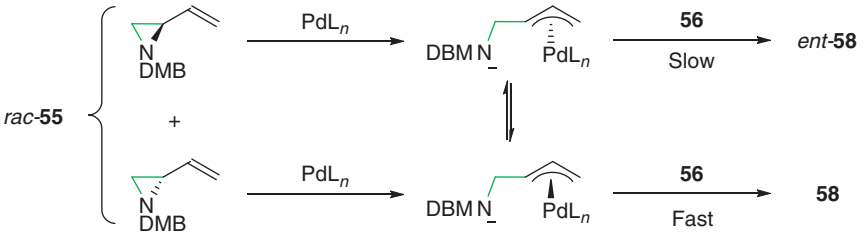
Scheme 10 Chemoselectivity for aryl substituted TMM complexes in the [3 + 3] cycloaddition.

A number of similar cycloadditions, which do not proceed through a TMM intermediate, afford [3 + 3] cycloadducts in a sequential palladium-catalyzed allylic alkylation/allylic etherification with *β*-diketones and *β*-ketoesters. Although the reaction affords related cycloadducts, this process is regarded as a Type I cycloaddition because it represents a donor–donor synthon reacting with an acceptor–acceptor synthon.[21]



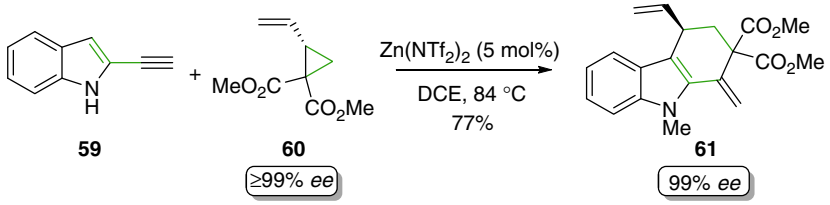
TMM derivatives can also be prepared in the absence of transition metals via the formation of a thermally promoted 1,3-dipole, which exists in rapid equilibrium with its neutral counterpart **52** (**Scheme 11**). These intermediates have also been utilized in [3 + 3] cycloadditions, however, a vital requirement is a strained MCP in conjunction with heteroatom stabilization.[22] The major drawback with the reaction is the formation of [3 + 2] cycloadducts as a result of the competitive cycloaddition of **52** with the carbonyl of the *β*-diketone/*β*-ketoester counterpart. The extent of the side reaction is primarily controlled by the ease of tautomerization of the *β*-diketone/*β*-ketoester to its enol form. Employing 3-methylpent-2,4-dione elegantly supported the intermediate ketene acetal, which has only one available proton for deprotonation. This prevents the *β*-diketone from tautomerizing to an enol, and subsequently prohibits the final cyclization step. It is noteworthy that this type of TMM is not a donor–acceptor synthon, as described for palladium TMM complexes, rather an acceptor–acceptor *α*,*β*-unsaturated carbonyl is developed *in situ*, making this a Type I process.[22]

Scheme 11 Thermally promoted formation of TMM.



5.14.2.1.5 1,3-Dipoles from three-membered rings

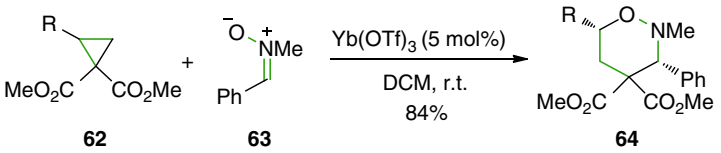
The asymmetric allylic alkylation reaction is an extremely useful reaction for the synthesis of a diverse range of structural motifs and has been the subject of intensive investigation. In this context, a variety of transition metals are able to ring-open vinyl oxiranes and aziridines with concomitant formation of a metal–allyl species, which can be formally envisioned as a 1,3-dipole. Hence, in the presence of an additional donor–acceptor, such as pyrrole **56**, the reaction has the potential to generate [3 + 3] cycloadducts in a highly controlled manner. This strategy was elegantly demonstrated by Trost and Dong in the concise enantioselective synthesis of longamide B (equation 6).[23]



(6)

The enantioselective construction of the pyrrolopiperazinone pharmacophore in this manner is particularly noteworthy given that the vinyl aziridine **55** is racemic (Scheme 12). Hence, the reaction involves a dynamic kinetic resolution, which relies on the rate of equilibration of the π-allyl-palladium intermediates via π–σ–π isomerization relative to the rate of nucleophilic attack leading to **58** and *ent*-**58**. This strategy allows a racemic aziridine to be directly employed, without the necessity for separation of the unreacted starting material, which is typically required in a classical kinetic resolution reaction.

Scheme 12 Dynamic kinetic asymmetric allylic alkylation.

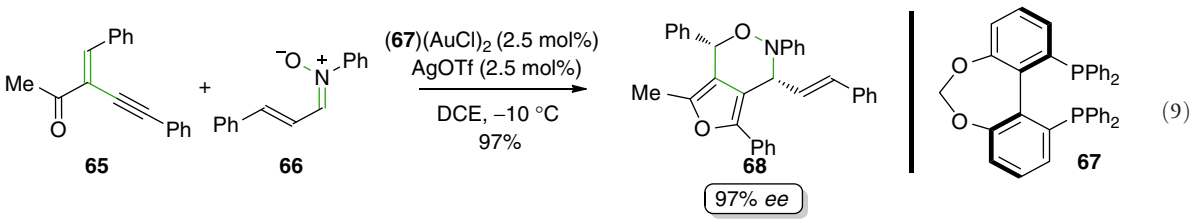


A number of [3 + 3] cycloadditions involve cyclopropane ring-opening as a precursor to 1,3-dipoles. To this end, one of the most common methods for ensuring the dipole lifetime is to utilize 1,1-cyclopropane diesters with Lewis acid catalysts to stabilize the developing anion in conjunction with a vicinal π-donor to assist the ring-opening. For example, vinyl and phenyl stabilizing groups provide a highly regioselective and efficient reaction, whereas less stabilizing groups lead to low regioselectivity because of competing steric and electronic factors. This type of three-carbon synthon behaves in a manner reminiscent of an α,β-unsaturated carbonyl compound, which undergoes Michael addition followed by enolate alkylation. In this regard, cyclopropane diesters have been widely developed by Johnson for [3 + 2] cycloaddition reactions,[24] and Kerr first utilized this concept in combination with three-carbon synthons in [3 + 3] cycloaddition reactions. Subsequent sections of this chapter will highlight cycloadditions between cyclopropanes and aza-ylides; however, in the context of other donor–acceptor groups, 2-alkynyl indoles have been utilized as three-carbon synthons and react via ring-opening of the cyclopropane followed by a Conia-ene cyclization of the malonate on to the alkyne.[25] The mechanism is thought to proceed in a stepwise manner with initial alkylation at the 3-position of the indole with the electron-deficient carbon of the cyclopropane followed by the coordination of the Lewis acid to the alkyne and subsequent Conia-ene cyclization. A critical component of the process is the ability for the metal complex to act as a Lewis acid for both the malonate and alkyne components. In this regard, $Zn(NTf_2)_2$ provides the optimal catalyst for this particular transformation (equation 7).

(7)

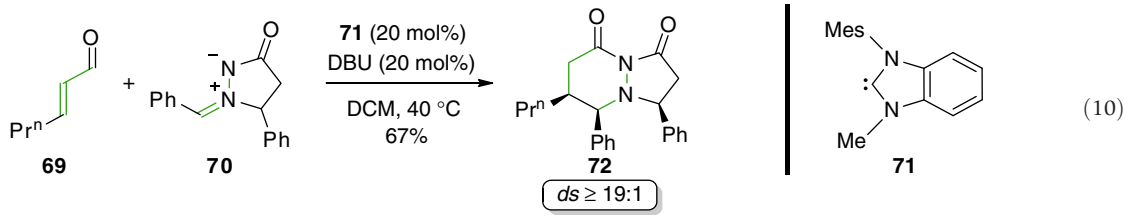
5.14.2.1.6 Y=N$^+$–X$^-$ 1,3-dipoles

Cyclopropanes also react with nitrones to generate a range of heterocycles with a nitrogen–oxygen bond. For instance, Kerr and Young reported the first example of this type of cycloaddition for the synthesis of tetrahydro-1,2-oxazines.[26] Although the exact reaction mechanism has not been determined, it is thought to be a concerted process, wherein the Lewis acid activates the cyclopropane for ring-opening by coordination to the malonate moiety. The mechanistic rationale is based on the fact that conventional stepwise S_N2 ring-opening followed by malonate addition to the iminium ion is more likely to provide lower diastereoselectivity with substituted cyclopropanes, albeit this cannot be ruled out. In these cases the formation of the tetrahydro-1,2-oxazine with α-oxy substitution is highly selective, favoring the formation of the *syn*-isomer **64** (R=Ph), which is the kinetic product (equation 8).



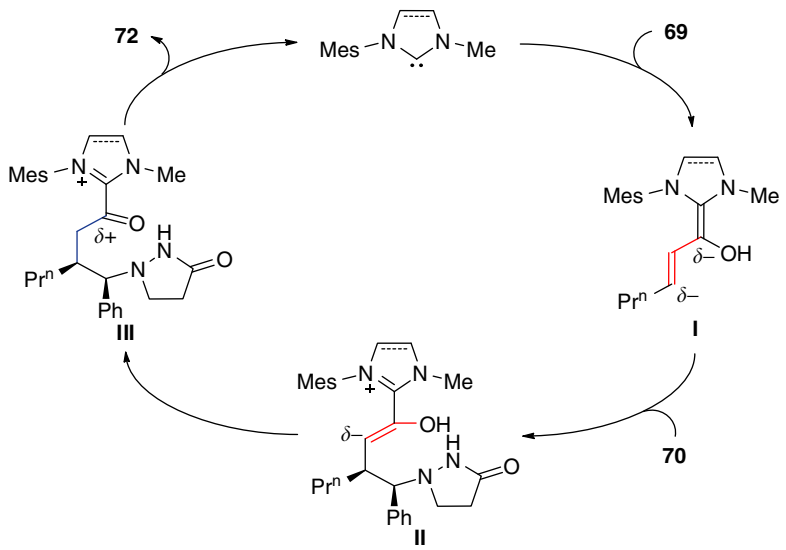
(8)

The rapid assembly of tetrahydro-1,2-oxazines is particularly attractive for medicinal chemistry, since this motif is present in a small class of antitumor and antibiotic natural products that provide challenging targets for conventional organic chemistry. Cleavage of the weak nitrogen–oxygen bond in tetrahydro-1,2-oxazines, by either hydrogenation or single-electron transfer reagents, provides a range 1,4-hydroxylamines. Moreover, *O*-mesylation of the resultant hydroxyamine promotes intramolecular amination to facilitate a stereocontrolled synthesis of substituted *anti*-2,5-pyrrolidines. This strategy was recently utilized in the total synthesis of nakadomarin A.[26b]



Asymmetric variants of this strategy have also been reported using chiral PyBox-derived nickel catalysts, which furnish the enantioenriched tetrahydro-1,2-oxazines with excellent selectivity.[27] For example, **64** (R=H) was generated under mild reaction conditions (DCM, r.t.) in 99% yield and with 92% enantiomeric excess. Although the reaction was initially limited to unsubstituted 1,1-cyclopropane diesters because the substituted systems provide poor diastereocontrol, Tang and coworkers improved the selectivity using a pseudo-C_3-symmetric triazoline ligand.[28] The diminished selectivity in the former case was attributed to a switch from a concerted to a stepwise process, which presumably allows the intermediate anion to freely rotate and thereby provide a mixture of stereoisomers.

2-(1-Alkynyl)-2-alken-1-ones have a rich history in the synthesis of furans and their small, but intrinsic complexity make them ideal candidates for elaboration into a range of functionalized polycycles. Many of these syntheses have relied on gold catalysts with nucleophiles to promote an intermolecular cyclization to afford a furanogold species, which concludes with the protonation of the carbon–gold bond. A recent [3+3] cycloaddition took advantage of this mechanism by employing nitrones, which initially provide a nucleophilic source in the formation of the furanogold species, and promotes addition onto the resultant iminium ion to generate the cycloadduct.[29] This transformation provided spectacular levels of enantioselectivity in excellent yield when the bisphosphine (*R*)-C_1-tunephos ligand **67** was employed; however, the level of selectivity is reliant on the number of aryl groups present in **65** and **66** (equation 9).

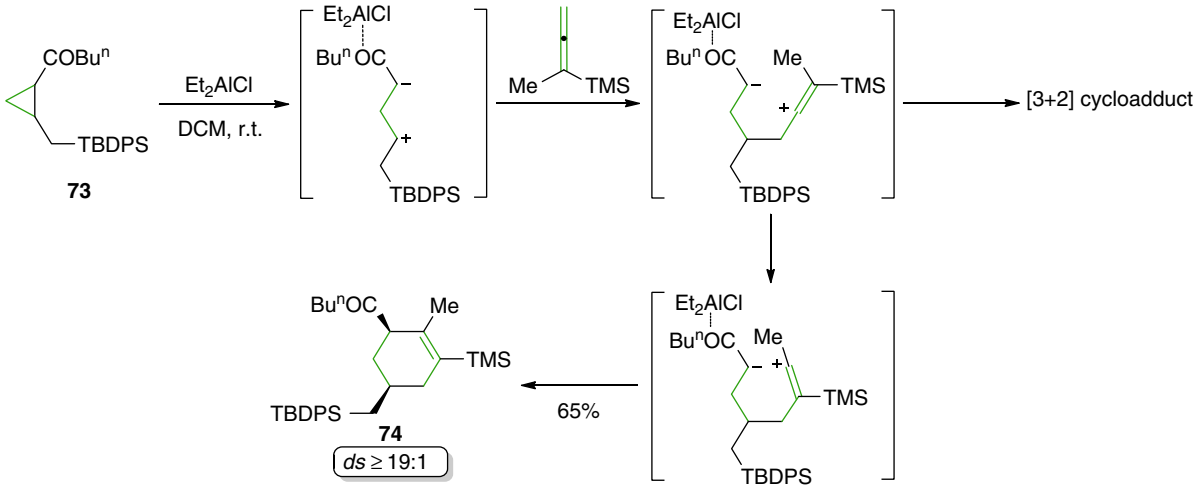


(9)

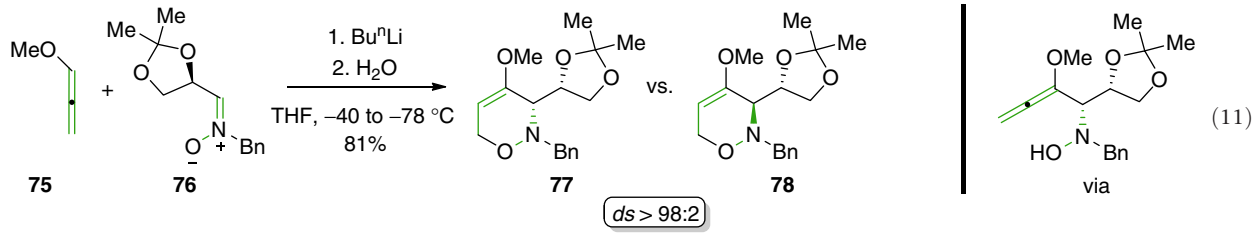
The advantages of organocatalysts in Michael addition-promoted Type I cycloadditions were outlined earlier; however, there are relatively few examples in the context of Type II [3+3] cycloaddition reactions. For example, the only 1,3-dipole system (Y=N$^+$–X$^-$) to utilize an organocatalyst was for the synthesis of pyridazinones, which relied on the capacity of *N*-heterocyclic carbenes (NHCs) to provide umpolung reactivity in the presence of α,β-unsaturated carbonyl compounds, albeit the reaction requires high catalyst loadings (equation 10).[30]

(10)

The mechanism of this transformation is intriguing, with the initial attack of the NHC onto the formally acceptor–acceptor α,β-unsaturated aldehyde **69** to afford the Breslow intermediate **I**, which switches the polarization (Scheme 13). Hence, the system becomes a donor–donor species, which as a consequence promotes nucleophilic attack onto the azomethine imine **70**. Proton transfer results in an acceptor at the same position, which leads to the desired pyridazinone **72** on elimination of the catalyst via nucleophilic acyl substitution. The ambiphilic nature of the α,β-unsaturated aldehyde functionality makes this transformation feasible, however, it can formally be represented as a donor–acceptor group.

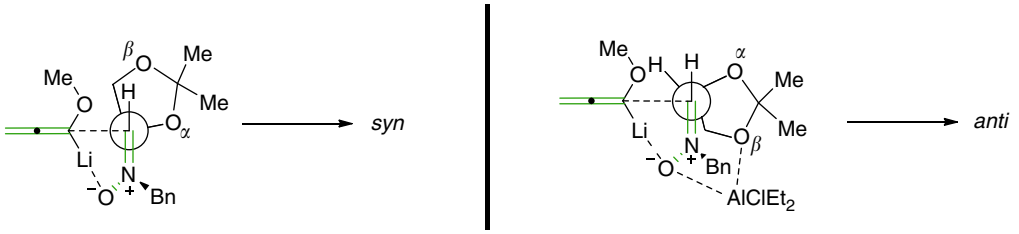


Scheme 13 Catalytic cycle for the NHC-catalyzed [3 + 3] cycloaddition reaction.



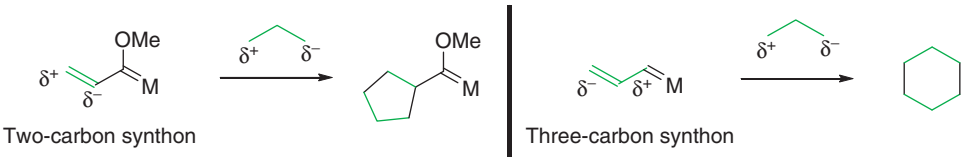
5.14.2.1.7 Allene/metal–carbene-promoted reactions

Allenes represent interesting intermediates in cycloaddition reactions because they display varied reactivity depending on a number of factors, which include allene substitution and the metal. Furthermore, because allenes can provide two- and three-carbon synthons, the ability to predict the outcome of a given transformation is often challenging. This is amply demonstrated with silylallenes and activated cyclopropanes where the silicon stabilizes the developing β-carbocations in both components. For example, cyclopropane **73**, which bears only one electron-withdrawing group, generates the acyclic dipolar intermediate in the presence of a Lewis acid, which is additionally stabilized by the silicon group *beta* to the newly formed carbocation. Nucleophilic addition of the allene generates a vinyl cation, which in some examples led to 1,2-silyl migration, followed by nucleophilic attack of the enolate to afford the [3 + 3] cycloadduct **74** (Scheme 14).[31] The reaction affords highly complex cyclohexene products with excellent diastereoselectivity; however, the inability to control the formation of [3 + 2] cycloadducts significantly detracts from the generality of this important transformation. The propensity for allenes to provide multiple synthetic equivalents has also reduced the synthetic utility of a number of recent phosphine-catalyzed [3 + 3] cycloadditions. These reactions, which employ azomethine imines with allenic esters, provide products resulting from the allene behaving as a two-, three-, and four-carbon synthon in [3 + 2], [3 + 3], [4 + 3] and [3 + 3 + 2] cycloaddition reactions, respectively.[32] Interestingly, the [3 + 3 + 2] cycloaddition represents the first example of this type and utilizes two equivalents of the allene ethyl buta-2,3-dienoate as a two- and three-carbon synthon.

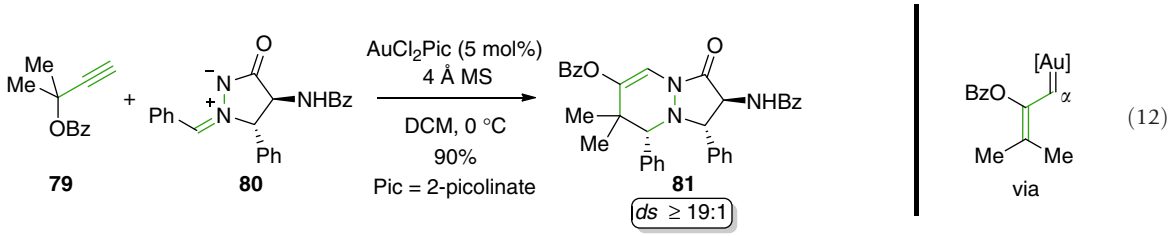


In 2005, Reißig and coworkers reported the stereodivergent synthesis of 1,2-oxazines from simple nitrones with lithiated allenes. Treatment of the methoxy-substituted allene **75** with *n*-butyllithium affords the metallated species that reacts with the nitrone to afford an acyclic allenyl hydroxylamine intermediate. This then undergoes a spontaneous and highly selective *O*-6-*endo* trig cyclization over the competing *N*-5-*endo* trig cyclization, to afford the 1,2-oxazine **77** in 81% yield with excellent diastereocontrol favoring the *syn*-product (equation 11).[33]

Scheme 14 [3 + 3] Cycloaddition reaction of allenes with cyclopropanes.



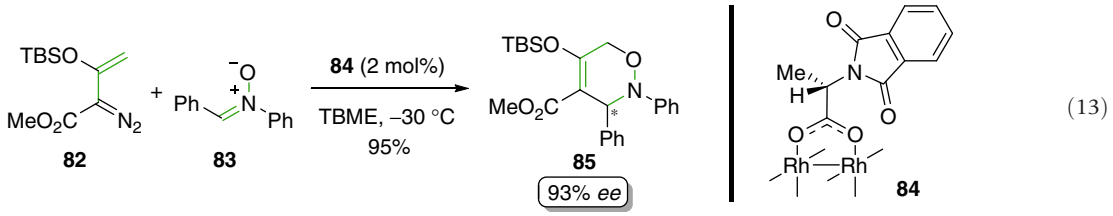
Scheme 15 outlines the origin of the excellent diasterocontrol in the addition, which utilizes the Felkin–Anh model for nucleophilic additions to C=X bonds. In a similar manner to related reactions, the Lewis acid promotes the formation of the *anti*-product via a chelate controlled addition. For example, precomplexation of Et_2AlCl to the nitrone, followed by addition of the allenyl lithium afforded the *anti*-diastereoisomer **78** in 77% yield with >98:2 diastereoselectivity.



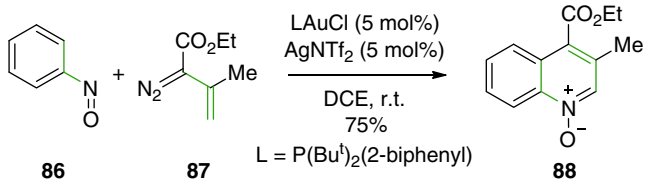
Scheme 15 Rationalization for the observed stereocontrol for nucleophilic addition.

Alkenyl Fischer carbenes provide useful two-carbon synthons for the formation of metal containing [3 + 2] cycloadducts. The metal facilitates the transformation by polarizing the alkene component, in which the alkene terminus is inherently electrophilic and the internal portion is nucleophilic (Scheme 16). Toste et al. recently reported the extension of this concept to vinyl metal-alkylidenes, which provide three-carbon synthons in what are formally stable vinyl carbene equivalents.[34] A critical limitation with this process is the necessity to generate the vinyl metal-alkylidenes from the decomposition of the requisite diazo compound. Since diazo species, particularly alkyldiazo compounds, are notoriously explosive, they generally require additional stabilization from α-carbonyl compounds.

In contrast, the gold(III)-catalyzed process provides the required vinyl metal-alkylidene from propargylic esters, which not only eliminate the necessity for a diazo precursor but also provide the reactive intermediate with high atom economy. The propargylic ester **79** reacts with the azomethine imine **80** to furnish the six-membered adduct **81** in excellent yield and diastereoselectivity (equation 12). The reaction proceeds in a stepwise manner with initial formation of the carbene via rearrangement of the propargylic ester **79**, followed by nucleophilic attack at the α-position by the azomethine imine **80** to generate a allylgold species, which on cyclization eliminates the gold catalyst to afford the pyrazolidinone **81**. Although the α-nitrogen stereogenic center primarily controls the selectivity, the level of distereocontrol was optimal for disubstituted azomethine imines, as exemplified by **80**.



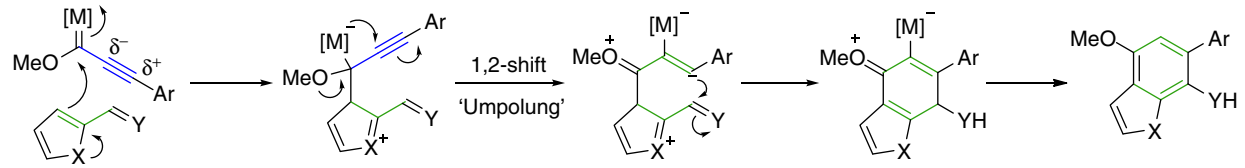
Scheme 16 Synthetic equivalents of vinyl carbenoids.



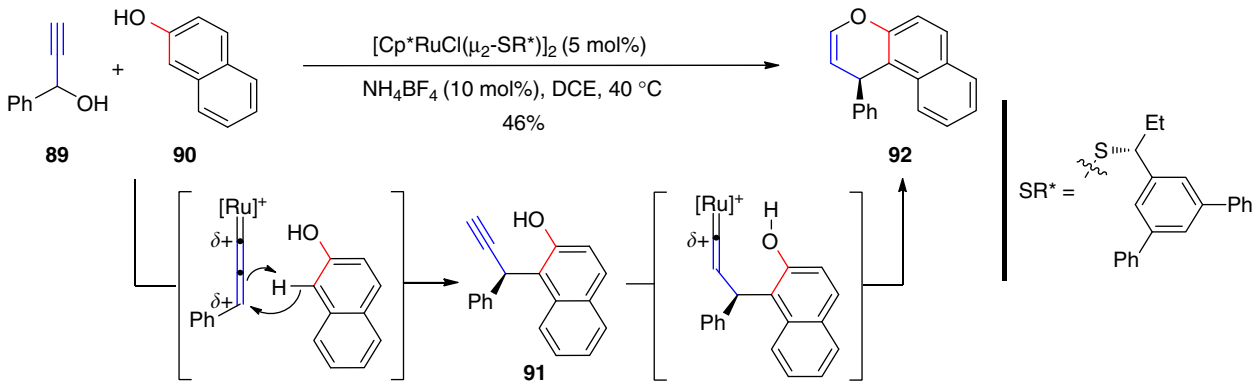
(12)

The asymmetric rhodium-catalyzed reaction, which employs the corresponding diazo precursors, generates the requisite cycloadducts with excellent enantioselectivity. For example, treatment of the diazo ester **82** with the nitrone **83** using the chiral dirhodium carboxylate catalyst **84**, furnished the 1,2-oxazine **85** in 95% yield and with 93% enantiomeric excess (equation 13).[35]

(13)



Despite the aforementioned advantages of employing propargylic esters as vinyl gold-alkylidene equivalents, they often lead to unwanted metathesis/[4 + 2] cascade byproducts rather than the anticipated [3 + 3] cycloaddition. For example, when Liu and coworkers explored the reaction of **79** with nitrobenzene **86** in the presence of a gold(I) catalyst (cf. equation 12), none of the desired cycloadduct was obtained. Nevertheless, the corresponding alkenyldiazoacetate **87** in the presence of rhodium(II), copper(I) or gold(I) promotes the desired [3 + 3] cycloaddition to afford **88**, in which the gold(I) catalyst proved optimal (equation 14).[36] The mechanism is proposed to proceed via initial carbene formation followed by *N*-attack on the terminal alkene of the carbene with concomitant 6π-electrocyclization to provide, on protodemetallation, the quinoline *N*-oxide **88**.

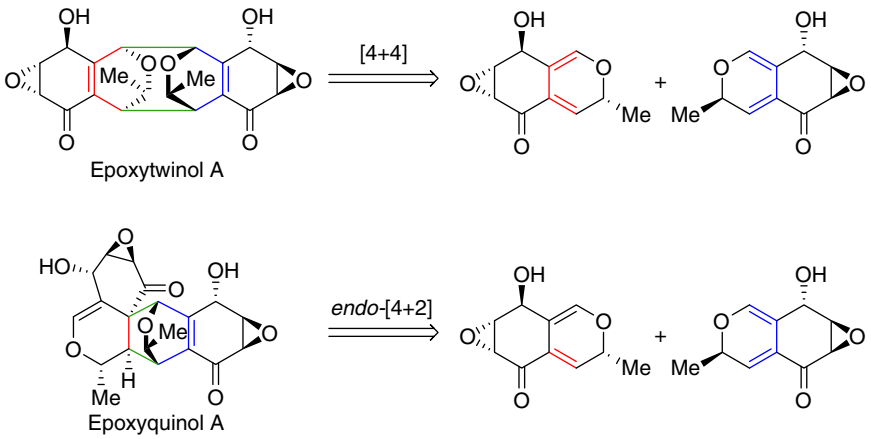


(14)

Notwithstanding the numerous examples of alkenyl and alkynyl Fischer carbenes behaving as two-carbon synthons in cycloaddition reactions (Scheme 16), an unusual 1,2-shift of an intermediate carbene provided a new approach to [3 + 3] cycloaddition reactions, thus permitting Fischer carbenes to provide three-carbon synthons (Scheme 17). The neutral coupling partner attacks the α-position of the carbene to generate a charged metal intermediate, which promotes the 1,2-migration to furnish a nucleophilic vinyl carbanion.[37] The intermediary carbanion undergoes a 6-*exo* cyclization to afford the six-membered zwitterion, which is followed by proton transfer, reductive elimination and tautomerization to furnish the aromatic product. Although the products of these reactions are purely organic cycloadducts, it requires a stoichiometric transition metal, which negatively impacts its synthetic utility for preparing these types of systems.

In a related manner to the gold cyclization of propargylic esters, propargylic alcohols undergo rearrangement in the presence of a chiral ruthenium complex to afford a ruthenium–allenylidene intermediate (Scheme 18).[38] This three-carbon acceptor–acceptor species, derived from **89**, undergoes dynamic kinetic resolution in the alkylation with 2-naphthol to afford the enantiomerically enriched acyclic intermediate **91**, which is an isolable intermediate. Cyclization of the propargylated adduct **91** via the ruthenium–vinylidene provides the enantioenriched cycloadduct **92** in 46% yield and with 72% enantiomeric excess. The reaction affords modest enantioselectivity in most cases; however, the yields are generally poor because of **91** failing to generate the ruthenium–vinylidene species.

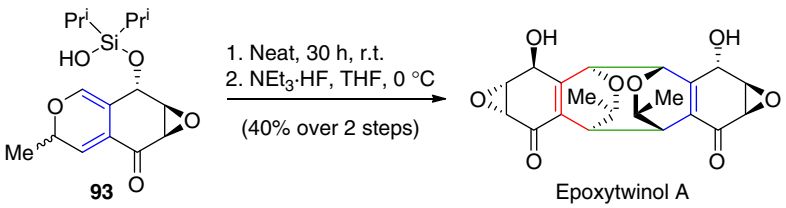
Scheme 17 Fischer carbenes as three-carbon synthons via a 1,2-shift.



Scheme 18 Sequential ruthenium allenylidene and vinylidene cyclizations.

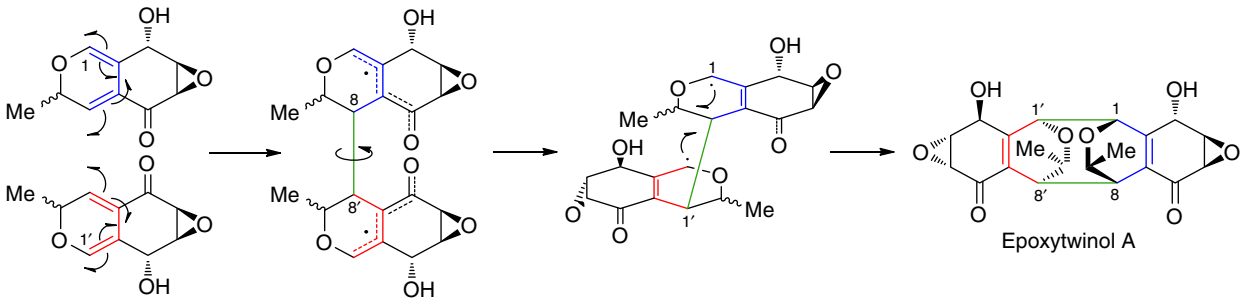
5.14.2.2 ['4 + 4'] Cycloadditions

The construction of eight-membered rings using ['4 + 4'] cycloadditions provides an important strategy, which has prompted the development of an array of synthetic methodology. Furthermore, the ability to affect a transannular cyclization of aliphatic cyclooctanes to provide bicyclo[3.3.0]octane adducts in a stereoselective manner provides an additional incentive for the development of this cycloaddition reaction. This section describes recent advances in thermal and metal-catalyzed ['4 + 4'] cycloaddition reactions; however, light-promoted photochemical cycloaddition reactions are discussed in Chapters 5.04 and 5.15.[1a,39] The color employed in this section provides clarity in distinguishing between the two four-carbon synthons and is not an indication on the electronic parameters of each fragment.



5.14.2.2.1 Thermal-promoted reactions

The thermal [4 + 4] cycloaddition reaction is relatively unexplored, which is presumably because of the fact that these cycloadditions are disfavored according to the Woodward–Hoffmann rules. In this context, a significant portion of the developments in this area have focused on the total synthesis of epoxytwinol A, because a formal [4 + 4] dimerization is the proposed biosynthetic pathway (Scheme 19).[40] Indeed, this represents the only natural product prepared in Nature via a [4 + 4] cycloaddition pathway, which coexists in the same fungus with [4 + 2] dimers, namely epoxyquinol A–C. Although structurally intriguing from a biosynthetic standpoint, epoxytwinol A is also an important biological agent since it exhibits potent antiangiogenic activity.



Scheme 19 Proposed retro-biosynthesis of epoxytwinol A and epoxyquinol A.

Despite extensive effort to optimize this process, the dimerization of the monomeric species is inefficient because of the competing [4 + 2] pathway and as a result the [4 + 4] adduct was obtained in only 8% yield.[40] Porco and Li recently improved the overall efficiency of this process, through a subtle modification to the monomer to disfavor the [4 + 2] pathway and thus promote the formation of epoxytwinol A.[41] In this context, they discovered that although protected hydroxyl groups, such as *tert*-butyldimethylsilyl ethers, are resistant to thermal [4 + 2] and [4 + 4] cyclizations, the unprotected monomer dimerizes during purification on silica gel (hexane/ethyl acetate). This prompted the utilization of diorganosilanol protecting groups, which favor the formation of the [4 + 4] cycloadduct in an improved 40% yield after removal of the protecting groups (equation 15).

(15)

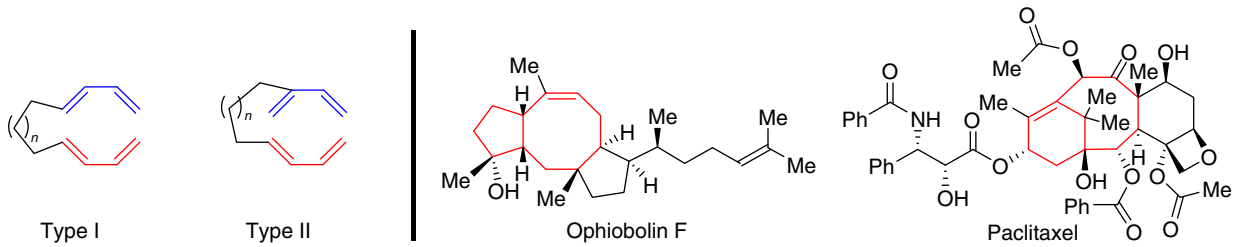
The facile rearrangement of epoxytwinol A to the epoxyquinols, in the absence of light, provides an additional challenge for the isolation. In addition, computational studies indicate that the dimerization is a stepwise process, which occurs through a biradical intermediate that is formed from the homolytic cleavage at C1 and C1′ (Scheme 20).[42] Subsequent rotation around C8–C8′ and recombination of the diradical furnishes epoxytwinol A. Hence, the total synthesis using the silanol protecting groups to promote free rotation between C8–C8′ eliminates the competing [4 + 2] pathways and supports the theoretical analysis. The thermodynamic formation of the epoxyquinols via rearrangement of epoxytwinol A was also supported computationally, which indicates that the [4 + 4] adduct is 6.0 kcal mol^{-1} higher in energy.

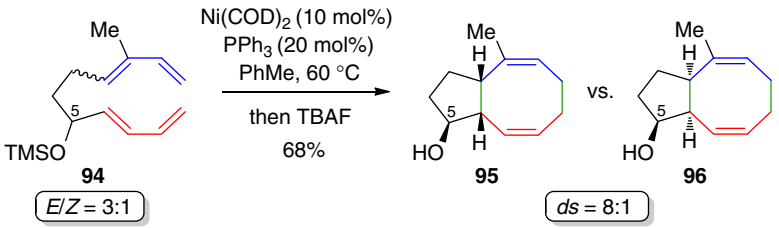
Scheme 20 Stepwise biradical mechanism for the synthesis of epoxytwinol A.

5.14.2.2.2 Metal-catalyzed reactions

Transition metal-catalyzed cycloaddition reactions continue to play an important role in the formation of polycyclic systems. In contrast to thermally promoted [4 + 4] reactions, the metal-catalyzed variants are not classified as pericyclic reactions and thereby are not rationalized by the aforementioned Woodward–Hoffmann rules as being disfavored. It is therefore unsurprising that the majority of work on ['4 + 4'] cycloaddition reactions have involved transition-metal catalysis. Inspired by the nickel-catalyzed oligomerization of dienes, Wender and coworkers explored the effect of intramolecularity to suppress the former process and promote the intramolecular [(4 + 4)] reactions of bis-dienes. In this context, intramolecularity provides the ability to control diene concentration and thereby promote a highly controlled process with an array of functionality that would otherwise not be possible in the intermolecular variant. Figure 3 depicts different types of intramolecular [(4 + 4)] cycloaddition reactions, which afford bicyclo[6.*m*.0] and [5.*m*.1] systems that are present in a number of biologically important natural products.

In a continued effort toward the synthesis of eight-membered polycycles, Wender has reported both types of [(4 + 4)] cycloadditions. For example, the Type I cyclization of the bis-diene **94** affords **95**/**96** in 68% yield with modest selectivity, where the C5 group dictates the facial selectivity of the reaction (equation 16).[43] Although the conversion of **95** to ophiobolin F was unsuccessful, the rapid formation of **94** and its expeditious conversion to the highly functionalized core of the natural product is noteworthy. In addition, efforts to improve the yield and selectivity, by exploring the effect of alkene geometry indicates that each isomer of the bis-diene affords a similar outcome.





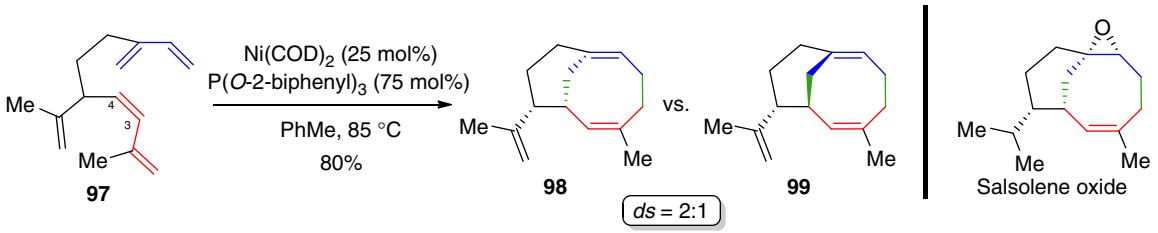


Figure 3 Various types of bis-diene [(4 + 4)] cycloaddition reactions and representative natural products that could be synthesized via these processes.

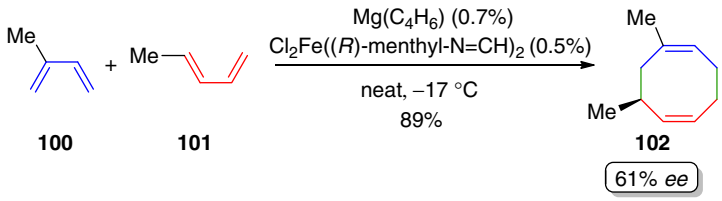
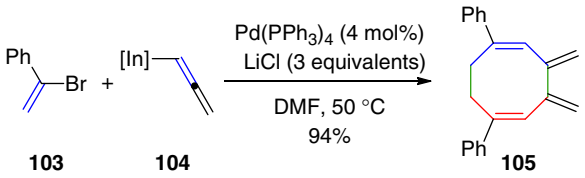


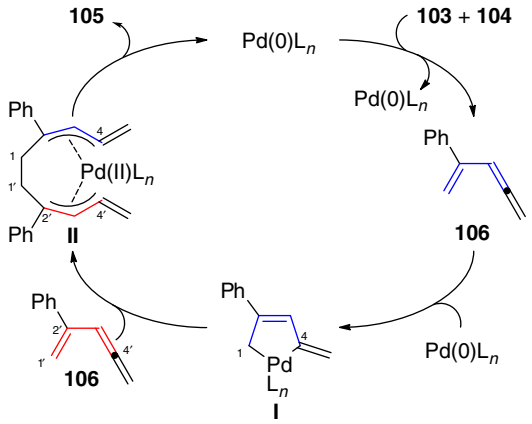
(16)

In contrast, the Type II cyclization is dependent on alkene geometry as exemplified in the concise total synthesis of salsolene oxide (equation 17).[44] For instance, the cyclization of bis-diene **97**, which has a *Z*-olefin at C3/C4, affords the bicyclo[5.3.1]undecanes **98**/**99** in excellent yield albeit with poor diastereocontrol, whereas the corresponding *E*-isomer afforded none of the desired cycloadducts. Despite the lack of reactivity of the *E*-isomer, it readily undergoes photoequilibration to a mixture of *E*/*Z*-isomers, which permits the recycling of the unreactive isomer.



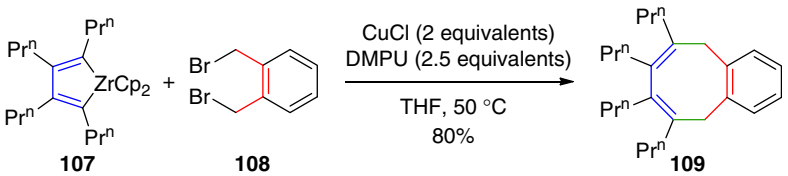
(17)

Notwithstanding the success of the intramolecular nickel-catalyzed [(4 + 4)] cycloaddition, the corresponding intermolecular reaction has received significantly less attention. Moreover, the intramolecular reaction is generally limited to diastereoselective reactions, which utilize preformed stereogenic centers to communicate stereochemical information. In contrast, the intermolecular iron-catalyzed [4 + 4] cycloaddition of **100** and **101**, using a chiral iron-complex, affords 1,5-cyclooctadiene **102** with moderate enantioselectivity (equation 18).[45] The reaction is highly selective for the formation of **102** despite the possibility of constitutional isomers and potential dimerization products. Although the reaction proceeds efficiently with a low catalyst loading using a cheap and nontoxic transition metal, it has not been further developed.



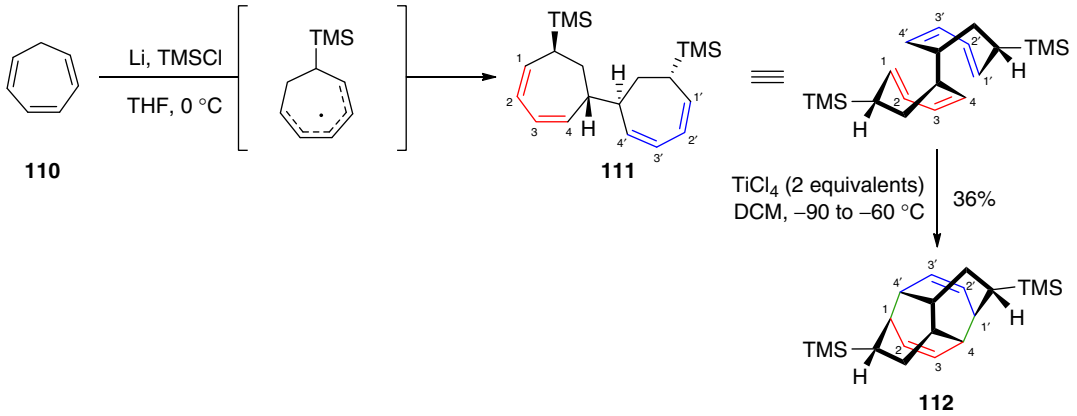
(18)

Vinyl allenes also provide four-carbon synthons for palladium-catalyzed [4 + 4] cycloadditions.[46] For instance, Lee and coworkers demonstrated that vinyl allenes can be generated *in situ* through a palladium-catalyzed cross-coupling of α-bromo styrene and allenyl indium (equation 19).[47] The one-pot sequential coupling/[4 + 4] cycloaddition generates the eight-membered adduct **105** in excellent yield favoring the head-to-head rather than the head-to-tail cycloadduct, in addition to providing competing [4 + 2] cycloadducts that are generated from sterically encumbered allenes (not depicted for clarity).



(19)

Scheme 21 highlights the proposed catalytic cycle for this process. Initial cross-coupling of **103** and **104**, via oxidative addition of palladium into the α-bromo styrene followed by transmetallation and reductive elimination, affords the vinyl allene **106** and regenerates the active palladium(0) catalyst. Oxidative addition of the metal into **106** affords palladacyclopentene **I** in a similar fashion to the corresponding isolable rhodium and platinum intermediates.[48] Subsequent chemo- and regioselective insertion at the internal double bond of a second allene into the generally less favorable alkyl–palladium bond (C1–Pd) furnishes the bis-allyl palladium complex **II** which undergoes reductive elimination between C4 and C4′ to provide the [4 + 4] adduct **105**. The existence of intermediate **II** also rationalizes the formation of the [4 + 2] cycloadduct, which arises via reductive elimination between C4 and C2′. Despite efforts to increase the synthetic potential of this multicomponent reaction, including manipulation of the exocyclic olefins in a sequential Diels–Alder reaction, the products are limited to aryl and silyl groups at C2 (and C2′).[47]

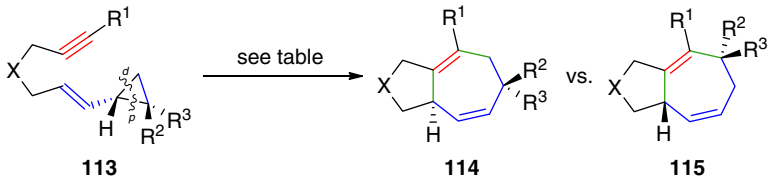


Scheme 21 Catalytic cycle for the palladium-catalyzed [4 + 4] dimerization of vinyl allenes.

The combination of bis-electrophiles with bis-nucleophiles also provides a convenient approach to eight-membered cycloadducts. Moreover, this process provides almost unlimited versatility given that the number of atoms linking each component defines the type of cycloaddition. For example, nucleophile **107** and electrophile **108** behave as four-carbon synthons and provide the desired [4 + 4] product in 80% yield (equation 20), whereas 1,8-bis(bromomethyl)naphthalene provides a five-carbon electrophile for the [5 + 4] cycloaddition with **107**.[49] The reaction proceeds via a sequential transmetallation/nucleophilic substitution reaction of the zirconium species with copper(I) chloride, in which catalytic copper can be utilized in the absence of *N*,*N*′-dimethyl-*N*,*N*′-trimethyleneurea (DMPU), albeit extended reaction times and a reduction in yield is usually observed.

(20)

Santelli et al. recently reported the titanium-mediated intramolecular [(4 + 4)] cycloaddition of 1,3-cycloheptadienes to generate the highly intriguing cage structure **112** from bis-cycloheptadiene **111**, which in turn can be constructed from the dimerization of the radical anion derived from cycloheptatriene (**110**) (Scheme 22).[50] The structure of the cycloadduct **112** was confirmed by X-ray diffraction, which provided additional physical information on the nature of the cage structure. Interestingly, the longest carbon–carbon bonds in the molecule were the newly formed C1–C4′ and C1′–C4, which highlights the inherent strain and rigidity within the molecule. Although the role of stoichiometric titanium is unclear but vital for this process, it is proposed to most likely serve as a one-electron oxidant.



Scheme 22 Formation of cage structures via a [(4 + 4)] cycloaddition.

5.14.2.3 ['5 + 2'] Cycloadditions

The ['5 + 2'] cycloaddition has been widely utilized in the synthesis of seven-membered rings. The following section will mainly focus on the transition metal-catalyzed [5 + 2] cycloaddition of vinylcyclopropanes (VCPs), which act as five-carbon synthons. Several photochemical cycloadditions of this nature, including arene/alkene cycloadditions, are described in Chapters 5.04 and 5.15. In addition, the thermal rearrangement of VCPs is outlined in Chapter 5.22.

Since the discovery of the transition metal-catalyzed [(5 + 2)] reaction by Wender and coworkers in 1995,[51] this process has been the focal point of extensive investigation. The transition metal-catalyzed process circumvents many of the limitations associated with the thermal rearrangement of VCPs by reducing the activation barriers. The exponential growth of this reaction has led to the introduction of several transition metals to catalyze the formation of seven-membered rings, which include rhodium, ruthenium, iron and nickel. Despite the extensive research on rhodium as the catalytic species, ruthenium and iron provide important alternatives, albeit in most cases less general and certainly less well explored relative to rhodium.[52]

The intramolecular [(5 + 2)] reaction of VCP **113** bearing a tethered alkyne provides entry to highly functionalized bicyclo[5.3.0] adducts **114**/**115** in an atom-economical transformation (equation 21). Preliminary reaction conditions provided proof-of-concept for this challenging cycloaddition and required cationic Wilkinson's catalyst in toluene at 110 °C (**Table 2**, entries 1–3). In addition, the cycloadditions tolerate several substituents at R^1 to provide the corresponding cycloadducts in excellent yield.

(21)

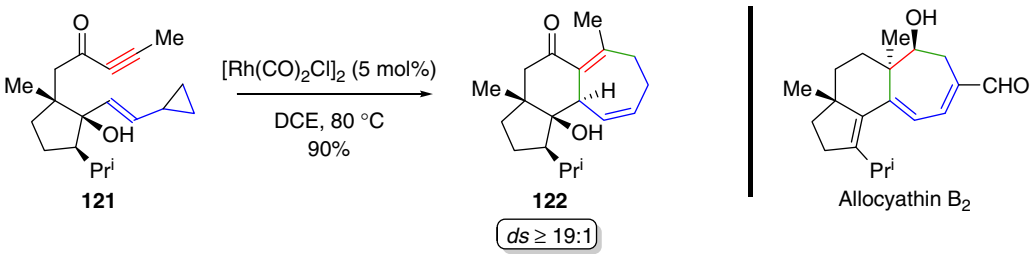
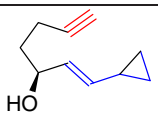
Employing substituted cyclopropane derivatives is particularly challenging for these systems because the breaking of the cyclopropane ring can occur distal or proximal to the substituent (R^2/R^3). Although mechanistically more demanding, these systems provide additional functionality in the cycloadducts and stereodefined enantioenriched cyclopropanes have the potential to generate optically active products with high diastereoselectivity. In this regard, the original cationic rhodium conditions proved fruitful for this system with *anti*-substituted cyclopropanes. For example, **113** ($X=C(CO_2Me)_2$, $R^1=Me$, $R^2=CH_2OH$, $R^3=H$) furnished **114** as a single diastereoisomer in which the configuration of the cyclopropane is translated to the cycloadduct via the breaking of the distal bond (entry 4).[53] In contrast, the corresponding neutral complex, $[Rh(CO)_2Cl]_2$, because of the inner-sphere chloride counterion, furnished the same cycloadducts with poor selectivity (entry 5). Nevertheless, this system does provide advantages over the cationic complex. For instance, when R^2 is electron-withdrawing, as in **113e** (entry 6), the cycloadduct is generated via the breaking of the proximal bond. A possible explanation for the reversal in bond breaking may be attributed to the stabilization of negative charge by the electron-withdrawing group in a similar manner to 1,3-dipoles (cf. Scheme 14). Moreover, this system is far superior to others, including a ruthenium-based catalytic system, which provides poor selectivity for this cycloadduct (entry 7).[54] However, the ruthenium system is highly dependent on the stereochemistry of the cyclopropane, in which the corresponding *syn*-substituted cyclopropane afforded **114** as a single isomer in excellent yield (entry 8), whereas rhodium afforded modest diastereocontrol (entry 9). It is also noteworthy that the ruthenium catalytic system permits the reaction at room temperature.

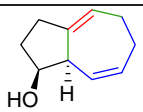
The discovery of a more effective rhodium catalyst improves the synthetic potential of this class of reactions by facilitating these transformations under milder conditions in an analogous manner to the aforementioned ruthenium catalyst. In addition, this enables the more challenging applications, namely, cycloadditions of more demanding alkene- and allene-tethered VCPs (*vide infra*). In 2002, Wender and Williams isolated the cationic rhodium complex $[(Np)Rh(COD)]SbF_6$ (Np = naphthyl), which furnished the cycloadducts with superior results relative to other rhodium systems and has considerable stability to air and moisture.[55] For example, **113c** was converted to the desired cycloadduct in 96% yield in about 16 minutes at room temperature using only 2 mol% of this catalyst (cf. entry 3).

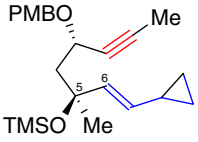


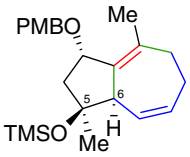
In 2004, Evans and coworkers reported the first metal-catalyzed ['$m+n+o$'] cycloaddition (*vide infra*) using a rhodium–NHC-catalyst.[56] Interestingly, this catalyst was applied to the [(5 + 2)] cycloaddition and provided analogous results to Wender's catalyst.[57] Despite several efforts to develop an asymmetric version, the only general catalytic system to afford high levels of asymmetric induction utilizes rhodium–phosphoramidite complexes (equation 22).[58] For example, the cycloadduct **118** was generated in high yield and with excellent enantioselectivity using the chiral ligand **117**, in which the combination of the chirality in the binaphthyl and amine components are crucial for asymmetric induction.

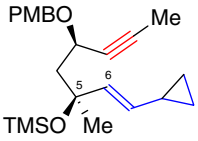
(22)

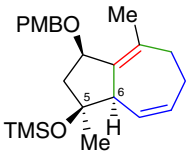


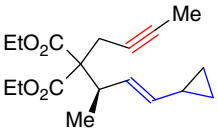


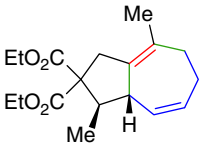












Although Wender and Trost have independently examined substituted cyclopropanes in diastereoselective [5 + 2] reactions, substituted 1,6-enynes have received significantly less attention. In this regard, ruthenium complexes are excellent catalysts, providing excellent diastereocontrol with a series of secondary and ternary allylic alcohols (Table 3).

The stereoinduction for the unprotected and trimethylsilyl-protected hydroxyls is remarkable, particularly the tertiary derivatives, because the ability to distinguish between a methyl and hydroxyl group is very challenging. In addition, the diastereoselectivity is controlled solely by the allylic stereochemistry (vs. proparglic), for example, **119b** and **119c** furnish **120b** and **120c**, respectively, which have the same relative configuration at C5/C6. Moreover, the stereoselectivity cannot be rationalized by invoking a steric repulsion model for the approaching metal, which prompted the authors to propose an 'inside alkoxy' model to provide a plausible rationale for the stereoinduction, in which the σ^*_{CO} orbital is aligned orthogonal to the alkene to minimize overlap with the alkene π-orbital.[54b] In contrast, the rhodium-catalyzed cycloaddition of **121**, in which the 1,6-enyne component is tethered via a fused five-membered ring, provides the cycloadduct **122** with the opposite stereochemistry (equation 23). The stereoselective synthesis of **122** provided a key step in the asymmetric synthesis of the tricyclic core of (+)-allocyathin B_2.[59]

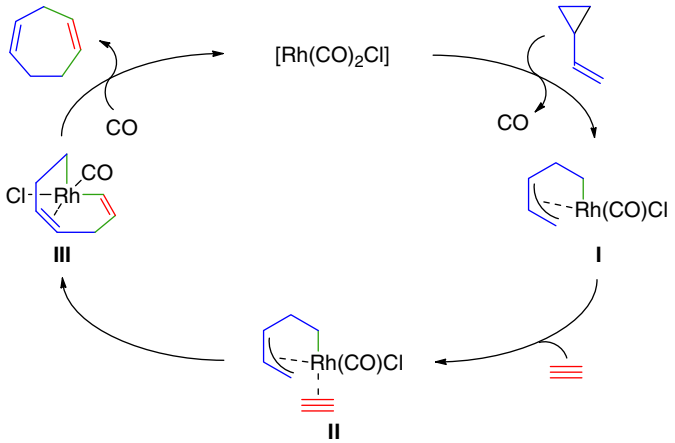
[a]Combined yield of cycloadduct and desilylated cycloadduct.

Interestingly, iron also catalyzes this type of transformation, which provides great advantages over ruthenium and rhodium catalysts, because iron is cheap, nontoxic, and abundant compared to the others. The iron-catalyzed [5 + 2] reaction was reported in 2008 by Fürstner and coworkers and affords good levels of stereoselectivity in excellent yield for a range of substituted VCPs.[60] Although the reaction provides inferior results compared to the rhodium and ruthenium systems with respect to the reaction conditions, catalyst loading, and so on, the ability to utilize iron in this type of transformation is significant and has far-reaching implications for the development of this field.

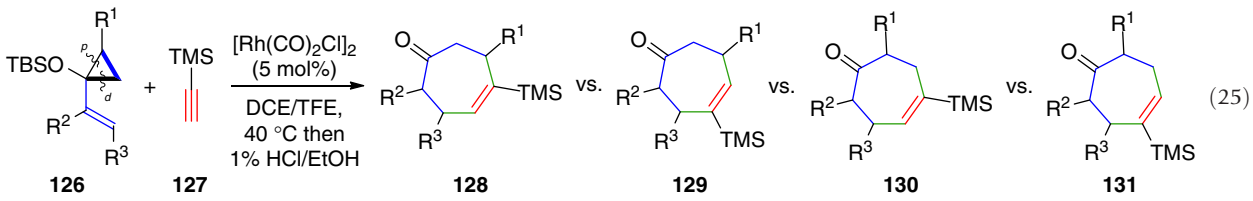
Wender and coworkers also developed the intermolecular rhodium-catalyzed [5 + 2] cycloaddition. Extensive studies identified the methoxyethyl substituted VCP as the optimal precursor, which is readily prepared on a preparative scale and facilitates mild cleavage of the resulting enol ether to the cycloheptanone upon hydrolytic work-up.[61] Moreover, the cationic complex $[(Np)Rh(COD)]SbF_6$ provided an ideal precatalyst, which allowed for very low loadings to be employed at room temperature (0.5 mol%), affording a library of cycloadducts in excellent yield (equation 24).

123 **124** **125**



R^1 = alkyl, aryl, EWG, silyl
R^2 = H, alkyl

(24)



Two plausible mechanisms for the intra- and intermolecular rhodium-catalyzed ['5 + 2'] reactions have been proposed, in which the former is thought to be analogous to 1,6-enyne cycloadditions (*vide infra*) that proceed via initial oxidative addition to furnish a metallacyclopentene intermediate that undergoes *β*-carbon elimination and reductive elimination. The selectivity in the cycloadducts supports this hypothesis, albeit the evidence is circumstantial rather than definitive. Extensive computational studies using density functional theory (DFT) for the intermolecular variant provides insight into the mechanism and suggests that oxidative addition occurs solely with the VCP to generate the η^3-allyl-rhodium species **I** (**Scheme 23**). Coordination of the alkyne provides the 18-electron complex **II**, which undergoes an unusual migratory insertion into the generally less nucleophilic η^3-allyl–rhodium bond (vs. alkyl–rhodium). The calculated transition state energy for the insertion is 13.9 kcal mol^{-1} lower than the corresponding insertion into the alkyl–rhodium bond. A $C(sp^2)$-$C(sp^3)$ reductive elimination of metallacycle **III** provides the cycloheptadiene.[62a,b]

In the intermolecular reaction, the orientation of the alkyne during the insertion step dictates the regioselectivity of the reaction using unsymmetrical alkynes. However, the combination of pseudosymmetric VCPs (**124**) with *in situ* deprotection

provides **125**, in which the regiochemical information is effectively destroyed (equation 24). Table 4 outlines the extension of this process to the selective combination of monosubstituted alkyne **127** with substituted VCPs **126** (equation 25).[62c,d]

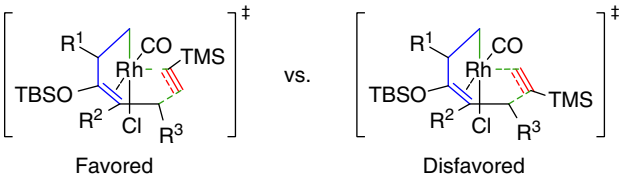
Scheme 23 Catalytic cycle for the intermolecular rhodium-catalyzed [5 + 2] cycloaddition between VCP and acetylene.

(25)

Table 4 Regioselective intermolecular [5 + 2] cycloadditions of VCPs and alkynes (equation 25)

	126						
Entry	R^1	R^2	R^3		***128*:*129*:*130*:*131***	*Yield (%)*	*Reference*
1	Me	H	H	**a**	1:1:≥19:1	87	62d
2	H	Me	H	**b**	≥19:1:–:–	85	62d
3	H	H	Me	**c**	≥19:1:–:–	74	62d

In a similar manner to the intramolecular reaction, substituted cyclopropanes can undergo bond cleavage at the proximal or distal position. When R^1 = Me, the reaction affords cycloheptanone **130** as a single constitutional isomer, in which the methyl group is α to the ketone. This product arises from cleavage of the less substituted distal bond of the cyclopropane (*d*), which is consistent with the results observed in the intramolecular process. In addition, the regioselectivity for **130** over **131** is a result of a less congested transition state in the C–C bond forming process, which is 2.2 kcal mol^{-1} lower in energy (entry 1). The steric influence in the transition state is more pronounced when R^2 and R^3 are methylated (entries 2 and 3), which is reflected by the calculated relative energies between the favored and disfavored transition states of 2.3 and 8.0 kcal mol^{-1}, respectively (Figure 4). Although the in-depth analysis of such processes is crucial for future applications in synthetic chemistry, the scope of the regioselective intermolecular [5 + 2] is limited, in most examples, to sterically encumbered trimethylsilyl groups.[62d]



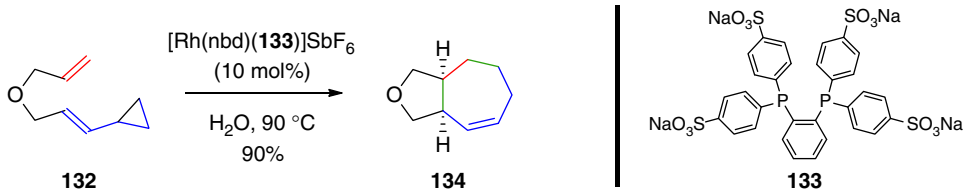


Figure 4 Transition states for alkyne insertion in the intermolecular [5 + 2] cycloaddition.

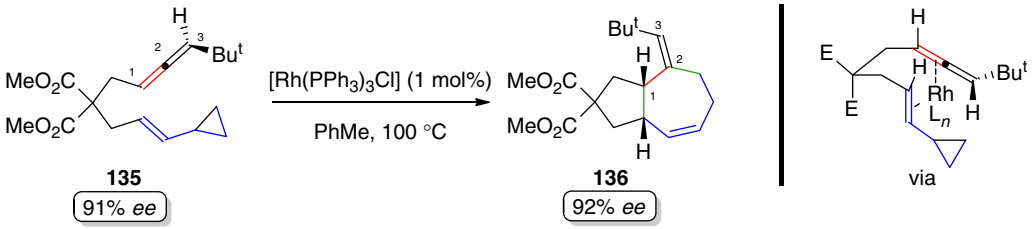
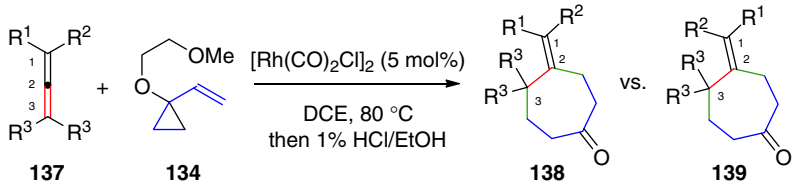
Additional computational studies also probed the analogous process of VCPs with alkenes and allenes. Although the corresponding intramolecular reactions have been described (*vide infra*), DFT analysis provided an important insight into the lack of reactivity in the intermolecular reaction between VCPs and alkenes.[62b] For example, the rate-limiting step for the reaction of alkynes and allenes with VCPs is the insertion of the exogenous π-component, whereas the rate-limiting step for the corresponding alkenes is the reductive elimination. This can be attributed to a more challenging C(sp^3)-C(sp^3) versus C(sp^2)–C(sp^3) reductive elimination (**Scheme 23**). Although the energy barriers for insertion of the π-components are all similar, the difference in reductive elimination between acetylene and ethylene is 33.6 kcal mol^{-1}. These observations also rationalize why more forcing conditions are required for alkenes in the corresponding intramolecular reaction ($RhCl(PPh_3)_3$/AgOTf (10 mol%), PhMe, 110 °C). Nevertheless, alkene- and allene-tethered VCPs readily undergo this type of transformation, in which new and improved catalysts facilitate these reactions under milder conditions.



In an effort to improve the economical and environmental factors surrounding homogenous transition metal catalysts in organic media, a water-soluble rhodium-catalyst has been developed.[63] The reusable catalyst is soluble in water because of the incorporation of a tetrasulfonated bis-phosphine ligand, which coordinates to the rhodium via phosphorus. The reactions can be performed in either a methanol/water mixture or water, albeit the low solubility of the alkene-tethered VCPs in these solvents requires the reactions to be performed at high dilution (2 mM). Nevertheless, the low substrate solubility provides a high catalyst-to-substrate concentration, which reduces oligomerization and the formation of intermolecular byproducts often encountered in organic media. Hence, the process provides a highly efficient protocol for the generation of **134**, and the catalyst can be easily recovered by extraction and reused without significant reduction in the overall efficiency of the process (equation 26).

(26)



Wender and coworkers also reported the asymmetric version using an axially chiral bis-phosphine, albeit in an organic medium, and highlights the aforementioned challenges. For instance, although excellent selectivities can be achieved for specific substrates, the reaction has limited scope in terms of variations on the cycloheptene ring and requires extended reaction times (up to 8 days).[64]

The intramolecular allene-tethered VCP [(5 + 2)] cycloaddition also provides cycloadducts with two stereogenic centers and affords high *syn*-selectivity in a similar manner to alkene-tethered systems.[65] Allenes provide advantages over other systems because they furnish bicycloheptadienes that contain an *exo*-olefin adjacent to the ring-junction, a motif that is found in a variety of biologically important natural products. This is particularly interesting in light of the fact that alkene-tethered VCP systems do not tolerate terminal alkene substitution (cf. equation 26), which accounts for the number of applications utilizing allene-tethered systems to challenging natural products. In accord with the aforementioned calculations, this process was anticipated to be facile compared to the analogous alkene-tethered reaction, which is evident from the relatively short reaction times (up to 16 h). Another advantage of this system is the potential for stereospecific reactions using enantiomerically enriched allenes. For example, the cycloaddition with the chiral nonracemic allene **135** provides complete chirality transfer to afford **136** in a highly chemo- and diastereoselective fashion (equation 27).[65] The formation of a single geometrical isomer is consistent with the formation of a metallacyclopentane via oxidative addition into the allene–alkene moiety whereby the rhodium coordinates to the opposite face of the sterically demanding *tert*-butyl substituent. The preferential oxidative addition into the C1/C2 allene bond is particularly noteworthy because related rhodium-catalyzed [(2 + 2) + 1] and [(4 + 2)] cycloadditions provide products resulting from the breaking of the C2/C3 allene bond.[1i]

(27)

The intermolecular variant of this process is more challenging due to the formation of geometrical isomers, and mirrors many of the problems encountered in the intermolecular reaction of VCPs with alkynes (equation 28).[66] The bicycloheptanones are generated via the selective insertion of the C2/C3 double bond of the allene, which affords products with quaternary stereogenic centers when R^3 is substituted (**Table 5**). However, the orientation of the allene is nonselective and gives rise to geometrical isomers **138**/**139**, in which typical selectivities range from 1.2:1 to 5:2.

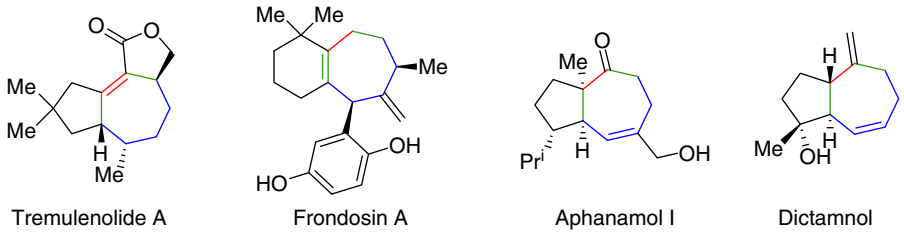
In 2008, Yu and coworkers described the rhodium-catalyzed [(5 + 2)] and [(3 + 2)] cycloadditions of alkene-tethered internal VCPs.[67] The internal allylic cyclopropane was utilized, which depending on the diastereoisomer employed led to the formation of five- and seven-membered adducts. For example, the *syn*-substituted cyclopropane afforded the [(5 + 2)] cycloadduct, whereas the *anti*-substituted cyclopropane furnished the [(3 + 2)] product (Scheme 24). The reaction is thought to proceed via oxidative addition into the VCP followed by carbometallation into the pendant alkene. This provides an η^3-allyl-rhodium at C5–C7 which can either undergo reductive elimination at the termini to afford the [(5 + 2)] adduct **141** or at the internal position to furnish the [(3 + 2)] adduct **142**. The location of the olefin in cycloadduct **141** is noteworthy, because this complements the products obtained from terminal VCPs (cf. equation 26).

Scheme 24 Divergent rhodium-catalyzed [(5 + 2)] and [(3 + 2)] cycloadditions of alkene-tethered VCPs.

Overall, the use of transition metals to catalyze ['5 + 2'] cycloaddition reactions of VCPs has been very successful. Although work is still required for the development of a general enantioselective protocol, the ability to utilize enantioenriched VCPs and peripheral stereogenic centers to provide enantiopure cycloadducts is noteworthy. This strategy has been successfully employed in the total synthesis of a number of challenging natural products. For example, tremulenolide A was prepared using a rhodium-catalyzed [(5 + 2)] cycloaddition of an alkyne-tethered VCP, whereas the synthesis of frondosin A utilized a ruthenium-catalyzed reaction (Figure 5). Aphanamol I and dictamnol were also constructed via rhodium-catalyzed cycloadditions of allene-tethered VCPs.[68]



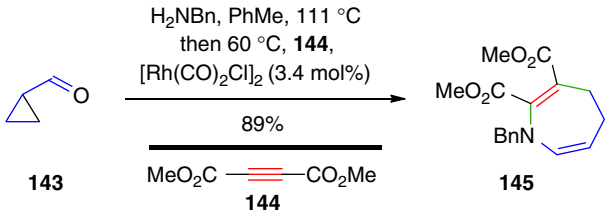


Figure 5 Natural products synthesized via transition metal-catalyzed [(5 + 2)] cycloadditions of VCPs.

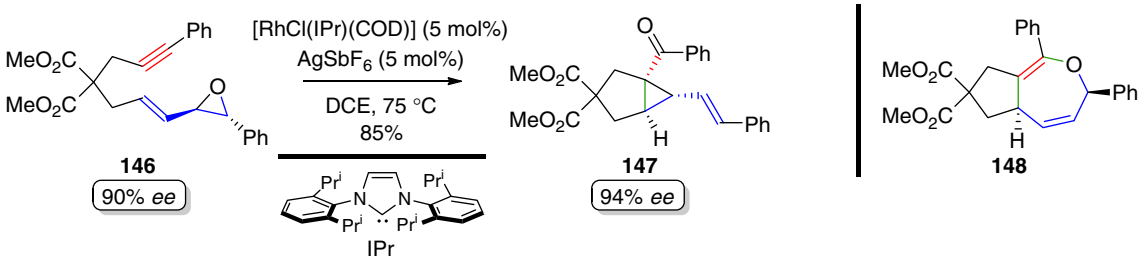
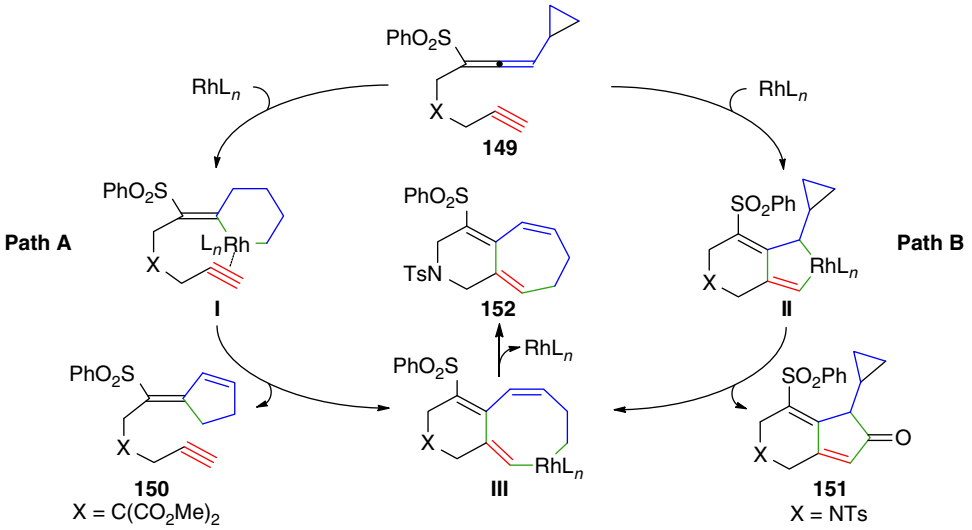


Several adaptations to the more classical VCP cycloaddition chemistry broaden the scope of these transformations to the addition of heteroatoms and the preparation of different ring sizes. For example, the aforementioned [5 + 2] adducts have all focused on the formation of carbocycles, however, two examples have been described that provide access to heterocycles via similar pathways. In 2002, cyclopropyl imines were utilized with activated alkynes in an analogous manner to VCPs (equation 29),[69] to afford seven-membered dihydroazepines in excellent yield on a preparative scale (15 mmol). Interestingly, the

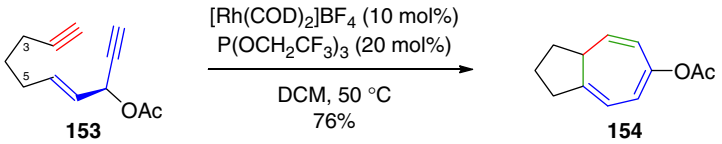
lower reactivity of the *in situ* generated cyclopropylimine mandates the slow addition of the alkyne **144** (12 h) to eliminate competing [2 + 2 + 2] cycloadducts from the combination of two alkynes with the imine.

(29)



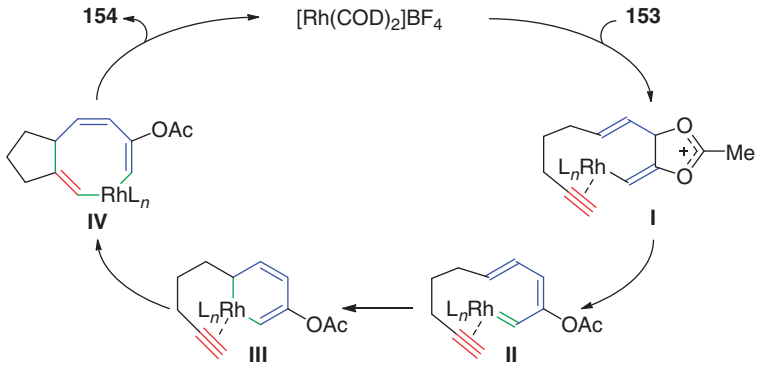
Heteroatom substituents in the cyclopropane ring, namely vinyl epoxides, can also participate in such transformations. The predicted products from this transformation are 2,5-dihydrooxepins, which are known to undergo intramolecular Claisen rearrangement to afford the corresponding aldehydes.[70] Hence, the rhodium-catalyzed rearrangement of vinyl epoxide **146** affords the 2,5-dihydrooxepin **148** *en route* to VCP **147** (equation 30).

(30)



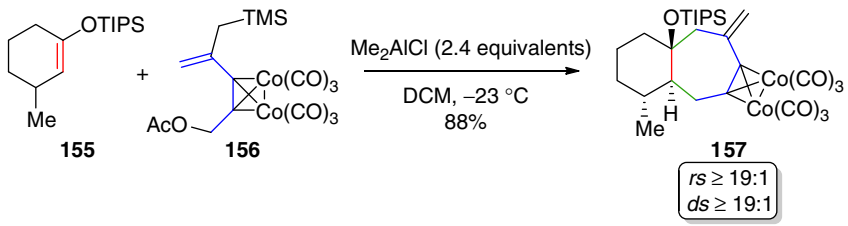
The proposed mechanism is similar to the intramolecular cycloaddition of alkyne-tethered VCPs developed by Wender and Trost, albeit leading to the formation of the heterocyclic cycloadduct **148**. Moreover, it is unclear whether the rearrangement of **148** to afford **147** is a thermal or rhodium-catalyzed process. Nevertheless, the rearrangement favors the formation of **147** by virtue of the stable carbonyl functionality, which compensates for the ring strain in the formation of the cyclopropane. Despite the reversibility of the Claisen rearrangement, enantioenriched vinyl epoxides, such as **146**, afford excellent chirality transfer to the Claisen product **147** (equation 30).

In a recent adaptation to utilizing VCPs, alkyne-tethered allenylcyclopropanes were reported to undergo facile intramolecular [(5 + 2)] cyclization to afford bicyclo[5.4.0] and bicyclo[5.5.0] systems.[71] The reaction occurs exclusively at the allene C=C bond in **149** that is proximal to the cyclopropane to afford the bicyclo[5.4.0]undecatriene **152** in 86% yield (**Scheme 25**). The reaction conditions mimic those previously reported for similar transformations, with $[Rh(CO)_2(dppp)Cl]_2$ (10 mol%) in toluene at 80 °C being optimal. The formation of cycloadduct **152** can occur via two plausible pathways. Oxidative addition into allenylcyclopropane to afford **I**, followed by alkyne insertion should furnish **III**, which on reductive elimination will provide **152** (Path A). Alternatively, oxidative coupling into the enyne moiety of **149** would provide **II**, which could generate the [(5 + 2)] adduct via *β*-carbon elimination and reductive elimination (Path B). It is conceivable that both pathways may be operating depending on the reaction conditions and substrate, because **150** was isolated as a byproduct under the optimal reaction conditions and **151** was isolated when the reaction was performed under an atmosphere of carbon monoxide.



Scheme 25 Rhodium-catalyzed [(5 + 2)] cycloaddition of alkyne-tethered alleneylcyclopropanes.

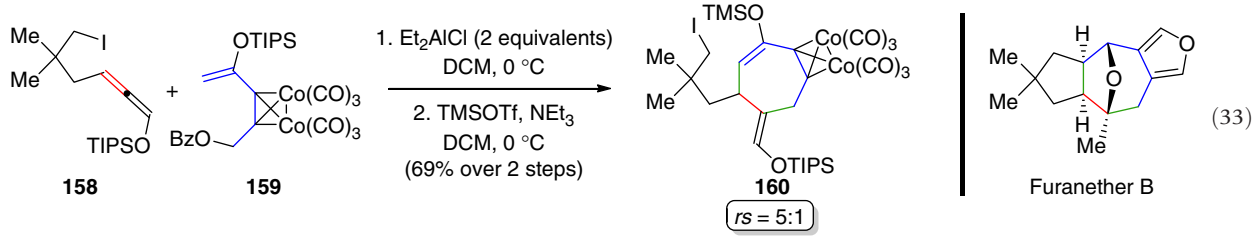
Recently, the development of the rhodium-catalyzed [(5 + 2)] cycloaddition, which employs propargylic acetates rather than strained rings, further highlights the versatility of this process. The vinyl propargylic acetate provides a five-carbon synthon, which undergoes intramolecular cycloaddition with tethered π-components (equation 31).[72] For example, enediyne **153** affords **154**, which represents a synthetically useful intermediate; however, a major limitation of this reaction is that substituents at C3 or C5 do not provide useful levels of stereocontrol.



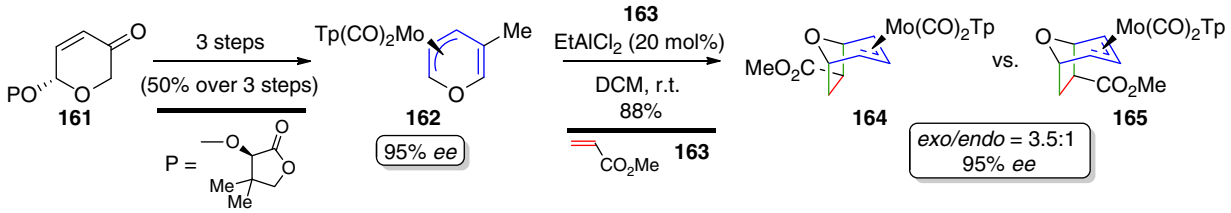
(31)

Propargylic acetates afford Rautenstrauch intermediates similar to **I** via a 1,2-acyloxy migration, which rearrange to afford the rhodium(I)-carbene (**II**). Electrocyclization of **II** to provide **III**, followed by migratory insertion of the pendent alkyne affords **IV**, which undergoes C(sp^2)–C(sp^2) reductive elimination to provide cycloadduct **154**. Additional support for the formation of a rhodium–carbene **II** was established through the isolation of a small amount of a cyclopropane byproduct, generated from the reaction with the olefin of the 1,5-cyclooctadiene ligand. Interestingly, performing the reaction in the presence of excess 1,5-cyclooctadiene furnished the [2 + 1] adduct as the major product. Despite the well-established rearrangement reactions of propargylic acetates in the presence of gold and platinum complexes, in addition to Brønsted acids, none of these systems promote the [(5 + 2)] cycloaddition (**Scheme 26**).

Scheme 26 Rhodium-catalyzed [(5 + 2)] cycloaddition via a Rautenstrauch intermediate.



The construction of seven-membered carbocycles from a [5 + 2] cycloaddition using conventional organic chemistry has been relatively unexplored, which is somewhat surprising given the number of [3 + 3] cycloadditions that employ this type of chemistry. Nevertheless, there are examples of sequential nucleophilic substitution reactions of substrates that contain reactive nucleophilic and electrophilic moieties that participate in formal [5 + 2] cycloadditions to generate highly functionalized polycycles. For example, **155** and **156**, which have nucleophilic and electrophilic sites, react to furnish the cycloadduct **157** in excellent yield (equation 32).[73a] The reaction affords excellent diastereoselectivity for the formation of the *anti,anti*-stereotriad by using the resident stereogenic center to direct the allylation. The stereoselectivity for the formation of the *anti*-ring junction is controlled by the facial attack of the allyl silane on the intermediary oxocarbenium ion, which forms from the direct alkylation of the silyl enol ether **155** with **156**. Interestingly, acyclic silyl enol ethers afford the *syn* ring junction irrespective of the nature of the starting olefin, which further supports the proposed stepwise mechanism. In addition, the formation of five-membered adducts from the intramolecular cyclization of **156** were not observed in these reactions.

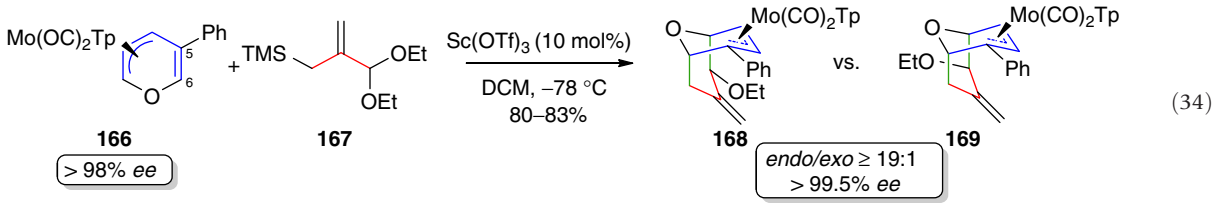


(32)

This concept was recently adapted to allow silyl enol ethers, instead of allyl silanes, as the nucleophilic coupling partner on the cobalt species. Although, the replacement of the silyl enol ether with a silyloxyallene provides comparable reactivity, the reactions

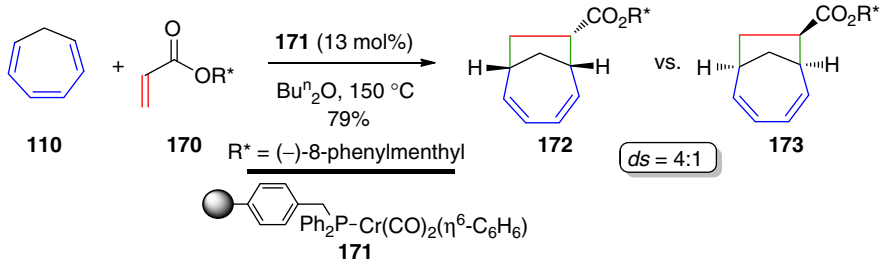
are significantly less selective (*rs*=5:1). This process was highlighted in a 15-step synthesis of the lactarane natural product, furanether B (equation 33).[73b]

In a series of reports, Liebeskind and coworkers described the synthetic utility of enantiomerically enriched molybdenum complexes, which provide five-carbon synthons.[74] The air stable complexes can be prepared on gram scale with high enantiopurity by employing a diastereomerically pure chiral nonracemic precursor, such as **161**, which provides the enantiomerically enriched π-allyl molybdenum species via inversion of configuration. Addition of MeMgBr to the ketone and quenching with trifluoroacetic anhydride/triethylamine afforded, after elimination, the highly enantioenriched molybdenum complex **162**. The bulky complex contains a trispyrazolylborate (Tp) ligand to effectively block the β-face in the [5 + 2] cycloaddition with methyl acrylate (**163**) to afford a mixture of *exo*- and *endo*-cycloadducts (**Scheme 27**). The reaction is highly stereospecific affording **164**/**165** with 95% enantiomeric excess, albeit with modest *exo*/*endo* selectivity. Several demetallation protocols, including iododemetallation with iodine, oxidative demetallation with ceric ammonium nitrate (CAN) and protodemetallation with strong acids, afford highly functionalized bicyclo[3.2.1] systems with excellent selectivity. These products resemble similar [3 + 3] cycloadducts previously reported and it is important to note that the terminology that describes a given cycloaddition is a result of the movement of electrons and not necessarily the position of the newly created bonds (cf. equations 2 and 4). For example, the movement of electrons dictates that **162** is a five-carbon synthon and not a three-carbon synthon.



Scheme 27 Lewis acid-catalyzed [5 + 2] cycloaddition of η^3-molybdenum complexes.

5.14.2.4 ['5 + *n*'] Cycloadditions

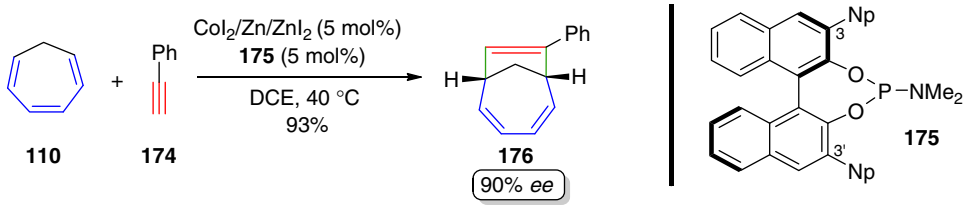


This section describes higher-order ['5 + *n*'] cycloadditions, where *n*=3–5, which have great potential for the rapid and stereoselective construction of eight-, nine-, and ten-membered carbocycles. Consistent with the theme of this chapter, photochemical [5 + 4] cycloadditions are described in Chapters 5.04 and 5.15. Despite the synthetic potential of this class of reactions, it is somewhat surprising that this area has received little consideration.

In this context, the extension of the synthetic utility of η^3-molybdenum complexes to the [5 + 3] cycloaddition was accomplished using oxyallyl cations to provide enantioenriched oxa- and aza-bridged eight-membered rings.[75] Substitution at C5 can be tolerated and affords the corresponding [5 + 3] adducts with excellent *endo*-selectivity and with complete chirality transfer (equation 34). However, the analogous C6 substituted molybdenum complexes afford [3 + 2] products, due to the C5–C6 bond behaving as a two-carbon synthon. This change in reactivity can be explained by a stepwise mechanism in which the formation of the [5 + 3] cycloadduct arises from initial attack by C6 in **166** with C3 of the oxocarbenium ion derived from **167**, followed by S_N2' addition of the allyl silane at C2 in **166**. When C6 is substituted, C5 is inherently more nucleophilic and is responsible for the initial attack onto **167**, followed by S_N2' of the allyl silane at C6 in the molybdenum complex to generate [3 + 2] cycloadducts.

5.14.2.5 ['6 + 2'] Cycloadditions

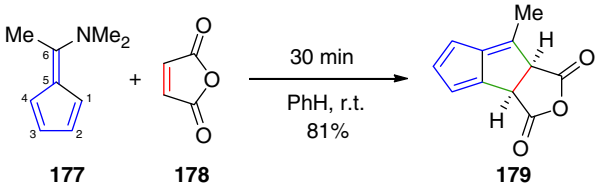
There are significantly fewer methods for the construction of medium sized rings compared to small rings, which can primarily be attributed to the challenges associated with their construction. As a result, ['6 + *n*'] cycloadditions or higher have been adapted to generate highly functionalized fused and bridged polycyclic structures from readily available precursors. The early development of this reaction involved metallated cycloheptatrienes, which provided six-carbon synthons, however, the necessity for precomplexed and stoichiometric quantities of transition metals to facilitate the transformation made it undesirable.[76] Recently, these limitations have been overcome with the development of catalytic systems using chromium and cobalt which not only eradicate the requirement for initial light irradiation, but also eliminate potential photochemical [2 + 2] byproducts that were previously observed. One of the most impressive accounts in this area has been the polymer-supported chromium-catalyzed reaction of cycloheptatriene **110** with the electron-deficient alkene **170** (equation 35).[77]



110 + **170** → **172** (*ds* = 4:1) vs. **173** (35)

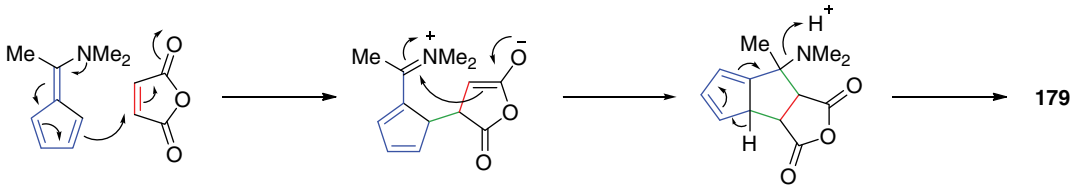
171

A major drawback of the chromium-catalyzed process compared to other transition metals is the high toxicity and the difficulty associated in removing trace quantities of the transition metal catalyst. In this context, the polymer-supported chromium-complexes, which furnish the cycloadducts via filtration, provide a convenient solution for the removal of the chromium catalyst. For example, the isolated cycloadducts **172**/**173** contain less than 0.53 ppm chromium and the recovered and recycled chromium complex **171** provides similar turnover and efficiency.



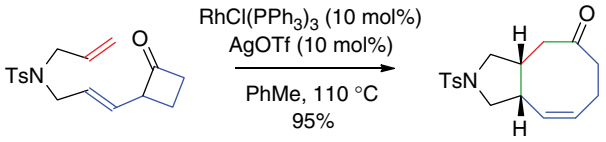
The asymmetric cobalt-catalyzed [6 + 2] cycloaddition using a chiral monodentate ligand has also been developed.[78] Treatment of cycloheptatriene **110** with phenylacetylene (**174**) in the presence of a phosphoramidite-modified cobalt-complex furnished the desired cycloadduct **176** in excellent yield and with excellent enantiomeric excess (equation 36). Interestingly, the amino component on the ligand has little impact on the enantioselectivity of the reaction, whereas the 1,1′-bi-2-naphthol (BINOL) backbone is extremely sensitive to modifications. For example, bulky aryl substituents at C3 and C3′ are optimal for the formation of the desired cycloadduct, albeit the reaction is limited to bulky terminal alkynes as the 2π-component.

110 + **174** → **176** (90% *ee*) | **175** (36)



The reaction was expanded to include terminal allenes as 2π-components in a nonasymmetric fashion utilizing 1,3-bis(diphenylphosphino)propane (dppp) as an achiral bidentate phosphine ligand.[79] The most striking feature of this transformation is the stereospecific formation of tri- and tetrasubstituted *E*-alkenes in the cycloadduct, which is a result of the stereoselective incorporation of the distal allene bond.

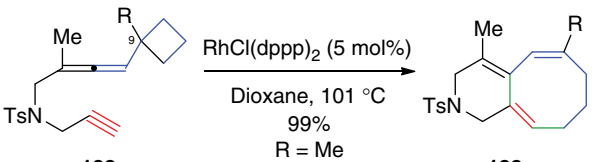
Substituted fulvenes provide six-carbon synthons in a variety of [6 + 4] cycloadditions (*vide infra*), which nicely complements their ability to provide two- and four-carbon synthons in [2 + 2] and [4 + 2] cycloadditions, respectively. Nevertheless, the development of the [6 + 2] cycloaddition has been limited to a single example, namely the spontaneous room temperature reaction of 6-aminofulvene **177** with maleimide (**178**) to afford the tricyclic adduct **179** in 81% yield (equation 37).[80]



177 + **178** → **179** (37)

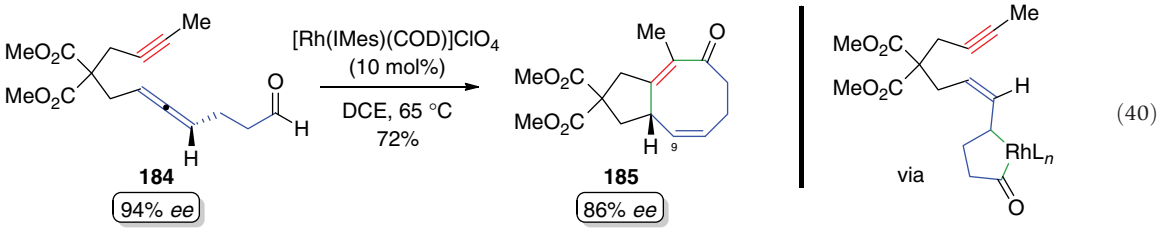
Scheme 28 outlines the proposed mechanism for the cycloaddition, which involves stepwise conjugate addition of the fulvene at C1 to the maleimide to furnish a zwitterionic intermediate. Enolate addition to the intermediary iminium ion followed by the elimination of protonated dimethyl amine affords the desired cycloadduct.

Scheme 28 Thermal [6 + 2] cycloaddition of fulvenes with electron-deficient alkenes.



The extension of the concepts outlined in the development of the metal-catalyzed [(5 + 2)] cycloadditions provides the basis for the corresponding [(6 + 2)] cycloaddition (*vide supra*). For example, the [(5 + 2)] cycloaddition of VCPs with tethered 2π-components generates a variety of bicyclo[5.3.0] adducts, which relies on the ring strain of the cyclopropane to promote ring expansion. This concept was extended to cyclobutanones, which contain a similar amount of ring strain (29.5 kcal mol^{-1} vs. 27.5 kcal mol^{-1}), to furnish the corresponding eight-membered [(6 + 2)] cycloadducts (equation 38).[81]

180 **181** (38)

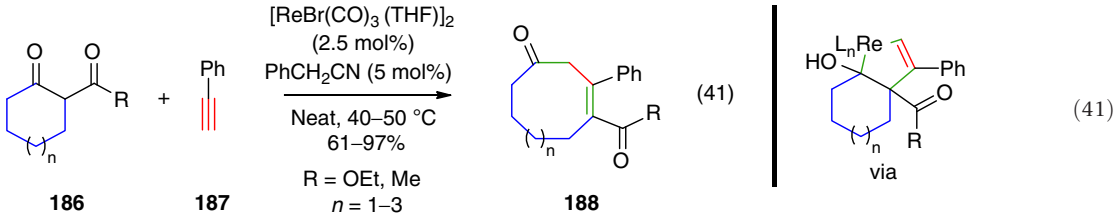


In an analogous manner to the VCP variant, the reaction concentration is critical for efficiency, in which high dilution is required to minimize oligomeric byproducts. Interestingly, the reactivity of the π-component is opposite to the VCPs, in which the alkynyl-tethered vinylcyclobutanones are unreactive in contrast to the alkene- and allene-tethered counterparts. Additionally, the reaction is amenable to the introduction of quaternary carbon stereogenic centers at either ring junction.

Mukai and coworkers described the extension of alkyne-tethered allenylcyclopropanes to the corresponding cyclobutane derivatives (cf. Scheme 25).[82] Treatment of the alkyne-tethered allenylcyclobutane **182** with the rhodium complex $RhCl(dppp)_2$ promoted intramolecular cycloaddition to afford the bicyclo[6.4.0] system **183** in excellent yield (equation 39). The mechanism is consistent with the process outlined in Scheme 25 (Path B), because the lack of substitution at C9 (R≠H) results in competitive β-hydride elimination (vs. β-carbon elimination) of the rhodacyclopentene intermediate to provide ene-cycloisomerization byproducts with varying degrees of chemoselectivity. Hence, synthetically useful yields in this process are only achieved when R≠H.

182 **183** (39)

A particularly impressive example of a formal rhodium-catalyzed [(6 + 2)] cycloaddition was reported by Sato and coworkers, in which they demonstrated that intramolecular cyclization of the alkynyl-tethered allenal **184** furnished the cyclooctadienone **185** in good yield (equation 40).[83] The reaction is mechanistically intriguing because it is thought to resemble a hydroacylation pathway rather than the more common rhodacyclopentene intermediate observed via direct oxidative addition into a 1,6-unsaturated moiety.

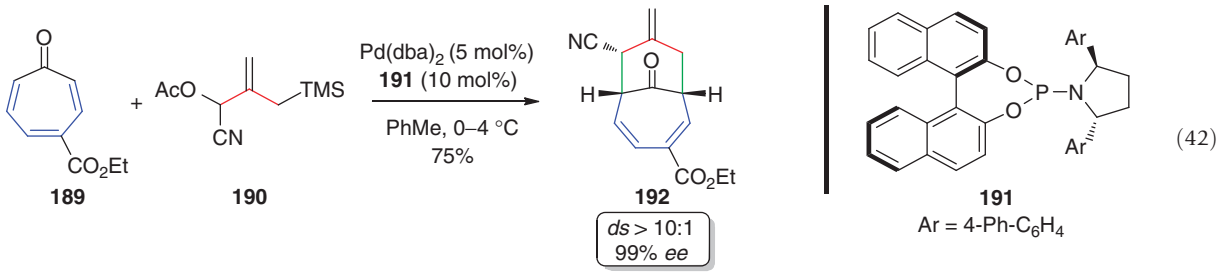


184 94% *ee* **185** 86% *ee* (40)

Hence, the cycloaddition is consistent with an initial oxidative addition into the C–H bond of the aldehyde, followed by the hydrometallation onto the proximal allene bond, which favors the formation of the five- rather than the six-membered rhodacycle. The η^1-allyl then undergoes σ–π–σ isomerization to generate a rhodacycloheptanone. The relative proximity of the pendant alkyne promotes facile insertion and reductive elimination to generate the cycloadduct. Several aspects of this work are

noteworthy; firstly, the stereospecific hydrometallation and isomerization step to furnish enantioenriched products, and secondly, deuterium labeling of the aldehyde affords the cycloadduct with 100% incorporation at C9 to support the mechanistic proposal. The reaction can also tolerate alkene-tethered allenals, which generate *syn*-fused bicycles, however, the ability to utilize alkynes is particularly significant because these products complement those generated in the rhodium-catalyzed cyclization of alkenyl-tethered vinylcyclobutanones, which fail for alkyne-tethered systems (cf. equation 38).

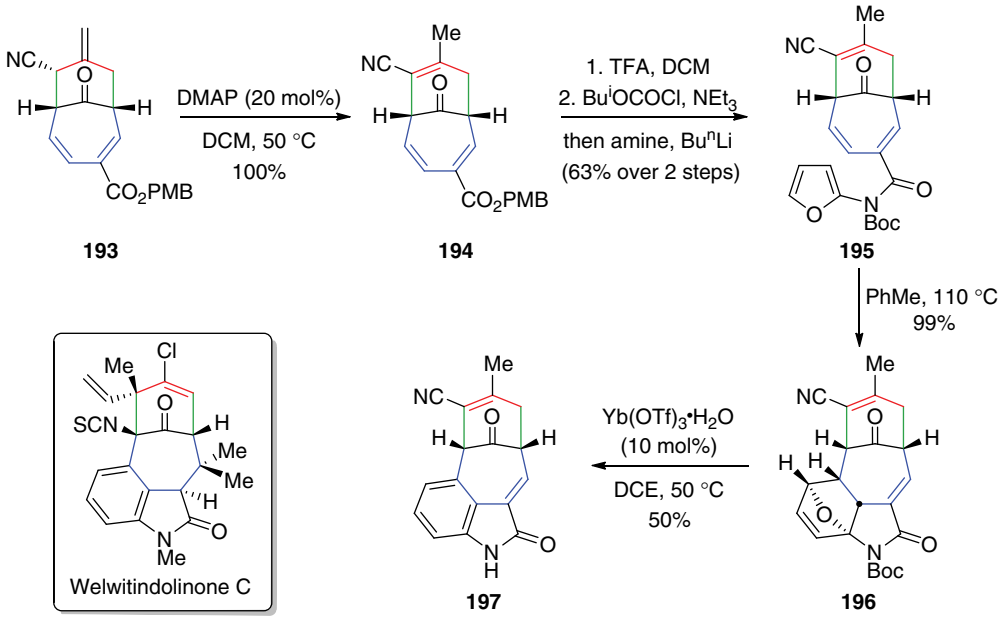
In 2006, Kuninobu and coworkers reported the rhenium-catalyzed insertion of acetylenes into cyclic *β*-diketones and *β*-keto esters (equation 41).[84] Although the precise mechanism of the reaction is unknown, one proposed pathway is that the reaction proceeds via oxidative addition of the rhenium into the acetylene and enol form of **186** to generate a rhenacyclopentene intermediate. Reductive elimination of the metallacyclopentene generates a 6,4-bicycle, which upon ring-opening through a retro-aldol reaction, generates the eight-membered ring. A particularly attractive feature of this transformation is the ability to extend this chemistry to [7 + 2] and [8 + 2] cycloadditions by simply increasing the number of atoms in **186** to provide nine- and ten-membered carbocyclic intermediates in comparable yields (n = 2–3). A similar one-pot [2 + 2]/ring-opening sequence was reported by Carreira and co-workers, in which the reaction of *in situ* generated benzynes with potassium keto-enolates facilitates the synthesis of bicyclic scaffolds.[85] Interestingly, the authors isolated the expected [2 + 2] adduct and demonstrated that the addition of a suitable base promoted the retro-aldol to afford the formal [5 + 2] cycloadduct.



186 **187** **188** (41)

(41)

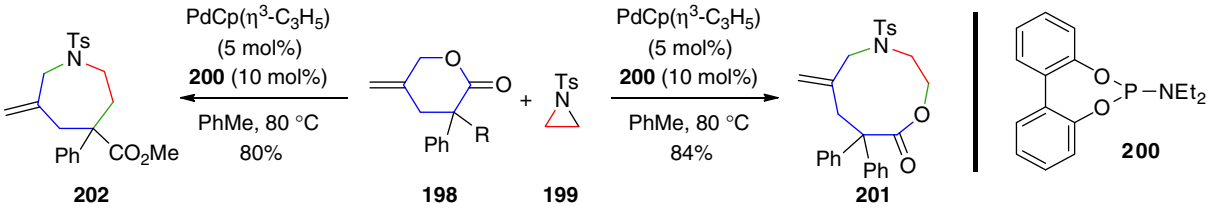
5.14.2.6 ['6 + 3'] Cycloadditions



One of the most impressive developments in the ['6 + 3'] cycloaddition class has been the successful union of two well-established components, namely, cycloheptatrienes (or tropones) with TMM complexes as six- and three-carbon synthons, respectively. Initially developed in 1987 by Trost and coworkers, the same research group took advantage of the successful implementation of chiral phosphoramidites in the related [3 + 2] cycloaddition between TMM complexes and electron-deficient alkenes. This highlights the generality of TMM complexes as three-carbon surrogates in ['3 + m'] cycloadditions, because very little deviation in the reaction conditions was required for the development of the [6 + 3] version. For instance, treatment of the tropone derivative **189** with the TMM precursor **190** with the chiral phosphoramidite-modified palladium-complex furnished the bicyclo[4.3.1]-decadiene **192** in good yield and with excellent diastereo- and enantioselectivity (equation 42).[86a]

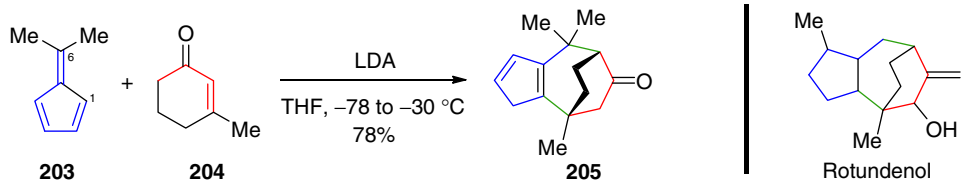
189 **190** **192** **191** (42)

X-ray crystallographic analysis of one of the cycloadducts concluded that the exocyclic alkene is within close proximity to the endocyclic 1,3-diene, which prompted the investigation of a potential [3,3]-sigmatopic rearrangement. Interestingly, microwave irradiation of the cycloadduct **192** at 170 °C provided the bicyclo[3.3.2]decadiene Cope adduct. Nevertheless, this process hampered efforts toward the synthesis of welwitindolinone C, which required the conversion of the exocyclic alkene in **193** to the *endo*-isomer **194** to suppress the [3,3] sigmatopic rearrangement (**Scheme 29**). Conversion to the amide **195**, followed by a thermal intramolecular [(4 + 2)] Diels–Alder cycloaddition generated **196** as a single diastereoisomer. Deprotection of the carbamate in **196** resulted in spontaneous dehydration of the oxabicycle to provide the oxindole **197**, which represents the tetracyclic core of the natural product.[86b]



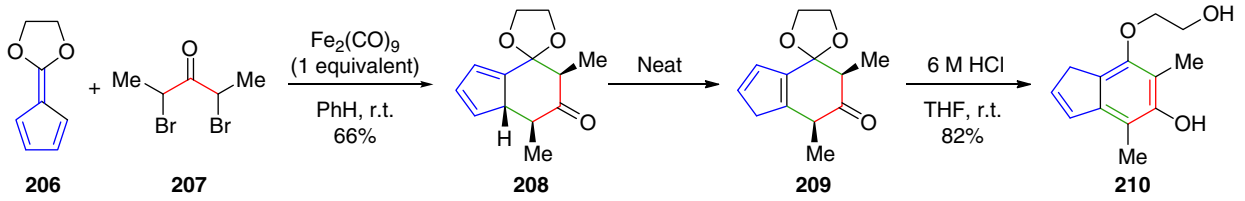
In 2005, Lu and coworkers further expanded the repertoire of cycloadditions involving tropones with the development of a phosphine-catalyzed [6 + 3] cycloaddition.[87] The reaction between tropones and Morita–Baylis–Hillman adducts (cf. **17**) afforded bicyclo[4.3.1]decane systems in good yield with no detectable levels of competing cycloadditions. Similar to the [3 + 3]

Scheme 29 Sequential [6 + 3] and [(4 + 2)] cycloadditions for the synthesis of the core of welwitindolinone C.



cycloaddition described earlier, *tert*-butyl carbonates provide the corresponding *tert*-butoxide anion, which acts as an internal base for the reaction (cf. Scheme 5). It is noteworthy that tropones can also undergo [4 + 2] and [8 + 2] cycloadditions with electron deficient alkenes.[1a,88]

A rare example of a ['6 + *n*'] cycloaddition that does not generate bridged bicycles was reported using γ-methylidene-δ-valerolactones and aziridines (Scheme 30).[89] This combination, under palladium catalysis, generates nine-membered rings with excellent efficiency. Moreover, the substitution of the γ-methylidene-δ-valerolactones dictates the outcome of the transformation since ester substituents (R=CO$_2$Me) provide [4 + 3] cycloadducts via a decarboxylative pathway.

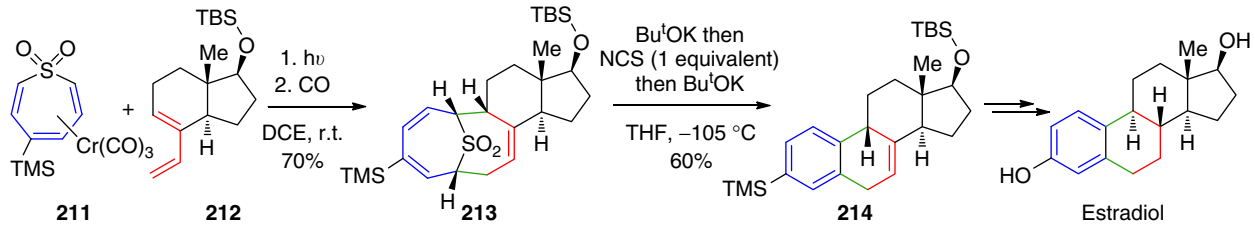


Scheme 30 Divergent [6 + 3] and decarboxylative [4 + 3] cycloadditions of γ-methylidene-δ-valerolactones and aziridines.

As described in Section 5.14.2.5 along with tropones and cycloheptatrienes, fulvenes have six π-electrons that behave as six-carbon synthons in higher-order cycloaddition reactions and, analogously to tropones, they also undergo [6 + 3] cycloadditions. Consistent with the 6-aminofulvene, 6,6-dimethylfulvenes mimic α,β-unsaturated carbonyls, which are inherently electron deficient. For example, the lithium enolate of **204** attacks C6 of the fulvene **203** to generate a new carbon–carbon bond, which enables the anion at C1 to undergo an intramolecular Michael addition onto the α,β-unsaturated ketone, which upon protonation generates the carbocycle **205** (equation 43).[90a] It is noteworthy that in one simple operation, readily available starting materials can generate an intermediate that resembles the natural sesquiterpene, rotundenol.

(43)

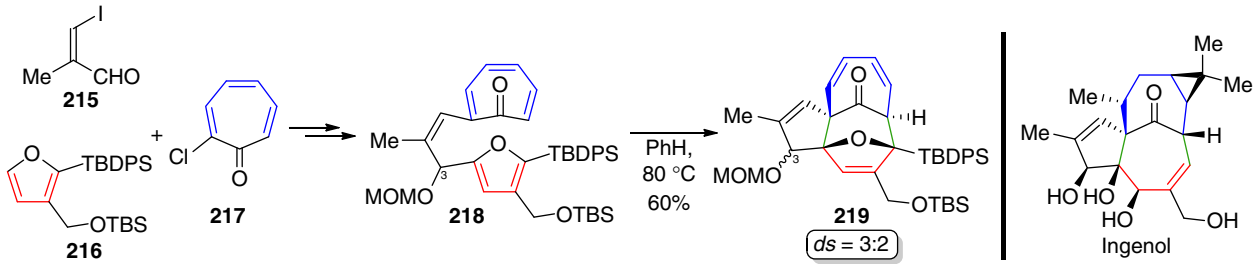
Oxyallyl cations also participate in the [6 + 3] cycloaddition with activated fulvenes to provide bicyclo[4.3.0]nonadienes in a highly stereoselective manner (Scheme 31).[90b] The mechanism for the cycloaddition is thought to be a stepwise process similar to that previously described for electron-rich fulvenes in the related [6 + 2] cycloaddition (cf. Scheme 28). Nevertheless, although this process generates α,α′-disubstituted ketones with good stereocontrol, it is particularly sensitive to the type of substituents on the fulvene. For example, 6-monoalkyl- and 6,6-dialkylfulvenes do not participate in the [6 + 3] cycloaddition, but preferentially react as four-carbon synthons to provide [4 + 3] cycloaddition products.



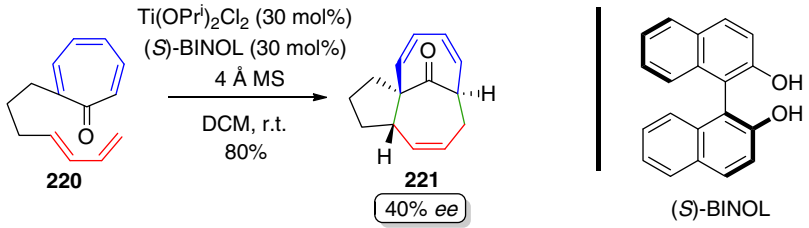
Scheme 31 [6 + 3] Cycloaddition reaction of fulvene ketene acetal with 2-oxyallyl cations.

5.14.2.7 ['6 + *n*'] Cycloadditions

Prior to the first report of a ['6 + 4'] cycloaddition, Woodward and Hoffmann's prediction provided the impetus for the development of this transformation. Hence, this process provided the focus of various synthetic and theoretical investigations, because the cycloadducts represent complex intermediates that would otherwise be difficult to prepare using conventional methods. As a result of these investigations, several reviews by Rigby have provided up-to-date accounts of their application in organic synthesis.[1a,d] The following section will briefly report on more recent state-of-the-art developments in this exciting area.



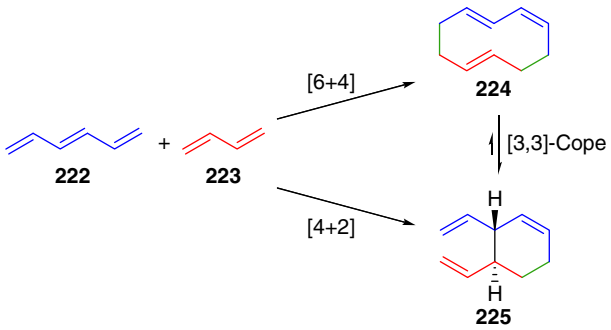
In 1999, Rigby and coworkers reported the [6 + 4] cycloaddition of metallated 6π systems with dienes for the synthesis of complex tetracyclic intermediates, which was employed as a key step in an elegant synthesis of estradiol (Scheme 32).[91] As described previously, irradiation of metallated six-carbon synthons is required to dissociate a ligand, and thereby initiate the reaction to afford the metallated [6 + 4] adduct. In this example, subjecting the crude material to an atmosphere of carbon monoxide facilitates decomplexation of the metal to generate **213**. It is important to note that the cyclic sulfones can undergo a Ramberg–Bäcklund ring contraction to provide bicyclo[3.3.0]decane systems in an efficient manner. Additionally it is possible for the sulfone to provide a tether, which would afford a monocyclic ten-membered ring upon reduction, a strategy that would be highly desirable because acyclic six- and four-carbon synthons in a [6 + 4] cycloaddition have been unsuccessful in this regard (*vide infra*).



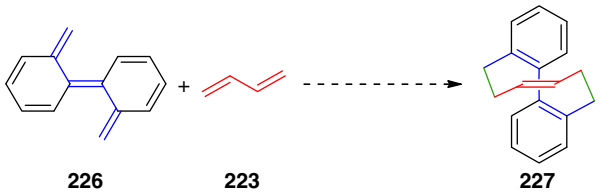
Scheme 32 Total synthesis of estradiol via an intermolecular [6 + 4] cycloaddition.

The thermal intramolecular cycloaddition of furanotropones, which do not require a metallated 6π synthon, was reported by Rigby and Chouraqui for the synthesis of oxabridged polycycles (Scheme 33).[92] The rapid construction of the precursor **218** from the vinyl iodide **215**, furan **216** and tropone **217** is particularly attractive because the final cycloadduct contains all of the required functionality for a convergent synthesis of ingenol. Moreover, the reaction occurs under relatively mild conditions, because tropones have a lower activation barrier than cycloheptatrienes in these types of cycloadditions.[93] Nevertheless, a minor limitation with this methodology is the poor diastereocontrol from the C3 methoxymethyl ether, albeit the actual cycloaddition is completely selective, due to the reaction proceeding through a well-established *exo* transition state.

Additional studies by Rigby and Fleming culminated in the first enantioselective [6 + 4] cycloaddition, which proceeded in the presence of a chiral Lewis acid catalyst at room temperature (equation 44).[94] For example, the (*S*)-BINOL-modified titanium catalyst furnished tricycle **221** from tropone **220** in excellent yield. Although the enantioselectivity was poor, this provided proof-of-principle for what is likely to be the first of several studies on enantioselective Lewis acid-catalyzed [6 + 4] cycloaddition reactions.



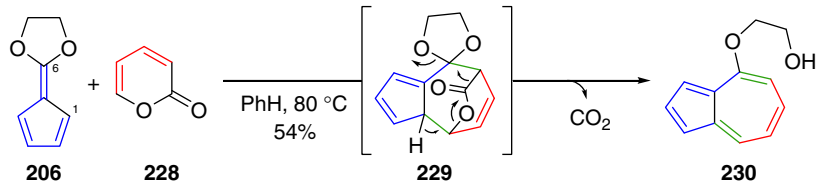
Scheme 33 Synthesis of the core of ingenol via an intramolecular [6 + 4] cycloaddition.



(44)

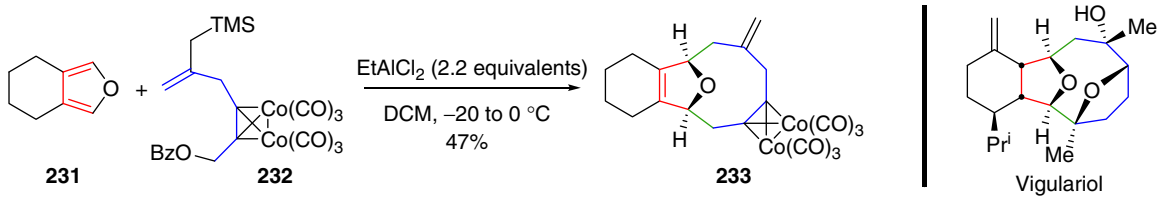
The successful implementation of acyclic components in the [6 + 4] cycloaddition reaction has been an ongoing challenge for synthetic chemistry, primarily because of competing [4 + 2] cycloadditions. Moreover, the formation of [4 + 2] adducts can also result from a favorable [3,3]-Cope rearrangement of the [6 + 4] adduct.[93,95] Hence, the preconception that the cyclization of the triene **222** with diene **223** to provide the ten-membered cycloadduct **224** would be unsuccessful, because of the facile formation of the rearranged cycloadducts, is supported by DFT studies (Scheme 34). Nevertheless, despite the fact that the 10-membered cycloadducts contain several unsaturated bonds, including *E*-alkenes, many have lower strain energies than cyclodecane, which indicates that this factor is not contributing to the failure of this type of process.

Scheme 34 Failure of the [6 + 4] cycloaddition from heptatriene and butadiene.



In an alternative approach, Alder and coworkers predicted that **226** and **223** should react spontaneously to afford the ten-membered ring without concomitant formation of the [4 + 2] cycloadduct (equation 45).[95] Moreover, the computed activation energy of the Cope rearrangement suggests that it should not be a spontaneous reaction, since the substituents will be deconjugated. However, this process is purely hypothetical, because this prediction has not been successfully demonstrated at this juncture.

(45)



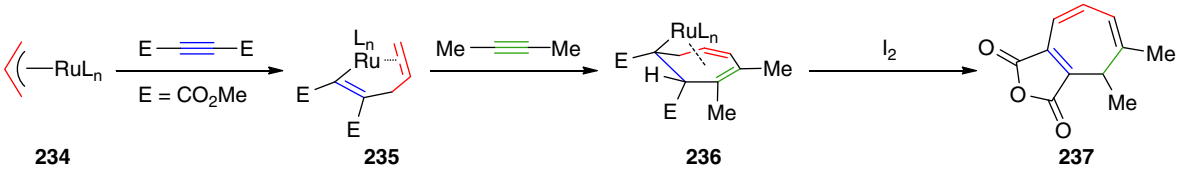
In contrast, the fulvene-derived six-carbon synthon **206** undergoes a thermal [6 + 4] cycloaddition with the butadiene equivalent **228**, which upon decarboxylative aromatization of **229** generates the azulene cycloadduct **230** in moderate yield

(equation 46). Although 6-aminofulvenes can be employed in this reaction, the yields for the formation of the azulenes are generally low, whereas alkylfulvenes are completely unreactive as six-carbon components.[96] This behavior is rationalized by frontier molecular orbital (FMO) theory, which suggests that larger coefficients at C6 (cf. **177** and **206**) promote the [6 + 4] cycloaddition by increasing the energy of the next highest occupied molecular orbital (NHOMO).

(46)

Continuing on the theme of six-carbon synthons, the final example in this section involves the extension of a five-carbon synthon outlined in Section 5.14.2.3. Hence, the addition of a methylene unit to the dicobalt acetylene complex provides a six-carbon synthon to facilitate a [6 + 4] cycloaddition with furan derivatives. For example, treatment of furan **231** with **232** in the presence of a Lewis acid, affords the corresponding nine-membered ring commonly found in the cladiellin family of diterpenes, which includes vigulariol (equation 47). Although the reaction afforded poor yield of the cycloadduct, monosubstituted furans furnish the corresponding cycloadducts with improved yield (up to 85%).[97]

(47)

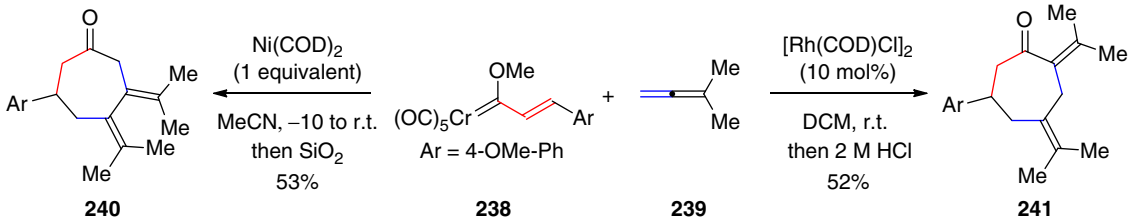


5.14.3 ['*m* + *n* + *o*'] Cycloadditions

The intermolecular three-component cycloaddition is intrinsically more difficult than two-component variants, because in the most challenging scenario they require the successful union of three different π-components. Hence, the ability to prepare the 1:1:1 adducts over competing 1:2 adducts as well as products from dimerization and trimerization highlights the challenges associated with the development of novel ['*m* + *n* + *o*'] cycloadditions. It is therefore unsurprising that transition metals have played a critical role in the development of this field, because they facilitate the selective and systematic construction of systems that are generally not accessible via classical pericyclic reactions, often in a chemo-, regio-, and stereoselective manner. The following section will describe ['3 + 2 + 2'], ['4 + 2 + 2'] and ['4 + 3 + 2'] cycloadditions, however, ['2 + 2 + 2'] (*see* Chapter 5.31) and ['2 + 2 + 1'] (*see* Chapter 5.24) cycloadditions are not discussed.

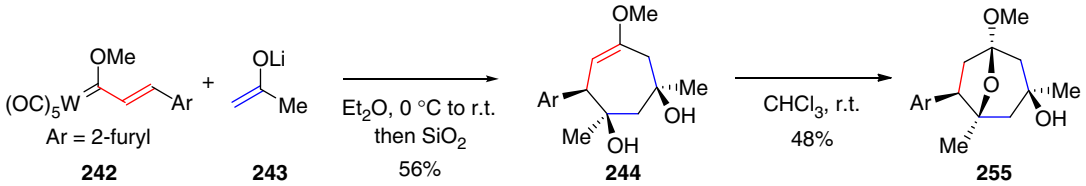
5.14.3.1 ['3 + 2 + 2'] Cycloadditions

The ['3 + 2 + 2'] cycloaddition is one of the least explored classes of cycloaddition reactions. Nevertheless, some of the developments in this class represent groundbreaking achievements in providing highly functionalized seven-membered rings. The paucity of new developments in this field is presumably the result of relatively few three-atom synthons that can participate in transition metals catalyzed reactions, and as a result, these have been largely limited to π-allyls, Fischer carbenes and cyclopropanes.



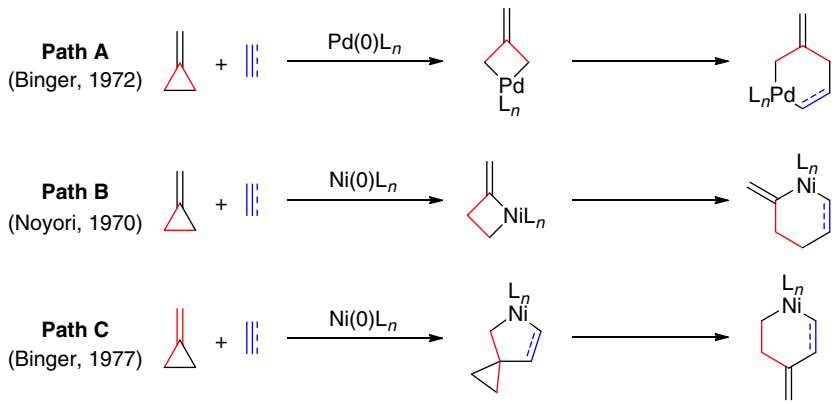
In the 1990s, Stryker and coworkers reported a number of transition metal-mediated [3 + 2 + 2] cycloaddition reactions of metal π-allyls with two alkynes.[98] The insertion of the first alkyne into the precomplexed π-allyl (**234**) affords the ruthenium complex **235**, which is followed by the insertion of the second alkyne to generate the seven-membered carbocycle **236**, in which the metal can undergo iodinolysis to afford the bicycloheptatriene **237** (Scheme 35). Interestingly, the isolation of the intermediates **235** and **236** coupled with the fact that the cycloadduct can either be formed in a single step or sequentially supports the proposed mechanism. The unusual η^1,η^4-bonding mode in **236** (E = CO_2Me), which was established by nuclear magnetic resonance, is thermodynamically more

Scheme 35 Transition metal-mediated [3 + 2 + 2] cycloaddition.



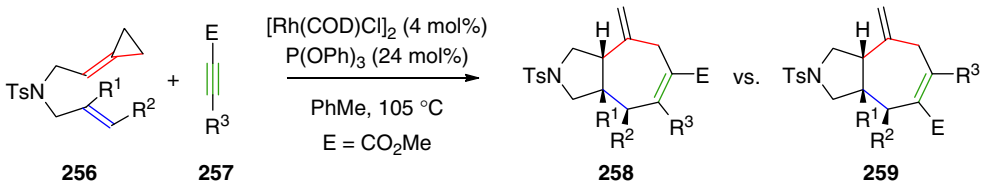
stable than the more commonly invoked η^5-cycloheptadienyl species. This mechanism is also considered to be similar for the corresponding iridium, cobalt, and palladium reactions of this type.[98,99]

Although Fischer carbenes have been used extensively as two-carbon synthons in cycloaddition reactions (cf. **Scheme 16**), the aryl substituted chromium-carbene **238** was recently introduced as a three-carbon synthon in a [3 + 2 + 2] cycloaddition with allenes (**Scheme 36**).[100] The regioselectivity of the reaction is intriguing, with nickel affording **240** and rhodium furnishing the complementary regioisomer **241**. Interestingly, the formation of the constitutional isomers is thought to be a result of a switch in the reaction mechanism rather than differences in the orientation of the allene in the migratory insertion step. Although **240** is formed as a single diastereoisomer, because the proximity of the alkenes restricts atropisomerism (diastereoisomers not depicted for clarity), heating above 80 °C promotes atropisomerism to afford a 2:3 mixture of diastereoisomers.



Scheme 36 Regiodivergent [3 + 2 + 2] cycloadditions via nickel-mediated and rhodium-catalyzed processes.

The reaction was expanded to lithium enolates, which eliminated the necessity to use additional transition metals, albeit the carbene **242** still requires stoichiometric tungsten (**Scheme 37**).[101] The reaction furnished cycloadduct **244** as a single diastereoisomer, which contains two ternary alcohols. Interestingly, on standing in chloroform, traces of hydrochloric acid promoted the cyclization of **244** to afford the oxabicycle **255** in 48% yield, which is a particularly attractive entry into these types of cycloadducts.

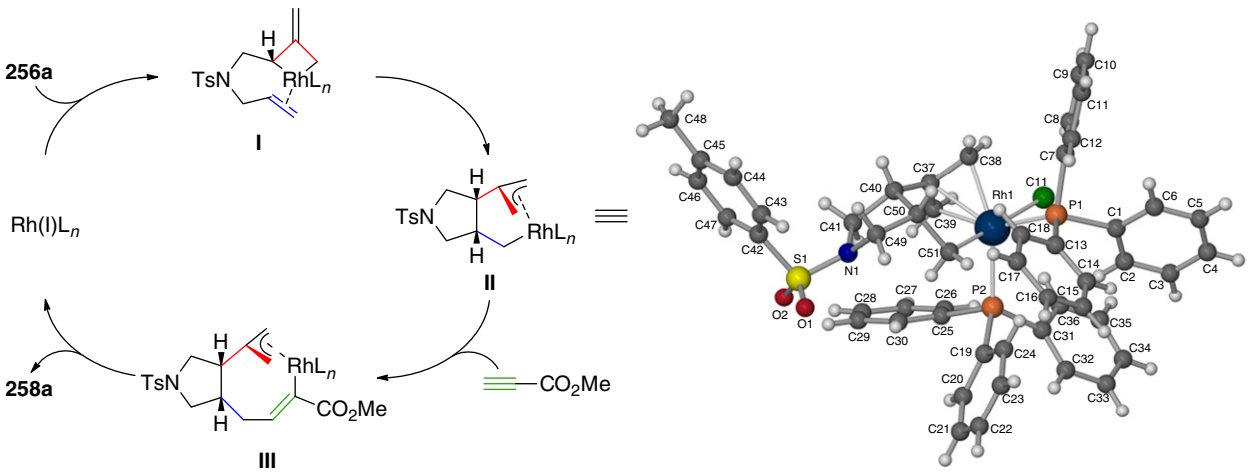


Scheme 37 [3 + 2 + 2] cycloaddition of tungsten-carbenes and lithium enolates.

Noyori and Binger proposed three different mechanisms during the 1970s to rationalize the cycloadducts formed from the reaction of transition metals with methylenecyclopropanes (**Scheme 38**).[102] For example, Binger proposed that palladium undergoes oxidative insertion into the distal cyclopropane bond to afford the palladacyclobutene intermediate (Path A), shortly after Noyori's initial discovery that nickel proceeds via initial proximal insertion (Path B). Nevertheless, these two pathways do not rationalize all of the observed cycloadducts, which prompted Binger to propose a third pathway (Path C) that involves a formal [2 + 2] oxidative addition to afford a metallacyclopentene, followed by a cyclopropylmethyl–butenyl rearrangement. It is noteworthy that, despite the similarities of the three pathways, the methylenecyclopropane represents a different synthetic equivalent in each example. Hence, the position of the olefin in the metallacyclohexene is β, α, and γ for Path A, B, and C, respectively, which provides the potential for the development of regiodivergent processes. This groundbreaking work provided the impetus for a plethora of [3 + 2] cycloadditions using various transition metals.

Scheme 38 Reactivity of methylenecyclopropane in the presence of transition metals.

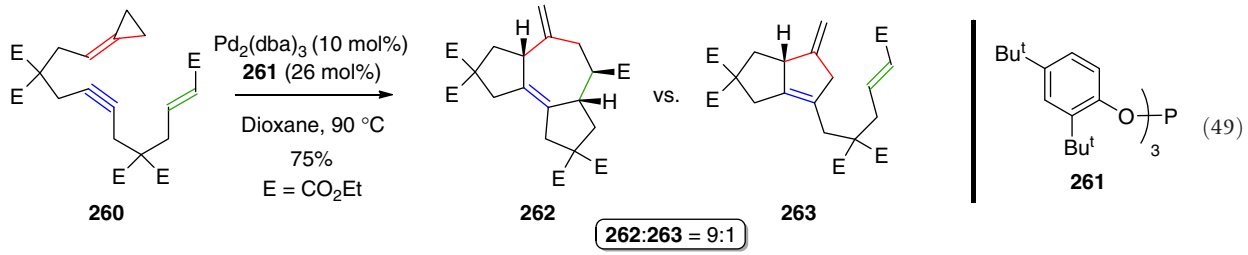
In 2008, Evans and Inglesby reported the first rhodium-catalyzed [(3 + 2) + 2] cycloaddition of alkylidenecyclopropanes (ACPs), which react via a process reminiscent of Path A. The combination of **256** and alkyne **257**, in the presence of the rhodium(I) complex derived from $[Rh(COD)Cl]_2$ and triphenylphosphite, furnished the cycloheptadienes **258**/**259** in a highly regio- and diastereoselective manner (equation 48).[103] The ease of preparation of the precursor **256** and subsequent reaction with alkynes makes this an extremely attractive approach to [5.3.0] systems, which are ubiquitous in bioactive natural products. Interestingly, the substrate and alkyne substitution impacts the selectivity (Table 6), for example, when $R^1/R^2/R^3 = H$, the reaction affords poor regiocontrol (entry 1), whereas substitution at R^1, R^3, and R^2 affords progressively greater selectivity (entries 2–4). It is noteworthy that all reactions of this type furnish the cycloadducts as a single diastereoisomer, thereby making this an important development in this area.



256 **257** **258** **259** (48)

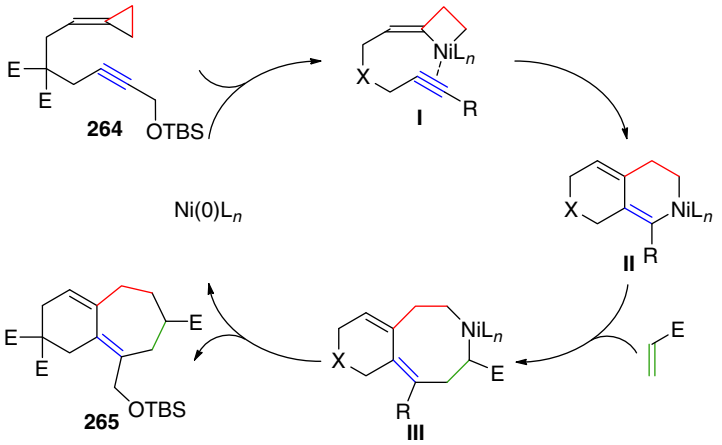
Table 6 Regio- and diastereoselective rhodium-catalyzed [(3 + 2) + 2] cycloadditions of ACPs with alkynes (equation 48)

	256		***257***				
Entry	R^1	R^2	R^3		***258*:*259***	*Yield (%)*	*Reference*
1	H	H	H	**a**	2:1	90	103
2	Me	H	H	**b**	5:1	85	103
3	H	H	Me	**c**	10:1	80	103
4	H	Me	H	**d**	≥19:1	85	103



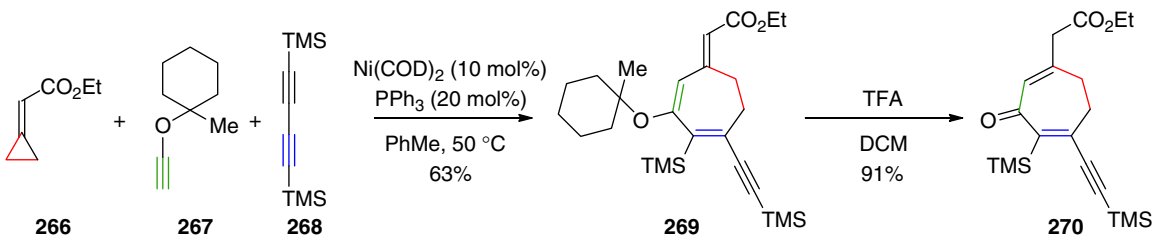
Scheme 39 outlines the proposed mechanism for this transformation, which rationalizes the observed regio- and diastereoselective outcome. Oxidative insertion of rhodium(I) into the distal bond of the cyclopropane, followed by rearrangement affords metallacyclobutene **I**. Carbometallation to the pendant alkene affords the rhodium(III) intermediate **II**, which upon alkyne insertion into the rhodium–alkyl bond and reductive elimination affords **258a**. Support for this mechanistic hypothesis was elegantly established via the isolation of rhodacycle **II**, which was demonstrated to promote the conversion of **256a** to **258a**, thereby confirming the catalytic competency of the intermediate. Moreover, the rhodium complex showed remarkable stability and did not undergo competitive reduction elimination to afford bicyclo[3.3.0]adducts.

Scheme 39 Catalytic cycle for the rhodium-catalyzed [(3 + 2) + 2] cycloaddition of ACPs and alkynes.



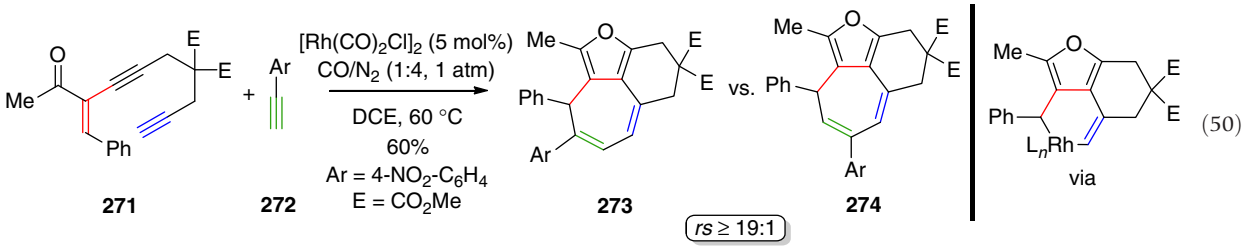
Contrary to the reactivity of rhodium, palladium-catalyzed reactions involving ACPs are prone to premature reductive elimination to furnish bicyclo[3.3.0]adducts. For example, the corresponding intramolecular [(3 + 2 + 2)] cycloaddition of **260** affords the desired tricycle **262** in competition with the undesired bicyclic adduct **263**.[104] This limitation significantly impacted the

development of palladium-catalyzed higher-order cycloadditions of this type, which has prompted the examination of nickel catalysis.



(49)

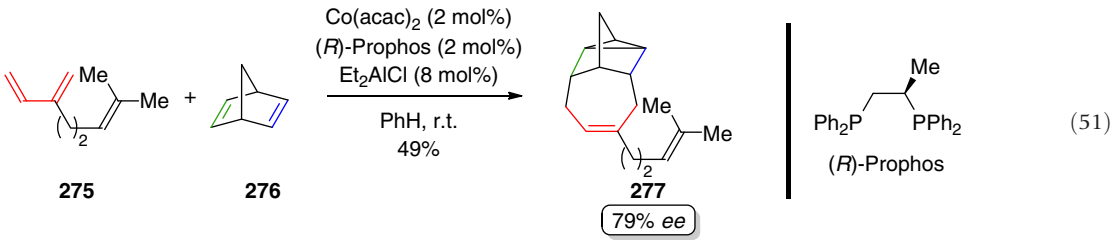
In accord with the mechanism outlined by Noyori (Path B), the ACP **264** provides the bicyclo[5.4.0]undediene **265** (Scheme 40). This process is consistent with proximal addition followed by carbometallation to afford metallacycle **II**, which on alkene insertion and reductive elimination affords the desired cycloadduct **265** as a single constitutional isomer.[105] The formation of intermediate **I** was supported by DFT and via the isolation of byproducts from competitive alkene insertion into **I** followed by reductive elimination to afford five-membered [3 + 2] cycloadducts.



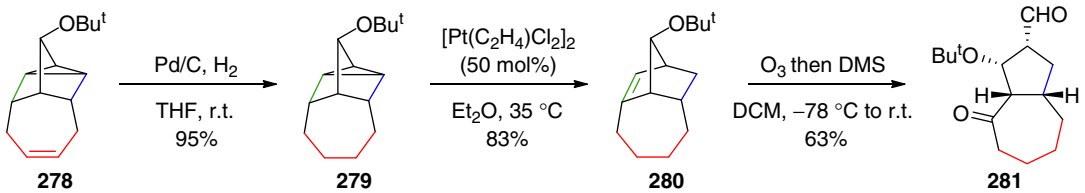
Scheme 40 Catalytic cycle for the nickel-catalyzed [(3 + 2) + 2] cycloaddition of ACPs and alkenes.

Cyclopropylidene acetates react with alkynes in the presence of a nickel(0) catalyst to afford the corresponding [3 + 2 + 2] cycloadducts. Several reports by Saito et al. have illustrated that this reaction is consistent with the selective oxidative coupling of the two alkynes, followed by insertion of ethyl cyclopropylidene acetate (**266**) in either an intra- or intermolecular fashion (Scheme 38; Path C).[106] A particularly impressive feature with this process is that the intermolecular reaction can employ two different alkynes, which provides extraordinary versatility and thereby provides a library of cycloheptadiene products in a rapid and economical manner. Recently, the ynol ether **267** was successfully coupled with **266** and **268** to provide the cycloadduct **269** in 63% yield.[106c] The advantage of employing ynol ethers is that the resulting enol ethers can be readily cleaved to effectively allow the insertion of an 'ethanal' synthon, which represents a motif that has been challenging to incorporate directly (Scheme 41).

Scheme 41 Nickel-catalyzed [3 + 2 + 2] cycloaddition of ethyl cyclopropylideneacetate with two different alkynes.



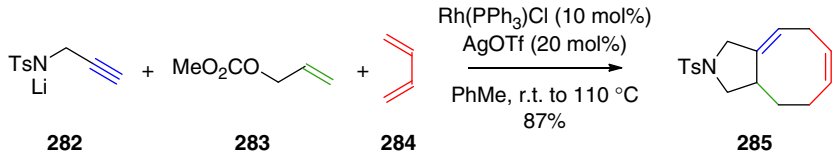
One of the few transition metal-catalyzed [(3 + 2) + 2] cycloadditions that eliminated the requirement for cyclopropanes was in the development of diyne-enones.[107] This motif provides a three-carbon surrogate between β-carbon of the enone and the internal alkyne in the presence of a rhodium catalyst, with the driving force for metallacycle formation being the construction of a furan from the cyclization of the carbonyl. Although alkyne insertion is generally more favorable into the rhodium–vinyl bond to promote reductive elimination to the cycloadduct **273**, the analogous insertion into the rhodium–alkyl bond provides an alternative pathway.



5.14.3.2 ['4 + 2 + 2'] Cycloadditions

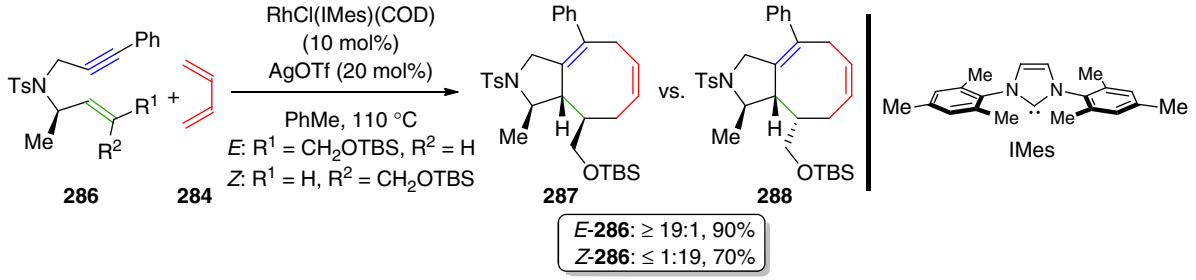
The ['4 + 2 + 2'] cycloaddition has attracted significantly more interest than the related ['3 + 2 + 2'] process, presumably because of the dearth of four-carbon synthons. In this context, 1,3-dienes provide one of the most versatile forms of this synthon, which react in the presence of transition metals with various 2π-components to prepare eight-membered rings. Medium rings are extremely difficult to prepare from readily available building blocks using conventional chemistry, which is presumably why this process has attracted so much attention. Moreover, the process is generally atom-economical and tolerant to an array of functionality, which makes this a very powerful synthetic strategy.

One of the earliest examples of a transition metal-catalyzed [4 + (2 + 2)] cycloaddition reaction utilized a strained norbornadiene (**276**) to provide the necessary reactivity for this cycloaddition.[108] Lautens and coworkers later reported the enantioselective variant of this processes.[109] For instance, treatment of **276** with butadiene **275** in the presence of a chiral cobalt catalyst, furnished the polycycle **277** in modest yield and enantioselectivity (equation 51).



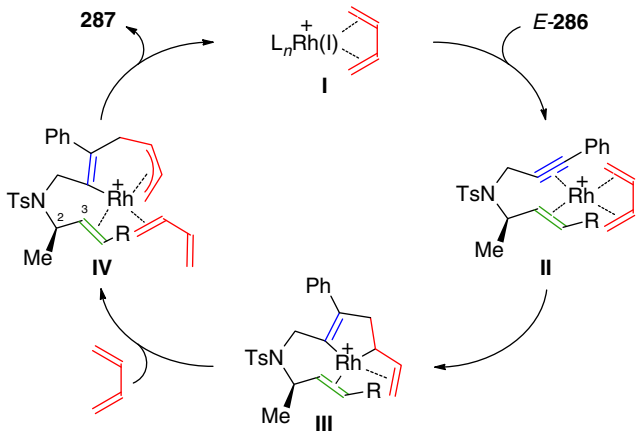
Snyder and coworkers expanded the scope of the achiral [4 + (2 + 2)] cycloaddition with functionalized norbornadienes and thus provided a more compelling rationale for the synthetic utility of this process with the conversion of the cycloadducts into useful bicyclo[5.3.0]decanes (**Scheme 42**).[110] For example, hydrogenation of the cycloadduct **278** to provide the saturated polycycle **279**, followed by platinum-mediated ring opening, afforded **280** in excellent yield. The mechanism of the ring-opening is thought to involve initial oxidative insertion to afford a platinacyclobutane, followed by a series of hydride transfers to furnish the thermodynamically stable trisubstituted alkene. Finally, ozonolysis of tricycle **280** gave the bicyclo[5.3.0]decane **281** as a single diastereoisomer. It is noteworthy that although the product from this derivatization resembles the bicyclo[5.3.0]adducts accessible via a [(3 + 2) + 2] cycloaddition, this approach offers alternative bond forming and bond breaking processes.

Scheme 42 Derivatization of [4 + (2 + 2)] cycloadducts to furnish bicyclo[5.3.0]decanes.



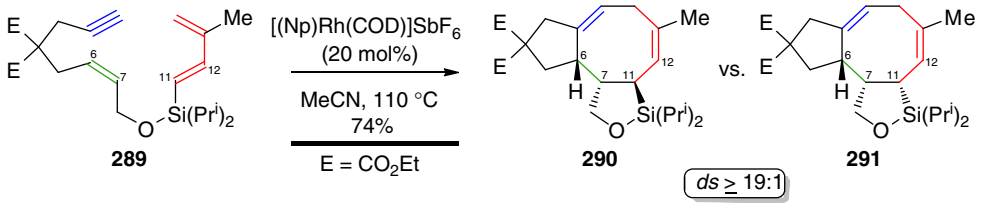
In 2002, Evans and coworkers described the first rhodium-catalyzed [4 + (2 + 2)] cycloaddition of tethered 1,6-enynes with butadiene. A particularly attractive feature with this reaction is the ability to couple the cycloaddition with an allylic substitution to prepare the reactive 1,6-enynes. For instance, the lithium anion **282** and allylic carbonate **283** react at room temperature in the presence of the rhodium catalyst and butadiene (**284**) to furnish the 1,6-enyne, which upon elevating the temperature to 110 °C

promoted the rhodium-catalyzed [4 + (2 + 2)] cycloaddition and provided the cycloadduct **285** in excellent overall yield (equation 52). Although preformed 1,6-enynes tolerate various tethers, including nitrogen, sulfur, and oxygen, the carbon-tethered 1,6-enynes were unsuccessful, which is somewhat unusual for these type of reactions.[56,111]



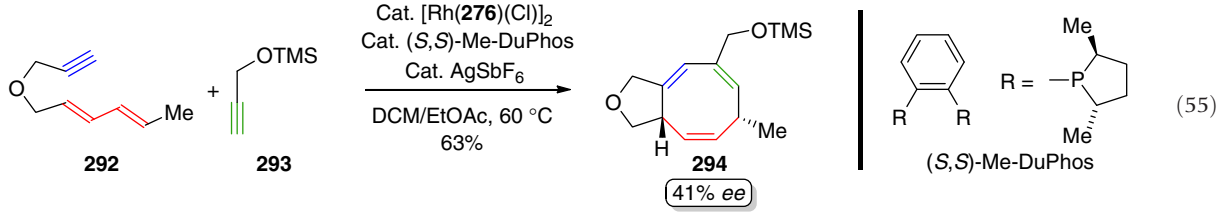
(52)

Additionally, the incorporation of a stereogenic center at the allylic position of the 1,6-enyne provided an excellent source of stereoinduction, in which 1,2-disubstituted alkenes undergo stereospecific insertion to provide three contiguous stereogenic centers in a highly controlled process. For example, *E*-**286** affords the *anti*,*anti*-cycloadduct **287** in 90% yield as a single diastereoisomer, whereas *Z*-**286** furnishes the *anti*,*syn*-diastereoisomer **288** with comparable efficiency and selectivity (equation 53). It is noteworthy that treatment of *E*-**286** to the analogous Pauson–Khand conditions (carbon monoxide atmosphere) provided the [(2 + 2) + 1] cycloadduct with poor diastereocontrol, which implied that the stereochemical-determining step for the two processes is different.[56,111]



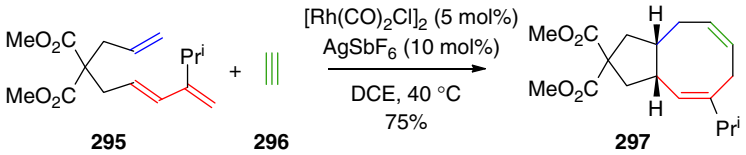
(53)

High-level DFT calculations provided support for an alternative mechanism, wherein preferential oxidative addition of rhodium(I) into the alkyne and butadiene olefin is favored over the more classical oxidative addition into the 1,6-enyne, which is well established for the Pauson–Khand reaction (**Scheme 43**). Moreover, metallacycle **IV** is significantly more stable than **III**, which has an additional butadiene molecule coordinated. Interestingly, alkene insertion into **IV**, which leads to the *anti*-metallacycle (C2–C3) is 3.27 kcal mol^{-1} lower in energy than the corresponding *syn*-metallacycle, which clearly explains the contrasting levels of diastereocontrol between the [4 + (2 + 2)] and [(2 + 2) + 1] cycloadditions.



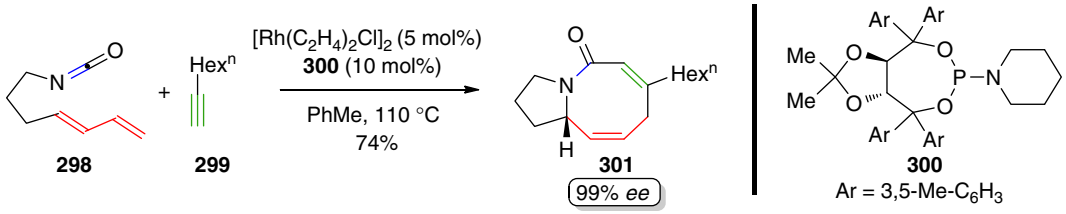
Scheme 43 Mechanism of the intermolecular rhodium-catalyzed [4 + (2 + 2)] cycloaddition.

Critical limitations with the intermolecular rhodium-catalyzed [4 + (2 + 2)] cycloaddition are the lack of regiocontrol with unsymmetrical butadiene derivatives and the inability to utilize carbon–tethers which severely limits the ability to apply this process to target-directed synthesis. In 2004, Evans and Baum provided a convenient solution to these problems by utilizing a temporary silicon-tether, which rendered the process both regiospecific and highly diastereoselective (equation 54).[111c] Similar to the intermolecular variant (cf. equation 53), the reaction is stereospecific with respect to alkene incorporation, which provides access to *syn*- and *anti*-diastereoisomers at C6/C7. Additionally, the reaction provides exclusively the *anti*-diastereoisomer with respect to C7/C11, which was attributed to nonbonding interactions in the transition state between the proton at C11 olefin with one of the isopropyl groups on the silicon-tether.



(54)

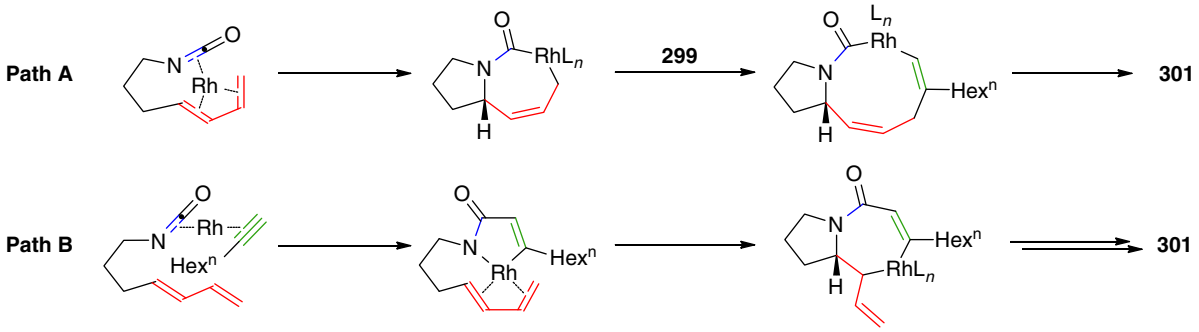
Gilbertson and DeBoef concurrently reported the construction of cyclooctatrienes via a related [(4 + 2) + 2] cycloaddition of tethered 1,3-dienynes with alkynes, in which the alkyne insertion is highly regioselective for 1,4-disubstituted 1,3-butadienes (equation 55). Interestingly, this reaction evolved from the serendipitous isolation of the [(4 + 2) + 2] cyclodimer of **292** during an investigation into the intramolecular rhodium-catalyzed [(4 + 2)] cycloaddition. Nevertheless, the formation of the dimer is difficult to completely suppress, even in the presence of an excess of alkyne (5 equivalents).[112]



(55)

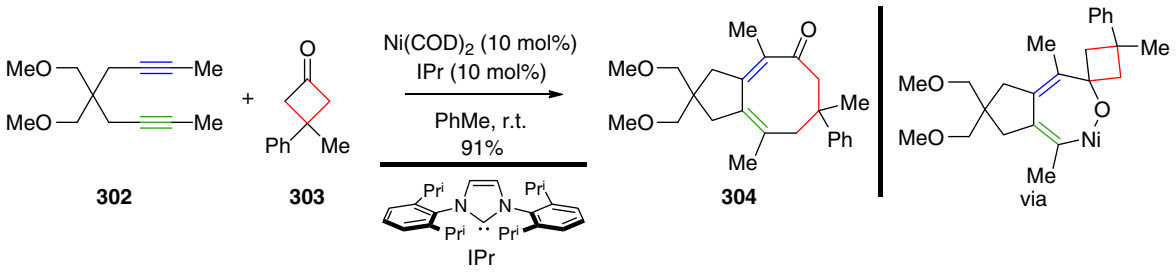
Wender and coworkers expanded the scope of the [(4 + 2) + 2] cycloaddition to alkenyl-tethered 1,3-dienes with alkynes (equation 56), which is based on their previous work on the [(2 + 2) + 1] Pauson–Khand reaction using 1,3-dienes as alkyne equivalents.[113] For example, triene **295** reacts with acetylene (**296**) in the presence of catalytic rhodium(I) to furnish the cyclooctadiene **297** in good yield. In contrast to the process outlined by Gilbertson, the reaction suffers from poor selectivity with unsymmetrical alkynes (cf. equation 55).

(56)



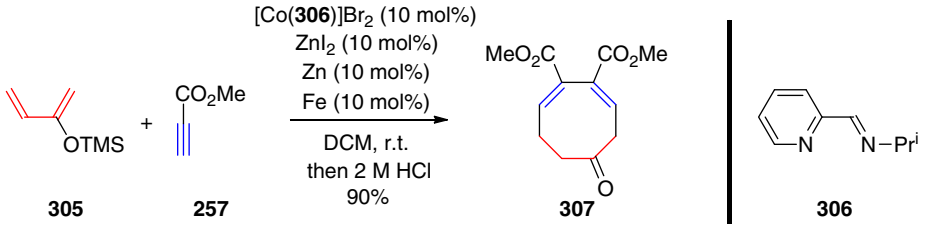
The only highly enantioselective [(4 + 2) + 2] cycloaddition reported to date is the rhodium-catalyzed reaction of dienyl isocyanates with alkynes (equation 57).[114] The reaction provides bicyclo[6.3.0]azocine systems with excellent enantioselectivity for a number of monosubstituted alkynes. Although the piperidine (vs. pyrrolidine) substituent on the phosphoramidite ligand does not impact the level of enantioselectivity, it is crucial for high conversion.

(57)



The reaction proceeds via an alternative mechanism to that proposed for the related [(2 + 2) + 2] cycloaddition between alkynes and isocyanates, which involves the direct intermolecular oxidative addition between the alkyne and isocyanate components. In contrast, the 1,3-dienyl isocyanates are proposed to undergo oxidative addition with rhodium(I) to afford the metallacycloheptene intermediate, which is followed by alkyne insertion and reductive elimination to furnish **301** (Path A). The deviation in reaction mechanism is supported by the fact that, although the alkene geometry and 1,3-dienyl substitution impact isocyanate reactivity, the level of enantioselectivity remains consistent, which suggests that the alkyne is not involved in the enantiodetermining step. Nevertheless, the nature of the alkyne does impact the reaction mechanism, because Path B becomes a competing pathway for more nucleophilic alkynes (Scheme 44).

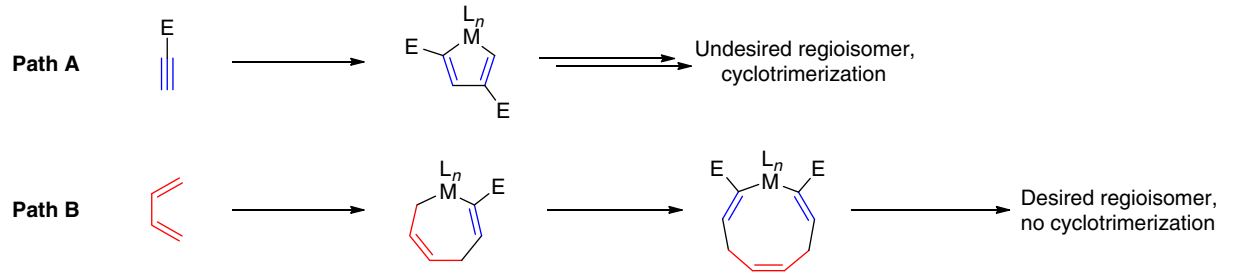
Despite the plethora of examples that employ 1,3-dienes, cyclobutanones also provide excellent four-carbon synthons. For example, the reaction of **302** with **303** in the presence of the nickel–NHC catalyst affords the [4 + (2 + 2)] cycloadduct in excellent



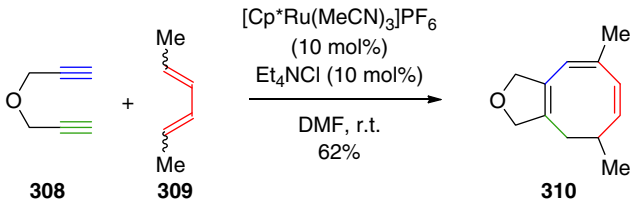
Scheme 44 Plausible pathways for the rhodium-catalyzed [(4 + 2) + 2] cycloaddition leading to bicyclo[6.3.0]azocines.

yield (equation 58). Interestingly, direct oxidative insertion into the cyclobutanone is not thought to be involved in the catalytic cycle, but the carbonyl of **303** acts as a 2π-component and inserts into a nickelacyclopentadiene generated through oxidative addition into **302**. The resultant oxanickelacycloheptadiene then undergoes cyclobutane ring-opening via β-carbon elimination followed by reductive elimination to provide **304**. The nickel–NHC catalyst also successfully converts unsymmetrical 1,6-enynes into the corresponding cycloadducts with excellent selectivity, albeit in poor yield.[115]

(58)



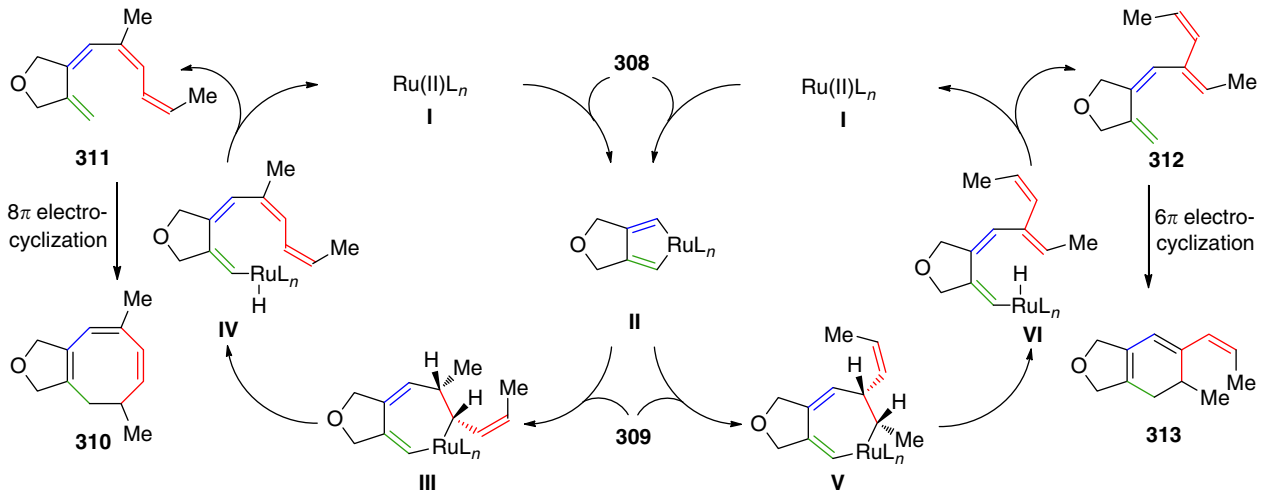
In 2008, Hilt and Janikowski reported the cobalt-catalyzed intermolecular [4 + 2 + 2] cycloaddition of two alkynes and a 1,3-butadiene derivative (equation 59). Although the reaction is cobalt-catalyzed, the addition of iron powder is critical for reducing competitive side reactions and increasing the overall efficiency. For example, the cycloaddition of **305** with methyl propiolate (**257**) in the presence of the catalyst mixture afforded the cyclooctadienone **307** in 90% yield after the acid-catalyzed deprotection of the silyl enol ether.[116]



(59)

Remarkably, an excess of the alkyne component is not required, which suggests that the mechanism does not proceed via oxidative addition into the alkynes because this would lead to a high degree of cyclotrimerization (Scheme 45; Path A). The regioselectivity is however indicative of metallacycle formation between the 1,3-diene and one alkyne, followed by insertion of the second alkyne and reductive elimination (Scheme 45; Path B).

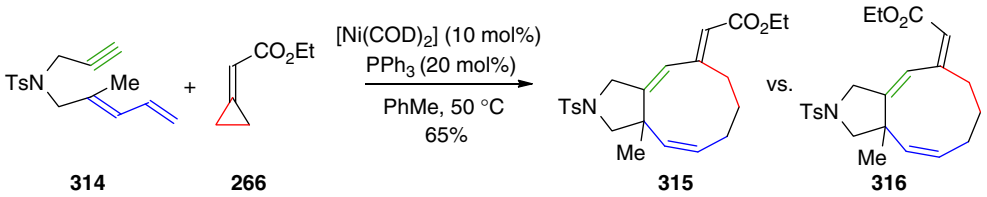
Saá and coworkers reported an approach to eight-membered rings via a formal [4 + (2 + 2)] cycloaddition, which involved an unusual 8π-electrocyclization of a 1,3,5,7-tetraene.[117] The reaction was discovered while probing the direct ruthenium-catalyzed [4 + (2 + 2)] reaction of 1,6-diynes with butadienes, however, the resulting substitution in the cyclooctatriene was not consistent with a direct cycloaddition. For example, the reaction of the 1,6-diyne **308** with excess **309** in the presence of the ruthenium catalyst affords the cycloadduct **310** in modest yield (equation 60).



Scheme 45 Mechanistic ralionale for the regioselective cobalt-catalyzed [4 + 2 + 2] cycloaddition.

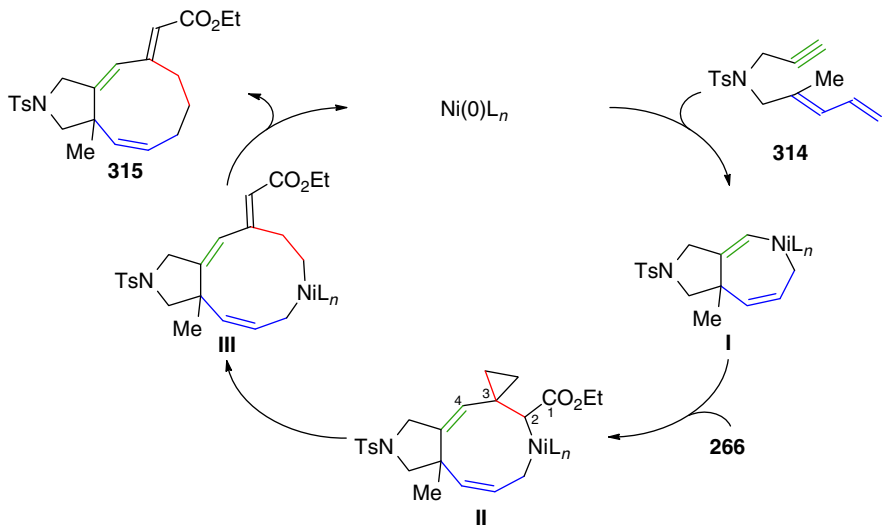
(60)

As predicted for this type of electrocyclization reaction, alkene geometry impacts the feasibility of the cyclization, in which only the *Z*-isomers of **309** react in the ene-cycloisomerization reaction to afford the corresponding *Z*-1,3,5,7-tetraene **311** which leads to the smooth conrotary cyclization to afford **310** (Scheme 46). Additional control experiments demonstrated that *E*,*E*-**309** was unreactive and afforded none of the cycloadduct. It is noteworthy that this reaction is selective for the formation of the eight-membered adduct whereas other 1,3-dienes afford large amounts of six-membered adducts as a result of poor regioselective insertion into ruthenacycle **II**. This leads to the tetraene **312**, which undergoes a disrotary 6π-electrocyclization reaction to afford **313**.



Scheme 46 Sequential intermolecular ruthenium-catalyzed ene-cycloisomerization/8π electrocyclization.

5.14.3.3 ['4 + 3 + 2'] Cycloadditions

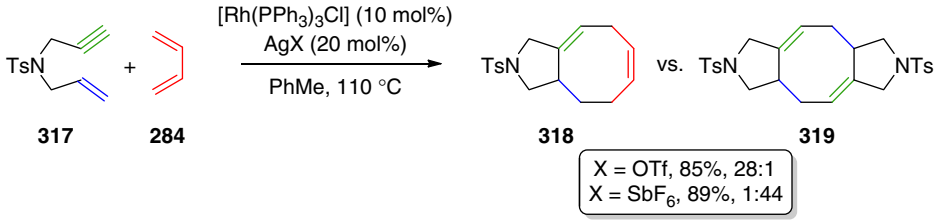


The ['4 + 3 + 2'] cycloaddition is one of the least studied transformations in this area and it is therefore understandable that examples of this complex process have only recently been developed, because it requires the coupling of three extremely different components. Moreover, the ability to overcome inherent low energy barriers that provide alternative cycloadducts can be challenging. Despite the fact that the dienyne **314** readily participates in transition metal-catalyzed [(2 + 2) + 2], [(4 + 2)] and [(4 + 2) + 2] cycloadditions, none of these adducts were observed in the [(4 + 2) + 3] process with the ACP **266**. For example, the

slow addition of **266** to a solution of **314** and the nickel complex in toluene at 50 °C affords **315** as a single geometrical isomer, albeit related examples proceed with poor geometrical selectivity (equation 61).[118]

(61)

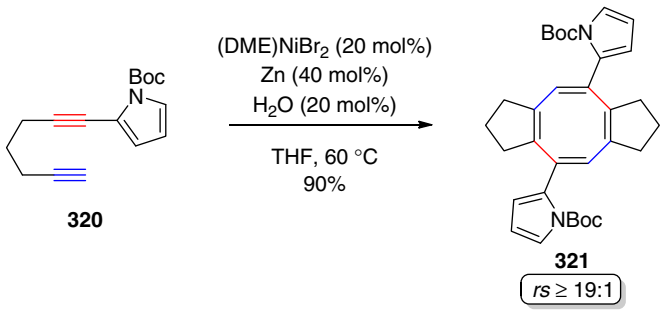
The reaction proceeds via initial oxidative addition into **314** to generate the nickel(II) intermediate **I** (Scheme 47). Regioselective insertion of ethyl cyclopropylideneacetate (**266**) into the nickel–vinyl (vs. nickel alkyl) bond affords the nine-membered metallacycle **II**, which upon cyclopropylmethyl–butenyl rearrangement and reductive elimination affords the [(4 + 2) + 3] cycloadduct. The formation of exocyclic alkene geometrical isomers is rationalized by the relative conformation of the metallacyclic intermediates. For example, when the dihedral angle between C1–C2 and C3–C4 in metallacycle **II** is large, the selective cyclopropylmethyl–butenyl rearrangement furnishes metallacycle **III** with *trans*-stereochemistry, whereas a small dihedral angle favors the *cis*-geometry. Therefore, the nature of the tether and ligands on the metal center dramatically impact the level of stereocontrol in this transformation.



Scheme 47 Mechanism of the nickel-catalyzed [(4 + 2) + 3] cycloaddition.

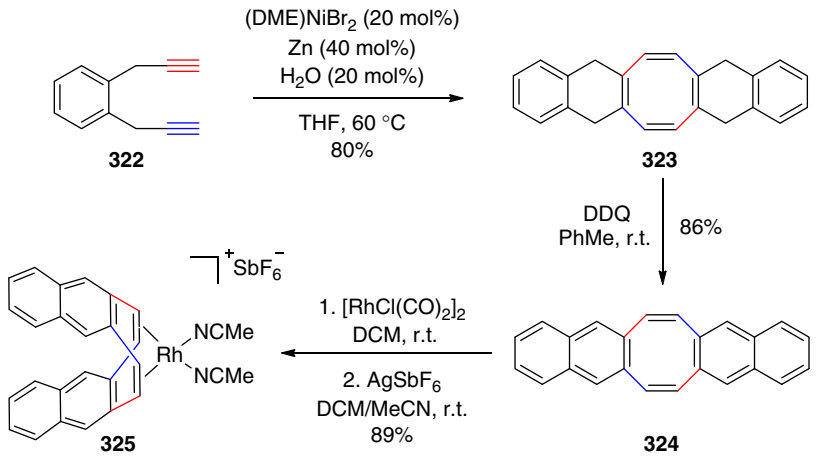
5.14.4 ['*m* + *n* + *o* + *p*'] Cycloadditions

5.14.4.1 ['2 + 2 + 2 + 2'] Cycloadditions



The transition metal-catalyzed [2 + 2 + 2 + 2] cycloaddition[1p] was first reported in 1948 by Reppe who demonstrated the nickel tetramerization of acetylene to furnish cyclooctatetraene,[119] which remains one of the most impressive examples of a four component cycloaddition because the products can be readily ring contracted to afford a range of substituted benzenes. Moreover, the one-step synthesis of cyclooctatetraene represents a significant improvement over the earlier 10-step synthesis and formed the basis for an industrial process. Despite efforts to expand the scope of the reaction by employing unsymmetrical alkynes, poor regio- and stereoselectivity have severely limited the productive translation of this process into more challenging systems.[120]

In 2002, during the investigation into the rhodium-catalyzed [4 + (2 + 2)] cycloaddition (*vide supra*), Evans and coworkers serendipitously discovered that modification of the counter-ion resulted in the selective formation of the [(2 + 2) + (2 + 2)] dimer **319** (equation 62). The complementary reactivity of the two outer-sphere counter-ions was attributed to the propensity of the hexafluoroantimonate modified catalyst to promote butadiene oligermerization, hence reducing its effective concentration and promoting homodimerization.[111a]



(62)

Recently, nickel complexes have also been demonstrated to promote this type of reaction, albeit the competitive [(2 + 2) + 2] dimerization adducts were, in many examples, the major product.[121] Nevertheless, along with the initial discovery by Reppe, many of the examples in this class utilize four alkyne components and ultimately afford cyclooctatetraenes. In 2007, Wender reported the nickel-catalyzed dimerization of 1,6- and 1,7-diynes for the synthesis of cyclooctatetraenes.[122] The reaction is highly selective (>50:1) for the formation of the [(2 + 2) + (2 + 2)] adduct versus [(2 + 2) + 2] adducts when a large catalyst loading is used (40 mol%), however, at a lower catalyst concentration (1 mol%) the [(2 + 2) + 2] adduct predominates. This provided support for the mechanism outlined by Wilke, which invokes a bimetallic dimerization of two nickallacyclopentadiene intermediates generated via oxidative addition of the *in situ* formed nickel(0) into the diyne.[123] Recent advances have expanded the scope to unsymmetrical diynes, which proceed with excellent regioselectivity when one of the acetylene substituents is aromatic (equation 63).[124]

(63)

In contrast to their numerous applications in natural product synthesis, cyclooctatetraenes have also been utilized as ligands in the synthesis of stable transition metal complexes. For example, Wender and coworkers reported the preparation of the tetracyclic [(2 + 2) + (2 + 2)] cycloadduct **323**, which undergoes oxidation to generate the dinaphtho[*a*,*e*]cyclooctatetraene **324** (Scheme 48).[125] They demonstrated that this intermediate acts as a bidentate ligand for rhodium(I)- and iridium(I)-complexes in a similar manner to 1,5-cyclooctadiene. Furthermore the ability to tune the reactivity of **324** via a two-step bromination/palladium-catalyzed coupling allows for the rapid synthesis of a number of sterically and electronically diverse metal complexes. Interestingly, rhodium complex **325** shows varied, but often superior selectivity to the rhodium complex [(Np)Rh(COD)]SbF_6 in the intermolecular [5 + 2] cycloaddition between VCPs and alkynes (cf. equation 24). In contrast, **325** showed comparable results to [(Np)Rh(COD)]SbF_6 in the intramolecular [(5 + 2)] reactions of alkynyl- and alkenyl-tethered VCPs (cf. equations 21 and 26).

Scheme 48 Application of cyclooctatetraenes in the synthesis of stable transition metal complexes.

In an advancement on the issues relating to the practicalities of the nickel-catalyzed [(2 + 2) + (2 + 2)] dimerization of 1,6-diynes, Okamoto and coworkers recently devised a strategy that circumvented the necessity to employ high catalyst loadings.[126] Since there had been previous support for the aforementioned bimetallic mechanism, they hypothesized that the effective substrate-to-catalyst concentration could be increased by performing the reaction in a biphasic medium and hence low catalyst loading may be tolerated if the nickel is adequately modified with water-solubilizing ligands. They demonstrated that an organic/ionic liquid mixture (toluene/imidazolium salt, 20:1 (v/v)) proved successful in providing good yields with 5 mol% of the catalyst, albeit competing [(2 + 2) + 2] and polymerization byproducts were still observed.

5.14.5 Conclusion

The development of higher-order cycloaddition reactions has aided in the formation of hitherto unknown molecular architecture that would otherwise be difficult to construct. The past 20 years has resulted in an exponential growth of this exciting field with the development of highly stereoselective syntheses of cyclic structures. Moreover, the atom- and step-economy of many of these reactions represents unparalleled versatility in the art of preparing complex polycyclic structures. Despite these achievements, this area remains in its infancy and is thereby likely to continue to develop as the search for new and improved reactions continue to be at the forefront of synthetic sequences.

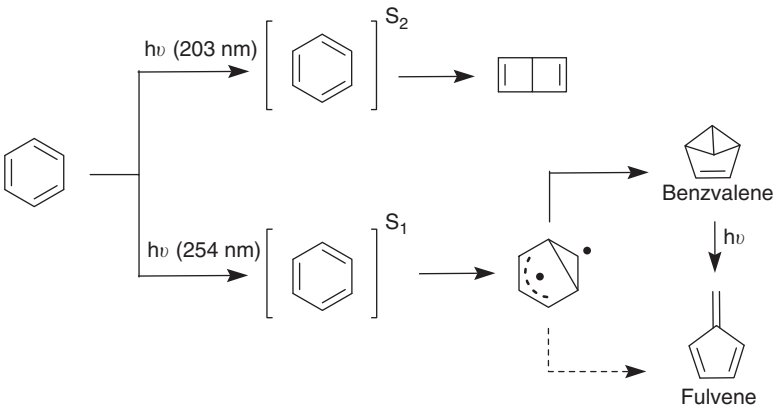
Glossary

Exciplex An electronically excited complex of definite stoichiometry, 'nonbonding' in the ground state. For example, a complex formed by the interaction of an excited molecular entity with a ground state counterpart of a different structure.

Intersystem crossing An isoenergetic radiationless transition between two electronic states having different multiplicities. It often results in a vibrationally excited molecular entity in the lower electronic state, which then usually deactivates to its lowest vibrational level.

Photocycloaddition Intermolecular photochemical process leading to carbo- or heterocyclic ring systems by formation of two new single bonds, either by a concerted process or by multistep processes.



Singlet state A state having a total electron spin quantum number equal to 0.

Triplet state A state having a total electron spin quantum number of 1.

5.15.1 Introduction

Photocycloadditions can be carried out in various modes,[1] and are not limited to simple alkenes. A benzene core, which is very stable under thermal conditions, can become highly reactive on excitation with photons. Conversion into benzvalene[2] and fulvene,[3] when excited to its first excited state, or to Dewar benzene[4] via excitation to its second excited-state (**Scheme 1**) will occur.[5]

In the presence of an alkene, a photocycloaddition with benzene derivatives takes place. Three different modes are known for this reaction, the [2 + 2] or *ortho*, the [3 + 2] or *meta*, and the [4 + 2] or *para* photocycloaddition (**Figure 1**). The descriptors *ortho*, *meta*, and *para* only indicate the connectivity to the former aromatic ring, and do not have any implication with regard to the reaction mechanism. Arene–alkene photocycloadditions are among the most theoretically intriguing and synthetically promising discoveries in organic chemistry. They provide an efficient synthetic access to a range of natural and nonnatural compounds from simple, readily available precursors.

Scheme 1 Photochemistry of benzene.

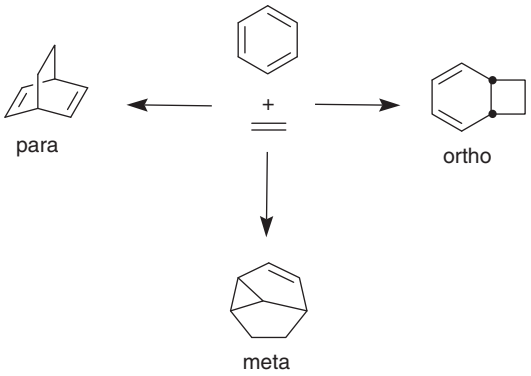


Figure 1 The three modes of the arene–alkene photocycloaddition.

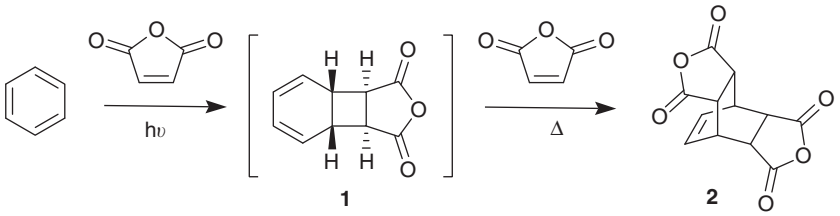
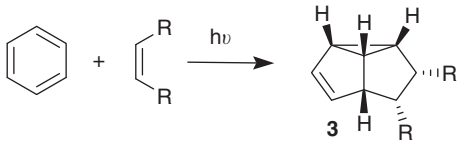


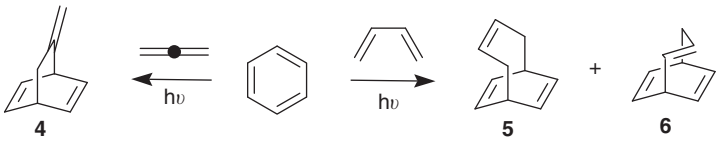
These remarkable reactions, which have no counterpart in thermal chemistry, have inspired physical organic chemists, synthetic organic chemists, and theoretical chemists during a period of more than 50 years.[6] There are beautiful examples of applications in organic synthesis, but the potential of the intermolecular variants have by no means been fully exploited. Theoretical description of the processes were intensively investigated and have led to an improved understanding, but are far from complete, especially with regard to the stereochemical aspects. This chapter starts with a brief historical perspective and carries on with simple theoretical considerations and mechanistic insights, where stereochemical and regiochemical issues are highlighted. In so doing, a special emphasis will be placed on the intramolecular variant of the *meta* photocycloaddition because it is very well documented in the literature and has been used many times in organic synthesis. The subsequent sections deal with applications in total syntheses and discuss the influence of the substitution patterns with regard to the structures that can be delineated thereof. The *ortho* and particularly the *para* photocycloadditions are discussed in Sections 5.15.6 and 5.15.7 of this chapter. They have not received as much attention and literature is few and far between. Additionally, the processes that have been described are low yielding and so far not applicable to organic synthesis, but bear a huge potential for further developments.

5.15.2 Historical Perspective



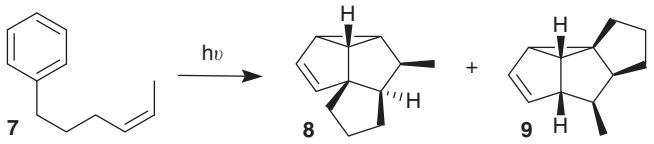
The first 'classical' $[2\pi + 2\pi]$ photocycloaddition of benzene was described by Angus and Bryce-Smith in 1959.[7] They attempted to trap fulvene produced during the irradiation of benzene by conducting the reaction in the presence of maleic anhydride. Instead of the expected Diels–Alder product, they obtained a novel adduct **2**, which was shown to be formed via initial *ortho* cycloaddition and subsequent Diels–Alder reaction (Scheme 2).

However, Ayer, Bradford, and Büchi had obtained similar *ortho* products approximately 4 years earlier and recorded their findings in a patent.[8] These early discoveries stimulated interest in the photochemistry of other arene–alkene systems, leading to a codiscovery of a second type of cycloaddition by Wilzbach and Kaplan[9] and by Bryce-Smith et al. in 1966.[10] In this reaction, an alkene is bound to the arene in a 1,3- or *meta* fashion (Scheme 3).



Shortly thereafter, the first examples of 1,4-bonding or para photocycloadditions to the initial arene ring were discovered (Scheme 4).[11]

Scheme 2 The first [2 + 2] photocycloaddition by Angus and Bryce-Smith in 1959.



Scheme 3 The discovery of the *meta* photocycloaddition in 1966 by Wilzbach, Kaplan, and Bryce-Smith.

Scheme 4 The discovery of the *para* photocycloaddition.

In 1969, Morrison and Ferree reported the first examples of an intramolecular arene–alkene photocycloaddition, discovered in the course of their exciting studies of bichromophoric compounds (Scheme 5).[12]

Scheme 5 The first intramolecular *meta* photocycloaddition by Morrison and Ferree in 1969.

Especially, the complexity of the products **8** and **9** formed during the intramolecular variant immediately drew the awareness of the synthetic community to this reaction.[6c,13] Subsequently, considerable effort has been invested to understand and further develop benzene photocycloadditions. This has resulted in some spectacular results, among which the application of the *meta* photocycloaddition in the total synthesis of natural products is worth mentioning, particularly by Wender et al.,[14] who pioneered this field. The topic has been reviewed on several occasions mainly by Cornelisse,[6g] Mattay,[15] Wender,[16] Hoffmann,[6i] and de Keukeleire,[6h] with a strong focus on the *meta* mode.

5.15.3 Mechanistic Considerations

A number of processes can take place when an arene is irradiated in the presence of an olefin, including exciplex formation, excitation transfer, isomerization, addition, and cycloaddition. These pathways can lead to substitutions, *ene*-addition products, and to *ortho*, *meta*, or *para* cycloadducts. Control of these different modes is crucial if one aims to obtain defined photocycloadducts in synthetically useful yields. In 1974, Bryce-Smith et al.[17] devised a rule that has become famous for its predictive power: $\varphi_{ortho} > \varphi_{meta}$ when 9.6 eV < IP (alkene) < 8.65 eV. In general, *ortho* cycloaddition is the preferred process with relatively powerful donor and acceptor alkenes, whereas for alkenes with a similar ionization potential (IP) as benzene (9.24 eV), *meta* addition is the preferred process.[18] Bryce-Smith et al.[19] have discussed some deviations from the rule and remarked that the range 8.65–9.6 eV may prove a little too restricted to cover all addends. Gilbert et al.[20] have argued that IPs only of structurally closely related alkenes can be compared in a meaningful manner with regard to the efficiencies of *ortho* versus *meta* cycloadditions.

Nevertheless, successful predictions of many systems concerning the preferred mode of ethane–benzene photocycloaddition have been carried out.[21] Houk[22] came to the same conclusion by deriving the Bryce-Smith/Gilbert generalization on the basis of

orbital interactions. He also found that the *ortho* adduct is favored when the alkene is either a better donor or a better acceptor than benzene. Mattay[15a,23] also derived a rule, which enables the prediction of the mode of reaction between an arene and an alkene if the donor and acceptor properties of the reactants are known. The *ortho* and *meta* photocycloadditions as well as electron-transfer reactions leading to substitution on the arene or on its side chain are considered. Mattay's rule is based on the Weller theory of electron transfer. He considers the free enthalpies of electron transfer according to the Rehm–Weller equation:

$$\Delta G = F\left[E^{ox}_{1/2}(D) - E^{red}_{1/2}(A)\right] - \Delta E_{excit} + \frac{e^2 N}{4\pi a \varepsilon_0}\left[\frac{1}{e} - \frac{2}{37.5}\right] \quad (1)$$

where $E^{ox}_{1/2}(D)$ = oxidation potential of the donor; $E^{red}_{1/2}(A)$ = reduction potential of the acceptor; ΔE_{excit} = excitation energy; $F = 96\,490$ C; $e = 1.602 \times 10^{-19}$ C; $\varepsilon_0 = 8.854 \times 10^{-12}$ Fm^{-1}; ε = dielectric constant of the solvent (ε of acetonitrile is 37.5); $N = 6.023 \times 10^{23}$ mol^{-1}; a = encounter distance, 7 Å; the energies are in eV.

Olefins possessing poor electron-donor or poor electron-acceptor abilities preferentially yield *meta* cycloadducts in photoreactions with benzene; this is the case if $\Delta G > 1.4 - 1.6$ eV (Figure 2).[24] All other alkenes undergo *ortho* cycloaddition. In photoreactions of alkenes with substituted benzenes similar correlations with the ΔG values exist. For example, in reactions of alkenes with benzonitrile, the rule correctly predicts that electron transfer prevails if $\Delta G < 0$, addition of the alkene to the nitrile group occurs if $0 < \Delta G < 0.5$, *ortho* addition in the region $0.5 < \Delta G < -1.7$ and *meta* addition if $\Delta G > -1.7$ eV. The boundaries of the ΔG areas are not very sharp and in overlapping regions two types of reaction with one alkene are observed. However, a biradical intermediate was proposed in the photocycloaddition mechanism, but all attempts to trap a biradical or a zwitterionic intermediate have so far been unsuccessful. A very clever study to test the presence of a biradical intermediate was carried out by Reedich and Sheridan.[25] They incorporated a diazo group into the last formed bond of the cyclopropyl ring (compound **10**) in the *meta* photocycloadduct.[26] If a biradical is an actual intermediate in the course of the reaction, extrusion of nitrogen from **10** should form the same products as the *meta* photocycloaddition. Indeed, they were able to isolate the same products formed by the *meta* photocycloaddition (Scheme 6).

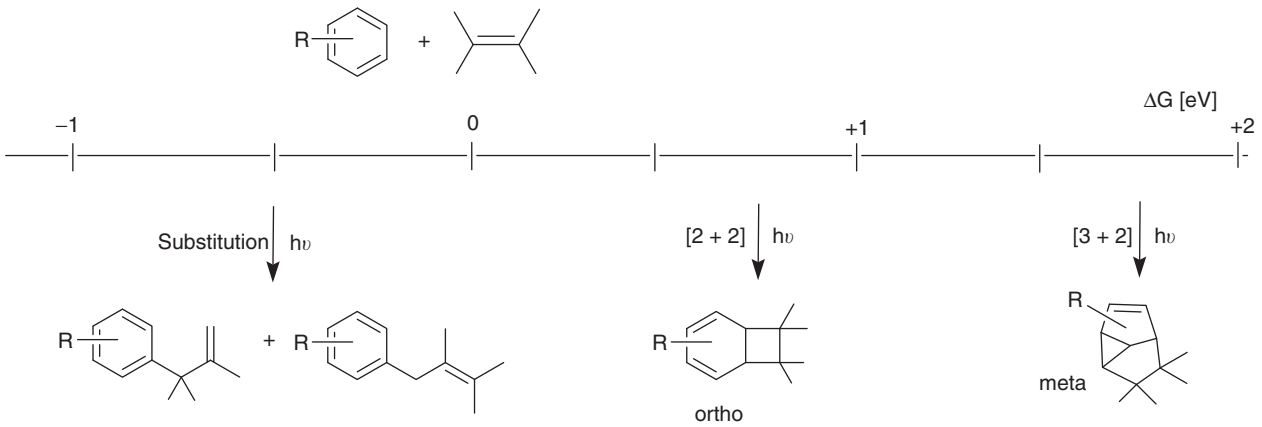


Figure 2 Mode selectivity in dependence of the free enthalpy of radical formation.

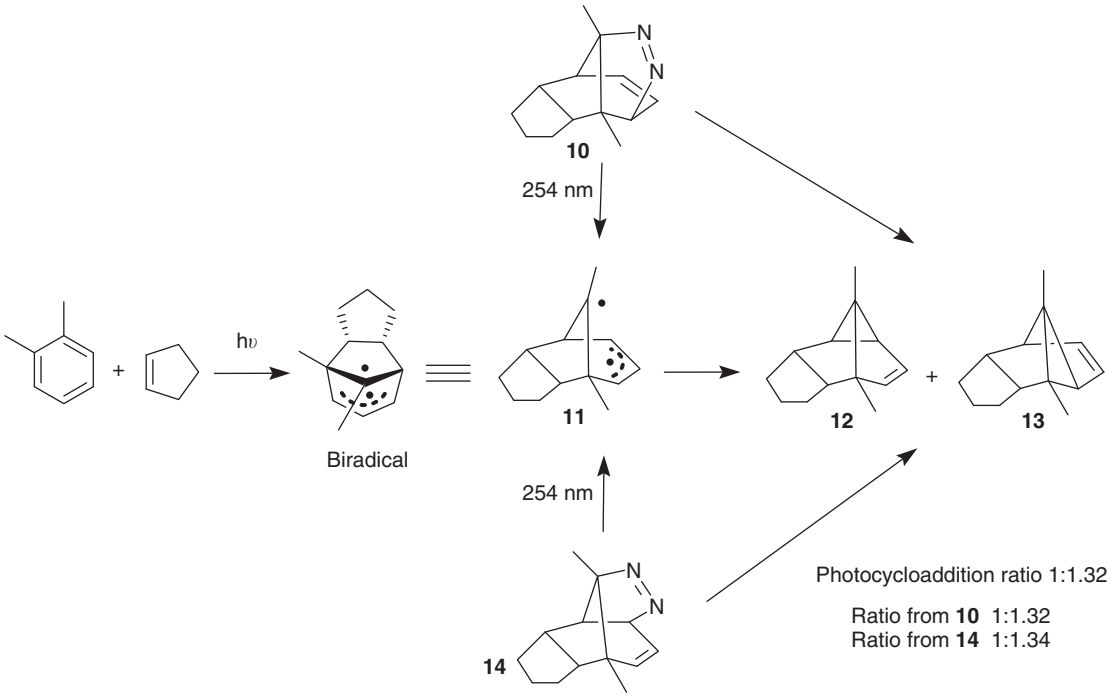

Even very similar ratios of the two distinct stereoisomers **12** and **13** were found to be formed from the diazo compounds **10** and **14** as well as from the photocycloaddition of *o*-xylene to cyclopentadiene. These findings indicated the participation of a biradical structure **11** in the *meta* photocycloaddition pathway; however, it remains unclear whether this biradical is an intermediate with a well-defined half-life or if it is just a transitory species.[27]

5.15.4 The *Meta* Photocycloaddition

Among the three modes of arene–alkene photocycloaddition reactions the *meta* product exhibits the largest increase in molecular complexity. The author, therefore, considered it useful to pinpoint the most representative drawings used in literature to the reader (Figure 3). The numbering is in accordance to the International Union of Pure and Applied Chemistry rules. Each representation emphasizes specific features of the structure. Picture I clearly shows the bond formation between C5 and C8, whereas structures II and IV display the symmetry of the product best. Diagram III is most suitable when stereochemical issues are discussed, as it illustrates the spatial approach of the olefin to the aromatic ring.

5.15.4.1 Regioselectivity

As soon as substituents are attached, either to the aromatic ring or the alkene, regioselectivity becomes an issue. There are two distinct regioselectivities involved in the *meta* photocycloaddition.

Scheme 6 Mechanistic investigations on biradical formation.

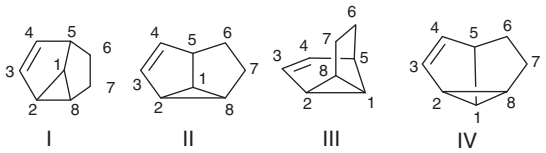

Figure 3 Different representations of the *meta* photocycloaddition adduct.

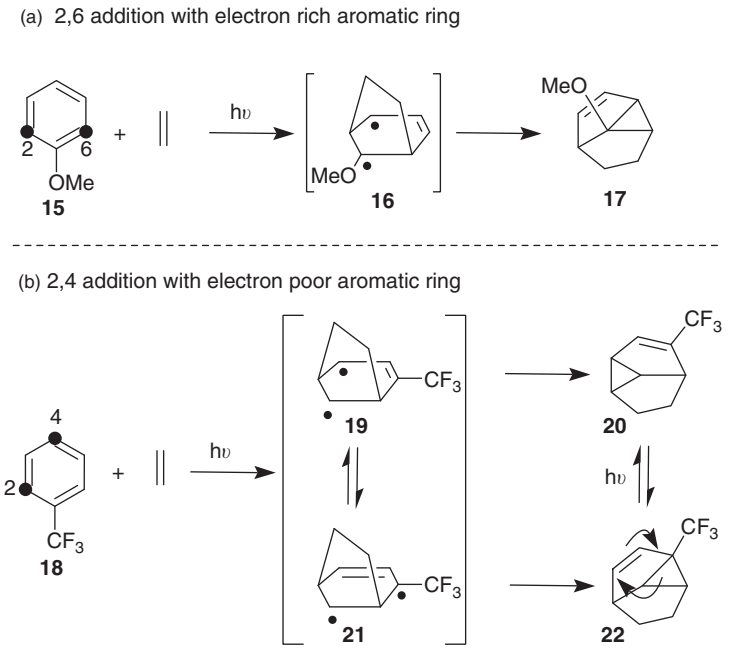
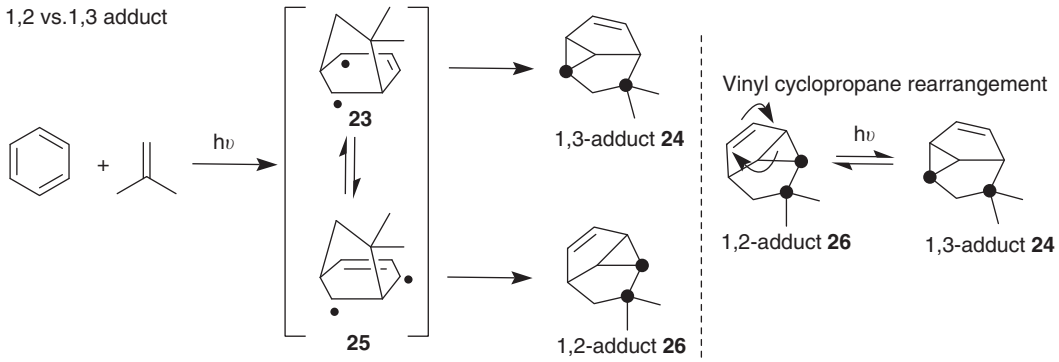
The first concerns the substitution pattern of the aromatic ring. Electron-donating and electron-withdrawing groups on the benzene ring exhibit a different influence on the polarized intermediate in the course of the reaction. It is generally observed that the alkene addition takes place preferentially 2,6 across the benzene ring if the substituent is electron donating (Scheme 7(a)), and preferentially 2,4 across the benzene with an electron-withdrawing substituent (Scheme 7(b)).[6b,6c,6e–j,15a,28]



The second regioselectivity originates from the recombination of the biradical formed in the course of the reaction. This regioselectivity is inconsequential only in one case: if the olefin is symmetrical and the aromatic ring bears an electron-donating group (Scheme 7(a)). If the olefin is symmetrical and the benzene ring contains an electron-withdrawing group, two regioisomers are formed, which can be interconverted by a vinylcyclopropane rearrangement (Scheme 7(b)).

Irradiation of benzene in the presence of an unsymmetrical olefin gives two distinct products with respect to the position of the cyclopropane ring compared to the olefin substituents (Scheme 8, compounds **24** and **26**). These compounds are referred to as 1,2-adduct **26** and the 1,3-adduct **24**, which again originate from the two possible biradical recombinations. In both products the cyclopropane ring is in allylic position to the double bond, but the distance between the olefin substituents (*gem*-dimethyl group) and the cyclopropane ring is either vicinal (1,2-adduct) or in the *meta* position (1,3-adduct) (indicated by the black dots in **24** and **26**, Scheme 8). Both regioisomers are interconvertible through a vinylcyclopropane rearrangement (Scheme 8).[19a,21]

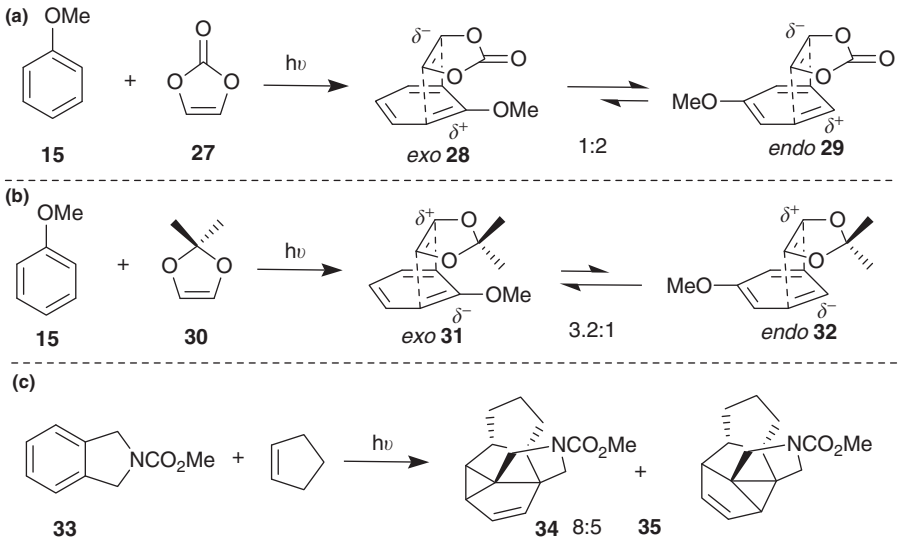


Meta photocycloadditions usually show good intrinsic regioselectivities with respect to the substitution pattern of the aromatic ring, but lack regioselectivity in the recombination step of the biradical, which results in cyclopropane formation.[29]

5.15.4.2 Stereoselectivity (*Endo* vs. *Exo*)

The *meta* photocycloaddition creates a compound containing up to six stereocenters in a single step from planar achiral starting materials. The reaction can either occur from the *exo* or the *endo* exciplex, defining four out of the six possible stereocenters directly. Recombination of the diradical in the last step puts the last two stereocenters in place. In terms of stereocontrol the *exo*/*endo* selectivity is, therefore, of utmost importance, and extensive investigations have been carried out to rationalize the experimental findings.

Scheme 7 Regioselectivity of the *meta* photocycloaddition with respect to the substituent on the aromatic ring.

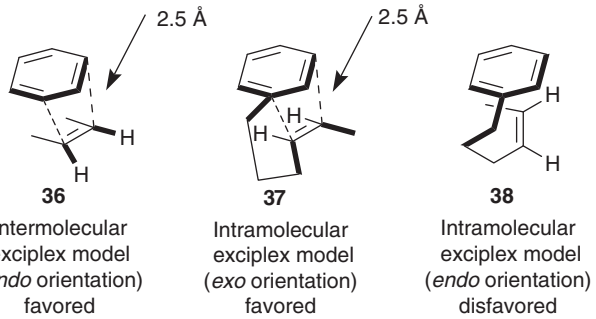


Scheme 8 Regioselectivity with respect to biradical recombination and cyclopropane formation.

An interesting example is provided by the *meta* cycloadditions of anisole with vinylene carbonate **27** and dioxole **30** (Scheme 9). Reactions of **27** give an *exo*/*endo* cycloadduct ratio of 1:2, whereas for alkene **30** a reversed preference is found, i.e., *exo*/*endo* 3.2:1 (Scheme 9(b)). In contrast to what would be expected on the basis of steric effects, a larger substituent on the arene, such as a trimethylsilyloxy group, gives even greater *exo* selectivity (9.3:1). This can only be explained if charge-transfer processes are considered. Thus polarization arising during the cycloaddition with **27** would electrostatically stabilize the *endo* addition mode **29** and destabilize the *exo* mode **28**, the latter due to charge repulsion between the vinylene carbonate subunit and the alkoxy group of the arene. However, the more electron-rich dioxole **30** can serve as a donor in the cycloaddition, in which case charge repulsion is minimized along with steric effects in the *exo* orientation **31**. Intermolecular *meta* photocycloadditions involving alkyl- or alkoxy-substituted arenes and simple alkenes usually proceed with *endo* selectivity as can be seen in Scheme 9(c). The product mixture stems from the recombination of the cyclopropane and is not related to the *endo*/*exo* problem. In contrast, intramolecular photocycloadditions generally give high, if not exclusive, *exo* selectivity and will be discussed in the following chapter.[28]

5.15.5 Intramolecular *Meta* Photocycloadditions

5.15.5.1 *Endo* versus *Exo* Selectivity

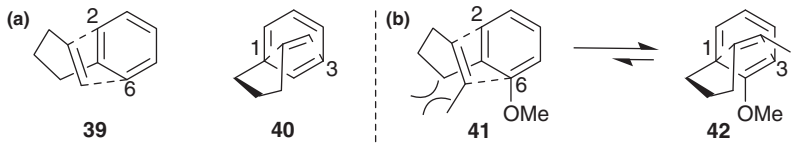


The first intramolecular *meta* photocycloaddition was reported in 1969 by Morrison and Ferree.[12] The intramolecular reaction was shown to be very efficient when three atom tethers were employed, but the quantum yield drops considerably when four atom tethers were involved,[30] apart from some exceptional cases when the flexibility of the tether is restricted and a

Scheme 9 *Endo* versus *exo* selectivity in the intermolecular *meta* photocycloaddition.

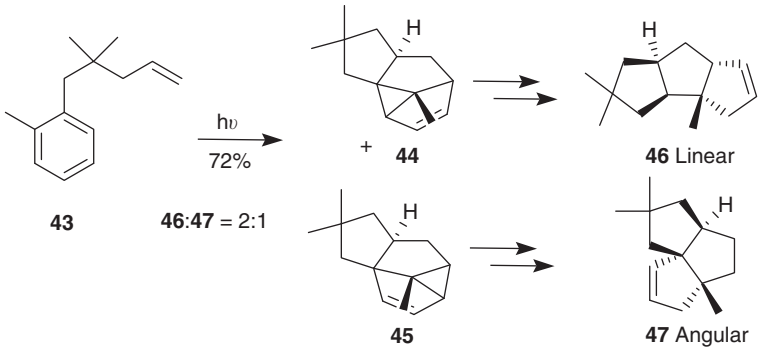
suitable conformation can be found.[31] The influence of the incorporation of oxygen in the tether has been reviewed by de Keukeleire.[32] The *exo*/*endo* selectivities mentioned above change completely in intramolecular reactions. In this mode, the *endo* approach of the alkene cannot be achieved without introducing significant strain, which usually outweighs secondary orbital interactions, and thus *exo* rather than *endo* adducts are obtained.[30]

This difference in selectivity has been rationalized in numerous studies by Wender's group on the basis of steric effects associated with the formation and reaction of an exciplex.[33] In this analysis (Scheme 10), the plane of the alkene and that of the excited-state arene are oriented in a parallel fashion and separated by a distance of approximately 2.5 Å, in reasonable agreement with previous studies on exciplex systems.[24b,34] The intermolecular reaction would then involve exciplex **36**, in which an *endo* orientation is preferred due to secondary orbital interactions and, depending on substitution, electrostatic effects. In the corresponding intramolecular exciplexes, the favorable orbital alignment for *meta* cycloaddition is preserved only if an *exo* orientation **37** is adopted, as the *endo* exciplex **36** is poorly aligned. Moreover, *meta* cycloaddition proceeding via **38** would lead to the formation of a product with a highly strained *trans*-fused bicyclo[3.3.0]octane subunit. The corresponding *exo* cycloaddition process leads to a less-strained *cis*-fused bicyclo[3.3.0]octane product.



Scheme 10 Inter- versus intramolecular exciplex model.

5.15.5.2 Mode Selectivity

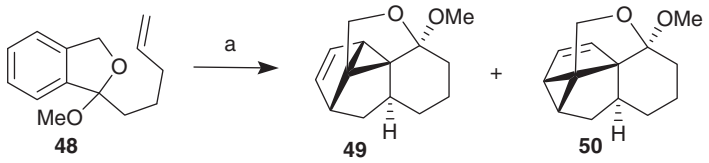


Besides the *endo* versus *exo* selectivity issues in the intramolecular mode, either 2,6- (**39**) or 1,3-addition (**40**) to the tether can be observed (Scheme 11(a)).[35] 1,3-Addition is usually observed selectively when electron-donating groups are attached to the aromatic moiety *ortho* to the tether, or if the olefin contains additional *cis* substituents; this is due to repulsion of the substituents on the olefin with the hydrogen atoms of the tether in the *exo*-addition, which prevents the 2,6-addition mode **41** (Scheme 11(b)). Concerning the double-bond geometry in the course of the photocycloaddition, the general rule applies that the geometry of the double bond is retained unless it is a sterically encumbered olefin. In this case, excitation transfer from the arene to the alkene can occur.

Intramolecular *meta* photocycloadditions that occur at positions 1,3 relative to the tether may give either a linear or an angular isomer (Scheme 12).[36] Calculations of the relative stabilities are a useful tool to predict the selectivity. If no additional

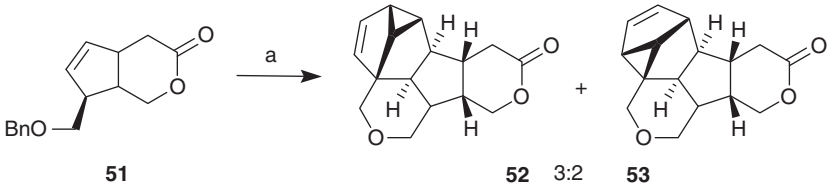
Scheme 11 Explanation of mode selectivity in the intramolecular *meta* photocycloaddition.

substituents are present, the linear compounds are slightly more stable.[30] However, some examples show that this selectivity can be changed.[37] The linear and angular isomer names are derived from the opening of the cyclopropane ring to afford linearly and angularly fused triquinanes.



Scheme 12 Linear versus angular product a matter of selective biradical recombination to the cyclopropane ring.

5.15.5.3 The Influence of the Tether Length



As briefly mentioned, the intramolecular *meta* photocycloaddition displays a significant difference whether a three-[12,38] or four-atom tether length is applied. It was shown that the quantum yields significantly dropped when changing from a three- to a four-atom tether.[6d] One reason might be the strong increase in conformational freedom in the latter case. This might have discouraged further use in complex natural product synthesis, and only a few examples are known. In those cases (shown in Schemes 13 and 14) inherent conformational restraints are responsible for the good yields obtained.

Wender and DeLong's study on tether length used cyclic acetal **48** with a four-atom tether (Scheme 13).[39] This exerts conformational restrictions on the system, and thus products **49** and **50** could be obtained in unusual high yields of 68% of both regioisomers (60% conversion).

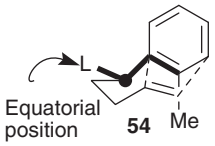
Scheme 13 Wender and DeLong's four-atom tether study. Reagents and conditions: (a) hυ (Vycor filter) 60% conversion 68% yield.

In a similar manner, De Keukeleire and coworkers took out the *meta* photocycloaddition on substrate **51** bearing a four-atom tether. The photoadducts **52** and **53** were obtained in 42% yield as 3:2 mixtures of regioisomers originating from cyclopropane formation (Scheme 14).[32,40]

Scheme 14 De Keukeleire's study. Reagents and conditions: (a) hυ (254 nm) 60% Rayonet reactor 42% yield.

5.15.5.4 Diastereoselectivity in the *Meta* Photocycloaddition

Morales et al. have observed diastereoselectivity by the introduction of a chiral center in the α-position to the aromatic moiety on the tether.[38a] In fact, the control element for the intramolecular photocycloaddition is the benzylic position on the tether. If this position bears a stereogenic center, high diastereoselectivities can be expected. Diastereoselectivity in the *meta* photocycloaddition is a synonym for π-facial selectivity. The selectivity originates from allylic strain as displayed in Figure 4 (bold bonds). The tether adopts a distorted *syn*-pentane conformation with the large substituent (L) in the equatorial position. Diastereoselective approaches with chiral induction at position 3 of the tether have also been reported.[41]



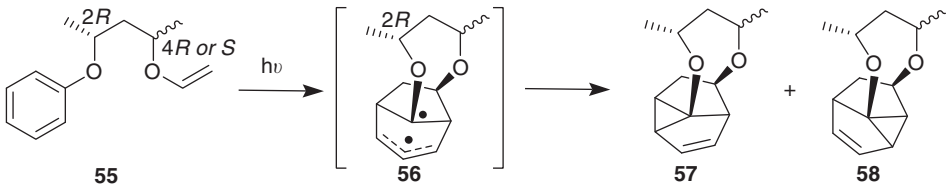


Figure 4 Diastereoselectivity in the intramolecular *meta* photocycloaddition – the ^{1,3}A-starin model.

5.15.5.5 Enantioselective *Meta* Photocycloadditions

The *meta* photocycloaddition has the ability to transform two-dimensional planar molecules into spatial chiral molecules. Therefore, many attempts have been made to carry out this process in an enantioselective fashion. The most commonly used strategy in an intramolecular photocycloaddition is the introduction of a chiral center on the tether, and to carry out the reaction in a diastereoselective way. This approach was first implemented into the total synthesis of (±)-α-cedrene published by Wender et al. in 1981.[33] Further studies aimed to understand and predict the diastereoselectivity of this photocycloaddition were undertaken. Sugimura et al. have shown that chiral 2,4-pentanediol tethers are very efficient for face differentiation (Scheme 15),[42] in which the 2-position of the tether in **55** completely directs the diastereoselectivity of the reaction. Precursors with (2*R*)-configuration react exclusively at the *Si*-face of the vinyl group, and form the (*R*)-configuration at the newly formed stereocenter. Nevertheless, regioselectivity issues in the formation of the cyclopropane ring lead to product mixtures, and both regioisomers are obtained. Van der Eycken et al. carried out a *meta* photocycloaddition in a chiral cavity (*β*-cyclodextrin), which afforded the photocycloaddition products in 17% *ee*.[43]

Scheme 15 Auxillary controlled cycloadditions.

5.15.5.6 Elaboration of Cycloadducts

The value of the arene–alkene *meta* cycloaddition arises from its capacity to produce a cycloadduct with three new rings and up to six new stereocenters. This is an impressive feature even if compared with the highly regarded Diels–Alder reaction. Furthermore, the cycloadduct is a commonly encountered structural motif in many natural products containing cyclopentanes such as triquinanes, cycloheptanes, bicyclo[3.2.1]octanes, and bicyclo[3.3.0]octanes. The *ortho* and the *para* mode provide less of an increase in molecular complexity, but nevertheless afford a new ring and four contiguous stereocenters. However, the core structures obtained in the *meta* photocycloaddition require further elaboration (Figure 5), especially cleavage of the cyclopropyl ring, in order to be useful in total synthesis of naturally occurring polycyclic systems. Many results have been achieved by a variety of research groups to diversify the molecular scaffolds accessible by this synthetic route: the cyclopropyl ring of the *meta* product is either opened to give a bicyclo[3.3.0]octane system (**59**, **63**, **64**, **65**, and **66**), or it is cleaved to give bicyclo[3.2.1]octane derivatives (**60, 61**, and **62**) (Figure 5). Acidolysis of *meta* photocycloaddition compounds opens the cyclopropane ring on protonation of the double bond, and leads to compounds **59** and **60**.[44] The formation of these two diverging carbon frameworks depends on the substituent at position 1. Although R^1 = H affords hexahydropentalene **59**, bicyclo[3.2.1]octane derivatives **60** are obtained if R^1 is an alkyl group.

Other electrophiles such as bromine add to the double bond and thus trigger the opening of the cyclopropane moiety to give compounds of type **61**.[33] Penkett demonstrated that in the course of an epoxidation reaction with *m*-CPBA the cyclopropane ring was opened to directly give an allylic alcohol of type **61** (with E = OH).[45] A Heck-type reaction with concomitant opening of the cyclopropane ring is facilitated by a methoxy group at C-1[46] to give bicyclo[3.2.1]octane derivatives of type **60**. Thermolysis results in [1,5]-sigmatropic shifts, either of hydrogen,[47] or a carbon atom[48] to yield tetrahydropentalenes **64**. Radical opening of the

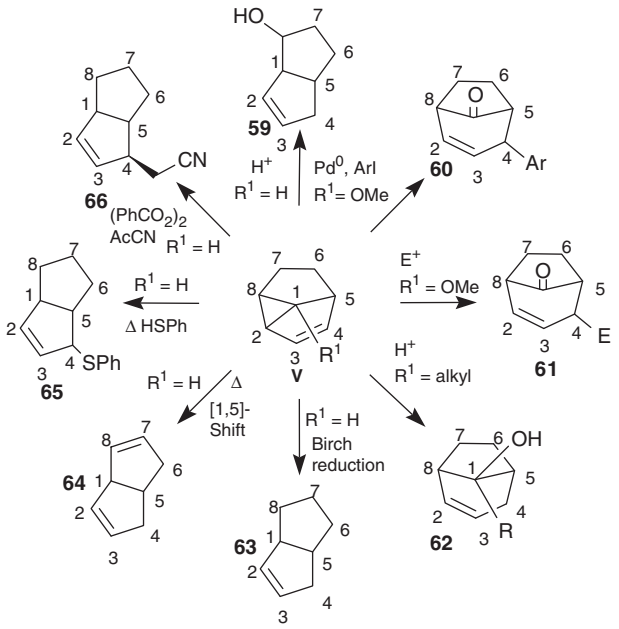

Figure 5 Possible elaborations of photoadducts.

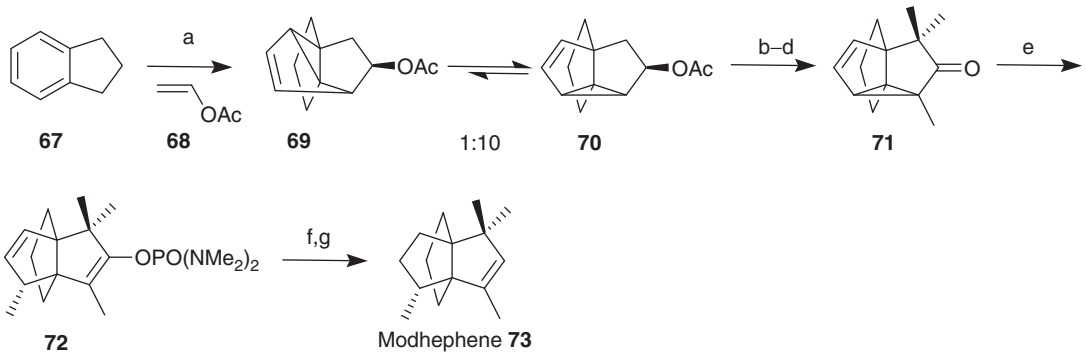


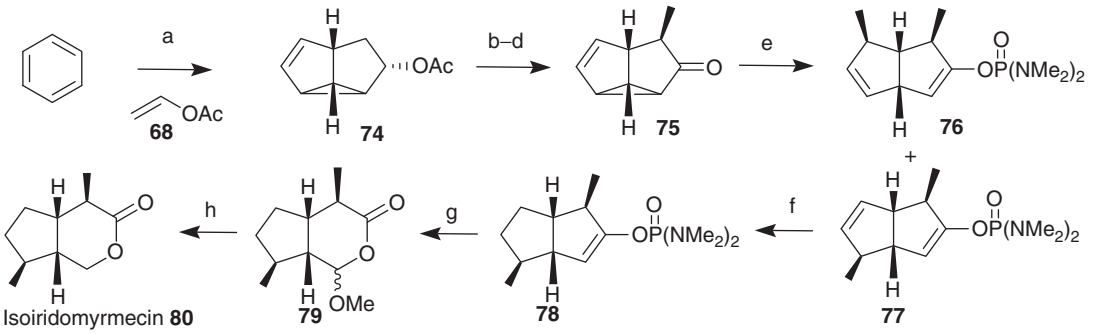
cyclopropyl ring for instance under Birch reaction conditions delivers the reduced hexahydropentalene of type **63**.[49] Radicals such as thiophenoxy radicals can also add to the double bond and induce the opening of the cyclopropane ring to afford compound **65**.[36,50] Acetonitrile radicals can be added to the olefin and open the cyclopropane ring to yield a hexahydropentalene **66**.[51]

5.15.5.7 Applications in Total Synthesis

To expediently use the *meta* photocycloaddition in natural product synthesis, certain criteria have to be fulfilled. The photocycloaddition precursor has to be easily accessible, the cycloaddition itself should be selective or the isomers at least separable. And last but not the least, the conversion of the cycloaddition product to the target structure should not be cumbersome. Paul Wender's group pioneered this field, but of course other groups have also made significant contributions. As mentioned above, the syntheses discussed in the following section are grouped according to the substitution pattern of the aromatic ring.

5.15.5.8 Intermolecular Variants

Total synthesis of modhephene **73** (Scheme 16):[29]

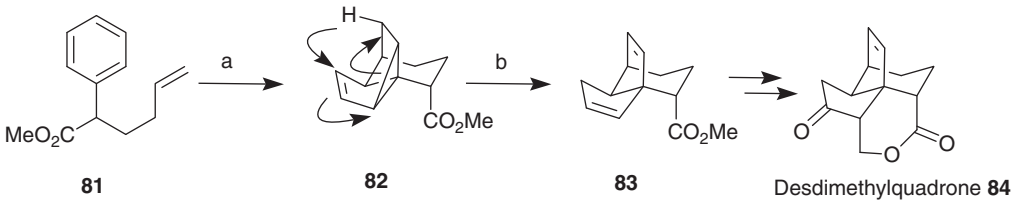


Scheme 16 Wender's synthesis of modhephene: Reagents and conditions: (a) hυ (Vycor filter) cyclohexane, 21%; (b) KOH, MeOH, 86%; (c) $Ba(MnO_4)_2$, 95%; (d) *t*-BuOK (15 equivalents), MeI, THF, 68%; (e) Me_2CuLi, THF, −78 °C, $ClPO(NMe_2)_2$, then Me_2NH, 76%; (f) Li, $EtNH_2$, THF, *t*-BuOH, 0 °C, 93%; (g) H_2, PtO_2, 100%.

Modhephene (Scheme 16) represents an intermolecular application of the *meta* photocycloaddition in total synthesis and varies in this respect from the previous applications. Dihydroindane and vinylacetate underwent the photoreaction to give

regioisomers **69** and **70** (10:1 for the desired compound **70**). The acetate group was cleaved under basic conditions and the resulting alcohol oxidized to the ketone, which was extensively methylated in the α-position to give compound **71**. Homo-1,4-addition of dimethyl-cuprate to **71** introduces the missing methyl group stereoselectively with opening of the cyclopropane ring to give **72**. The resulting enolate was trapped as phosphodiamidate. Subsequent Birch reduction delivered modhephene **73**.

Total synthesis of isoiridomyrmecin **80** (Scheme 17):[52]



Scheme 17 Synthesis of isoiridomyrmecin, photocycloaddition and cyclopropane cleavage. Reagents and conditions: (a) hυ (Vycor filter); (b) $LiAlH_4$ (89%); (c) MnO_2 (95%); (d) LDA, −78 °C, MeI (75%); (e) Me_2CuLi, THF, −78 °C, then $Cl_2PO(NMe_2)$, then Me_2NH (100%); (f) H_2, PtO_2 (90%); (g) O_3, MeOH, CH_2Cl_2, −78 °C, then $NaBH_4$ (92%, 1:1-epimers); (h) $NaBH_3CN$, H_2O, THF, H_2SO_4 (68%).

The synthesis of this natural product builds on an intermolecular *meta* photocycloaddition as a key step. In accordance with theoretical investigations the *endo*-adduct was formed, albeit in low yields.[53] Anyway the cheapness of starting materials compensates for the low yields. Photoadduct **74** was converted to ketone **75** by deacetylation, oxidation, and methylation. Conjugate addition with dimethyl-cuprate cleaved the cyclopropane ring. The enolate formed in this reaction was trapped as phosphordiamidates **76** and **77** (4.5:1 in favor of **77**). Removal of the disubstituted olefin with Adam's catalyst afforded compound **78**. This was subjected to ozonolysis to give acylal **79**, which was reduced to iridomyrmecin **80** with sodium cyano-borohydride.

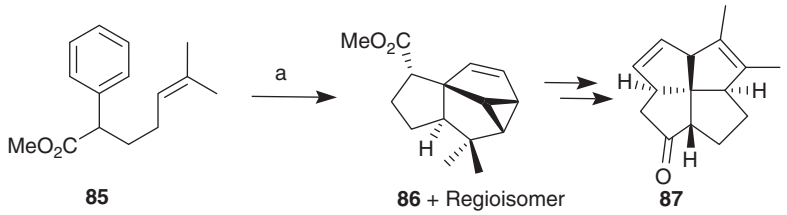
5.15.5.9 Intramolecular *Meta* Photocycloadditions

5.15.5.9.1 Monosubstituted arenes

Synthetic studies toward desdimethylquadrone **84** (Scheme 18):[54]

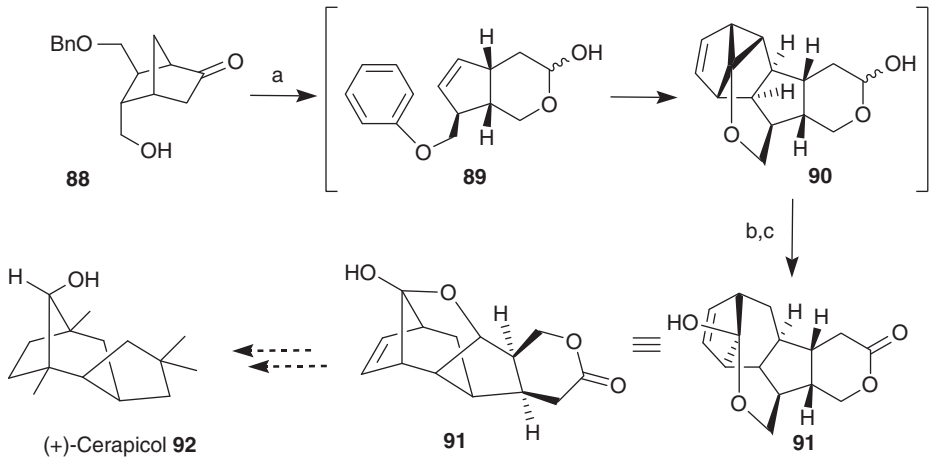
Scheme 18 Synthetic study toward desdimethylquadrone. Reagents and conditions: (a) hυ (Vycor filter) 10%; (b) 220 °C.

Quadrone is a tetracyclic sesquiterpene structure. With regard to the *meta* photocycloaddition two synthetic studies on simplified derivatives have been carried out. The first approach was carried out by Metha et al., who used an intermolecular mode to form decarboxyquadrone,[55] and the second one by Wender and Wolanin, which utilized an intramolecular approach. Photocyclization of **81** gave tetracycle **82** in low yield (10%) but very selective as a single product. Thermolysis of photoadduct **82** triggered a [1,5]-H-shift yielding product **83**. Addition across the tether is in accord with theory, stating that addition always takes place across the strongest donor.



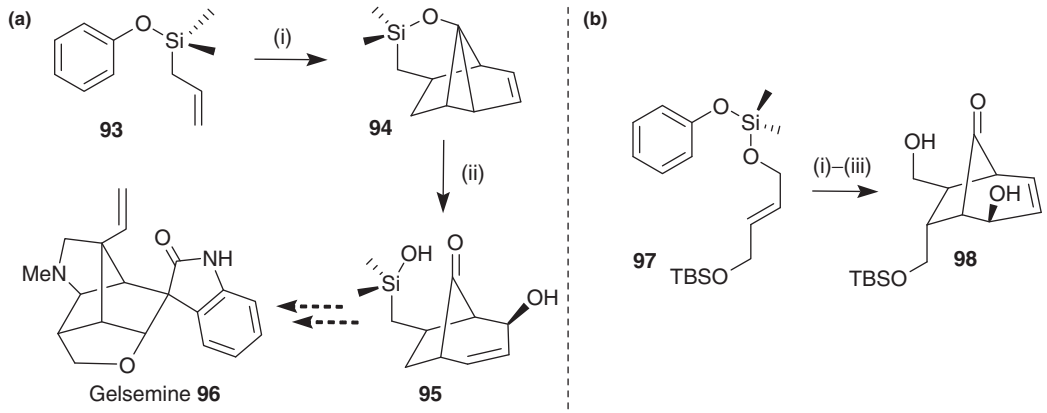
Synthetic studies toward fenestrane structure types **87** (Scheme 19):[50a,56]

This example published by Keese and coworkers comprises a parallel example to the synthesis of desdimethylquadrone with respect to the mode of addition (across the strongest donor group). Keese et al. carried out this synthesis starting from **85** when investigating fenestrane systems like **87**.



Synthetic studies toward cerapicol **92** (Scheme 20):[32,40]

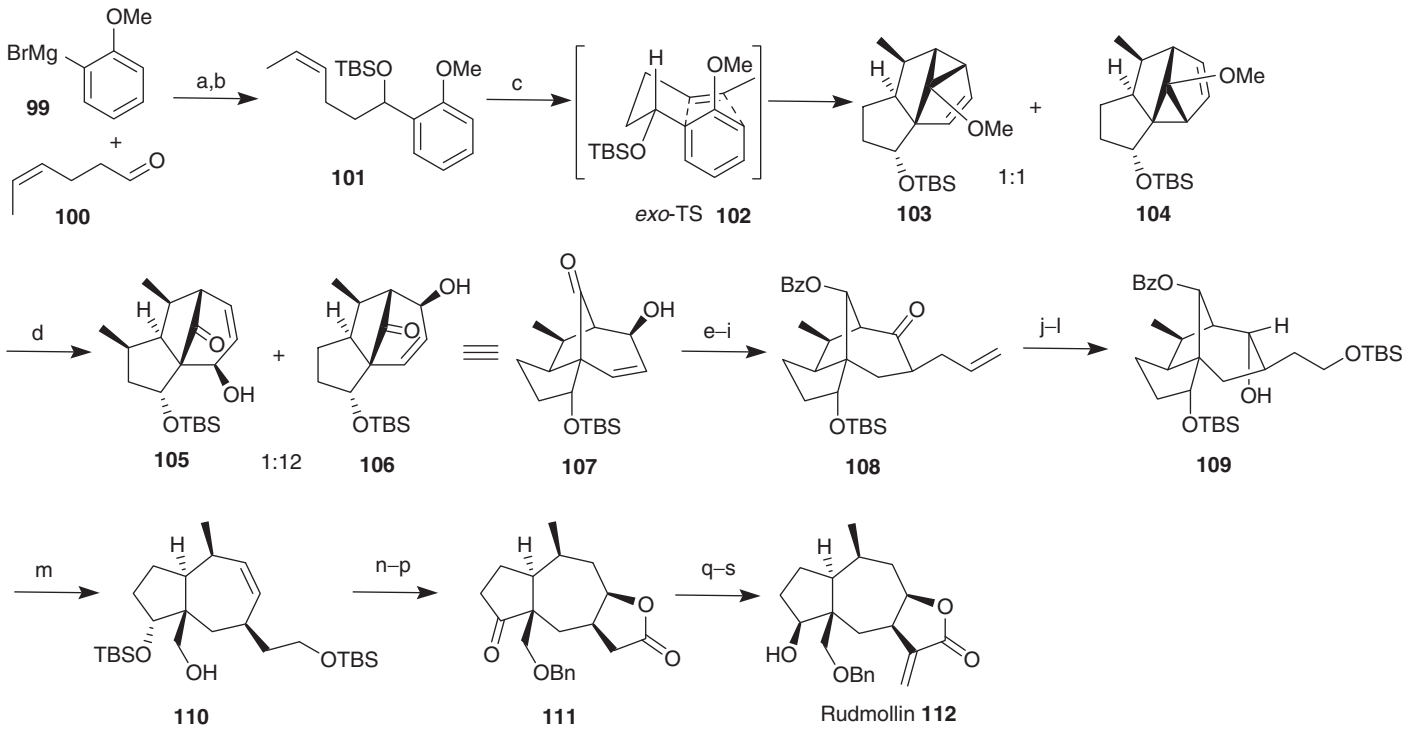
De Keukeleire obtained product **90** during studies on tandem Norrish type-I/*meta* photocycloaddition reactions. The substrate **88** first underwent a Norrish type-I reaction yielding lactol **89**. This in turn reacted in the photocycloaddition to give, after oxidation and cleavage of the cyclopropane ring, polycycle **91** in 34% overall yield.



Synthetic studies toward gelsemine **96** (Scheme 21):[45,46,57]

Scheme 19 Synthetic study of fenestranes. Reagents and conditions: (a) hυ (Vycor filter) 10%.

Scheme 20 Synthetic studies toward cerapicol. Reagents and conditions: (a) hυ, cyclohexane–EtOAc (5:1); (b) PDC, CH_2Cl_2 (34% overall); (c) dil. HCl (>95% yield).

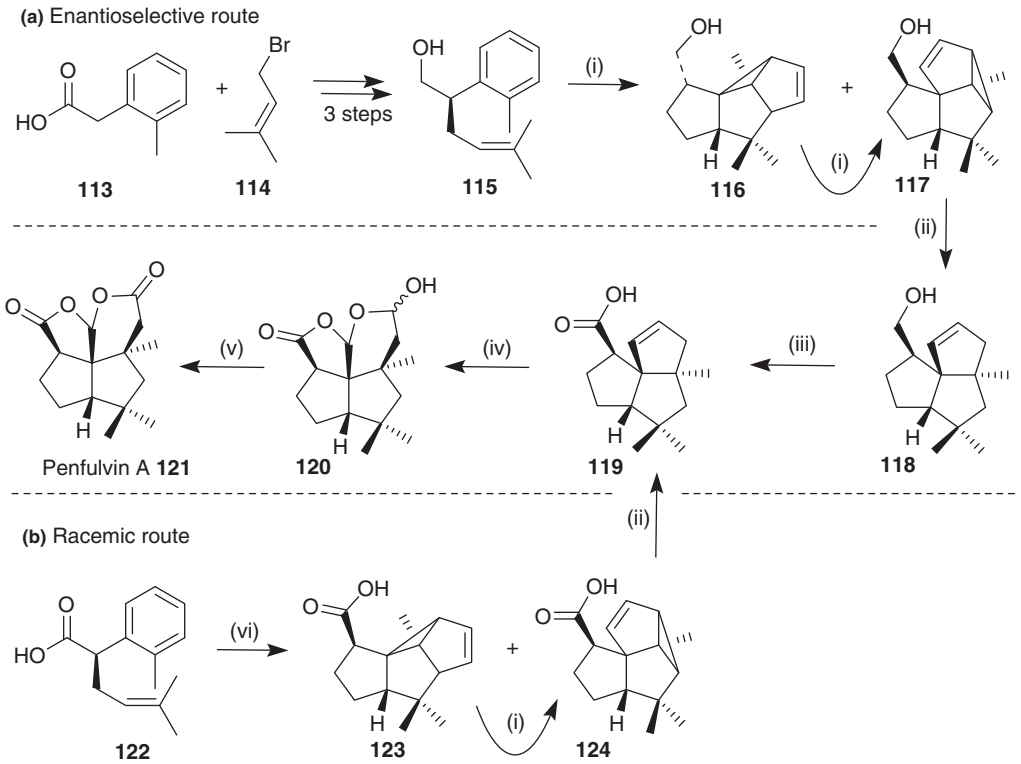


Scheme 21 (a) Synthetic studies toward gelsemine. Reagents and conditions: (i) hυ, hexane (38%); (ii) *m*-CPBA (56%). (b) Synthetic studies toward gelsemine. Reagents and conditions: (i) hυ (low pressure mercury lamp), cyclohexane, 4 h; (ii) *m*-CPBA, CH_2Cl_2; (iii) MeOH, PPTS, 4 days (11% overall).

Fleming and coworkers took out pioneering studies on the utility of silicon tethers in the *meta* photocycloaddition.[58] Following these initial studies, Penkett et al. carried out studies on the versatility of this reaction in the total synthesis of gelsemine **96**. Photolysis of **93** gave rise to cycloadduct **94** in 38% yield and some *ortho*-product (16%, not displayed). Fragmentation of the cyclopropane ring mediated by *m*-CPBA formed product **95**, which contained the signature structure element of gelsemine, the bicyclo[3.2.1]octane core (Scheme 21(a)). The subtle reactivity of the system can be seen in Scheme 21(b). When the photoadduct derived from **97** was treated with *N*-iodo-succinimide compound **98** was formed instead, which originates from bond cleavage of the cyclopropane bond distal to the double bond.

5.15.5.9.2 1,2-Disubstituted arenes

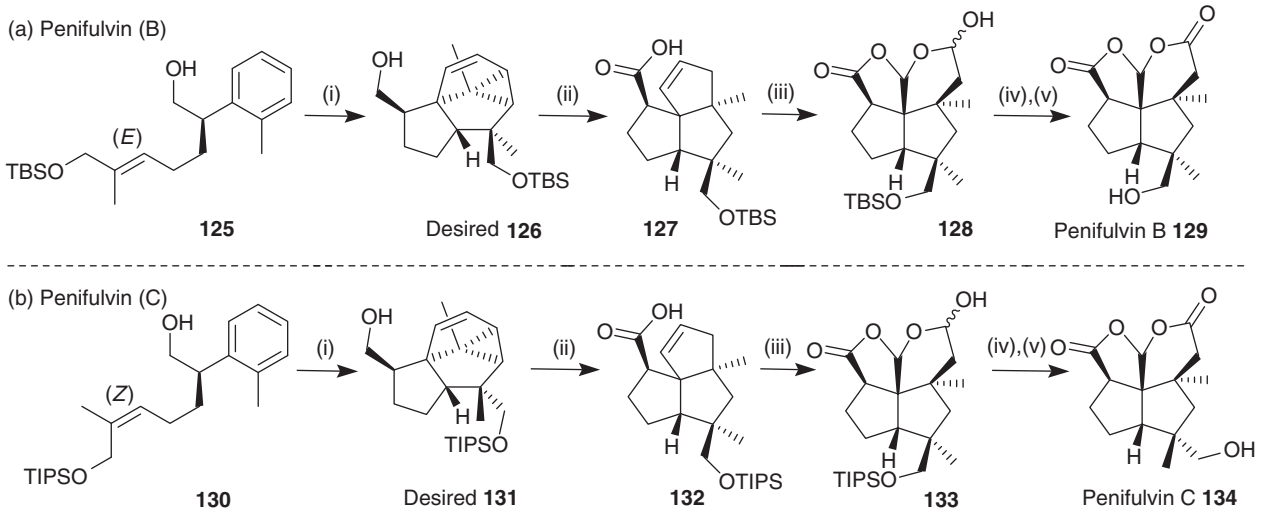
Total synthesis of rudmollin **112** (Scheme 22):[59]



Scheme 22 Wender's synthesis of rudmollin. Reagents and conditions: (a) THF, 0 °C, then **100**, 98%; (b) TBSCl, DMF, NEt_3, DMAP, 97%; (c) hυ (Vycor filter) pentane, 63%; (d) $Hg(OAc)_2$, THF, H_2O (71% **106** + 6% **105**); (e) $NaBH_4$, MeOH, 94%; (f) MnO_2, CH_2Cl_2, 93%; (g) H_2, 5%Pd/C, Et_2O, 99%; (h) $(PhO)_2O$, DMAP, NEt_3, DMF, 50 °C, 95%; (i) KHMDS, DME, 0 °C, then BEt_3, THF, allyl iodide, 50% (j) $NaBH_4$, $CeCl_3$, MeOH, 72% (α:β = 3:1); (k) O_3, MeOH, CH_2Cl_2, −78 °C then $NaBH_4$ 98%; (l) TBSCl, imidazole, DMF, 97%; (m) MsCl, pyridine, then $LiAlH_4$, DME, 0–25 °C, 84%; (n) KH, THF, BnBr, 96%; (o) HF-H_2O, CH_3CN, THF, Jones acetone, 82%; (p) I_2, *sym*-collidine, CH_3CN, Bu_3SnH, AIBN, PhH, 80 °C, 53%; (q) $NaBH_4$, MeOH, −78 to 25 °C, 92%; (r) H_2 (40 psi), 10% Pd/C, 70% $HClO_4$ (catalyst), MeOH, 82%; (s) $(Me_2N)_3CH$, 90 °C, then DIBAL, THF, 0 °C, 54%.

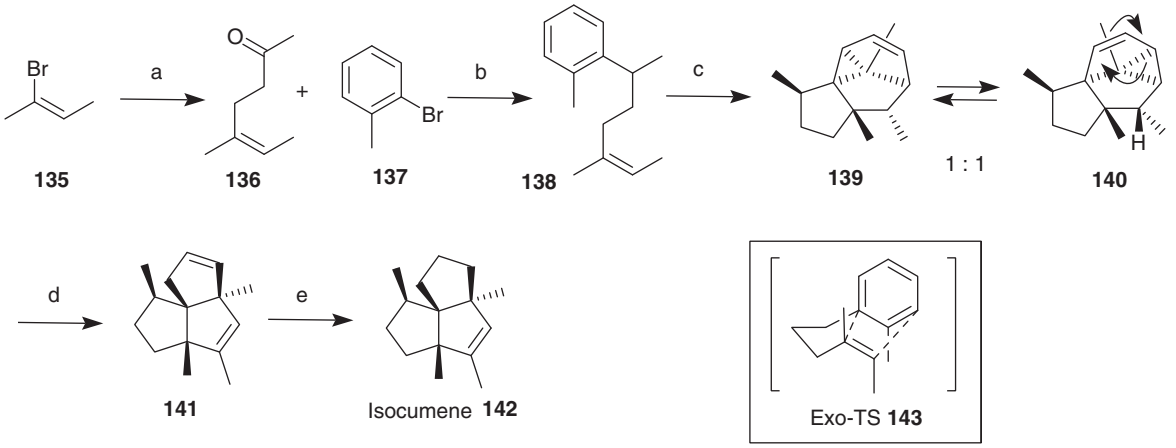
Rudmollin **112** was also synthesized by the Wender group. Its overall oxidation state is far higher than the previous examples and, therefore, more postcycloaddition modifications are necessary. Again the photoaddition precursor is rapidly accessible (**99**/**100**→**101** Scheme 22). In this synthesis, the tether contains a *Z*-double bond, and thus the *exo*-transition state **102** was formed. Regiomers **103** and **104** were obtained in a 1:1 ratio, but were both submitted to the next step – an oxy-mercuration with concomitant fragmentation – to give a 12:1 mixture in favor of the desired regioisomer **106**. This was reduced to the diol, and treatment with manganese dioxide selectively reoxidized the allylic alcohol, giving an enone-system. The double bond was hydrogenated, the remaining alcohol benzoylated and the ketone was alkylated with allyl iodide yielding **108**. Ketone **108** was reduced to give 3:1 in favor of the α-isomer **109**. The double bond was cleaved by ozonolysis, and the resulting aldehyde was reduced and selectively protected with TBSCl at the primary position giving **110**. Mesylation of the secondary alcohol in **110** with subsequent treatment with lithium aluminum hydride resulted in fragmentation to give compound **111**. Benzylation of the primary alcohol, iodolactonization and Barton–McCombie dehalogenation introduced the γ-lactone. The *exo*-methylene-double bond was introduced by a procedure from Wassermann[60] yielding rudmollin **112**.

Total synthesis of penifulvins A[61] **121**, B **129**, and C **134**.[62]



The synthesis of penifulvin A **121** was carried out both in racemic and in an enantioselective fashion. Thereby carboxylic acid **122** was obtained from alkylation (racemic synthesis, Scheme 23(b)). The benzylic stereocenter was established by Myer's alkylation[63] (enantioselective synthesis Scheme 23(a)). Irradiation of **115** and **122**, respectively, afforded a 1:1 mixture of regioisomers (**116** and **117** (enantioselective)/ **123** and **124** (racemic)) in each case, which could be separated and resubjected to photoequilibration conditions. Birch reduction of the cyclopropane moieties gave **118** and **119**. In the enantioselective route, compound **118** was oxidized to the carboxylic acid **119** and subjected to ozonolysis, which afforded acylal **120** in 78% yield. This in turn was oxidized to penifulvin A **121**.

Scheme 23 Gaich's synthesis of penifulvin. (a) Reagents and conditions: (i) hυ, pentane, 22 °C, 2 h, (Series (a)**: 116:117** R = CH_2OH, optically active, 70% yield; (ii) $EtNH_2$, Li, THF, −78 °C, 7 h, 72%; (iii) IBX, DMSO, 22 °C, 20 min, then $NaClO_2$, 2-methyl-2-butene, *tert*-BuOH, NaH_2PO_4, 1 h, 92%; (iv) O_3, DCM, −78 °C, 2 min, then thiourea, 22 °C, 40 min, 78%; (v) PDC (4 equivalents), DCM, 22 °C, 20 min, then AcOH (20 equivalents), 20 min, 82%; (vi) hυ, pentane, 22 °C, 2 h, Series (b)**: 123:124** R = CO_2H, racemic, 62% yield.

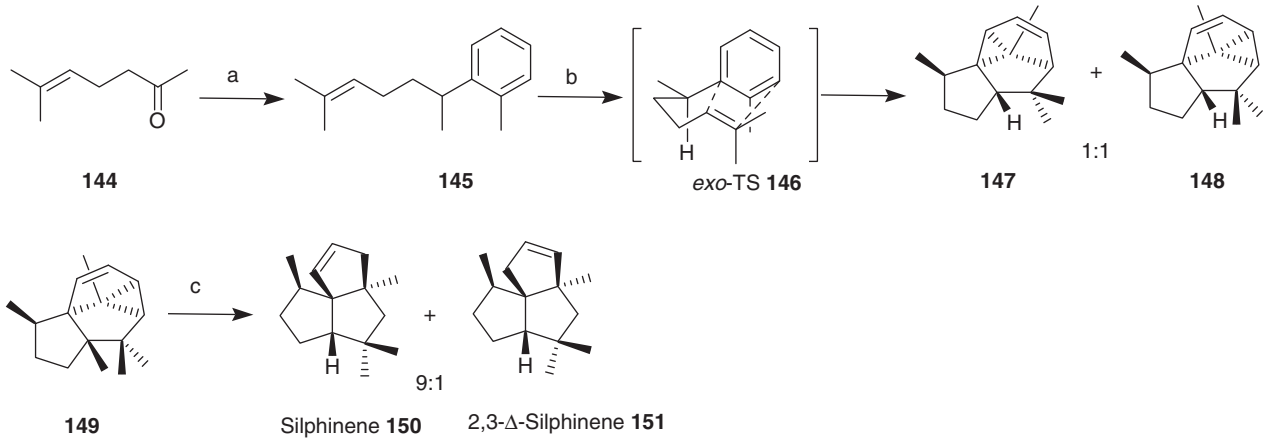


The total syntheses of penifulvin B **129** and C **134** (Scheme 24) were carried out in an analogous way to the synthesis of penifulvin A **121**. They comprise a special feature, which underscores the power of the *meta* photocycloaddition. The two natural products are epimers with respect to the quaternary stereocenter next to the primary alcohol. This stereocenter was to be constructed in the course of the cycloaddition from the double bond. If the geometry of the double bond correlates to the stereochemistry in the respective photoadducts, the synthesis of penifulvin B **129** required photoprecursor **125** with the *E*-double bond, whereas the synthesis of penifulvin C **134** required precursor **130** containing the *Z*-double bond. Indeed the photoadducts

126 and **131**, originating from the two respective geometric double-bond isomers, exhibited the opposite stereochemistry at this carbon atom. Till date this is the only example in the literature where a quaternary stereocenter is formed in this position.

Scheme 24 Gaich's synthesis of penifulvins B and C. Reagents and conditions: (i) hυ, pentane, 22 °C, 2 h, 64% (combined yields); (ii) $EtNH_2$, Li, THF, −78 °C, 7 h, 86%; (iii) IBX, DMSO, 22 °C, 20 min, then $NaClO_2$, 2-methyl-2-butene, *tert*-BuOH, NaH_2PO_4, 1 h, 96%; (iv) O_3, DCM, −78 °C, 2 min, then thiourea, 22 °C, 40 min, 36%; (v) PDC (4 equivalents), DCM, 22 °C, 20 min, then AcOH (20 equivalents), 20 min, 83%; 50% HF–pyr, CH_3CN, 82%.

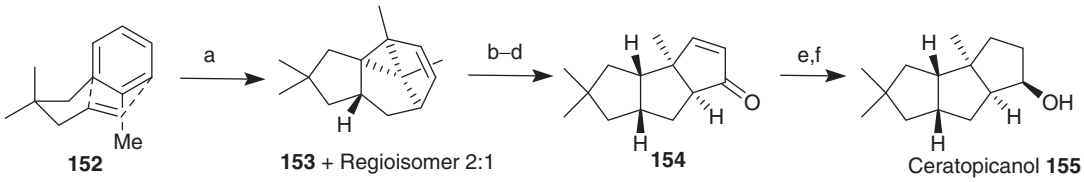
Total synthesis of isocumene **142** (Scheme 25):[47]



Scheme 25 Wender's synthesis of isocumene: Reagents and conditions: (a) Li, Et_2O then CuI, −65 °C, MVK, 56%; (b) *ortho*-bromotoluene, Li, Et_2O, r.t., then **136** then NH_3, −78 °C, 78%; (c) hυ (Vycor filter) cyclohexane, 72%; (d) 235–240 °C, 69%; (e) H_2, 5% Pd/C, hexane, 98%.

Isocumene **142**, a member of the pentalene family, was synthesized by Wender et al. via photoaddition precursor **138** yielding isomers **139** and **140**. In this case only one isomer was of further use in the synthesis, but fortunately the undesired **140** could be equilibrated to the desired isomer **139** on further irradiation. Dehydro-isocumene **141** was obtained via a 1,5-H-shift when heating to 240 °C.[64] The last step was a selective hydrogenation of the less substituted double bond yielding isocumene **142** (Scheme 25).

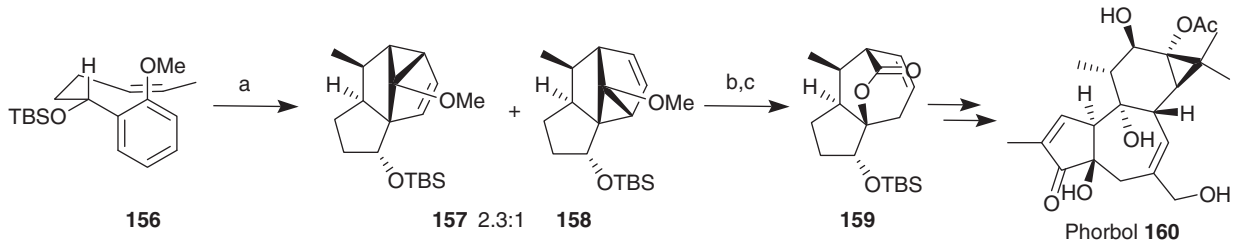
Total synthesis of silphinene **150** (Scheme 26):[65]



Silphinene **150** is a structure biogenetically related to penifulvins. Wender et al. performed a most elegant and rapid access to this compound without the introduction of any unnecessary functional group (Scheme 26). As in the foregoing syntheses, the stereochemical course of the cycloaddition was governed by the $A^{1,3}$-allyl-strain model (see transition state **146**) leading to regioisomers **147** and **148**. The tricyclic carbon-skeleton was set up in this way except that the cyclopropane ring needed to be

Scheme 26 Wender's synthesis of silphinene. Reagents and conditions: (a) Li, Et_2O, then *ortho*-bromotoluene, then NH_4Cl, 87%; (b) hυ (Vycor filter) pentane, 72%; (c) Li, $MeNH_2$, −78 °C, 74%.

cleaved. This was achieved by a Birch reduction giving silphinene **150** and its 2,3-Δ-double-bond isomer **151** in a 9:1 ratio for the desired natural product.

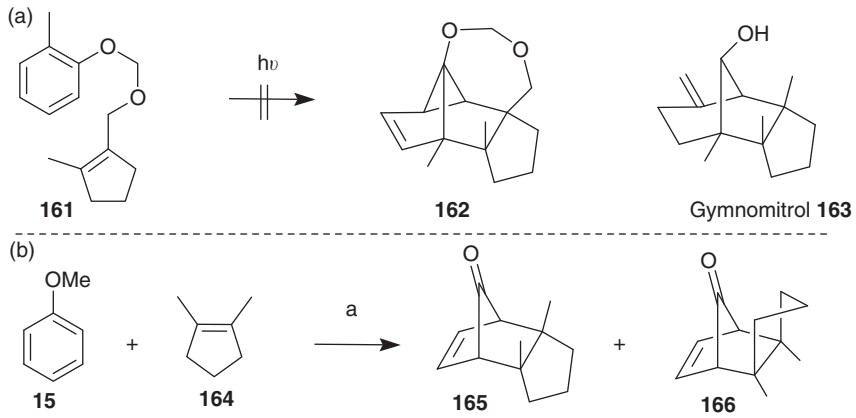


Total synthesis of ceratopicanol **155** (Scheme 27):[36]

Scheme 27 Total synthesis of ceratopicanol. Reagents and conditions: (a) hυ (254 nm) cyclohexane, 72%; (b) PhSH, 100 °C, ultrasound, 97%; (c) CSA, Li, NH_3, −78 °C, 80%; (d) CrO_3–3,5-dimethylpyrazole, 60%; (e) LDA, −78 °C, MeI, 97%; (f) $NaBH_4$, MeOH, 60%.

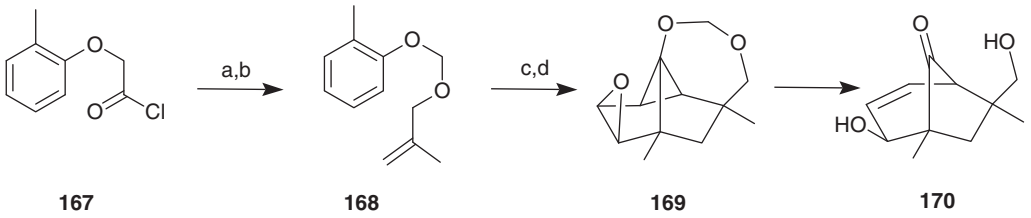
Chanon et al. have accomplished an effective synthesis of ceratopicanol **155** (Scheme 27). The combined yield in the *meta* photocycloaddition reaction from precursor **152** is 72%, giving two regioisomers; the major and desired one being the linear product **153** is displayed. The angular product was recycled. Radical addition of thiophenol cleaved the cyclopropane ring and the thiophenol was removed under Birch conditions. Chromium-mediated oxidation furnished ketone **154**, which was converted to ceratopicanol **155** in two further steps.

Synthetic studies toward phorbol **160** (Scheme 28):[59]



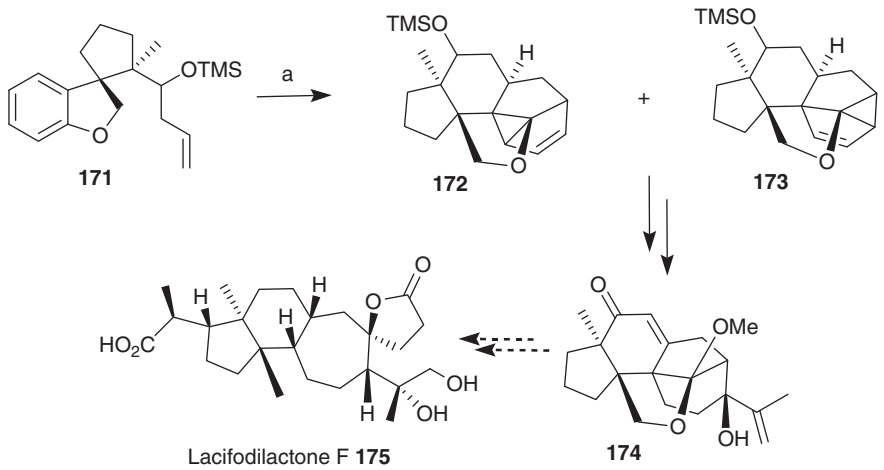
Scheme 28 Synthetic route to phorbol. Reagents and conditions: (a) hυ (Vycor filter) 63%; (b) H_2SO_4, H_2O, acetone reflux then TBSCl, NEt_3; (c) TMSOTf, $(TMSO)_2$, DCM −30 °C.

In the synthetic study to phorbol **160** the *meta* photocycloaddition of **156** yielded a mixture of regioisomers **157** and **158**. The major isomer **158** was subjected to cleavage of the cyclopropane ring under acidic conditions, and Baeyer–Villiger oxidation gave lactone **159**. It was planned to elaborate **159** to phorbol **160**. Product **159** contains the signature 5–7-fused ring system with the tertiary alcohol group.



Synthetic studies toward gymnomitrol **163** (Scheme 29):[57,66]

Penkett's synthetic study to gymnomitrol **163** displays one of the few examples of a *meta* photocycloaddition with a four-atom tether. The key to success in these transformations is the conformational lock of the substrate making it suited for the reaction.

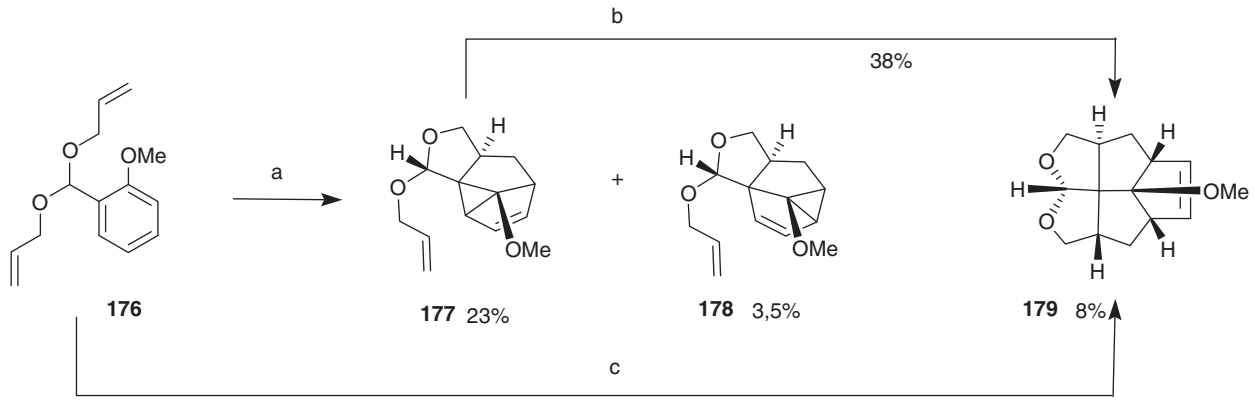


Scheme 29 Attempted photocycloaddition approaches to gymnomitrol. Reagents and conditions: (a) hυ (253.7 nm), cyclohexane, then H_3O^+ (0.1%).

As can be seen in Scheme 29(a) an intramolecular approach turned out to be unsuccessful due to steric hindrance of the tetrasubstituted double bond. The intermolecular reaction gave 0.1% yield of a 1:5 mixture of **165** to **166**, whereas the intramolecular reaction of **161** to **162** delivered no product at all. Only when switching to the less encumbered system **168**, the intramolecular cycloaddition product **169** could be obtained in 17% yield (Scheme 30).

Scheme 30 Attempted photocycloaddition approaches to gymnomitrol. Reagents and conditions: (a) $(PPh_3)_4RhCl$, 170 °C; (b) methallyl alcohol, 50% NaOH, 86%; (c) hυ (253.7 nm), cyclohexane, 17%; (d) DMDO, DCM-acetone (1:1), 0 °C, 100%; (e) HCl(aqueous), acetone, r.t., 55%.

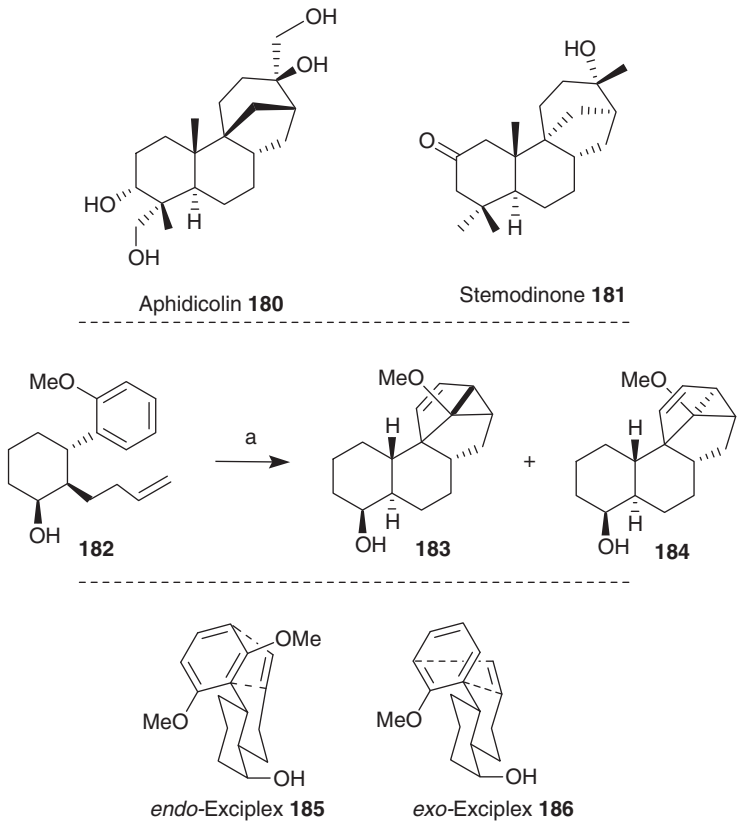
Synthetic studies toward lacifodilactone **175** (Scheme 31):[67]



Scheme 31 Studies toward lacifodilactone F. Reagents and conditions: (a) hυ (254 nm) 89%.

A recently published approach to lacifodilactone F **175** by Wang and Chen also featured a four-atom tether. The *spiro* moiety in **171** helped to conformationally restrict the tether and enabled the reaction in impressive 89% yield of **172** and **173**. Further elaboration to **174** gave access to an advanced intermediate en route to the natural product.

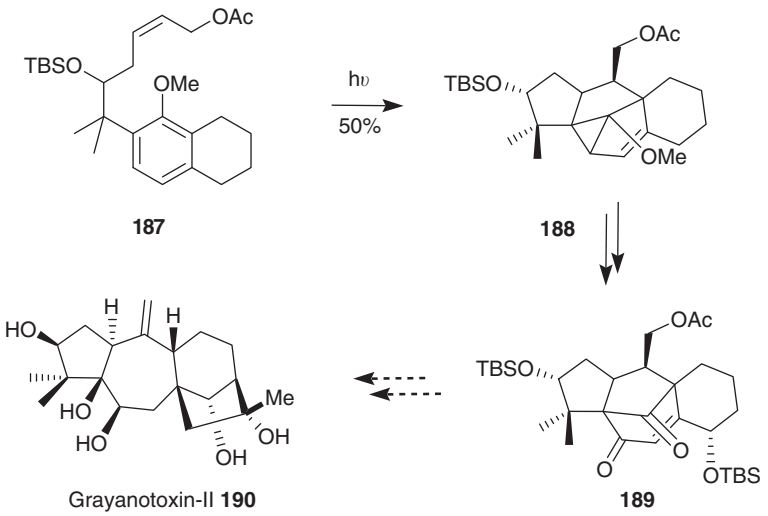
A tandem *meta* photocycloaddition/[3 + 2]-cycloaddition approach to fenestranes **179** (Scheme 32):[68]



The fenestrane structure has been targeted several times by total synthesis.[69] Recently, Penkett and coworkers described a tandem approach to fenestrane **179**. Their synthesis started from bisallyl acetal **176**. Irradiation in cyclohexane yielded product

Scheme 32 Tandem *meta* photocycloaddition/[3 + 2]-cycloaddition. Reagents and conditions: (a) hυ (254 nm), cyclohexane 4 h; (b) hυ (254 nm), cyclohexane 16 h; (c) hυ (254 nm), cyclohexane 18 h.

177 with 23% and regioisomer **178** with 3.5%. Prolonged exposure of the desired regioisomer **177** to the same reaction conditions resulted in fenestrane formation with 38% yield.



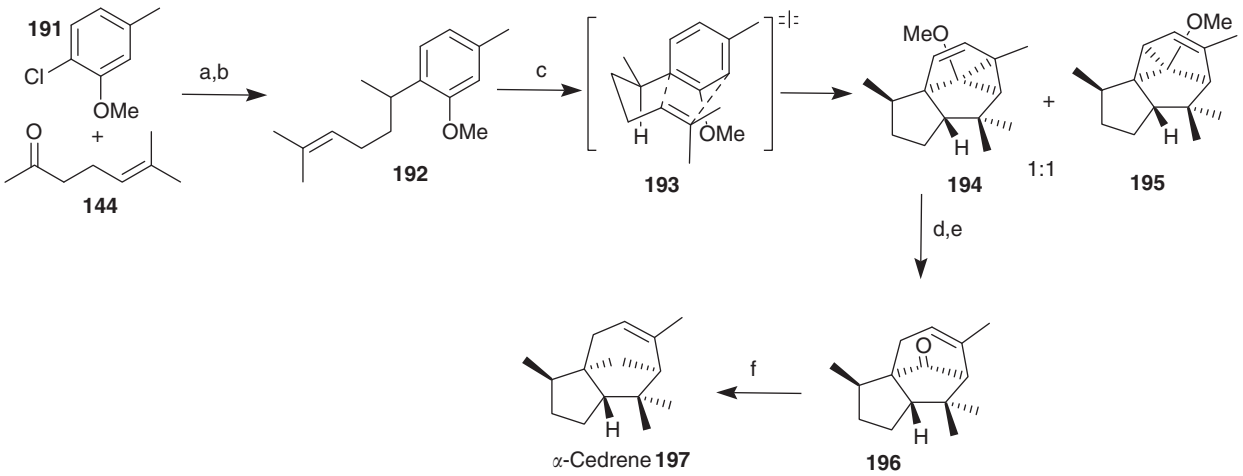
Synthetic studies toward aphidicolin **180** and stemodinone **181** (Scheme 33):[31]

Scheme 33 An approach to the aphidicolin and stemodinone ring systems. Reagents and conditions: (a) hυ (low pressure mercury vapor lamp), cyclohexane, **183**:**184** = 1.2:1 (90%).

In the attempt to provide the carbon-skeleton of aphidicolin **180** and stemodinone **181**, a four-atom-tether cycloaddition of **182** was accomplished. Besides the rarely found four-atom-tether, this is the only example where a *meta* photocycloaddition selectively (1.2:1) proceeds via an *endo*-transition state **185** to give **183** in 90% yield combined with the *exo*-adduct **184** stemming from **186**. Products **183** and **184** are, therefore, not regioisomers but diastereomeric in nature. As expected, the aromatic methoxy group controls the regiochemistry of the cycloaddition.

Synthetic studies toward grayanotoxin-II **190** (Scheme 34):[6f,70]

Scheme 34 Synthetic studies toward grayanotoxin-II.



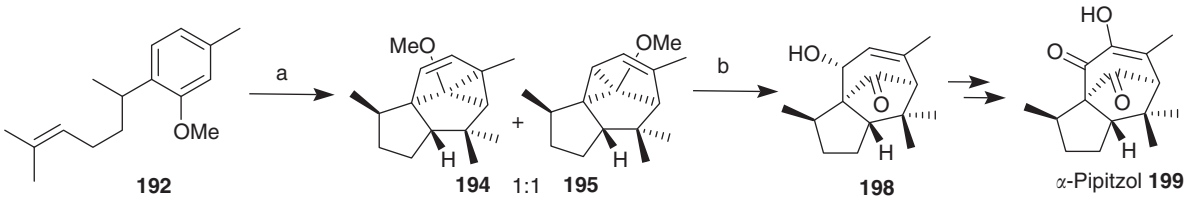
Wender and Oliviero designed a synthetic approach to grayanotoxin-II **190** starting with a tetrasubstituted arene **187**. Nevertheless this apparently hindered system **187**, which comprises a four-atom-tether, gave the desired photoadduct **188** in 50% yield. The carbon framework was thus set up and elaborated to intermediate **189**.

5.15.5.9.3 Trisubstituted arenes

With a trisubstituted arene as starter unit in the *meta* photocycloaddition a more complex carbon scaffold can be accessed, which is able to deliver more hindered photoadducts and thus the rise molecular complexity is drastically increased. So far two different substitution patterns on the arene have been investigated, the 1,2,4- and the 1,2,3-pattern. The next section deals with total syntheses of the first category.

1,2,4-Trisubstituted arenes:

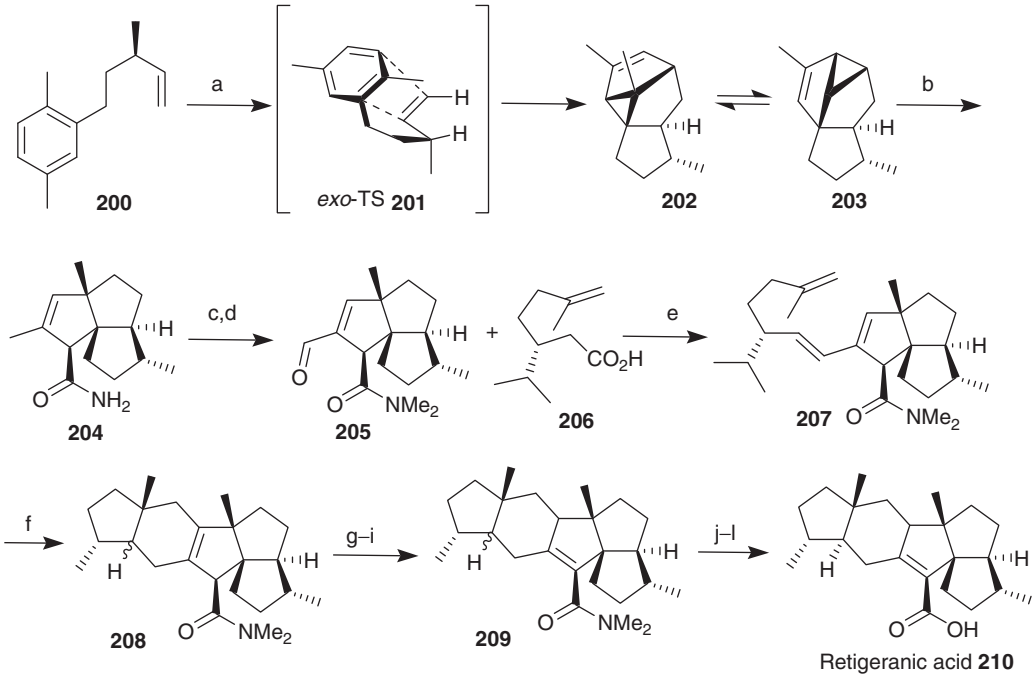
Total synthesis of cedrene **197** (Scheme 35):[33]



Scheme 35 Wender's synthesis of α-cedrene. Reagents and conditions: (a) Li, Et_2O, then **150**; (b) Li, NH_3, then NH_4Cl, 74% over two steps; (c) hυ (Vycor filter) pentane, 65%; (d) Br_2, CH_2Cl_2; (e) Bu_3SnH (neat), 59% over two steps; (f) NH_2NH_2, KOH, $(OHCH_2CH_2)O$, 200 °C, 58%.

The first example comprises the total synthesis α-cedrene **197** by Wender et al. Synthesis of the cycloaddition precursor **192** was achieved by addition of an aryllithium species generated from **191** to ketone **144**. The benzylic alcohol was reduced to give **192**. The stereogenic center in **192** allowed the stereoselectivity of the photocycloaddition to be controlled in such a way that, according to the $A^{1,3}$-strain model in **193**, the proton stayed in-plane with the aromatic ring. The regioisomers **194**/**195** were

converted to ketone **196** via a bromonium ion-induced fragmentation reaction of the cyclopropane ring. The allylic bromides were defunctionalized in a Barton–McCombie reaction, yielding only one double-bond isomer **196**. This compound was further defunctionalized in a Wolff–Kishner reduction to give α-cedrene **197**.

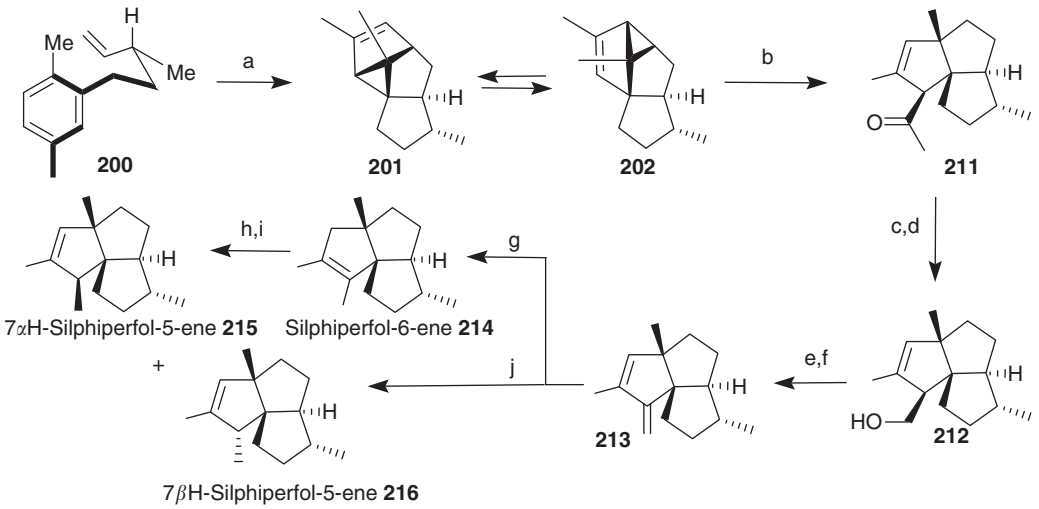


Total synthesis of pipitzol **199** (Scheme 36):[60b,71]

Scheme 36 Wender and Howbart's synthesis of pipitzol. Reagents and conditions: (a) hυ (Vycor filter) 65%; (b) I_2, THF.

Wender and Howbert accomplished a synthesis of pipitzol **199** utilizing the same photocycloaddition adducts **194** and **195** as in the synthesis of cedrene **197**. The synthesis was completed by different functional group interconversions after the photochemical key step.

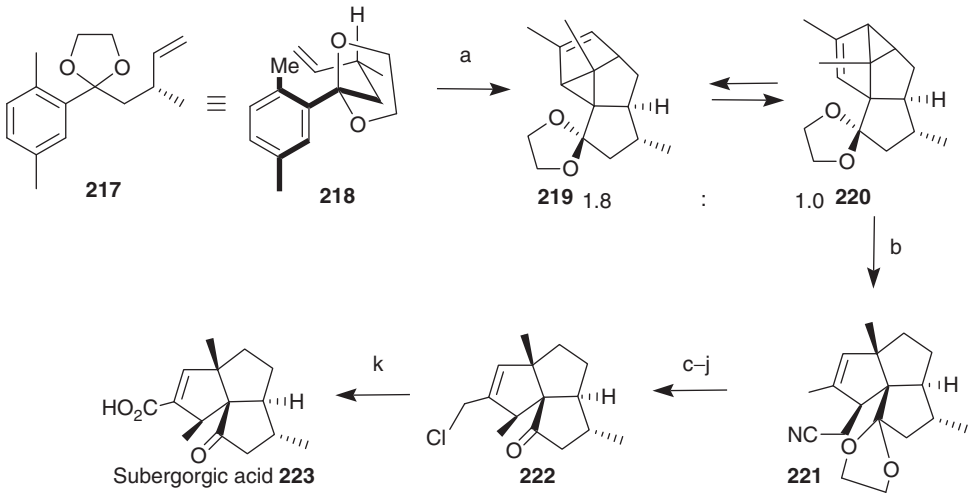
Total synthesis of retigeranic acid **210** (Scheme 37):[72]



Scheme 37 Wender's synthesis of retigeranic acid. Reagents and conditions: (a) hυ (Vycor filter) pentane, 72%; (b) hυ (pyrex filter) acetone, $HCONH_2$, *t*-BuOH; (c) KOH, DMSO, MeI, 80%; (d) SeO_2, *t*-BuOOH, $(CH_2Cl_2)_2$, Δ, 53%; (e) **206**, LDA, 50 to 0 °C then **205** (at −78 to 25 °C, AcOH, *N,N*-dimethylformamide dimethyl acetal, Δ, 65%; (f) 230 °C, $PhCH_3$, 65%; (g) *m*-CPBA, NaOAc, CH_2Cl_2; (h) *t*-BuOK, DMSO, 100 °C; (i) 10%-Pd/C, H_2, PhH, 400 psi; (j) $LiAlH_4$, THF, (k) PDC, CH_2Cl_2; (l) oxidation to the carboxylic acid.

Retigeranic acid **210** is a more complex pentacyclic structure, containing four cyclopentane and one cyclohexane rings. Photoprecursor **200** was generated in six steps. The two photoadducts **202** and **203** were equilibrated to the desired regioisomer **203**, which was elaborated to compound **204**. Thereby radical ring cleavage of the cyclopropane ring introduced the carbon atom that finally represents the carboxylic acid in the natural product. Methylation of the amide of **204** and allylic oxidation gave compound **205**, which was reacted with **206** to give triene **207**. On heating to 230 °C a Diels–Alder reaction took place to form the cyclohexane and the terminal cyclopentane ring. Further functional group manipulations finally lead to the natural product.

Total synthesis of silphiperfol-6-ene **214** and 7αH-silphiperfol-5-ene **215** (Scheme 38):[73]

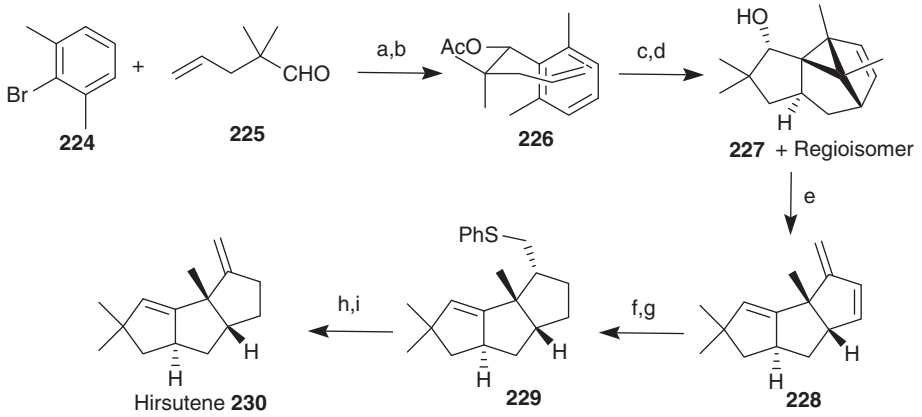


The photoreaction substrate **200** was prepared according to a procedure by McEnroe and Hall.[74] Irradiation of **200** proceeded from the conformation shown in Scheme 38, and gave in *exo*-selective fashion photoadducts **201** and **202** in 72% yield with a ratio of 1.9:1 in favor of **201** – the linear product. Fortunately, the authors were able to photoequilibrate the mixture to the desired regioisomer. Concomitant cleavage of the cyclopropane with introduction of the ketone functionality via addition of acetaldehyde

Scheme 38 Synthesis of silphiperfol-6-one and 7αH-silphiperfol-5-ene. Reagents and conditions: (a) hυ (Vycor filter), 72%; (b) hυ (pyrex) MeCHO, 0 °C, 60%; (c) Br_2, NaOH, reflux 95%; (d) LAH, THF, reflux 91%; (e) $PhNO_2SeCN$, *n*-Bu_3P, THF (99%); (f) H_2O_2, THF (78%); (g) Li, NH_3, Et_2O, −33 °C (91%); (h) *n*-BuLi, $(EtO)_2POCl$, THF-TMEDA (4:1) (76%); (i) Li, *t*-BuOH, $EtNH_2$, THF, 0 °C (55%); (j) $(Ph_3P)_3RhCl$, benzene:ethanol 3:1, (89%) **215**:**216** = 1:2.8.

gave **211**. Bromoform reaction followed by reduction to the corresponding alcohol resulted in the formation of product **212**. Elimination of the alcohol gave diene **213**, which yielded the desired natural product silphiperfol-6-ene **214** under Birch type conditions. In contrast, reduction of the terminal double bond of **213** with Wilkinson's catalyst provided a 2.8:1 mixture of 7αH-silphiperfol-5-ene **216** and 7βH-silphiperfol-5-ene **215**. The latter was synthesized in a stereoselective fashion by conversion of alcohol **212** to a diethyl phosphonate and subsequent reduction with lithium in ethylamine.

Total synthesis of subergorgic acid **223** (Scheme 39).[51]

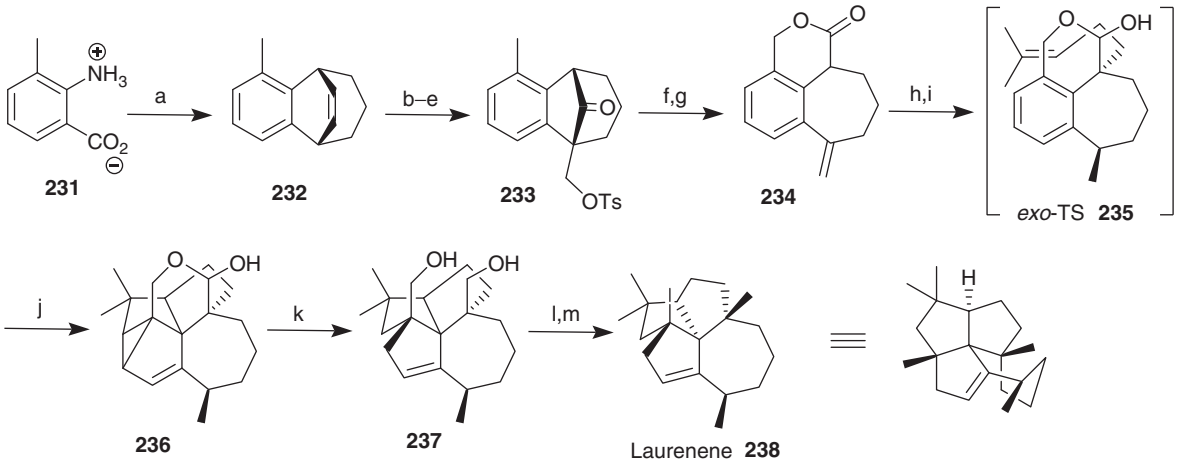


Scheme 39 Synthesis of subergorgic acid. Reagents and conditions: (a) hυ (Vycor filter), cyclohexane (42%); (b) dibenzoyl peroxide, CH_3CN, reflux (67%); (c) K, 18-crown-6, toluene (90%); (d) *m*-CPBA,(80%); (e) *N*-cyclo-hexyl, *N*-isopropylamine, MeMgBr (70%); (f) SOCl2, pyridine (85%); (g) DMSO, $AgBF_4$, Et_3N (85%) then $NaClO_2$.

In the synthesis of subergorgic acid **223**, Wender and deLong explored the influence of steric hindrance adjacent to the benzene ring. In this example, the steric hindrance is exerted by the acetal group in **217**. Photolysis of **217** gave rise to a 1.8:1 regioisomeric mixture of **219** and **220**, whereby three contiguous quaternary carbon centers were formed. Only the angular product **220** was ring-opened via a radical fragmentation reaction, catalyzed by dibenzoylperoxide, to give compound **221**. This was converted to chloro-ketone **222**, starting with the defunctionalization of the nitrile.[75] Epoxidation with *m*-CPBA followed by epoxide opening and allylic chlorination gave **222** in four steps. The final transformations contained a Kornblum oxidation followed by a Pinnick oxidation to the carboxylic acid of subergorgic acid **223**.

1,2,3-Trisubstituted arenes:

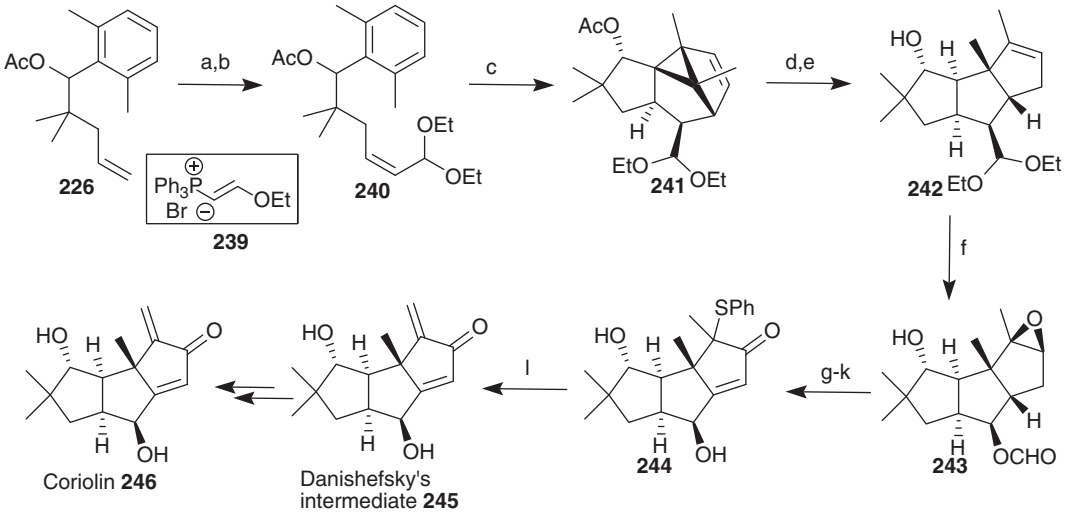
This specific substitution pattern of the arene allows for the construction of at least three contiguous quaternary carbon centers, all of them located at the cyclopropane ring. No doubt this synthetic challenge would be difficult to solve otherwise.



Total synthesis of hirsutene **230** (Scheme 40):[56a]

Scheme 40 Total synthesis of hirsutene. Reagents and conditions: (a) Mg, Et_2O; (b) Ac_2O, DMAP 79%; (c) hυ (Vycor filter) 23%; (d) $LiAlH_4$, Et_2O; (e) CSA, PhH, 71%; (f) PhSH, 100 °C, 78%; (g) H_2, DCM, $[Ir(cod)PyPCy_3]PF_6$; (h) $NaIO_4$,MeOH 86%; (i) 170 °C, $P(OMe)_3$ 60%.

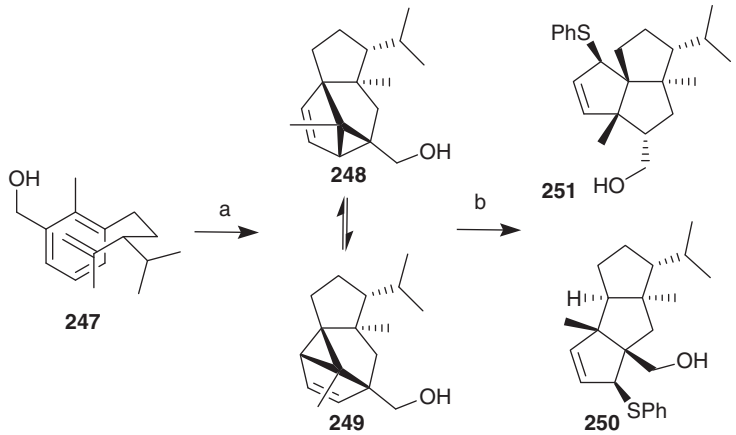
Wender and Howbart prepared the photoprecursor **226** of this total synthesis in a straightforward three-step sequence. Photolysis of **226** gave adduct **227** plus its regioisomer. Although the double bond is terminal and not a *Z*-double bond, the addition takes place in a 1,3-mode across the *ortho*-donor, presumably due to less steric hindrance compared to the 2,6-addition mode which normally takes place. Elaboration of the hirsutene carbon framework was pursued by cyclopropane ring opening with camphorsulfonic acid yielding **228** after elimination reaction. Radical thiophenole addition to the *exo*-olefin of **228** allowed for the selective removal of the disubstituted double bond with Crabtree's catalyst, leading to compound **229**. Restoration of the *exo*-methylene group by elimination of the corresponding sulfoxide of **229** gave hirsutene **230** in approximately 60% yield.



Total synthesis of laurenene **238** (Scheme 41):[37]

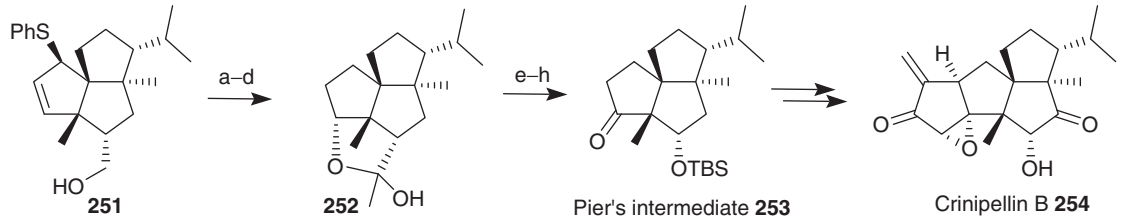
Scheme 41 Wender's synthesis of laurenene. Reagents and conditions: (a) isopentyl nitrite, Cl_3CCO_2H, cycloheptadiene, CH_2Cl_2, 84% brsm; (b) O_3, DMS, NEt_3, 68%; (c) $Zn(BH_4)_2$, Et_2O, 98%; (d) TsCl, 72%; (e) PCC, 98%; (f) NBS, AIBN, then KOH, 72%; (g) H_2, Pt, 96%; (h) LDA, DMPU, hompoprenyl iodide, 48%; (i) $LiALH_4$, THF, 95%; (j) hυ, ($BiCl_3$-filter), 51%; (k) Li, $MeNH_2$, −60 °C, 96%; (l) KHMDS, HMPA, $ClPO(NMe_2)_2$, 55%; (m) Li, $EtNH_2$, 65%.

Laurene **238** is one of the most complex natural products synthesized by using the *meta* photocycloaddition. It belongs to the diterpenes and has a fenestrane-type structure. The synthesis of the photoaddition precursor **235** was a little bit more laborious but proceeded through standard steps from amino acid **231**. Photocycloaddition of **235** gave compound **236**. The cyclopropane ring was removed in a Birch reduction to give **237**, and, after several defunctionalization reactions, laurenene **238** was obtained.



Total synthesis of coriolin **246** (Scheme 42):[50a]

Scheme 42 Formal total synthesis of coriolin. Reagents and conditions: (a) O_3, MeOH, 61%; (b) NaOEt, DCM; (c) hυ (Vycor filter) 15%; (d) PhSH, 100 °C, 72%; (e) Li, NH_3, Et_2O 80%; (f) *m*-CPBA, DCM, H_2O, 67%; (g) BF_3, PhH; (h) LDA, TMSCl; (i) $Pd(OAc)_2$, CH_3CN;%; (j) LDA, $PhSSO_2Ph$, 42% four steps; (k) AcOH:H_2O:THF (3:1:1) 100%; (l) *m*-CPBA, EtOAc, heat.



There are two routes to coriolin **246** via a *meta* photocycloaddition reaction. One is closely related to the synthesis of hirsutene **230** and is not mentioned here, as the same photoadduct was used.[76] A second more direct route to coriolin **246** started from compound **226**. Ozonolysis and Wittig olefination gave rise to photoprecursor **240**, which was transformed into **241** in 15% yield. The relatively modest yield is explained by extreme steric hindrance. Radical cyclopropane ring opening with thiophenol was followed by removal of the sulfur under Birch conditions to furnish the linear triquinane system **242** in 80% yield. Treatment of **242** with *m*-CPBA in moist dichloromethane not only introduced the epoxide, but, after acid-catalyzed cleavage of the acetal moiety, a concomitant Baeyer–Villiger oxidation gave compound **243**. Lewis acid-catalyzed epoxide rearrangement formed a ketone, which was transformed into an α,β-unsaturated ketone by Saegusa oxidation. Thiophenoxide was introduced in the α-position to the carbonyl via an addition/elimination process leading to compound **244**. Cleavage of the formiate group and oxidative elimination of the sulfur group furnished compound **245**, a known intermediate of Danishefsky's synthesis of coriolin **246**.[77]

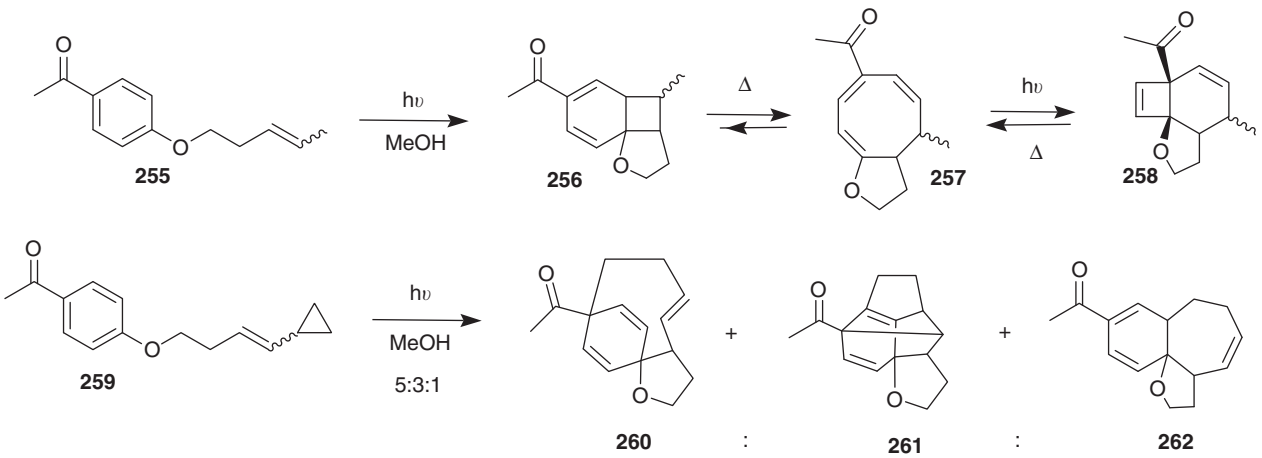
Total synthesis of crinipellin B **254** (Schemes 43 and 44):[50b]

Scheme 43 Formal total synthesis of coriolin. Reagents and conditions: (a) hυ (Vycor filter) 33%; (b) PhSH, 100 °C, 68%.

Wender and Dore accomplished the total synthesis of crinipellin B **254**. This approach required a rather complex precursor **247** for the photocycloaddition. Its synthesis is not displayed here. Despite its complexity, the cycloaddition gave rise to 33% yield of the regioisomers **248** and **249**. On treatment of the product mixture with thiophenol the cyclopropane moiety was cleaved and the two products **250** and **251** were formed which could be separated by flash column chromatography.

Scheme 44 Formal total synthesis of coriolin. Reagents and conditions: (a) Me_3OBF_4, DCM, reflux, 74%; (b) H_2, Pd/C 10%, EtOAc, 97%; (c) $RuCl_3$, $NaIO_4$, 72%; (d) MeLi, THF $-78\,^{\circ}C$, 95%; (e) *m*-CPBA, $CHCl_3$, 55%; (f) Dess–Martin reagent, DCM, 87%; (g) $Ba(OH)_2$, MeOH, 0 °C, 80%; (h) TBSOTf, NEt_3, DCM, $-78\,^{\circ}C$, 86%.

The desired angular product **251** was further elaborated to lactol **252**. To this end, **251** was methylated and the sulfonium-ion was displaced by the primary alcohol, to give the tetrahydrofuran ring of **252**. Hydrogenation of the double bond was followed by oxidation to the lactone, which was converted to lactol **252** by methyllithium addition. Baeyer–Villiger oxidation with *m*-CPBA gave a monoprotected diol, which was oxidized to the ketone. Subsequent cleavage of the acetate with barium hydroxide and reprotection gave compound **253**, called Pier's intermediate. The synthesis was completed starting from this compound.

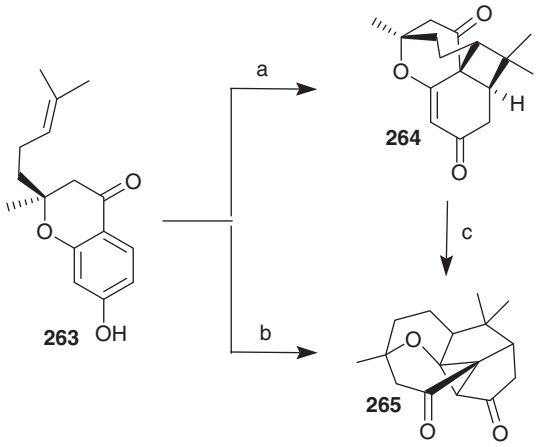


5.15.6 Examples of Applications of the *Ortho* Photocycloaddition

There is little data on the *ortho* photocycloaddition and its selectivity in the literature. The regioselectivity of the *ortho* photocycloaddition is dependent on the electronic properties of the two reaction partners.[15a] This selectivity is low and decreases with diminishing degree of charge-transfer processes. The role of charge transfer is also supported by the fact that regioselectivity is usually higher in polar solvents where charge separation is favored.[21,67,78] Substituted olefins may add in an *exo* or *endo* fashion. Electron-deficient alkenes give mixtures of both possible products; electron-rich compounds however, show stereoselectivity toward the *exo* products. *Ortho* photocycloaddition can also take place from the triplet excited-state by sensitization. This state is believed to have a higher biradical and less zwitterionic character.[79]

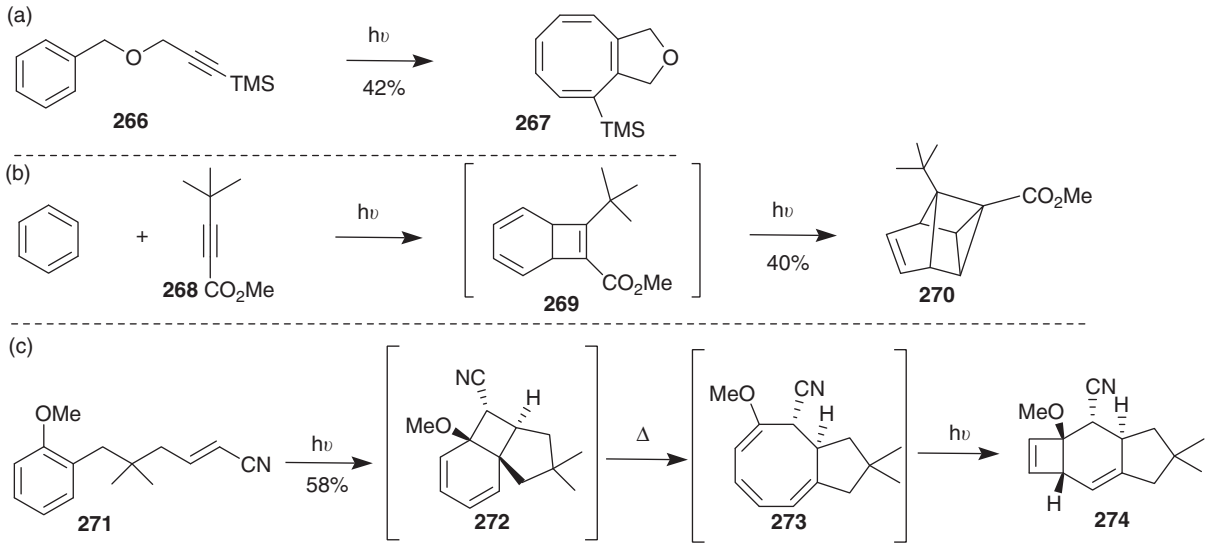
5.15.6.1 *Ortho* Photocycloadditions followed by Rearrangment Reactions

Ortho photocycloadducts are known to be inherently unstable, therefore often consecutive reactions take place, which give stable products that can often be isolated in high yields.



Photocycloadditions of alkanophenones (Scheme 45):

Scheme 45 *Ortho* photocycloadditions of alkanophenones.

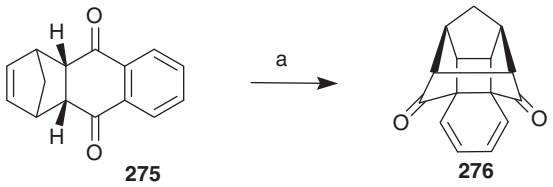


Ortho photocycloaddition of triplet excited benzenes have been extensively studied by Wagner and his group. They investigated [2 + 2] photocycloadditions of alkanophenones **255** and **259**, occurring from the triplet excited-state and via 1,4-biradicals.[80] Such radicals have been proven by the insertion of a cyclopropyl radical trap **259** in the olefin. On irradiation of this modified starting material, the *ortho* cycloadduct **256** could no longer be isolated (Scheme 23),[81] but the brigdehead like compounds **260** and **261** were formed instead.

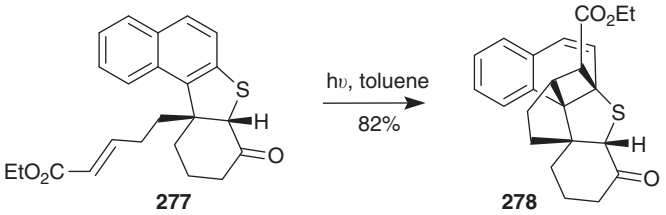
A very good example for consecutive reactions was published by Kalena et al. some years ago,[82] who observed that 2-alkenyl-7-hydroxy-4-chromanone **263** undergoes *ortho* photocycloaddition to afford tetracyclic compounds **264** and **265** (Scheme 46). Depending on the solvent used, the final product **265** is either formed directly or product **264** is formed first, which undergoes consecutive rearrangement to **265**.

Scheme 46 Reagents and conditions: (a) hυ, (>300 nm) PhH, 25%; (b) hυ, (>300 nm) MeOH, 38%; (c) hυ, 63%.

The *ortho* addition mode with benzenes is almost exclusively observed with alkynes such as **266** (Scheme 47). The photocycloaddition products usually undergo ring opening to cyclooctatetraenes **267** (Scheme 47(a))[83] or to other rearrangement products **270** on further irradiation (Scheme 47(b)).[84] This reaction provides access to bicyclo[4.2.0]octanes **272**, which undergo thermal electrocyclic ring opening to yield eight-membered ring systems like **273**, for example. Irradiation of **273** yields tricycle **274** (Scheme 47(c)).[79,85]



Scheme 47 *Ortho* photocycloadditions followed by rearrangement reactions. Reagents and conditions: (a) hυ, 42%; (b) hυ, 40%; (c) hυ, heat, then hυ, 58%.

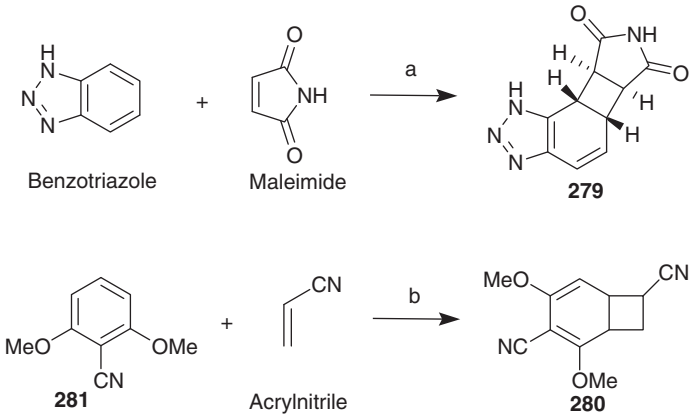


5.15.6.2 Stable *Ortho* Photocycloaddition Products

There are some rare examples where the [2 + 2]-cycloadduct is stable enough to be isolated as such, and in good yield (Schemes 48 and 49).

Naphthoquinones are known to undergo *ortho* cycloaddition (Scheme 48). Recently a very unconventional [2 + 2] photocycloaddition has been reported to afford the caged polycyclic structure **276** from **275**.[86] The attachment of the double bond very

Scheme 48 *Ortho* photocycloaddition of naphthoquinones. Reagents and conditions: (a) hυ, EtOAc, 78%.



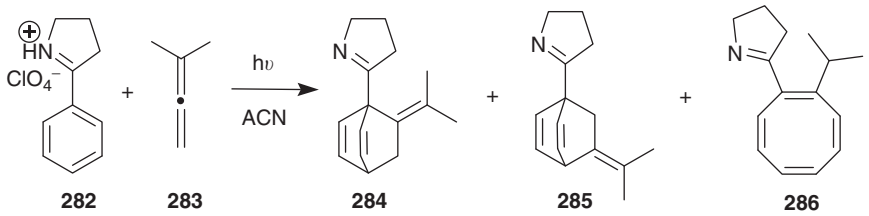
Scheme 49 Naphthalenes undergo *ortho* photocycloaddition.

close to the aromatic moiety leads to the desired cage compound **276** during the photocycloaddition in high yield. The product is stable enough to be isolated and recrystallized.

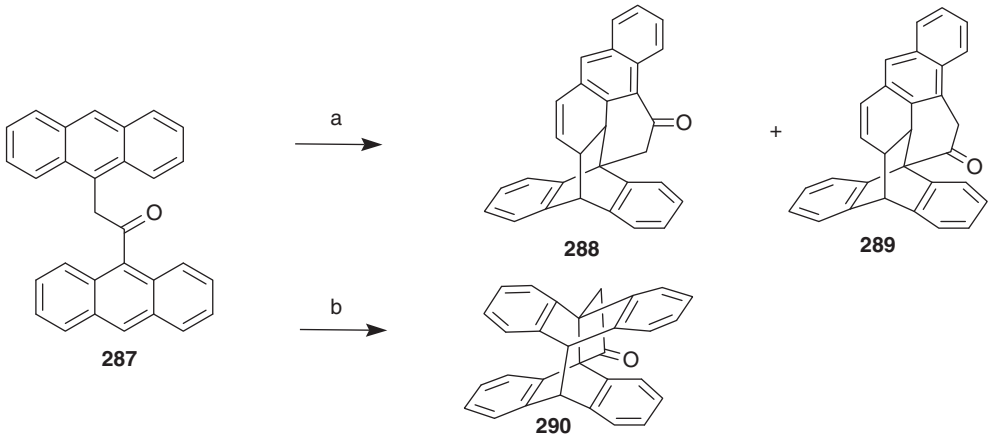
The *ortho* photocycloaddition with naphthalenes (Scheme 49):

Naphthalenes preferably undergo *ortho* photocycloadditions, whereas higher arenes usually react with olefins in a [2 + 2], [4 + 2], or [4 + 4] cycloaddition mode.

Benzotriazoles, when irradiated in the presence of maleic imide, form stable [2 + 2]-photocycloadducts **279** in 39% yield (Scheme 50). The same applies for 1,5-dimethoxy benzonitrile **281** with acrylnitrile, but in much better yields of 70%.[87]



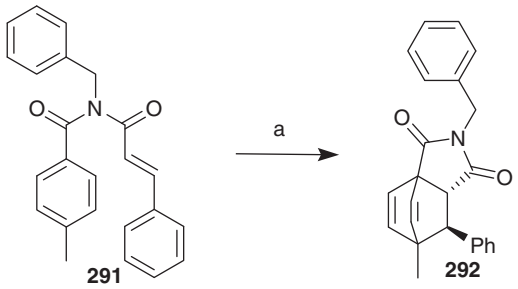
Scheme 50 Reagents and conditions: (a) hυ, MeCN, 39%; (b) hυ, 70%.



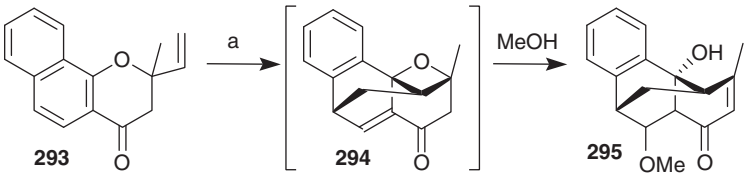
5.15.7 Applications of *Para* Photocycloaddtions

Para photocycloadditions give access to bicyclo[2.2.2]octadiene systems by a formal Diels–Alder type reaction and are rarely observed. Therefore little is known about this mode of transformation. It is known that higher aromatics are more likely to undergo *para* cycloadditions,[88] and that it is the main reaction course when allenes are involved.[11d] If the irradiation is carried out in the presence of conjugated dienes or a second arene, this photocycloaddition can also be performed in a [4 + 4] mode to afford bicyclo[4.2.2]decatrienes and more complex homocycles.[88,89] A high-yielding example of a *para* photocycloaddition with an allene has been published by Haddaway et al. (Scheme 51).[90]

Nonsensitized irradiation of dianthryls **287** usually triggers the [4 + 4] photocycloaddition[88] pathway leading to **290**, but on sensitizing to the triplet excited-state, the [4 + 2] mode prevails and products **288** and **289** are obtained (Scheme 52). Such [4 + 4] photocycloadditions have also been observed intermolecularly with very high yields.[91]



Scheme 51 Reagents and conditions: (a) hυ, MeCN **284:285:286**=38:6:2%.



Scheme 52 Reagents and conditions: (a) hυ, **288**:**289**=75:22, diacetyl, 97%; (b) hυ, 98%.

Only a few high-yielding examples leading to *para* products are reported in literature. However, one case is the intramolecular photocycloaddition of a cinnamoylamide and a benzamide in **291** moiety (Scheme 53).[92] This reaction is very efficient and leads to high yields of the bicyclo[2.2.2]octadiene derivative **292**.

Scheme 53 Reagents and conditions: (a) hυ, benzil, PhH, 93%.

The cinnamoylamide **291** is sensitized by benzil to its triplet excited state. The proposed mechanism involves the reaction of the olefin with the *ipso* position of the aromatic ring, affording a *spiro* biradical intermediate. Recombination of these radicals proceeds until formation of the final compound is accomplished. Kohmoto showed that similar enamides linked to a naphthyl moiety underwent preferably *ortho* photocycloaddition if the naphthyl moiety is sensitized.[93] Irradiation of a naphthyl precursor **293** with only two atoms in the tether to the olefin furnished the *para* photocycloadduct **295** formed via **294** (Scheme 54).[94]

Scheme 54 Reagents and conditions: (a) hυ, MeOH, 20%.

5.15.8 Conclusion

In summary, this chapter has highlighted the mechanistic features and synthetic applications of the alkene–arene photocycloaddition. This research field has received an ever-increasing attention over the past five decades culminating in a variety of elegant and efficient syntheses. The efficiency and elegance stems from a drastic increase in molecular complexity in a single chemical operation, building polycyclic carbon scaffolds with up to six stereocenters. For the *meta* photoreaction already sophisticated mechanistic models exist and are further refined, which is important concerning the control of the absolute stereochemistry in this process. In this respect a lot of research needs to be done, as there is no tool to control the absolute stereochemistry in this reaction with resonable enantiomeric excess to date. Although *meta* photocycloadditions have been exploited over the past 40 years, the *ortho* and *para* reactions still require more detailed investigations. Given the way in which such cycloadducts can be further manipulated, their synthetic potential is vast. Therefore, it is very clear that these transformations will continue to be a central topic in the future of organic synthesis.

Glossary

Annulation A transformation in which a new ring is attached to a parent molecule through the formation of two new bonds.

Cycloaddition A reaction in which two or more unsaturated molecules are combined to form a cyclic adduct with a net reduction of the bond multiplicity. The unsaturated entities can be parts of the same molecule.

Cyclobutene A four-membered carbocycle containing one double bond.

Electrocyclic reaction A molecular rearrangement transforming fully conjugated linear π-electron systems into cyclic structures. A σ-bond is formed between the termini with a decrease by one in the number of π-bonds (electrocyclization). Or the reverse process of the reaction mentioned above (cycloreversion, elecrocyclic ring opening reaction).

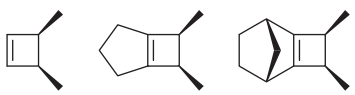
Torquoselectivity The selectivity on the rotational direction of substituents in electrocyclic ring opening reactions. The substituents undergo either 'inward' or 'outward' rotation.

5.16.1 Introduction

Numerous examples of ring opening reactions of cyclobutenes and benzocyclobutenes have appeared since 1985. The major focus of those studies has been on the investigation of the torquoselectivity, the sequential utilization of the resulting 1,3-dienes in electrocyclization reactions, and applications to natural product syntheses. This review features the typical examples.

5.16.2 Cyclobutene Ring Opening

The Woodward–Hoffmann rules allow the conrotatory ring opening of cyclobutenes.[1] The energy gap between the allowed conrotatory transition state and the forbidden one depends on the planarity of the transition structure, as supported by both experiments and calculation.[2] In case *cis*-3,4-dimethylcyclobutene is fused to another cyclic structure, planarity increases with the conrotatory transition structure and the energy gap is reduced, as evidenced by the experimentally observed $\Delta\Delta G^{\ddagger}$ values (Figure 1).



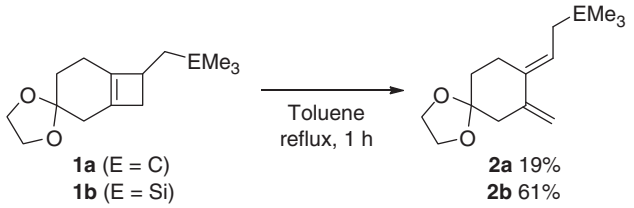


Figure 1 Differences in free energies of activation ($\Delta\Delta G^{\ddagger}$).

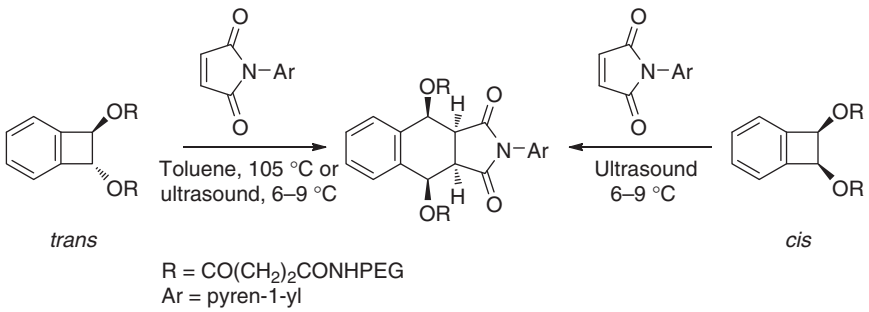
The accelerating effects of a neopentyl group and a trimethylsilylmethyl group were compared. On heating in refluxing toluene for 1 h, neopentylcyclobutene **1a** gave the diene product **2a** only in 19% yield, whereas (trimethylsilylmethyl)cyclobutene **1b**

 doi:10.1016/B978-0-08-097742-3.00517-6

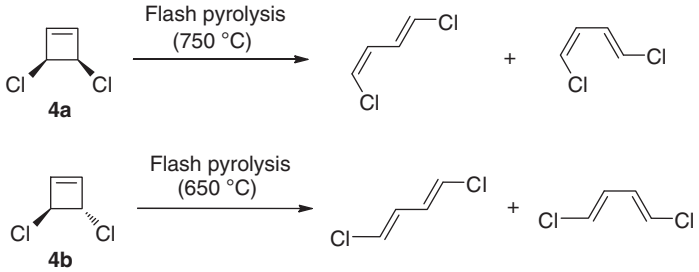
afforded diene **2b** in 61% yield (Scheme 1).[3] The rate acceleration was attributed to the σ-donating ability of the C–Si bond, which is associated with the β-effect of silicon.



Scheme 1 Thermal ring opening of neopentyl- and trimethylsilylcyclobutenes.

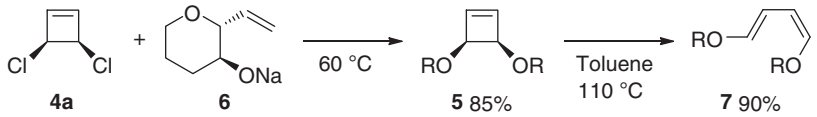
The thermal ring opening of fluorinated cyclobutenes in the gas phase was also studied.[4] The reaction of 3-fluorocyclobutene **3a** occurred at lower temperature than that of cyclobutene itself, and the thermodynamically less stable *E*-diene was selectively formed (Scheme 2). In contrast, 3,3-difluorocyclobutene (**3b**) and 3-(trifluoromethyl)cyclobutene (**3c**) were more reluctant to undergo ring opening than cyclobutene. The activation energy for the ring opening of **3b** was greater than that of the monofluoro analog **3a** by 16.9 kcal mol^{-1}. The rearrangement of **3c** led to a mixture of dienes with the thermodynamically more stable *E*-diene predominating. Cyclobutene **3c** exhibited an activation energy similar to that of cyclobutene.

Scheme 2 Thermal ring opening of fluorinated cyclobutenes **3**.



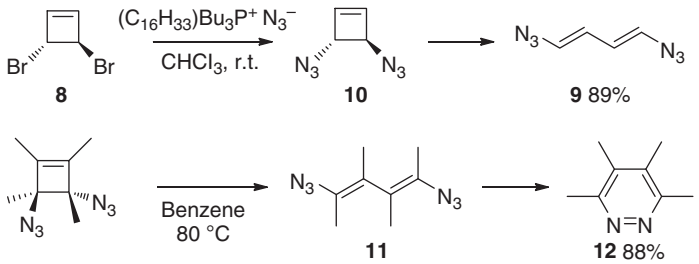
Unusual rotational behaviors were observed in an ultrasound-induced electrocyclic ring opening reaction of 1,2-disubstituted benzocyclobutenes (Scheme 3).[5] The *trans*-isomer yielded a product resulting from conrotatory ring opening, whereas the *cis*-isomer yielded a product resulting from disrotatory ring opening. As a result, the same product stereochemistry arose from the two diastereomers because of the mechanical forces associated with ultrasound. The violation of the Woodward–Hoffman rule was theoretically studied.[6]

Scheme 3 Ultrasound-induced ring opening of benzocyclobutene in MeCN solution.



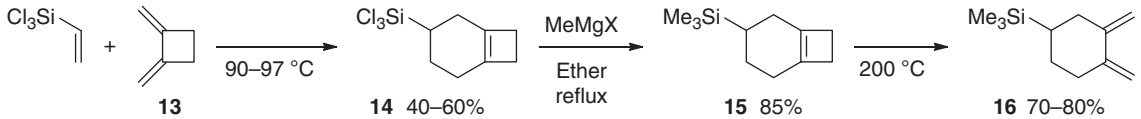
The products of flash pyrolysis of *cis*- and *trans*-3,4-dichlorocyclobutenes were trapped in a matrix (Xe, 12 Kelvin (K)). The *E,Z*-diene produced from *cis*-3,4-dichlorocyclobutene (**4a**) was found to exist in both the s-*cis* and the s-*trans* comformation

(Scheme 4). Likewise, the *E,E*-diene produced from *trans*-3,4-dichlorocyclobutene (**4b**) was also found in both the s-*cis* and s-*trans* conformations.[7] A lower activation energy was observed for the ring opening of **4b**.



Scheme 4 Flash pyrolysis of *cis*- and *trans*-3,4-dichlorocyclobutenes.

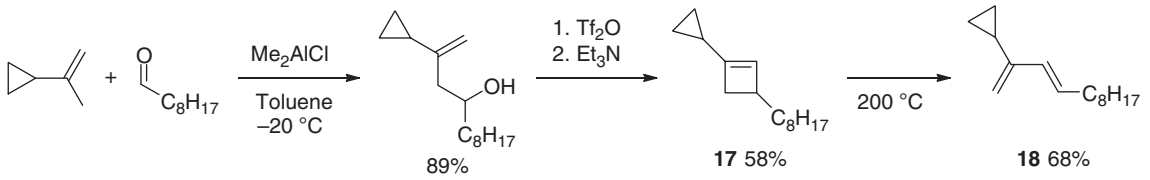
Dialkoxycyclobutene **5** was prepared by a reaction of *cis*-3,4-dichlorocyclobutene (**4a**) with 2 equivalents of *tert*-alkoxide **6** (Scheme 5). When **5** was heated in refluxing toluene, the *E,Z*-diene **7** was the only product formed by conrotatory ring opening.[8]



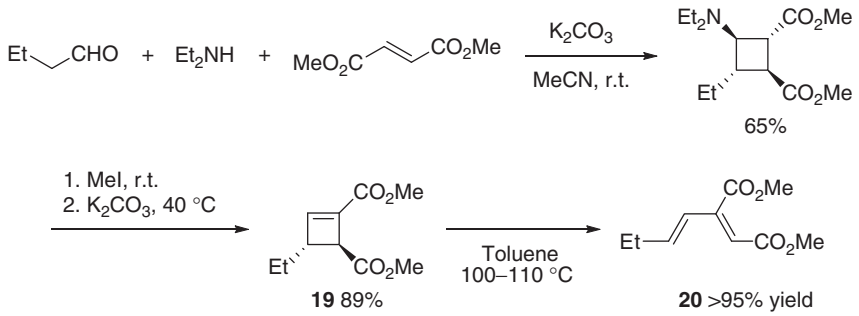
Scheme 5 Synthesis and ring opening of dialkoxycycobutene **5**.

The first synthesis of 1,4-diazidobuta-1,3-dienes was performed via ring opening of cyclobutenes.[9] When *trans*-3,4-dibromocyclobutene (**8**) was treated with tributylhexadecylphosphonium azide in $CHCl_3$ at 20 °C, (*E,E*)-3,4-diazidobuta-1,3-diene (**9**) was obtained as the major product through facile ring opening of *trans*-diazidocyclobutene (**10**) (Scheme 6). However, the corresponding *cis*-diazidocyclobutene was reluctant to undergo ring opening. A tetramethyl-substituted derivative **11** could be formed at 80 °C, which was transformed into pyridazine **12** on prolonged heating.

Scheme 6 Ring opening of 3,4-diazidocyclobutenes.



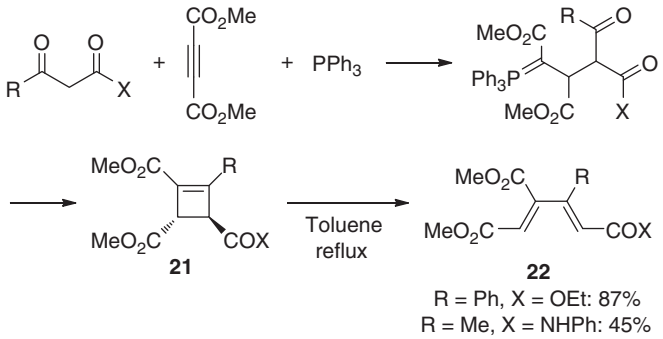
The Diels–Alder reaction of 1,2-dimethylenecyclobutane **13** with vinyltrichlorosilane afforded cyclobutene **14** (Scheme 7). After reaction of **14** with methyl Grignard reagent, the resulting cyclobutene **15** underwent thermal ring opening at 200 °C to give l,2-dimethylenecyclohexane **16**.[10]



Scheme 7 Ring opening of cyclobutene **15** giving 1,2-dimethylenecyclohexane **16**.

1-Cyclopropylcyclobutene **17** underwent ring opening rather than vinylcyclopropane–cyclopentene rearrangement to give 1,3-diene **18** when heated at 200 °C (Scheme 8).[11]

A thermal ring opening reaction of **19** occurred at 100–110 °C to give 1,3-diene **20** as a single isomer (Scheme 9).[12]



Scheme 8 Synthesis and ring opening of 1-cyclopropylcyclobutene **17**.

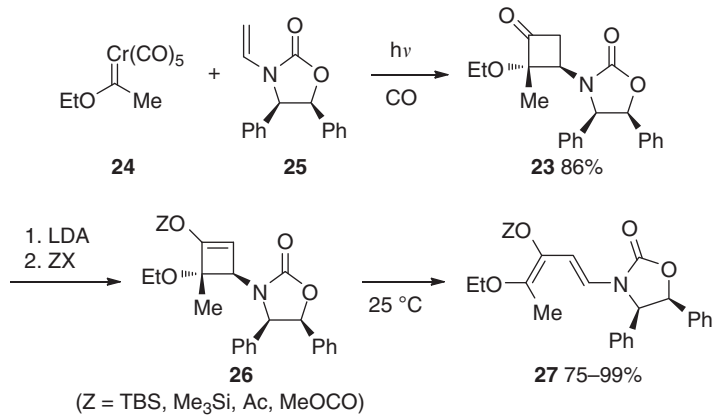
Scheme 9 Synthesis and ring opening of cyclobutene **19**.

Cyclobutenes were prepared by a stereoselective intramolecular Wittig reaction of a vinyltriphenylphosphonium salt with 1,3-dicarbonyl compounds. The cyclobutenes **21** underwent electrocyclic ring opening in refluxing toluene to produce the electron-deficient 1,3-dienes **22** (Scheme 10).[13]

Scheme 10 Synthesis and ring opening of cyclobutenes **21**.

Chiral cyclobutanone **23** was prepared by photochemical [2 + 2] cycloaddition between chromium alkoxycarbene complexes **24** and chiral ene-carbamate **25** (Scheme 11). Enolization followed by silylation produced the silyl enol ethers **26** which underwent facile conrotatory ring opening to give dienes **27** on standing at room temperature (r.t.).[14] When the enolate was trapped with acetic anhydride or methyl chloroformate, the corresponding dienes were directly formed.

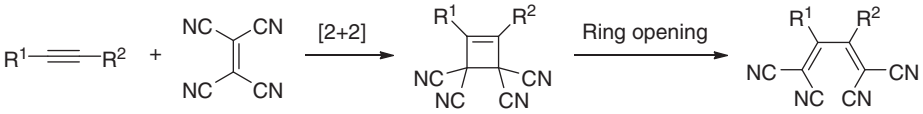
[2 + 2] Cycloaddition of tetracyanoethene (TCNE) with donor-substituted alkynes followed by electrocyclic ring opening produced 1,1,4,4-tetracyanobutadienes (Table 1).



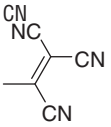
The analogous cycloaddition–cycloreversion occurred regioselectively with tetracyanoquinodimethane (TCNQ), affording a new family of nonplanar charge-transfer chromophores (Scheme 12).[18]

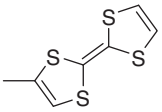
Methanolysis of the *N*-acetyl cyclobutene-lactam **28a** in the presence of LiOH at r.t. resulted in ring opening to give *E,Z*-diene **29a** (Scheme 13).[19] When the *N*-Boc, *N*-benzyl, and nonprotected cyclobutene-lactams **28b–d** were subjected to the methanolysis, *E,E*-dienes **29b–d** were obtained via isomerization under the basic conditions.

A platinum-catalyzed [2 + 2] cycloaddition reaction of a 1,7-enyne at 60 °C afforded cyclobutene **30**, which was converted into 1,3-diene **31** on heating at 120 °C (Scheme 14).[20]



Although the bicyclo[5.2.0]nona-1(9),2-diene **32**, obtained by gold(I)-catalyzed [2 + 2] cycloaddition of a 1,6-dien-8-ynes, was stable in CD_2Cl_2, it slowly underwent ring opening in $CDCl_3$ due to a trace amount of HCl present in this solvent (Scheme 15).[21]





The silyl ether **33**, which was synthesized from cyclobutenedione monoethylenedithioketal, underwent ring opening with outward rotation of the siloxy group at 50 °C to give diene **34** (Scheme 16).[22] The subsequent Diels–Alder reaction of **34** with

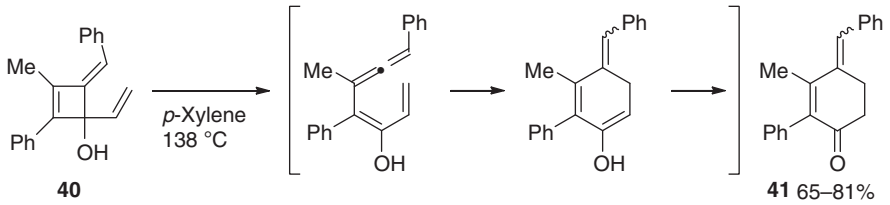
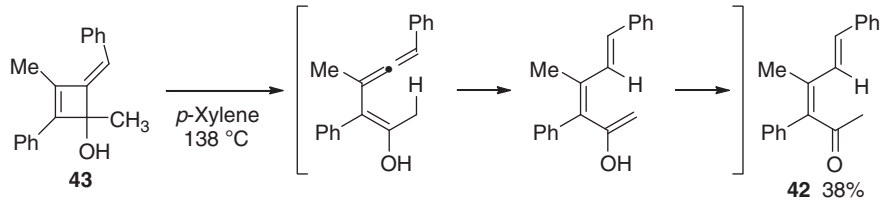
TCNE afforded adduct **35** in high yield. Likewise, thermal ring opening of cyclobutene **36** in the presence of TCNE gave the corresponding Diels–Alder adduct **37** (Scheme 17).[23] A twofold Diels–Alder cycloaddition of a biscyclobutene tethered to C_{60} was carried out in toluene under high dilution conditions to give *rac*- and *meso*-diastereomers of the bis-adduct in a 1:1 ratio.[24]



Scheme 17 Ring opening of cyclobutene **36**.



The ring opening of cyclobutenes bearing unsaturated groups provides an opportunity for the synthesis of ring-expanded carbocycles by subsequent electrocyclic reactions. On thermal reaction of 4-alkynyl-4-hydroxy-3-benzylidenecyclobutene **38** at 140 °C, phenol **39** was formed through electrocyclic ring opening, cycloaromatization, and H-abstraction (Scheme 18).[25] Reaction of 4-alkenyl-4-hydroxy-3-benzylidenecyclobutene **40** in refluxing *p*-xylene gave an *E*/*Z* mixture of 4-benzylidenecyclohexenones **41** (Scheme 19). Dienone **42** was obtained when 4-methyl-4-hydroxy-3-benzylidenecyclobutene **43** was heated in refluxing *p*-xylene (Scheme 20). A thermal reaction of 4-allenyl-4-hydroxy-3-benzylidenecyclobutene **44** afforded an *o*-quinodimethane intermediate, which immediately rearranged to the benzocyclobutene **45** (Scheme 21).[26]

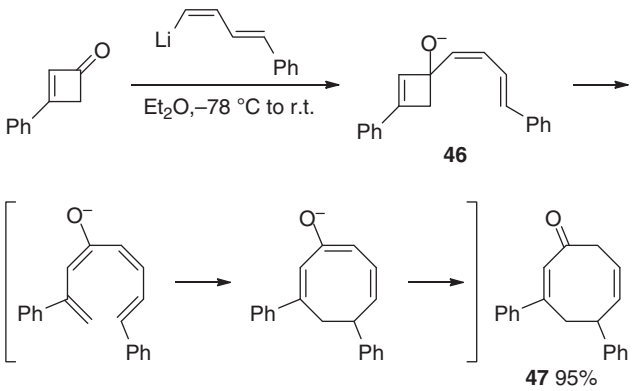
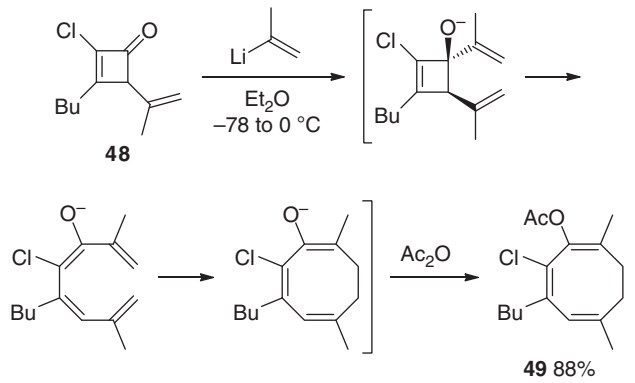
Scheme 20 Ring opening–cyclization of alkyl(benzylidene)cyclobutenol **43**.

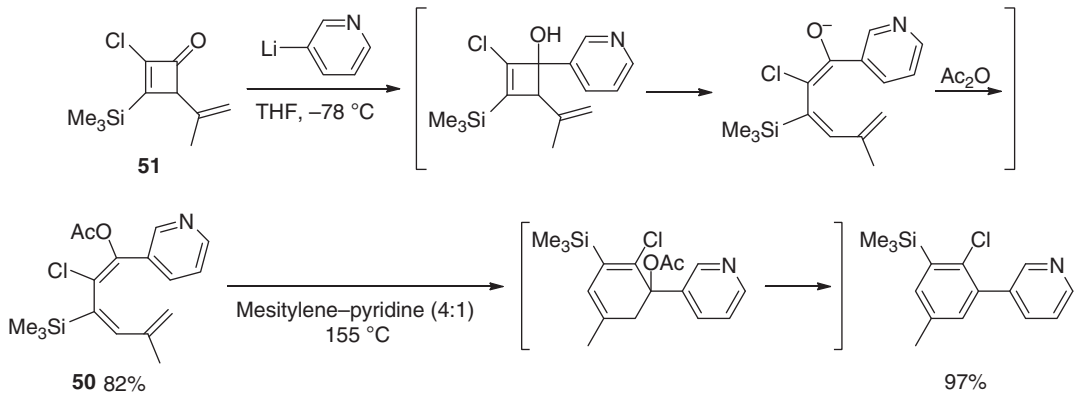


Scheme 21 Ring opening–cyclization of allenyl(benzylidene)cyclobutenol **44**.



When 3-phenylcyclobutenone was reacted with dienyllithium at −78 °C and the resultant reaction mixture was gradually warmed to r.t., the ring opening of cyclobutene **46** initially formed proceeded and was followed by an 8π electrocyclization to afford the eight-membered ring ketone **47** as a sole product in high yield (Scheme 22).[27]

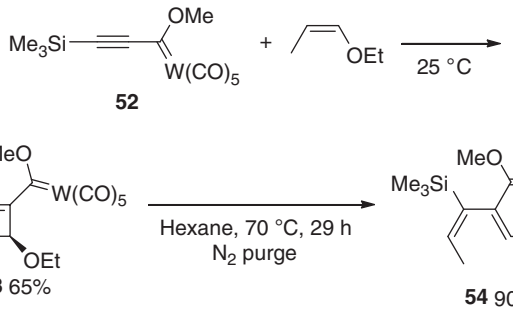
Addition of alkenyllithiums to 4-alkenylcyclobut-2-enones **48** also led to the production of eight-membered ring products **49** via such a ring opening–8π electrocyclization sequence (Scheme 23).[28]



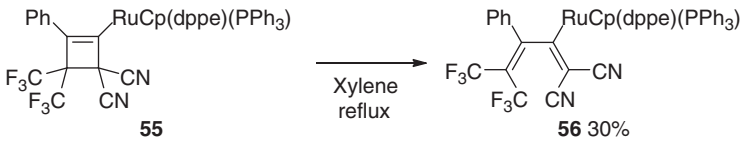
However, it required a higher temperature for the aryl-substituted triene **50**, generated by addition of aryllithium to alkenylcyclobutenone **51**, to undergo 6π electrocyclization (Scheme 24).[29]

Scheme 22 Ring opening–8π electrocyclization of dienylcyclobutenol **46**.

Scheme 23 Synthesis of cyclooctatriene **49** via ring opening–8π electrocyclization.

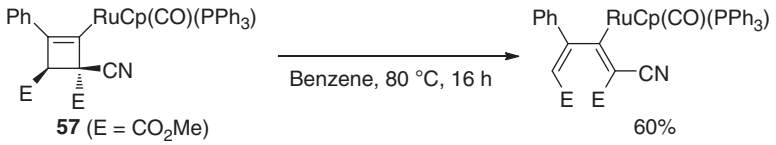


Scheme 24 Ring opening-6π electrocyclization.

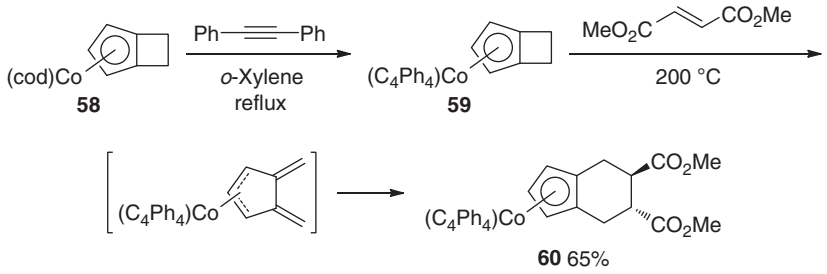


[2 + 2] Cycloaddition of the alkynylcarbene tungsten complex **52** with (*Z*)-ethyl prop-1-enyl ether afforded the cyclobutenylcarbene complex **53**, which underwent stereoselective electrocyclic ring opening at 70 °C to give the butadienylcarbene complex **54** (Scheme 25).[30] Carbon monoxide was expelled during the reaction to form the chelate complex **54**.

The cyclobuten-1-yl ruthenium complex **55** underwent thermal ring opening to give the buta-1,3-dien-2-yl ruthenium complex **56** (Scheme 26). In the electrocyclic reaction of **57**, the two CO_2Me substituents both rotated inward (Scheme 27).[31]



No ring opening of the four-membered ring occurred with the η^5-bicyclo[3.2.0]hepta-l,3-dienylcobalt(I) complex **58** bearing a COD ligand. In contrast, complex **59** having a tetraphenylcyclobutadiene ligand underwent ring opening at 200 °C and further reacted with dimethyl fumarate to afford the [4 + 2] cycloadduct **60** (Scheme 28).[32]



Scheme 25 Ring opening of cyclobutenylcarbene tungsten complex **53**.

Scheme 26 Ring opening of cyclobuten-1-ylruthenium complex **55**.

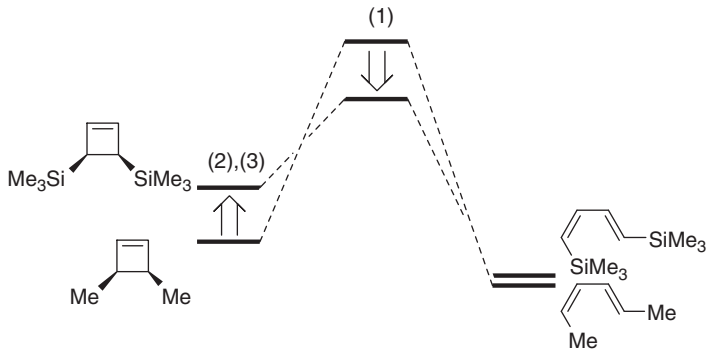
Scheme 28 Ring opening of bicycloheptadienylcobalt(I) complex **59**.

The reaction of $Cp^*Fe(CO)_2K$ with *cis*-3,4-dichlorocyclobutene at –25 °C gave the diiron cyclobutene complex **61** which was converted to the butadienediyl complex **62** on heating (Scheme 29).[33]

Scheme 29 Ring opening of diiron cyclobutene complex **61**.

The ring opening reaction of *cis*-3,4-bis(trimethylsilyl)cyclobutene proceeds remarkably faster than that of *cis*-3,4-dimethylcyclobutene.[34] The significant rate acceleration was explained by assuming that (1) a stabilization of the transition state by electron delocalization from the cyclobutene HOMO to the Si–CH_3 σ^* orbital, (2) the destabilization of the ground state by intramolecular interaction between the C–Si σ orbitals and the π orbital of cyclobutene, and (3) the steric repulsion between the two bulky trimethylsilyl groups in a *cis* arrangement (Figure 2).



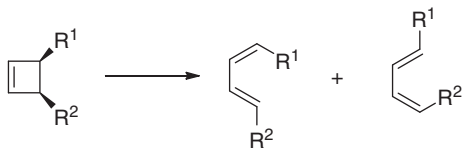


Figure 2 Three factors accelerating the ring opening reaction of *cis*-3,4-bis(trimethylsilyl)cyclobutene.

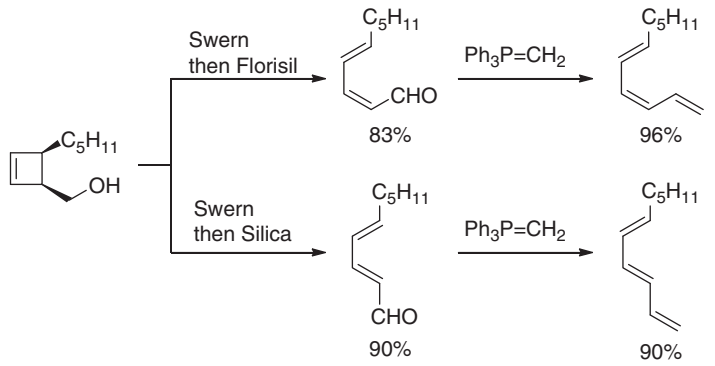
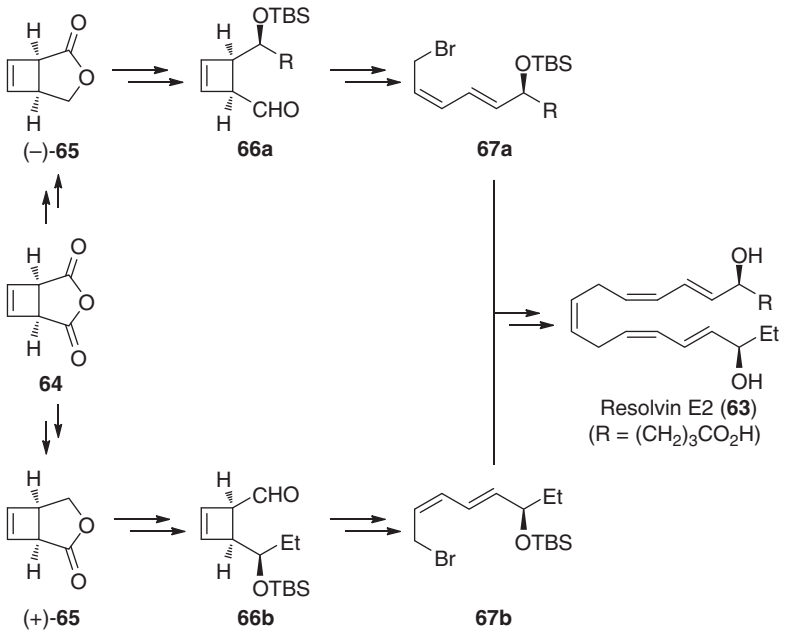


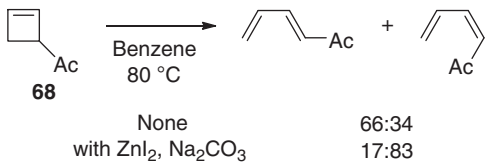
The conrotatory ring opening of unsymmetrically disubstituted cyclobutenes having different substituents at the 3- and 4-positions in a *cis* relationship can give two allowed *E,Z*-dienes (Table 2). The ratios disclose the electronic and steric preferences in rotational direction, i.e., the torquoselectivity.[35] Moderate selectivities were observed with combinations of electron-withdrawing substituents like ester/acid, ester/ester, and ester/acid chloride. The preference of various acid-derived groups toward inward conrotation follows the order: $COCl > CO_2H \approx CO_2(2\text{-Naph}) > CO_2Me$. Preferential inward rotation of a bulikier $CO_2(2\text{-Naph})$ group over a CO_2Me group is accounted for by assuming the greater π-donor capacity of OMe compared to OAr. In contrast, a formyl substituent exhibited a much stronger preference for inward conrotation.

Table 2 Ring opening of *cis*-3,4-disubstituted cyclobutenes



R^1	R^2	*Conditions*	*Ratio*
CO_2H	CO_2Me	Toluene, 110 °C, 1 h	2:1
CO_2H	CO_2(2-naphthyl)	$ClCH_2CH_2Cl$, 83 °C, 10 h	1:1
CO_2(2-naphthyl)	CO_2Me	Toluene, 110 °C, 2 h	1.4:1
COCl	CO_2Me	Toluene, 110 °C, 1 h	4:1
CHO	CH_2OPMB	CH_2Cl_2, <20 °C, <0.5 h	>20:1
CHO	Et	CH_2Cl_2, <20 °C, <0.5 h	>20:1

The strong preference of a formyl group for inward conrotation was exploited in the synthesis of naturally occurring isomeric trienes from a single precursor (Scheme 30).[36] Quenching the Swern oxidation at 20 °C and isolation by silica gel led to the formation of the more stable (*E,E*)-isomer.



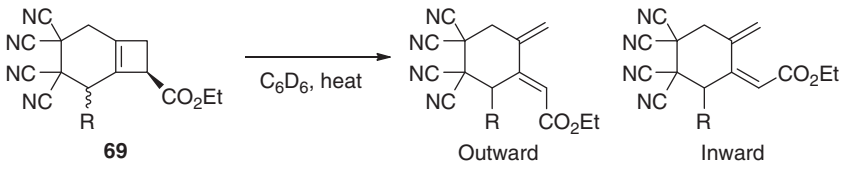
Scheme 30 Synthesis of trienes via ring opening of cyclobutene.

Inward preference of a formyl group was also successfully exploited in a total synthesis of resolvin E2 (**63**), which is derived from eicosapentaenoic acid. Desymmetrization of the anhydride **64** gave both enantiomers of lactone **65**, which were transformed to alkylated diols (Scheme 31). A subsequent Swern oxidation of the diols afforded the formylcyclobutenes **66**, which underwent facile ring opening (at −78 °C to r.t.) to furnish the *E,Z*-dienes **67a** and **67b** in 86% and 81% yields, respectively. Finally, they are coupled to afford product **63**.[37]

Scheme 31 Synthesis of resolvin E2 (**63**).

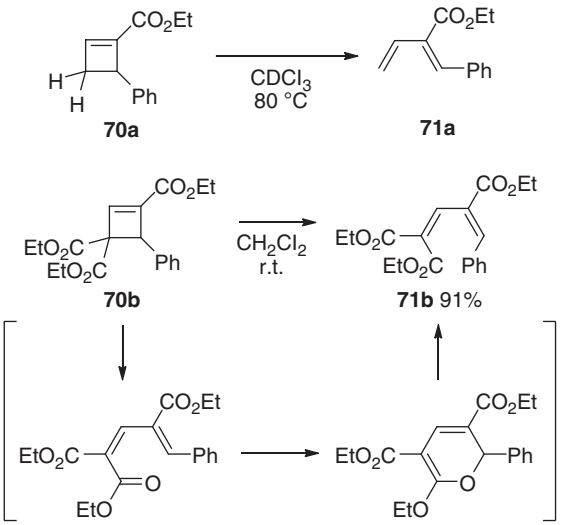
Thermal ring opening of the 3-acetylcyclobutene (**68**) resulted in a mixture of *E*- and *Z*-dienes, with the *E*-diene predominating (Scheme 32). This preference was reversed by addition of Lewis acidic ZnI_2.[38] The reversal of the torquoselectivity was theoretically studied.

Scheme 32 Study on the torquoselectivity of the ring opening of 3-acetylcyclobutene (**68**).



The torquoselectivity was also studied in thermal ring opening reactions of bicyclo[4.2.0]oct-1(6)-ene-7-carboxylates **69** (Table 3). Outward rotation of the CO_2Et group was sterically disfavored by the C5 substituent R. Product ratios obtained from the *trans*-isomers were comparable to those derived from the *cis*-isomers.[39]

A phenyl group exhibits a torquoselectivity-preference for outward rotation. Accordingly, cyclobutene **70a** opened at 80 °C to give *E*-diene **71a** in 24 h (Scheme 33). On the other hand, ring opening of the triester-substituted phenylcyclobutene **70b** completed in 5 min at r.t. to give *Z*-diene **71b** exclusively. However, a computational study supported a high selectivity for outward rotation. This disagreement was explained by assuming that the resulting (*E*)-dienyl ester cyclized to a pyran; its subsequent reopening led to the thermodynamically more stable isomer.[40]



When heated at 140 °C, the *t*-butylcyclobutene **72** underwent ring opening with outward rotation of the *t*-butyl substituent to give exclusively the *trans*-isomer (Scheme 34). However, 3-(trimethylsilyl)cyclobutene **73** furnished a mixture of *cis*- and *trans*-isomers, with the former predominating (69:31).[41] The reaction of **73** ($k = 0.53\ h^{-1}$ at 140 °C) was faster than that of **72** ($k = 0.32\ h^{-1}$ at 140 °C). The observed inward preference and accelerating effect of the silyl substituent can be explained by assuming electron-accepting interactions of the energetically low lying σ^* orbital of the silicon atom with the HOMO orbital of the inward transition state.

Cyclobutenone **74** was treated with a silylcuprate at −78 °C and the resultant 1,4-adduct was trapped with Ac_2O to afford 3-silyl-1-cyclobutene **75** (Scheme 35). When heated in refluxing benzene for 2 h, compound **75** underwent a ring opening

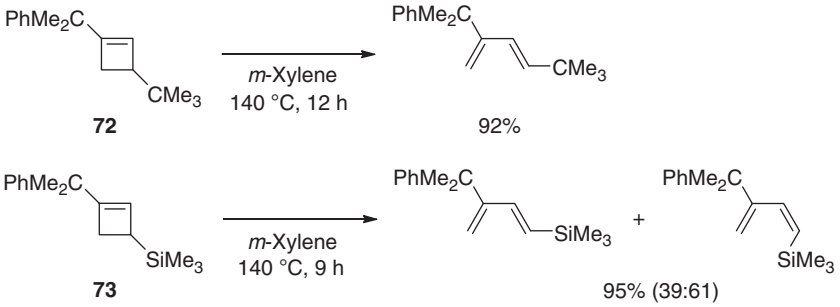


Table 3 Torquoselectivity in thermal ring opening of cyclobutenes **69**

R	*Outward:inward*

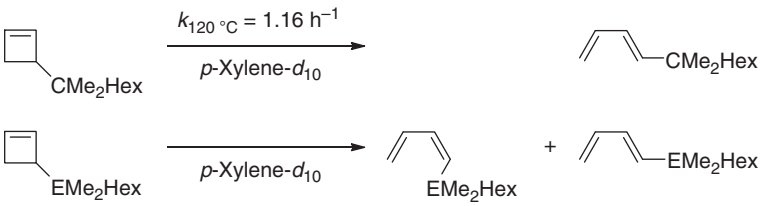
reaction with inward rotation of the silyl group to furnish the (*Z*)-1-silyl-1,3-diene **76**. However, when **74** was treated with silyllithium at –78 °C and subsequently with Ac_2O, the expected cyclobutene derivative was not isolated. Instead, the (*Z*)-1-silyl-1,3-diene **77** was directly obtained.[42]

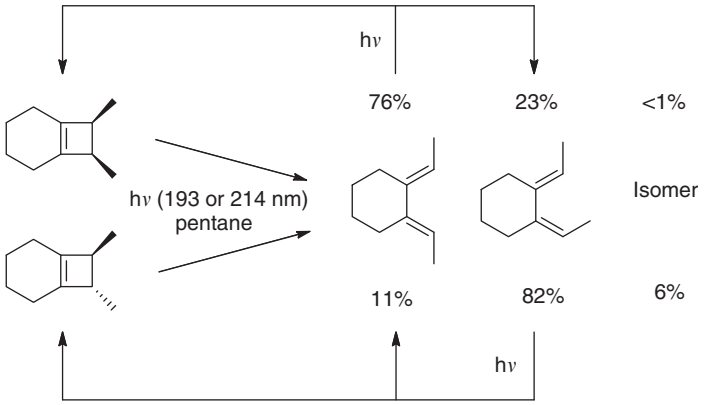


Scheme 35 Ring opening of silyl-substituted cyclobutenes.

trans-3,4-Disilylcyclobutene **78** underwent ring opening in a conrotatory fashion ($t_{1/2}$=1.7 h) to afford a mixture of dienes (Scheme 36).[43] *Z,Z*-**79** predominated over *E,E*-**79**, with a ratio of 78:22. The two trimethylsilyl substituents preferred inward rotation despite the significantly greater steric constraints occurring during this pathway.

Scheme 36 Study of the torquoselectivity of the thermal ring opening of *trans*-3,4-disilylcyclobutene **78**.

The thermal ring opening reaction of a series of cyclobutenes bearing group 14 elements at the 3-position was studied (Scheme 37).[44] Carbon-substituted cyclobutenes followed an outward pathway to afford the corresponding *E*-dienes exclusively. However, the silyl, germyl, and stannyl substituents rotated in both outward and inward directions, giving a mixture of *E*- and *Z*-isomers. The structural features of the calculated transition state and population analysis suggested that the preferential formation of the *Z*-isomer could be also ascribed to the donor/acceptor interaction between the HOMO and the σ^* orbital of the group 14 elements.



E	$k_{120\ °C}$	*Z*:*E*

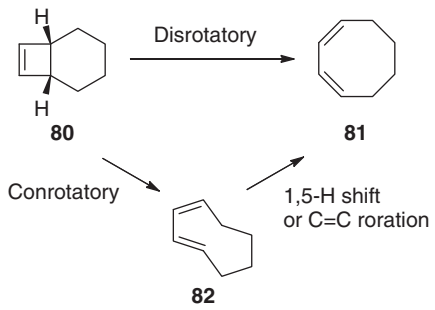
Sn	0.55 h^{-1}	71:29

Scheme 37 Ring opening of cyclobutenes bearing group 14 elements at the 3-position.

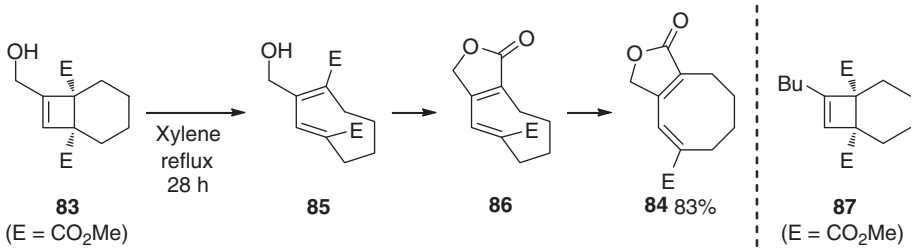


Direct photochemical reactions of *cis*- and *trans*-7,8-dimethylbicycl0[4.2.0]oct-1(6)-ene in pentane solution with 193 or 214 nm light resulted in the formation of (*E,E*)- and (*E,Z*)-1,2-diethylidenecyclohexane (Scheme 38).[45] Under these conditions, the reaction of a solution of the *E,E*-diene yielded *E,Z*-diene as well as *cis*-cyclobutene, whereas the *E,Z*-diene yielded *E,E*-diene together with the *trans*-cyclobutene. The ring closure of *E,E*- and *E,Z*-dienes occurred with >90% stereospecificity. The results stand in marked contrast to those obtained with *cis*- and *trans*-1,2,3,4-tetramethylcyclobutenes under similar conditions; these compounds afforded mixtures of isomeric 3,4-dimethyl-2,4-hexadienes with only a slight preference for the formally allowed product. The difference was attributed to the lower activation energy for the bicyclic cyclobutenes and the conformational rigidity of the dienes.

Thermal ring opening of cyclobutenes fused at the 3- and 4-positions results in ring expansion reactions that are useful for the synthesis of carbo- and heterocycles of various ring sizes. However, the mechanistic issue related to the stereochemistry of

Scheme 38 Photoinduced ring opening of *cis*- and *trans*-7,8-dimethylbicyclo[4.2.0]oct-1(6)-ene.

the resulting cyclic diene has been the subject of debate and still remains unsettled. For example, the ring opening of *cis*-bicyclo[4.2.0]oct-7-ene (**80**) to *cis*,*cis*-cycloocta-1,3-diene (**81**) was first reported in 1965.[46] Baldwin et al. examined a deuterium kinetic isotope effect using deuterated bicyclo[4.2.0]oct-7-ene.[47] The results were inconsistent with a mechanistic scenario involving *cis*,*trans*-cycloocta-1,3-diene (**82**), which led the authors to conclude that a direct disrotatory ring opening route was the preferred mechanism (Scheme 39).



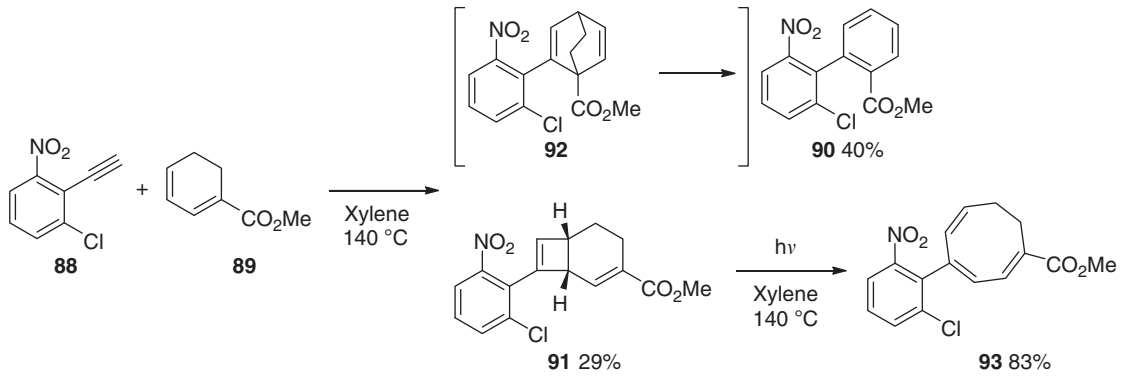
Scheme 39 Ring opening of *cis*-bicyclo[4.2.0]oct-7-ene (**80**).

However, de Lera et al. carried out a high-level computational study to ascertain the conrotatory electrocyclic ring opening followed by double-bond isomerization as the lowest-energy pathway for the net *anti*-Woodward–Hoffmann rearrangement of **80**–**81**.[48] They also examined the reaction of lower bicyclic homologs with [3.2.0], [2.2.0], and [2.1.0] skeletons. This investigation indicated a mechanistic change from a conrotatory ring opening–isomerization pathway toward a direct *anti*-Woodward–Hoffmann disrotatory pathway (Table 4).[49]

Table 4 Ring opening of *cis*-bicyclo[m.n.0]alkenes

Cyclobutene	*Pathway*
	A conrotatory ring opening followed by a higher energy direct *E*–*Z* isomerization
	
	A disrotatory electrocyclic opening is highly competitive with the conrotatory ring opening *E*–*Z* isomerization mechanism
	Thermal opening only through the disrotatory pathway to cyclopentadiene

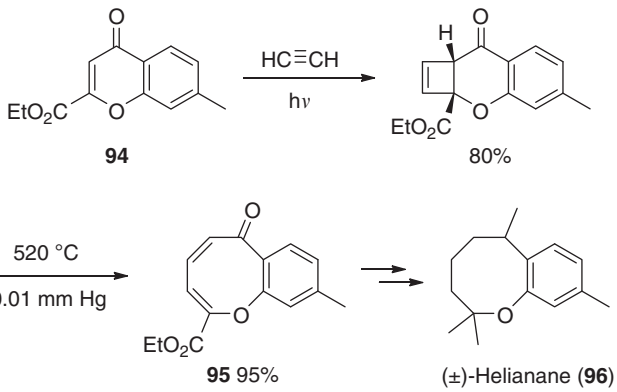
The conrotatory ring opening of bicyclo[4.2.0]oct-7-ene could occur at temperatures as low as 110 °C. However, the resulting *cis*,*trans*-cycloocta-1,3-diene was too reactive to be isolated. It spontaneously underwent ring closure back to the cyclobutene. However, heating cyclobutene diester **83** in refluxing xylene furnished butenolide **84** in 83% yield (Scheme 40).[50] Lactonization took place with the initial conrotatory ring opening product **85** to give the *cis*,*trans*-cycloocta-1,3-diene-fused butenolide **86**.



83 (E = CO_2Me) **85** **86** **84** 83% **87** (E = CO_2Me)

Scheme 40 Ring opening of cyclobutene diester **83**.

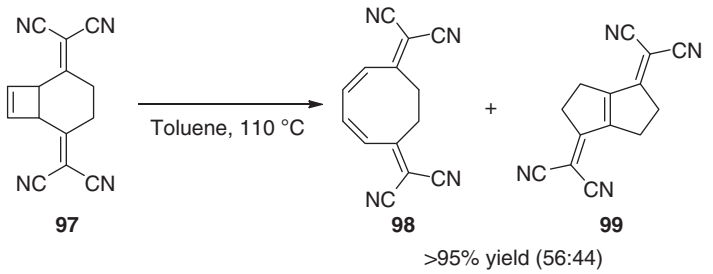
It failed to close back to the cyclobutene, but instead underwent isomerization to the more stable *cis,cis*-isomer **84** through a 1,5-hydrogen shift and the subsequent tautomerization. On the contrary, no reaction was observed with the butyl derivative **87**.



Heating of a mixture of 1-chloro-2-ethynyl-3-nitrobenzene (**88**) and 1-carbomethoxy-cyclohexadiene (**89**) at 140 °C in xylene resulted in the formation of two products **90** and **91** in a 1.3:1 ratio (Scheme 41).[51] The major biaryl **90** arose from a [4 + 2] cycloaddition forming the [2.2.2] bicycle **92** followed by [4 + 2] cycloreversion extruding ethylene, whereas the minor cyclobutene **91** was formed by [2 + 2] cycloaddition. Treatment of the isolated cyclobutene **91** at 160 °C resulted in the formation of two products: the biaryl **90** and the cyclooctatriene **93**. However, exposure of cyclobutene **91** to the light emmitted by a 120 W halogen bulb at 140 °C led to the formation of the cyclooctatriaene **93** as the sole product in good yield.

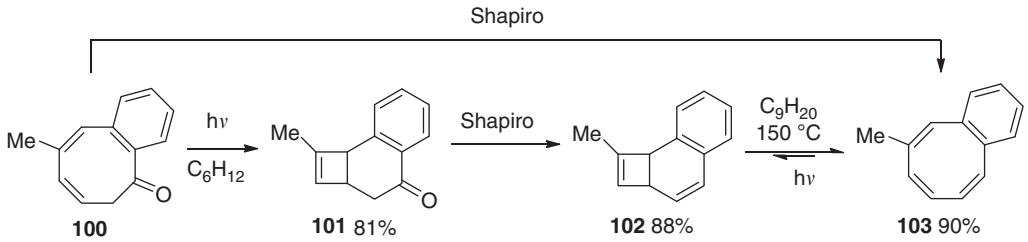
88 **89** **92** **90** 40% **91** 29% **93** 83%

Scheme 41 Reaction of **88** and **89**.



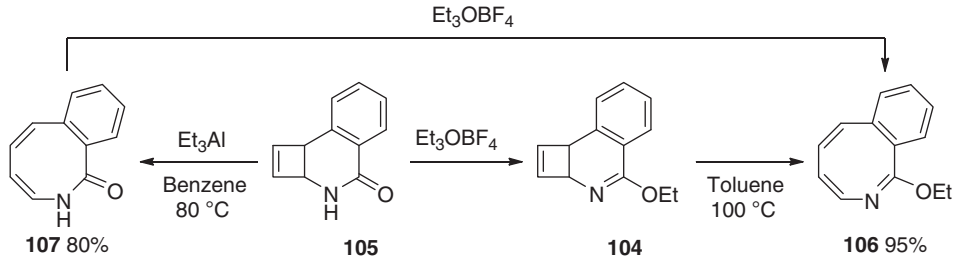
A photochemical reaction of acetylene with 4-chromenone **94** followed by flash vacuum thermolysis (520 °C, 0.01 mm Hg) caused a two-carbon ring expansion of the pyranone ring, giving benzo[*b*]oxocin-6-one **95** in excellent yield (Scheme 42).[52] The oxocinone **95** was then successfully converted to helianane (**96**), a heterocyclic sesquiterpene isolated from a marine sponge.

94 80% **95** 95% (±)-Helianane (**96**)



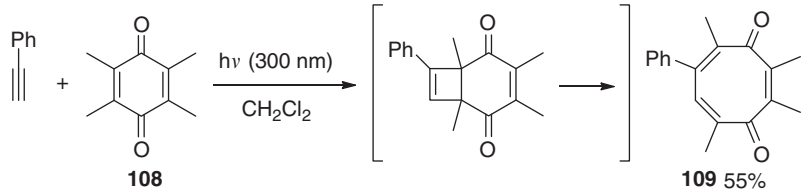
Scheme 42 Synthesis of (±)-helianane (**96**).

2,5-Bis(dicyanomethylene)bicyclo[4.2.0]octa-7-ene **97** underwent a thermal reaction at lower temperature (110 °C) to give cycloocta-1,3-diene **98**, the normal ring-opened product, and hexahydropentalene **99**, a rearranged product (Scheme 43).[53]



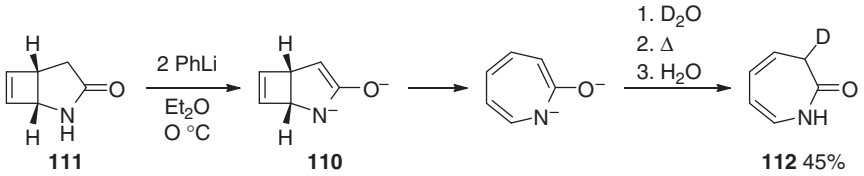
Scheme 43 Thermal reaction of **97**.

The ketone **100** cyclized on irradiation to give the bicyclo[4.2.0] system **101**, which was then transformed to **102** by the Shapiro reaction (Scheme 44). On heating at approximately 150 °C, **102** underwent ring opening to give the cyclooctatetraene derivative **103** quantitatively. Photoinduced conversion of **103** to the triene **102** was excessively slow.[54]



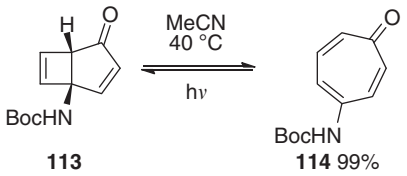
Scheme 44 Ring opening of cyclobutene **102**.

When the iminoether **104**, which was prepared from **105** and Et_3OBF_4, was heated in toluene at 100 °C, 1-ethoxybenzo[*c*]azocine **106** was obtained (Scheme 45).[55] However, heating of **105** in benzene in the presence of Et_3Al at 80 °C resulted in ring opening to give the benzoazocinone **107**. Treatment of **107** with Et_3OBF_4 gave **106**.



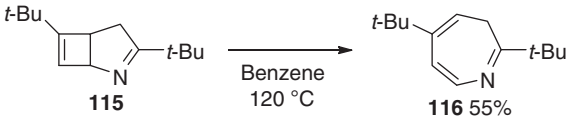
Scheme 45 Ring opening of cyclobutene **104**.

Irradiation of a mixture of duroquinone (**108**) and phenylacetylene (excess) afforded **109** via a [2 + 2] cycloaddition followed by ring opening of the cyclobutene moiety thus formed (Scheme 46).[56]



Scheme 46 Photochemical reaction of duroquinone (**108**) and phenylacetylene.

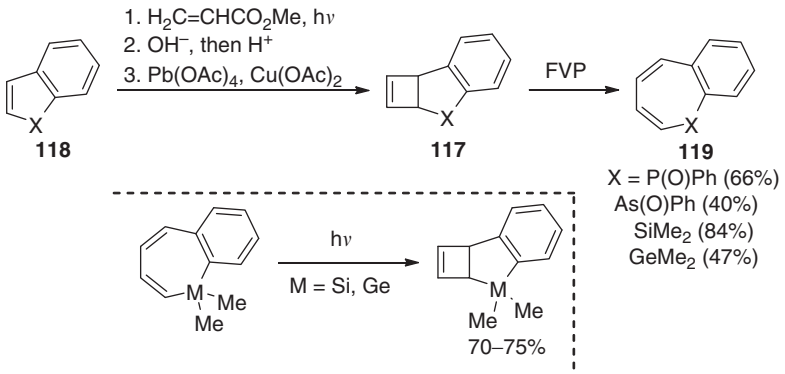
Dianion **110**, generated by deprotonation of 2-azabicyclo[3.2.0]hept-6-en-3-one **111**, underwent ring opening to afford 1*H*-azepin-2(3*H*)-one **112** after hydrolysis (Scheme 47).[57]



Scheme 47 Ring opening of dianion **110**.

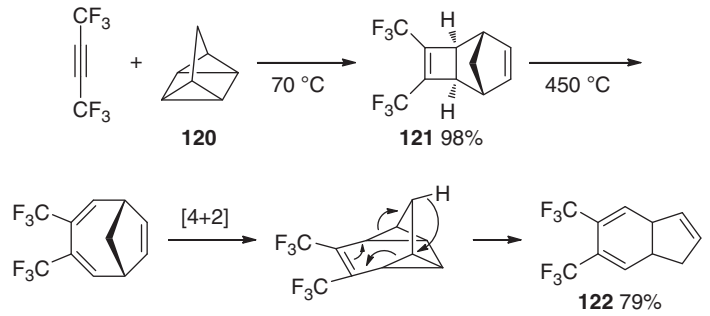
4-Aminocyclohepta-2,4,6-trienone was formed on heating of 5-aminobicyclo[3.2.0]hepta-3,6-dien-2-one **113** at 40 °C (Scheme 48).[58] On the contrary, the cyclobutene **113** was regenerated from the trienone **114** on irradiation by a 4π-electrocyclization.

Scheme 48 Ring opening of **113**.



The thermal reaction of 3,6-di-*tert*-butyl-2-azabicyclo[3.2.0]hepta-2,6-diene **115** gave 2,5-di-*tert*-butyl-3*H*-azepine **116** as a single product (Scheme 49).[59] The activation energy of the ring opening was determined by a kinetic study to be 28.7 kcal mol^{-1}.

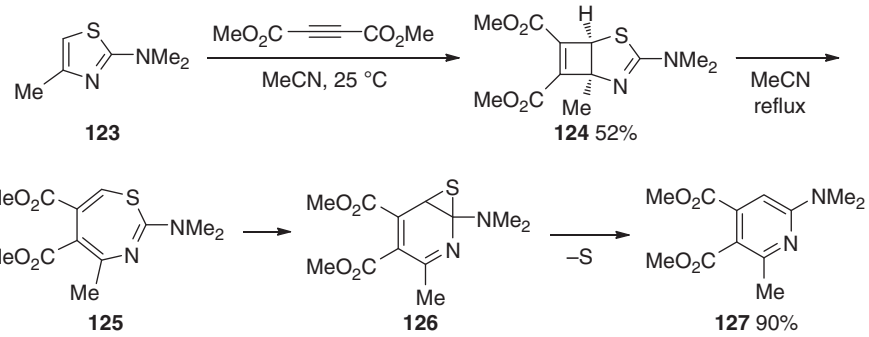
E_a = 28.7 kcal mol^{-1}



Scheme 49 Ring opening of **115**.

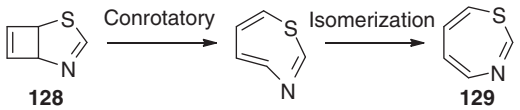
Benzo[*b*]cyclobuta[*d*]heteroles **117** are prepared by photoinduced [2 + 2] cycloaddition of benzoheteroles **118** with methyl acrylate and the subsequent oxidative decarboxylation with $Pb(OAc)_4$ (Scheme 50). Flash vacuum pyrolysis ($1.1–6.0 \times 10^{-5}$ mm Hg, 450–550 °C) of benzo[*b*]cyclobuta[*d*]heteroles **117** gave benzo[*b*]heteropines **119**.[60] The ring opening failed to occur when the substrates were simply heated at 180 °C. The silepine and germepine easily reverted back to the starting tricyclic compounds in good yields on irradiation in benzene.

Scheme 50 Synthesis and flash vacuum pyrolysis of benzo[*b*]cyclobuta[*d*]heteroles **117**.



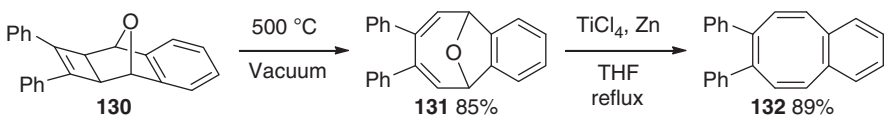
Thermal reaction of hexafluorobut-2-yne with quadricyclane (**120**) gave the 1:1 adduct **121** by a [$_\sigma$2$_s$ + $_\sigma$2$_s$ + $_\pi$2$_s$] pathway (Scheme 51). Flow pyrolysis of the cyclobutene **121** at 450 °C yielded bicyclo[4.3.0]nona-2,4,7-triene **122**.[61] Bicyclononatriene

Scheme 51 Thermal reaction of hexafluorobut-2-yne with quadricyclane (**120**).



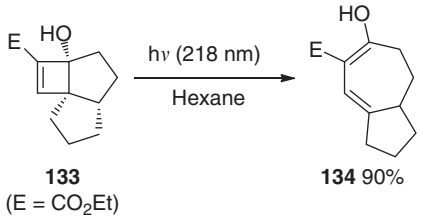
122 arose by a nonconcerted ring opening of cyclobutene **121**, an intramolecular Diels–Alder reaction, and a rearrangement involving a 1,2-hydrogen shift.

The reaction of 2-aminothiazole **123** with dimethyl acetylenedicarboxylate afforded dimethyl 6-amino-3,4-pyridinedicarboxylate **124** (Scheme 52).[62] The initial [2 + 2] cycloaddition proceeded via a two-step mechanism through zwitterionic intermediate. The formal disrotatory electrocyclic ring opening of the cyclobutene ring led to 1,3-thiazepine **125**, which rapidly gave its valence isomer, the 7-thia-2-azanorcaradiene **126** through a symmetry-allowed disrotatory 6π-electrocyclic ring closure. Finally, desulfurization gave rise to the pyridine **127**.



Scheme 52 Reaction of 2-aminothiazoles **123** with dimethyl acetylenedicarboxylate.

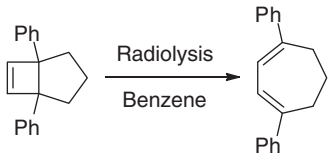
Density functional theory calculations were performed on the thermal ring opening reaction of 2-thia-4-azabicyclo[3.2.0]-hepta-3,6-dienes **128** (Scheme 53).[63] It was predicted that, regardless of the nature of the heteroatoms at positions 2 and 4 of the bicyclo[3.2.0]hepta-3,6-diene core, the electrocyclic ring opening reactions would follow the Woodward–Hoffmann-allowed conrotatory pathway leading to the corresponding *cis,cis,trans*-isomer and finally to the corresponding heterocyclic system **129** with *cis,cis,cis* geometry through double-bond isomerization.



Scheme 53 Theoretical study of the ring opening of **128**.

Nickel-catalyzed [2 + 2] cycloadditions of oxabenzonorbornadienes and alkynes provided cyclobutene derivatives such as **130**, which underwent ring opening on flash vacuum pyrolysis (500 °C) to afford diene **131** (Scheme 54).[64] Deoxygenation of the diene with $TiCl_4$ and Zn in refluxing tetrahydrofuran (THF) afforded the corresponding cyclooctatetraene derivative **132**.

Scheme 54 Flash vacuum pyrolysis of cyclobutene **130**.



A photochemical reaction of tricyclic cyclobutene **133** bearing a hydroxy group at the ring junction furnished the corresponding hydroazulenic derivative **134** in excellent yields (Scheme 55).[65]

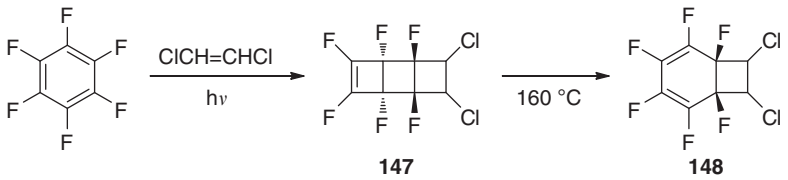
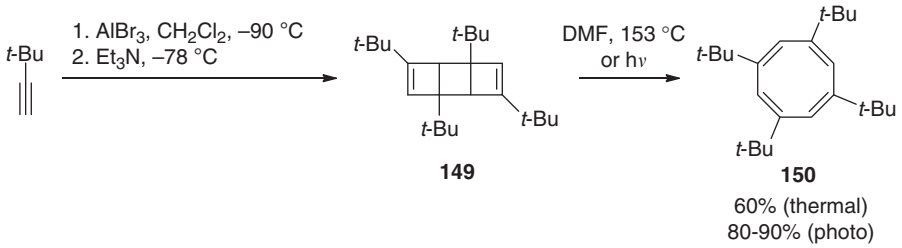
The conversion of 5-methylenebicyclo[2.2.0]hex-2-ene **142** to 5-methylenecyclohexa-1,3-diene **143** was found to be first order ($t_{1/2}$ = ~10 h at r.t., 89 min at 50 °C) (Scheme 59).[69]

Di-*tert*-butylsilylene, generated by photolysis, reacted with *N*-methylpyrrole to furnish 2-aza-3-silabicyclo[2.2.0]hex-5-ene **144** (Scheme 60).[70] An intermediate [2 + 1] cycloadduct **145** rearranged to the bicyclic cyclobutene **146**, which on heating underwent an electrocyclic ring opening reaction to give the corresponding 1-aza-2-silacyclohexa-3,5-diene **144**.

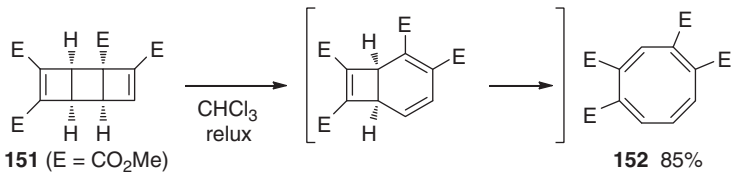


Photoinduced cycloaddition of 1,2-dichloroethylene with hexafluorobenzene yielded a stereoisomeric mixture of tricyclooctenes **147** (Scheme 61). Heating of **147** at 160 °C produced the bicyclic dienes **148**.[71]

Scheme 59 Conversion between **142** and **143**.

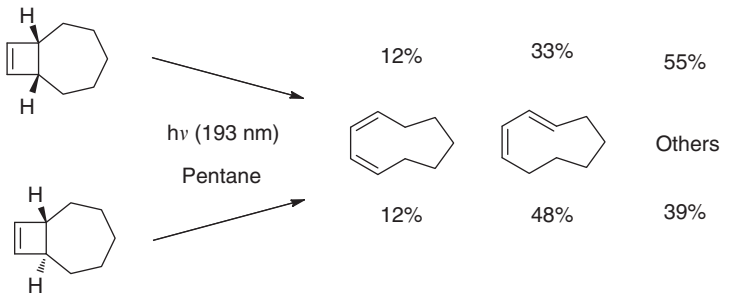


Scheme 60 Formation and ring opening of bicyclic cyclobutene **146**.



Scheme 61 Formation and ring opening of tricyclooctenes **147**.

The thermal conversion of cyclobutadiene dimer, tricyclo[4.2.0.0^{2,5}]octa-3,7-diene, to cyclooctatetraene was first reported in 1975.[72] *tert*-Butylacetylene underwent regioselective tetramerization in the presence of $AlBr_3$ and Et_3N to afford the cyclobutadiene dimer **149** (Scheme 62).[73] Thermal ring opening of this dimer occurred in refluxing DMF to produce 1,3,5,7-tetra-*tert*-butylcyclooctatetraene **150**. A photochemical reaction of **149** also gave **150** in higher (80–90%) yield.



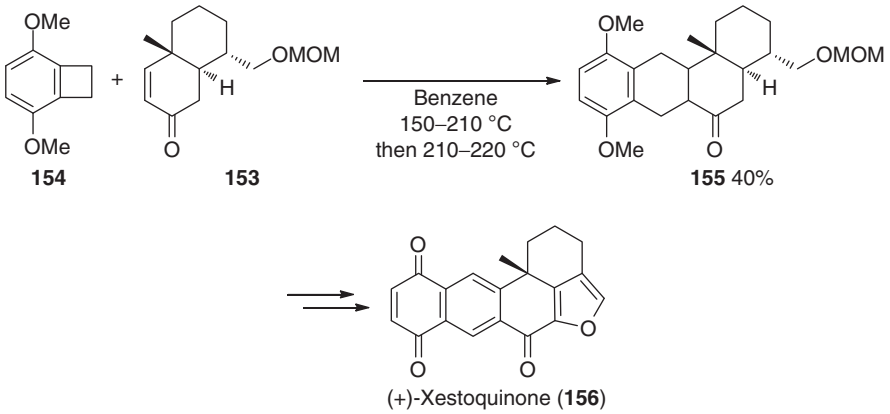
Scheme 62 Formation of cyclooctatetraene **150** via cyclobutadiene dimer **149**.

Cyclobutadiene-1,2-dicarboxylate, disengaged from its iron(0) tricarbonyl complex, dimerized through cycloaddition to furnish tricyclooctadiene **151** (Scheme 63). When tricyclooctadiene **151** was heated in refluxing $CHCl_3$, the 1,2,4,5-tetrasubstituted cyclooctatetraene **152** was formed in 85% isolated yield.[74]

Scheme 63 Thermal reaction of tricyclooctadiene **151**.

When *cis*- and *trans*-bicyclo[5.2.0]non-8-enes were irradiated with far-UV (185–214 nm) light, *cis,cis*-, and *cis,trans*-cyclonona-1,3-dienes were formed via formal electrocyclic ring opening along with other products (Scheme 64).[75] A nonconcerted pathway involving homolytic C–C bond cleavage and the subsequent relaxation of the resulting biradical intermediates was assumed.

Scheme 64 Photochemical reaction of *cis*- and *trans*-bicyclo[5.2.0]non-8-enes.



5.16.3 Benzocyclobutenes

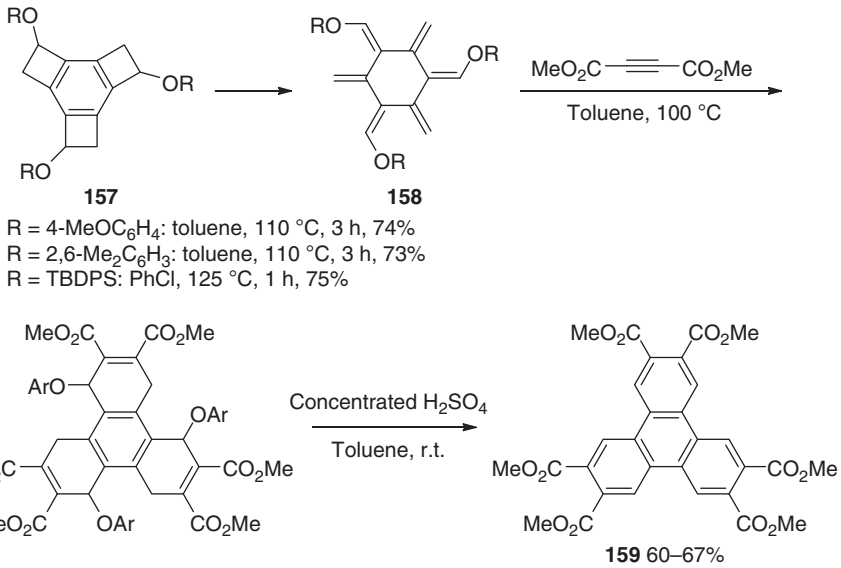
Benzocyclobutenes serve as precursors of *o*-quinodimethanes (*o*QDMs) which are generated through an electrocyclic ring opening reaction. Two major synthetic applications of the formed *o*-quinodimethanes are [4 + 2] cycloadditions and 6π electrocyclizations. Both reactions furnish new six-membered rings. Excellent reviews on the chemistry of benzocyclobutenes have recently been published.[76]

Unlike the case of the electrocyclic reaction of monocyclic cyclobutenes, the efficiency is difficult to assess for the reaction of benzocyclobutenes, because the *o*QDM produced readily undergoes cycloreversion to regain aromaticity. The cycloreversion, however, can be avoided by rapid capture of the *o*QDM with highly reactive dienophiles such as maleic anhydride.

5.16.3.1 [4 + 2] Cycloaddition of *o*-Quinodimethanes

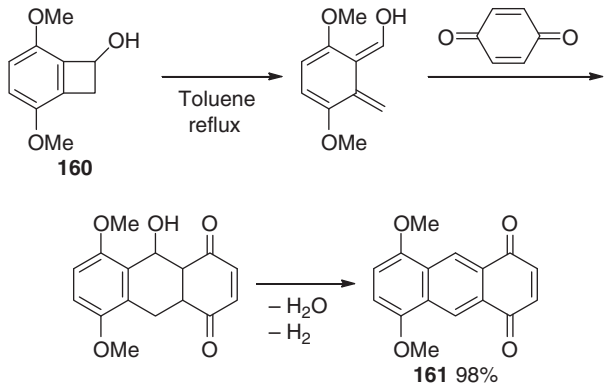
The Diels–Alder reaction of enone **153** with 3,6-dimethoxybenzocyclobutene (**154**) at temperatures greater than 200 °C gave the tetracyclic product **155**, which was converted via five steps to (+)-xestoquinone (**156**), a marine natural product (Scheme 65).[77]

Scheme 65 Synthesis of (+)-xestoquinone (**156**).



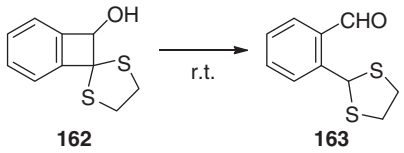
Ring opening of alkoxy-substituted tricyclobutabenzenes **157** generated hexaradialenes **158**, which underwent threefold [4 + 2] cycloaddition to produce triphenylenes **159** (Scheme 66).[78]

Benzocyclobutenol **160** underwent a [4 + 2] cycloaddition with benzoquinone in refluxing toluene to afford the tricyclic quinone **161** after dehydration (Scheme 67).[79] The product was converted into anthracene diquinone on oxidation.

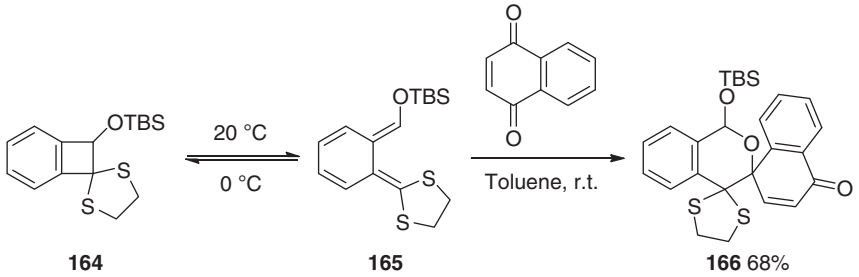


Fullerenes are reactive enough dienophiles to undergo Diels–Alder cycloaddition reactions with quinodimethanes derived from benzocyclobutenol and its methyl ether to afford the corresponding [4 + 2] cycloadducts.[80]

Cyclobutenol **162**, prepared by reduction of benzocyclobutenedione monothioketal, smoothly rearranged to aldehyde **163** at r.t. via ring opening and subsequent 1,5-hydrogen shift (Scheme 68).[81] However, the corresponding silyl ether was stable enough to be stored at r.t. The silyl ether **164** existed in equilibrium with the corresponding ring-opened product **165** (Scheme 69). Color changed when the diene (yellow at r.t.) converted to the benzocyclobutene (colorless at 0 °C). Various dienophiles were reacted with the silyl ether. Whereas the reaction with dimethyl acetylenedicarboxylate gave the expected [4 + 2] cycloadduct, the use of 1,4-naphthoquinone as the dienophile prompted a hetero Diels–Alder reaction to form isochromane **166** as the major product.



When benzocyclobutenol **167** and halonaphthalene **168** were treated with LiTMP in refluxing THP, two reactive species, a quinodimethane and a benzyne, were generated and coupled together, leading to the construction of anthracene skeleton **169** through dehydration (Scheme 70).[82]



Scheme 66 Synthesis of triphenylenes **159** via hexaradialenes **158**.

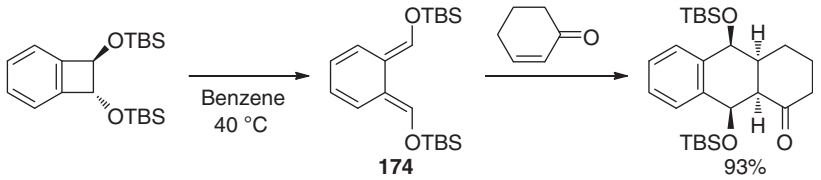
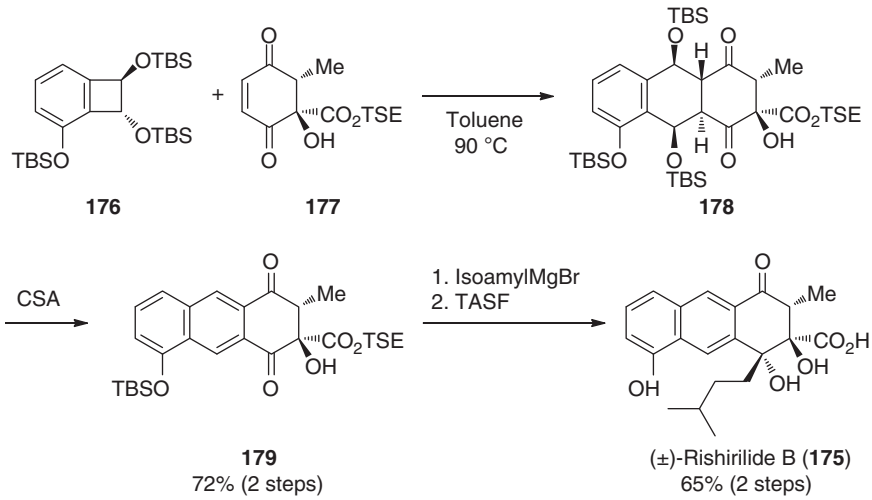
R^1 = H, R^2 = OMe, R^3 = CO_2Me, R^4 = Br: 82%

Scheme 71 Synthesis of multisubstituted naphthalenes via Diels–Alder reaction of 1-methoxybenzocyclobutenes **170**.

1-Cyanobenzocyclobutenes **172** thermally reacted with maleic anhydride to afford [4 + 2] cycloadducts **173** (Scheme 72).[3] The cyano group exhibited an inward torquoselectivity; an *endo* addition of maleic anhydride followed. A notable accelerating effect was observed with a silylmethyl substituent. The σ-donating ability of the C–Si bond facilitated the electrocyclic ring opening. This is closely related to the accelerating effect of an anionic oxy substituent, which is also a good electron donor.



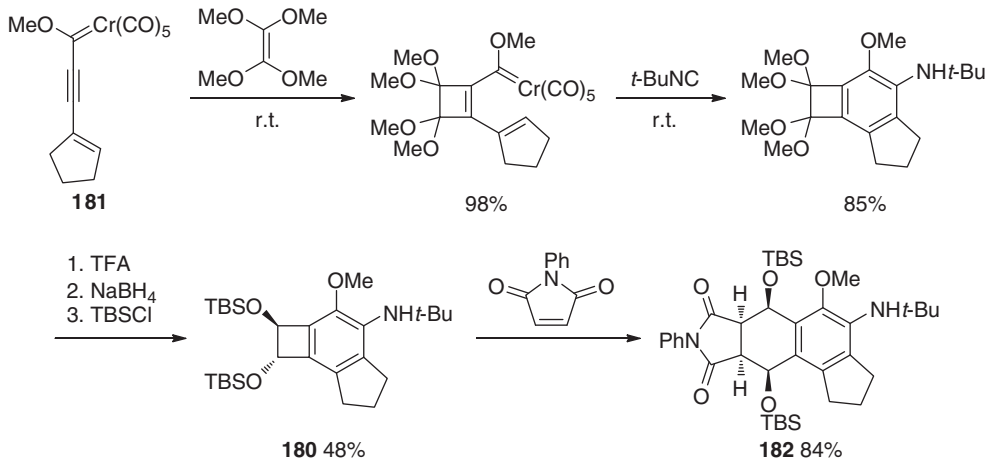
R = H: 9%
R = CH_2t-Bu: 30%
R = CH_2SiMe_3: 68%



Scheme 72 Thermal reaction of 1-cyanobenzocyclobutenes **172**.

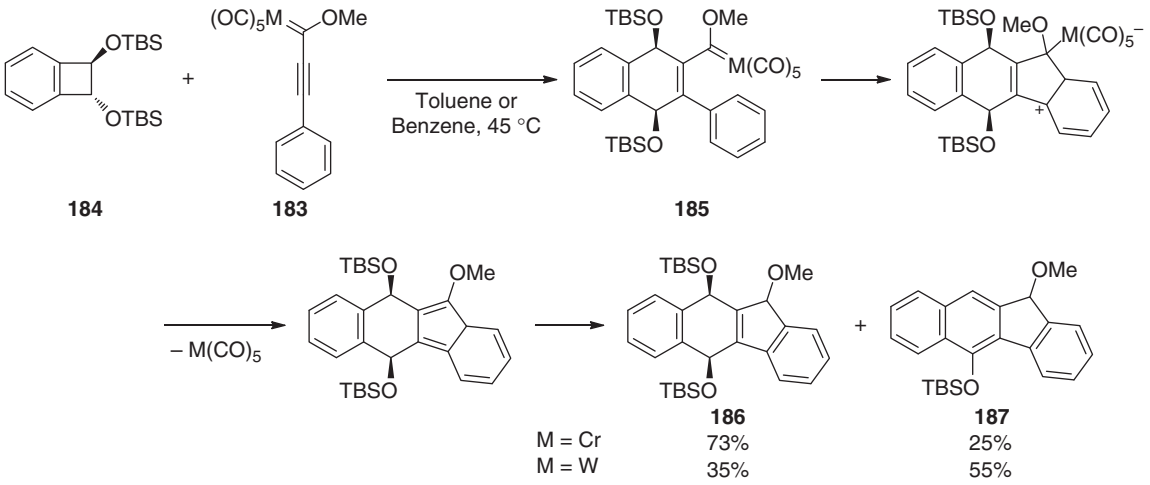
The ring opening of *trans*-1,2-disilyloxybenzocyclobutenes was studied by Danishefsky.[84] The two *trans*-attached siloxy groups underwent outward rotation in a conrotatory manner to generate the *E*,*E*-diene **174**, which subsequently reacted with cyclohexenone in an *endo* fashion (Scheme 73).

The total synthesis of (±)-rishirilide B (**175**) utilized the [4 + 2] cycloaddition of the *o*-quinodimethane (*o*QDM) as the key step (Scheme 74).[85] Cycloaddition of *trans*-disiloxycyclobutene **176** with the unsymmetrical enedione **177** occurred in a regio- and *endo*-selective manner to afford the desired tricyclic product **178** in 90% yield. Dehydration and aromatization were induced by the action of camphorsulfonic acid to give **179**. Monoalkylation of **179** with isoamylmagnesium bromide followed by desilylation with tris(dimethylamino)sulfonium afforded **175**.

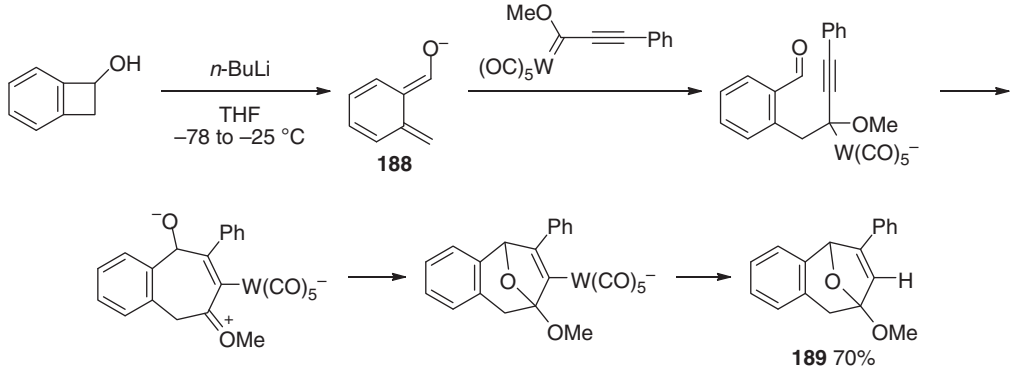


Scheme 73 Ring opening of *trans*-1,2-disilyloxybenzocyclobutenes.

Scheme 74 Synthesis of (±)-rishirilide B (**175**).



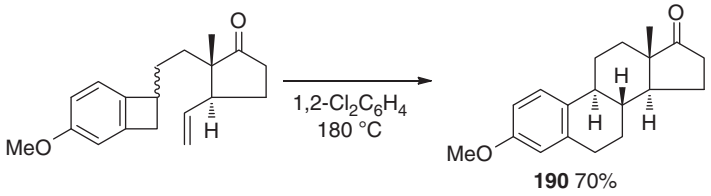
The densely functionalized *trans*-disiloxycyclobutene **180**, synthesized from [(2-alkenylcyclobutyl)carbene]chromium complexe **181** and an isocyanide, reacted with dienophiles to give *endo*-cycloadduct **182** (Scheme 75).[86] However, the corresponding *cis*-disiloxycyclobutenes required an elevated temperature (160 °C) to react with the dienophiles.



Scheme 75 Synthesis and reaction of *trans*-disiloxycyclobutene **180**.

When arylethynylcarbene metal complexes of chromium and tungsten **183** were reacted with *trans*-disiloxycyclobutene **184**, the initially formed [4 + 2] cycloadducts **185** underwent further annulation to afford benzo[*b*]fluorine derivatives **186** and **187** (Scheme 76).[87]

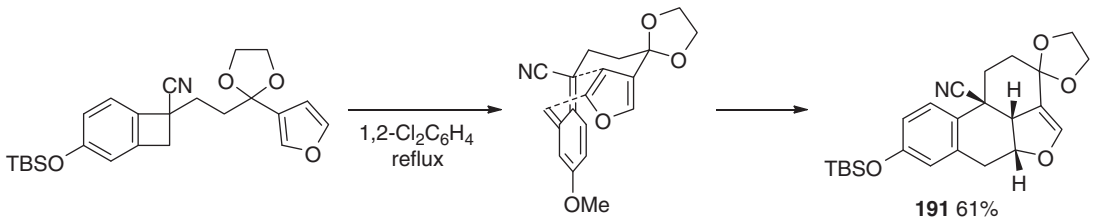
A reaction of the *o*QDM **188**, generated at −25 °C from lithium benzocyclobutenoxide, with an alkynylcarbene tungsten complex gave the formal [4 + 3] cycloadduct **189** exclusively (Scheme 77).[88] The *o*QDM behaved as a vinylogous enolate rather than as a 1,3-diene.



Scheme 76 Reaction of *trans*-disiloxycyclobutene **184** with arylethynylcarbene metal complexes **183**.

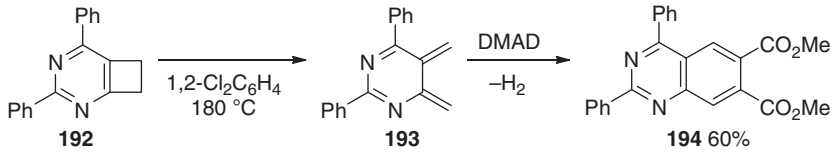
Scheme 77 Reaction of *o*QDM **188** and alkynylcarbene tungsten complex.

The synthesis of tetracyclic compounds such as steroids by using the *o*QDM cycloaddition has been extensively studied.[89] The intramolecular Diels–Alder reaction was efficiently utilized in the synthesis of estrone methyl ether **190** (Scheme 78).[90]



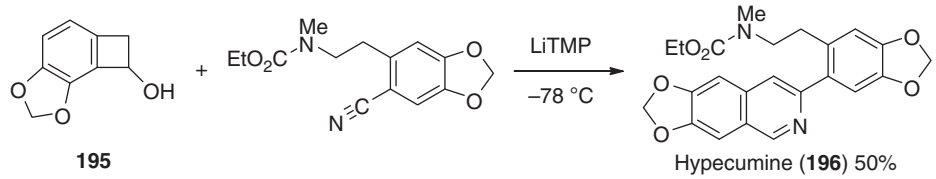
Scheme 78 Synthesis of estrone methyl ether **190**.

A series of furan-fused tetracyclic compounds such as **191** was synthesized via intramolecular [4 + 2] cycloaddition of *o*QDM for the evaluation of their antiviral activity (Scheme 79).[91] The reaction was exclusively *endo*-selective.

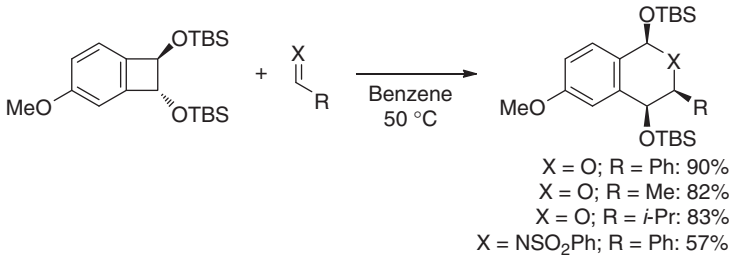


The [4 + 2] cycloaddition via *o*QDM analogs was used also for the construction of heteroaromatic rings. Pyrimidine analogs of benzocyclobutene **192** underwent ring opening in refluxing 1,2-dichlorobenzene to generate diene **193**, which reacted with dienophile to afford quinazoline derivative **194** (Scheme 80).[92]

(2-Formylphenyl)methanide, generated *in situ* by treatment of benzocyclobutenol **195** with LiTMP, reacted with nitriles to form isoquinolines (Scheme 81).[93] The reaction was applied to the total synthesis of hypecumine (**196**).



Simple thermal hetero Diels–Alder reactions with dienophiles like aldehydes and imines proceeded to give isochromans and tetrahydroisoquinolines (Scheme 82)[94]; a complete *endo* selectivity was observed. An electron-donating group on the aromatic



Scheme 79 Intramolecular [4 + 2] cycloaddition of *o*QDM.

Scheme 80 [4 + 2] Cycloaddition affording quinazoline derivative **194**.

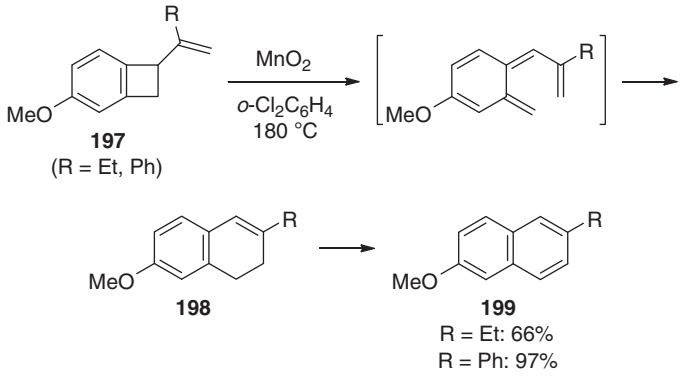
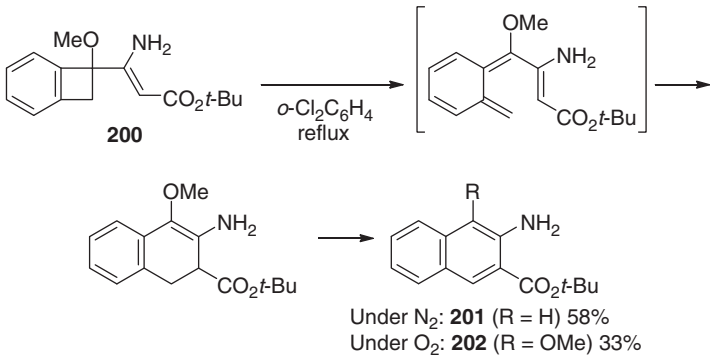
Scheme 82 Hetero Diels–Alder reaction giving isochromans and tetrahydroisoquinolines.

ring accelerated the reaction. Furthermore, the reaction of the unsymmetrically substituted disilyloxybenzocyclobutenes exhibited complete regioselectivity.



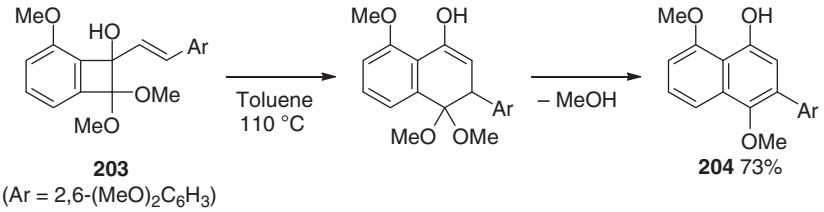
5.16.3.2 6π Electrocyclization

Electrocyclic reactions of *o*QDM are also useful for the synthesis of six-membered carbo- and heterocycles. Ring opening of benzocyclobutene is followed by 6π electrocyclization of the resulting *o*QDM.



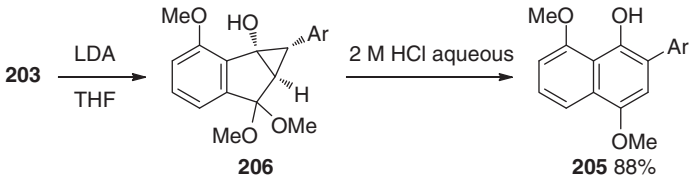
Alkenylbenzocyclobutenes **197** underwent such a cascade to afford dihydronaphthalanes **198**, which were oxidized by MnO_2 to provide the corresponding naphthalene derivatives **199** (Scheme 83).[95]

An analogous cascade reaction of 1-methoxy-1-alkenylbenzocyclobutene **200** having a β-aminoacrylate side chain under nitrogen atmosphere gave 3-amino-2-naphthalenecarboxylate **201** after removal of methanol (Scheme 84).[96] However, the reaction performed under oxygen atmosphere afforded the corresponding 4-methoxy derivative **202**. Synthesis of a potent Src kinase inhibitor utilized this thermal rearrangement of benzocyclobutenes.[97]



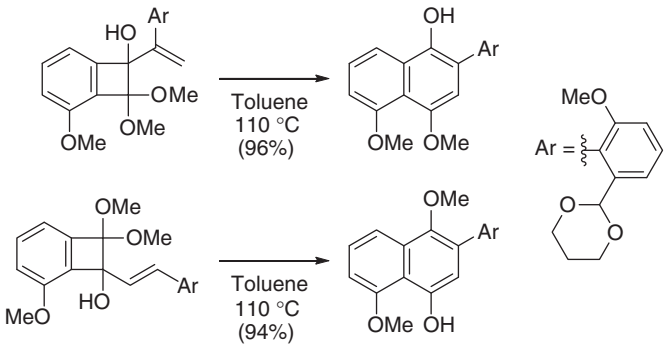
Heating of 1-arylethenylbenzocyclobuten-1-ol **203** in refluxing toluene gave the expected β-phenylnaphthalene **204** via ring opening and subsequent ring closing (Scheme 85).[98] In contrast, treatment of the benzocyclobutene with lithium

Scheme 83 Formation of naphthalenes via ring opening–6π electrocyclization.

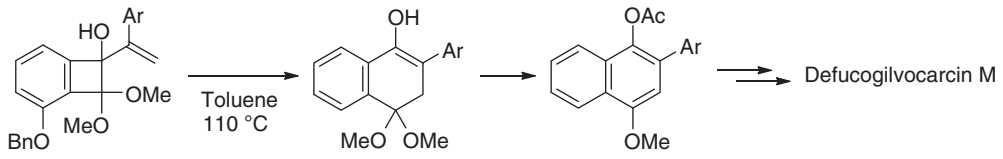


Scheme 84 Synthesis of 3-amino-2-naphthalenecarboxylates **201** and **202**.

Scheme 85 Thermal ring opening–ring closing of **203**.

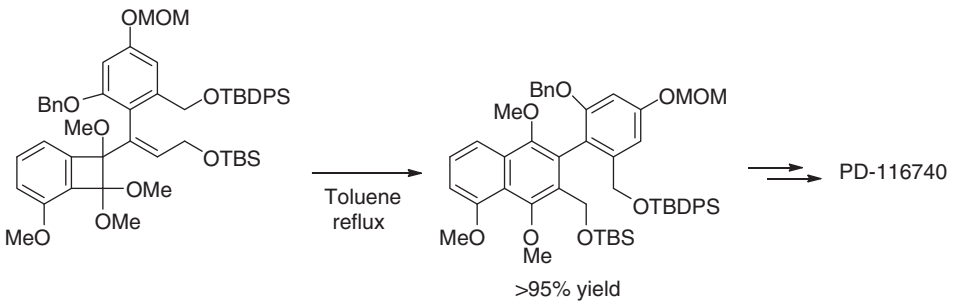


diisopropylamide afforded isomer **205** (Scheme 86). The skeletal rearrangement observed in the latter base-promoted reaction could be accounted for by assuming involvement of cyclopropanol species **206** as the intermediate.



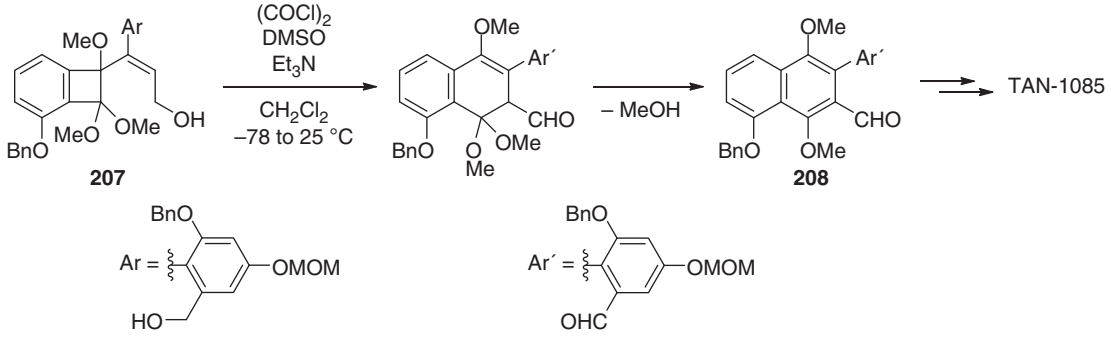
Scheme 86 Base-promoted skeletal rearrangement of **203**.

β-Phenylnaphthalene structures were accessed from two benzocyclobutenes having α- and β-styryl groups (Scheme 87).[99]

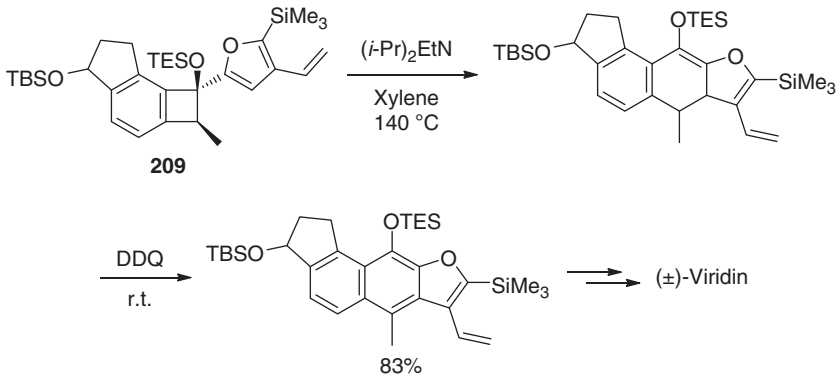


Several antibiotics were synthesized using the 6π elecrocyclization of *o*QDMs (Schemes 88 and 89).[100] The ring expansion reaction of (1-arylalkenyl)benzocyclobutenes gave β-arylnaphthalenes in excellent yield.

Scheme 87 β-Phenylnaphthalene from styryl-substituted benzocyclobutenes.

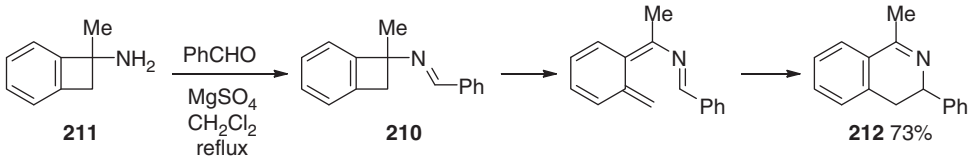


Scheme 88 Ring opening-6π elecrocyclization giving β-arylnaphthalenes (1).



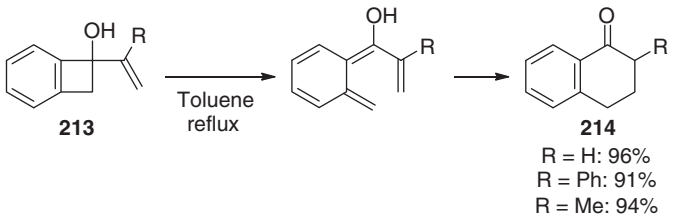
Scheme 89 Ring opening-6π elecrocyclization giving β-arylnaphthalenes (2).

When a reaction mixture formed by Swern oxidation of benzocyclobutene **207** having an allylic alcohol side chain was kept at 25 °C, ring opening and 6π ring closing occurred in sequence to afford aryl aldehyde **208** (Scheme 90).[101] This remarkable rate enhancement of the pericyclic processes was rationalized by assuming a cooperative effect of the electron-donating and electron-withdrawing substituents in their conrotatory motion.



Scheme 90 Oxidation and subsequent thermal reaction of **207**.

A furanosteroidal antibiotic viridin was synthesized based on a strategy including a thermal ring enlargement reaction of the furanylbenzocyclobutene **209** (Scheme 91).[102]



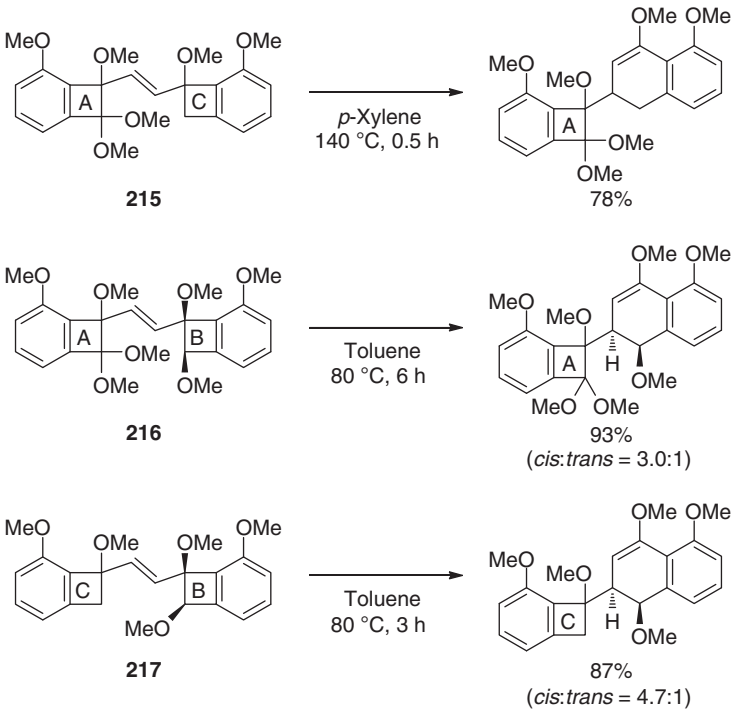
Scheme 91 Thermal ring enlargement of furyl-substituted benzocyclobutene **209**.

The formation of heteroaromatic rings via the 6π electrocyclization of *o*QDMs has also been studied.[103] Imine **210** derived from 1-aminobenzocyclobutenes **211** underwent a ring opening–ring closing sequence at 160 °C to afford 3,4-dihydroisoquinolines **212** (Scheme 92). The reaction was applied to the total synthesis of (±)-coralydine.

Scheme 92 3,4-Dihydroisoquinolines **212** via ring opening–ring closing.

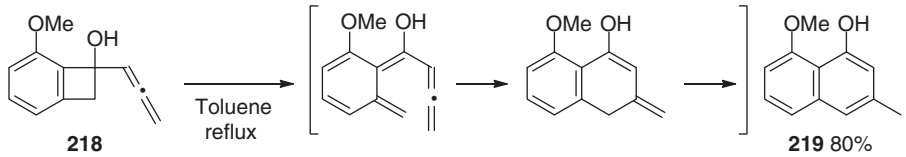
Electrocyclic ring expansion of 1-alkenylbenzocyclobuten-1-ols **213** produced 1-tetralone derivatives **214** after keto–enol tautomerization (Scheme 93).[104]

Scheme 93 Ring expansion of alkenylbenzocyclobutenols **213** producing 1-tetralones **214**.



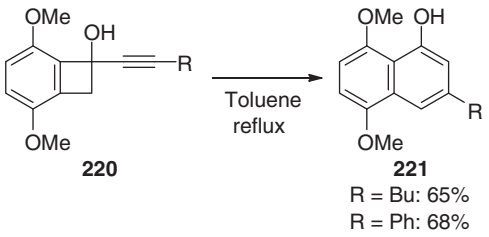
The reactivity of the two different four-membered rings in compounds **215**–**217** was compared (Scheme 94).[105] When **215** was reacted, the C-ring underwent ring expansion exclusively. In contrast, the reaction of **216** and **217** selectively gave the products occurring from ring expansion of the B-ring.

Orbital considerations based on a conrotatory ring opening followed by a disrotatory six-electron ring closure fail to accord with the stereochemistry observed in the products. This was attributed to a *cis*/*trans* isomerization of the starting benzocyclobutene through a biradical species. The resulting B-ring having two *trans* oxy-substituents is more reactive than the A- and C-rings.

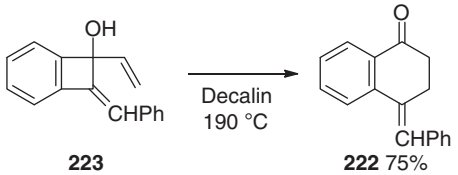


Thermal ring expansion of benzocyclobutenol **218** substituted with an allenyl group afforded the 3-methyl-1-naphthol **219** after migration of the exocyclic C=C bond into the ring (Scheme 95).[106]

1-Alkynylbenzocyclobuten-1-ols **220** were transformed into naphthol derivatives **221** on heating at 110 °C (Scheme 96).[104]



2-Benzylidenebenzocyclobuten-1-ol underwent analogous ring expansion reactions. However, they required higher temperatures, presumably because the allenyl analog of *o*QDMs was more difficult to generate.[107] 4-Benzylidene-1-tetralone **222** was formed from vinyl derivative **223** through ring opening at 190 °C and subsequent keto–enol tautomerization (Scheme 97). A mechanism involving a diradical species was assumed for the transformation of the alkynyl derivative **224** (Scheme 98). A phenyl group could also participate in the 6π electrocyclization, leading to the formation of 10-benzylideneanthrone **225** (Scheme 99).



Scheme 94 Ring opening of bis(benzocyclobutene)s **215**–**217**.

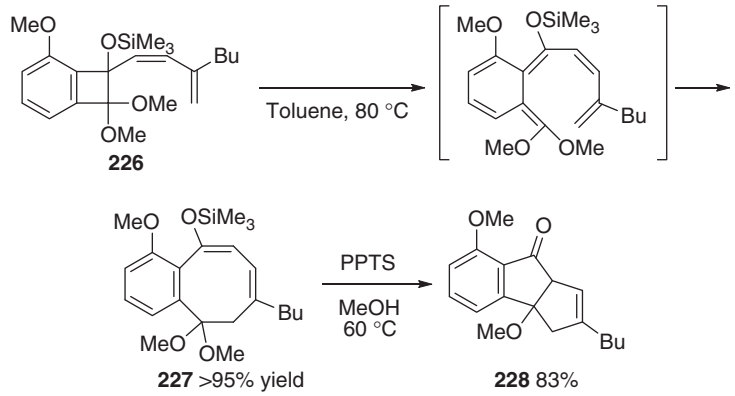
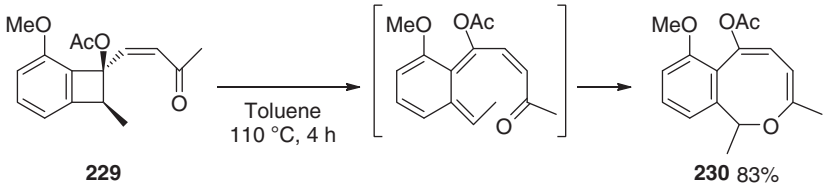


Scheme 98 Ring expansion of alkynyl(benzylidene)benzocyclobutene **224**.

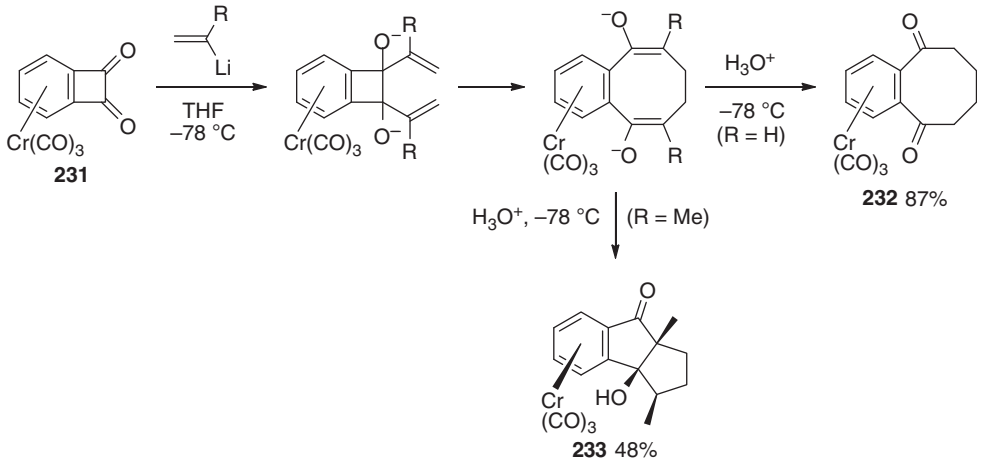
Scheme 99 Ring expansion to 10-benzylideneanthrone **225**.



5.16.3.3 8π Electrocyclization

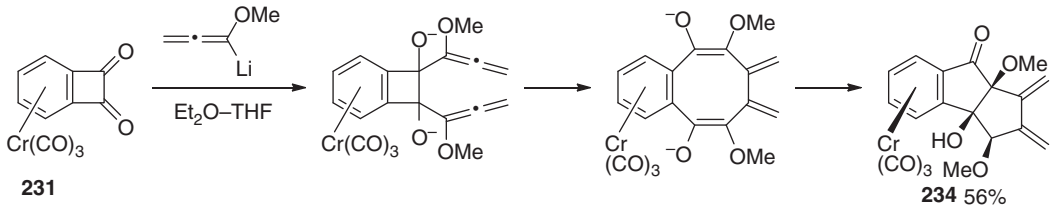
Construction of eight-membered rings via an 8π electrocyclization involving *o*QDM is viable if the benzocyclobutene precursors have a 4π side chain. For example, the dienylbenzocyclobutene **226** underwent the thermal four-carbon ring expansion at 80 °C to give the eight-membered product **227** (Scheme 100).[108] Treatment of the product with an acid (pyridinium *p*-toluenesulfonate) in methanol-induced transannular cyclization to afford the tricyclic product **228**.

Scheme 100 Thermal four-carbon ring expansion of dienylbenzocyclobutene **226**.



An analogous ring expansion by four atoms occurred with benzocyclobutenes having an α,β-unsaturated carbonyl group **229** to produce the eight-membered ether, benzoxocine **230** (Scheme 101).[109]

Scheme 101 Ring expansion of **229** giving benzoxocine **230**.

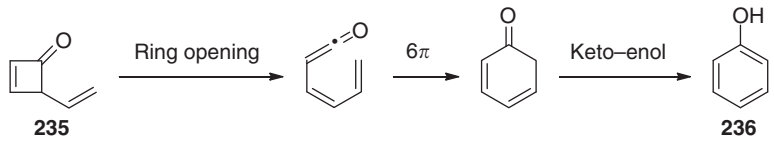


Introduction of two alkenyl groups on the cyclobutene ring offers another approach to eight-membered rings. When the tricarbonylchromium(0) complex **231** of benzocyclobutenedione was treated with vinyllithium, the tricarbonylchromium(0) complex of the eight-membered ring diketone **232** was obtained after hydrolysis (Scheme 102).[110] The two vinyl groups were introduced from the opposite side of the chromium and took a synperiplanar orientation, thereby assisting in the double anionic

oxy-Cope rearrangement. In the reaction with propenyllithium, an intramolecular aldol reaction followed to produce the tricyclic compound **233**.

Scheme 102 Double anionic oxy-Cope rearrangement of dialkenylbenzocyclobutenes.

The addition–ring opening reaction with an allenyllithium also resulted in the formation of a tricyclic compound **234** (Scheme 103).[111]

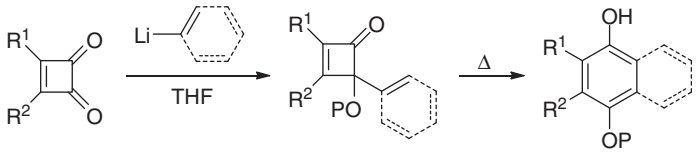


Scheme 103 Addition–ring opening reaction of tricarbonylchromium(0) complex **231**.

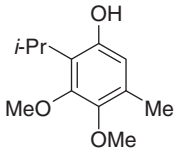
5.16.4 Cyclobutenones

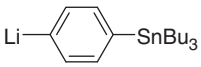
Heating of cyclobutenones generates reactive vinylketenes, which serve as the 4π component in 6π electrocyclization reactions or [4 + 2] annulation reactions to produce densely substituted phenol and quinone derivatives.

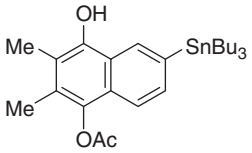
5.16.4.1 6π Electrocyclization

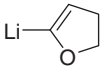


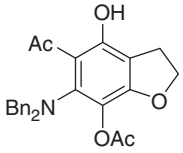
Cyclobutenones having an unsaturated functionality at the 4-position such as **235** undergo ring opening, 6π electrocyclization, and keto–enol tautomerization in sequence to afford phenol derivatives **236** (Scheme 104). A number of applications of this transformation have appeared.

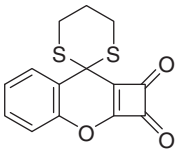


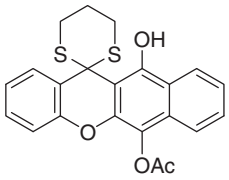


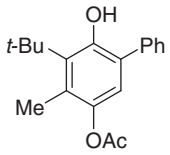


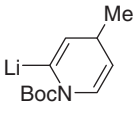


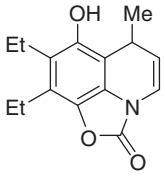












Scheme 104 Phenol synthesis from 4-vinylcyclobutenones **235**.

The requisite cyclobutenones are easily prepared by addition of organolithium reagents to substituted cyclobutenediones (Table 5). A good regioselectivity was observed with unsymmetrical cyclobutenediones. A heteroatom substituent deactivates the distal carbonyl group through resonance delocalization. As a result, nucleophilic addition occurred at the proximal carbonyl group. Thermal ring expansion of the adducts in refluxing xylene gave the corresponding benzannulation products in excellent yields.[112,113] Treatment of cyclobutenediones containing a vinylogous amide functionality with alkenyllithiums gave

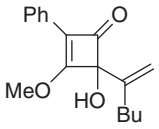
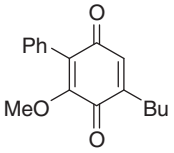
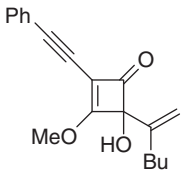
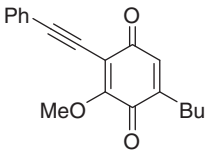
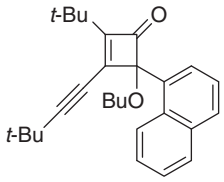
[a]Ring opening was performed at 69–165 °C.

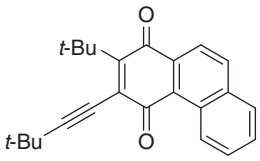


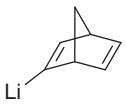


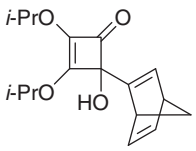


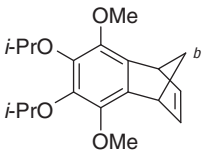






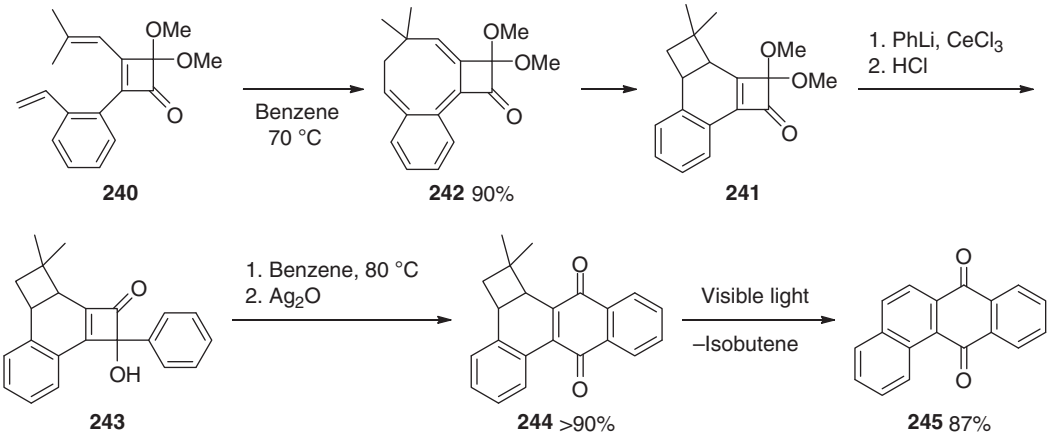






4-hydroxy-4-alkenylcyclobutenones, which underwent ring expansion to provide acyl amino phenol derivatives.[114] Highly substituted xanthones were synthesized by the reaction of dithiane-protected benzopyrone-fused cyclobutenediones with alkenyllithiums.[115] The 1,2-adducts were exceptionally prone to benzannulation; aromatized products were formed slowly even at r.t. In the reaction of cyclobutenediones having a *t*-butyl substituent, the addition of unsaturated carbon nucleophiles occurred regiospecifically at the carbonyl group distal to the *t*-butyl substituent.[116] After thermolysis of the adducts, the *t*-butyl group was removed under acidic conditions to afford 2-unsubstituted hydroquinone monoacetates. Adducts obtained from the reaction of 1-Boc-2-lithio-1,4-dihydropyridines and 3,4-disubstituted cyclobutenediones underwent thermal ring expansion to afford 1,4-dihydroquinolin-5-ols.[117] The 4-hydroxy substituent on the cyclobutenone ring displaced the *t*-butoxy residue of the Boc group, generating an oxazolone ring.

Electrocyclic ring opening–ring closing of nonprotected 4-alkenyl-4-hydroxycyclobutenones **237** gave the hydroquinones **238**, which were easily converted to the corresponding quinones **239** on oxidative workup (**Table 6**).[118–120]



Cyclobutenone **240** isomerized to the tetracyclic cyclobutenone **241** on heating. The transformation involved an 8π electrocyclization to give cyclooctatriene **242**, which was followed by a 6π electrocyclic ring closure (**Scheme 105**). Arylation of the

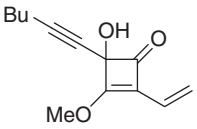
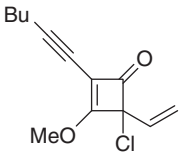
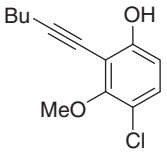
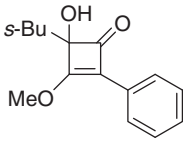
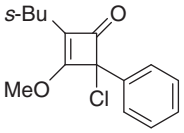
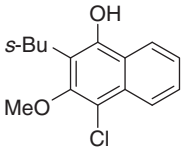


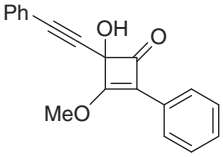


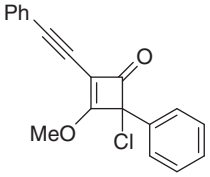


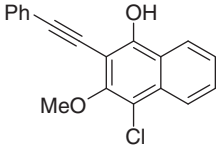






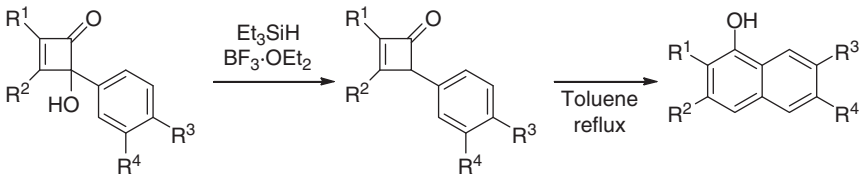






Scheme 105 Benzannulation of **243**.

carbonyl group followed by acid hydrolysis gave cyclobutenone **243**, which was then heated. The resulting ring-expanded hydroquinone was directly oxidized to quinone **244**. When irradiated, **244** underwent an efficient photofragmentation reaction to yield the benzo[*a*]anthracene-7,12-dione **245**, a compound representing the basic framework of the angucycline group of antibiotics.[121]



When 4-hydroxycyclobutenones of the general type **246** were treated with thionyl chloride, chlorination took place preferentially at the carbon which could generate the more stable carbocation. The resulting 4-chlorocyclobutenones **247** were converted into highly substituted *p*-chlorophenol derivatives **248** (Table 7).[122]

2,3,4-Trisubstituted cyclobutenones **249** were prepared by Lewis acid-mediated reduction of the corresponding 4-hydroxycyclobutenones **250** with Et_3SiH. Their thermal reaction afforded 2-naphthols **251** in excellent yields (Table 8).[123]

Conjugate addition of alkenyl- and arylcopper reagents led to the formation of the 4-alkenyl- and arylcyclobutenones **252**, which were converted to 1,2-dioxygenated aromatics **253** on heating (Table 9).[124]

4-Alkyenyl and 4-arylcyclobutenones **254** were synthesized by a palladium-catalyzed cross-coupling reaction of 4-chlorocyclobutenones **255** with alkenyl- and arylstannanes. On heating at 100 °C, the cyclobutenones **254** were transformed into the corresponding phenol derivatives **256** in good yields (Table 10).[125] A cross-coupling reaction and a thermal ring opening occurred subsequently in one-pot. When 2-stannylnaphthalenes were used as the cross-coupling partners, an electrocyclic reaction took place at the α-position to selectively furnish angularly fused products.[113] The reaction with stannylquinones afforded naphtho- and anthraquinones.[126] Furan- and thiophene-fused aromatics were also synthesized.[127] A cross-coupling–rearrangement sequence with 4-chlorocyclobutenones and 3-stannylcyclobutenones gave benzocyclobutenedione monoketals.[128]

A number of natural products were synthesized using the cyclobutenone chemistry. A reaction of dimethyl squarate **257** with *i*-PrMgCl followed by hydrolysis gave compound **258** (Scheme 106). Treatment of **258** with isopropenyllithium followed by quenching with Me_3SiCl resulted in the 4-isopropenylcyclobutenone **259**, which was directly subjected to thermolysis at 69 °C to give the monoprotected phenol **260**. Methylation and subsequent desilylation of the crude product gave espintanol (**261**).[112]

4-Vinylcyclobutenone **262** derived from diisopropyl squarate underwent thermal ring expansion at 160 °C to produce the corresponding hydroquinone, which was directly methylated to give **263** (Scheme 107). Cyclobutenone **264** was also synthesized in three steps from diisopropyl squarate. The aryllithium reagent generated from **263** added onto the more electrophilic carbonyl group of **264**. The resulting adduct **265** underwent the second thermal benzannulation to produce hydroquinone **266**, which yielded echinochrome A (**267**) after oxidation and deprotection.[129]

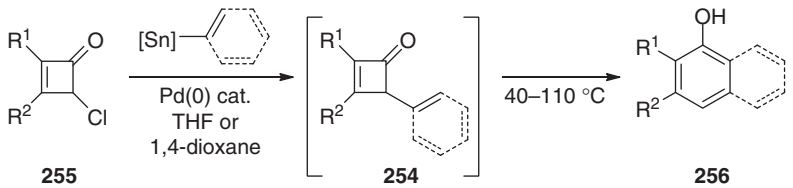
Perezone (**268**), a naturally occurring sesquiterpene hydroxyquinone, was synthesized starting from di-*t*-butyl squarate via the thermal rearrangement of the 4-alkenylcyclobutenone **269** (Scheme 108).[130]

Introduction of a dienyl or arylethenyl substituent at the 2-position of the cyclobutenones led to the generation of dienyl or arylethenyl ketene intermediates **270** suitable for the 6π electrocyclic ring closing reaction (Table 11).[131] Thermal reaction of 2-alkenylcyclobutenones **271** followed by treatment with trifluoroacetic acid produced naphthofurans **272**. Both geometrical isomers gave the desired furan, although the *E*-isomer took a significantly longer time to react than the *Z*-isomer.

Condensation of 3,4-diarylcyclobutenediones **273** with indole derivatives occurred in the presence of *p*-toluenesulfonic acid to afford carbazole derivatives **274** (Scheme 109).[132] The reaction proceeds through an acid-promoted diarylation of the cyclobutenediones and a subsequent thermal ring expansion.

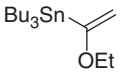
The thermal rearrangement of cyclobutenones was further extended to 4-allenylcyclobutenones and cyclobutenimines. 4-Allenylcyclobutenone **275** underwent a ring expansion on heating in refluxing toluene to afford the fully substituted hydroquinone **276** (Scheme 110).[133]

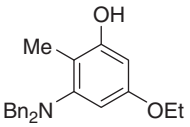
The thermal rearrangement of cyclobutenimines **277** in refluxing *p*-xylene afforded *p*-aminophenols **278** (Scheme 111).[134] The ring expansion of 4-methoxy-4-phenylcyclobutenimines **279** gave α-aminonaphthalenes **280** (Scheme 112).

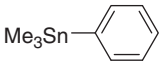


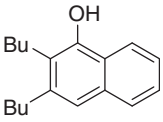
4-Alkynylcyclobutenones **281** were also used as the precursor for the six-membered ring formation (Table 12).[134,135] However, the reaction proceeds via a mechanism involving a diradical or a zwitterion species.

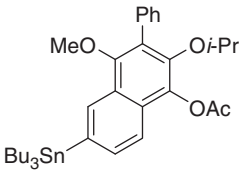
4-(Trimethylsilylpropynyl)cyclobutenones **282** underwent a thermal reaction in refluxing *p*-xylene to give quinones **283** (Scheme 113).[136] In contrast, a thermal ring expansion of 4-(trimethylsilylpropenyl)cyclobutenones **284** followed by oxidation with Ag_2O afforded the regioisomeric quinones **285**.

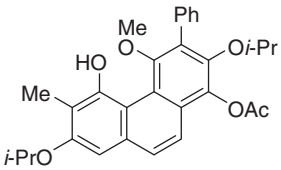


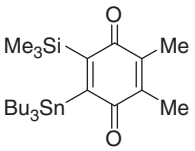


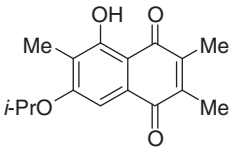


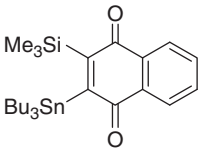


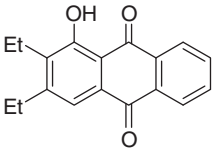


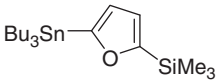


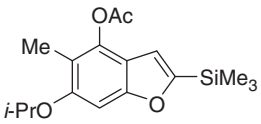


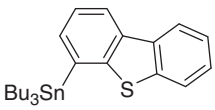


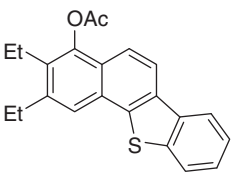


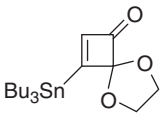


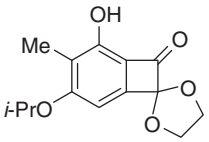












A thermal reaction of alkynyl alkynyloxy cyclobutenone **286** in refluxing *p*-xylene led to the production of methylenebenzofuran **287** (Scheme 114).[137] Initial electrocyclic ring opening of the cyclobutenone gave the conjugated ketene **288**, which generated a diradical species **289** on ring closure. Subsequently, the aryl radical **289** cyclized in a 5-*exo* mode to give another diradical species **290**. The vinylic radical abstracted a H-atom from the proximal butyl group. A second H-atom abstraction then followed to furnish the product **287**.

However, diyne-substituted cyclobutenones **291** rearranged to spirocyclic epoxides **292** (Scheme 115).[138] Initial formation of the ynenylketenes **293** led to the generation of the diradicals **294**. The more reactive carbon radical center underwent

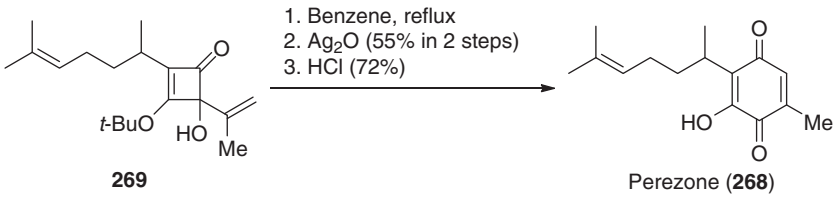
exo-cyclization onto the proximal alkyne moiety to give **295**. The resulting vinyl radical then abstracts a H-atom from the adjacent methoxy group to generate **296**, which formed the spiroepoxides **292**.



Although a thermal reaction of the 4-alkynyl-4-hydroxycyclobutenones of type **297** also caused similar ring expansion, the resulting products were not spiroepoxides but quinones **298** (Scheme 116).

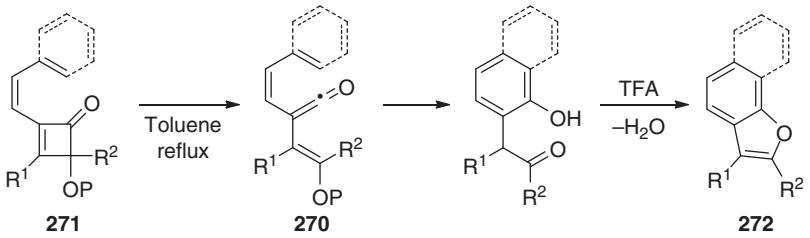
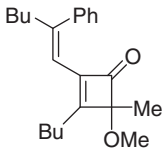
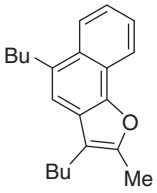
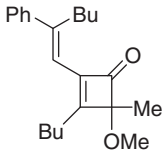
Heating of the squaric acid-derived 4-(3-*N*-methyl-*N*-arylpropynyl)cyclobutenones **299** in refluxing chlorobenzene gave benzophenanthridines **300**. An electrocyclic ring opening of the cyclobutenone, ring closure to a diradical intermediate **301**, and a radical arylation took place in sequence (Scheme 117).[139]

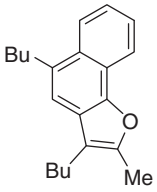


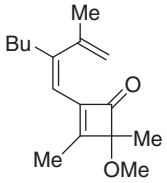
A concise total synthesis of cribrostatin 6, an antimicrobial and antineoplastic agent, involved a tandem electrocyclic ring opening–radical cyclization sequence (Scheme 118).[140]

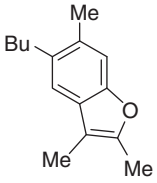


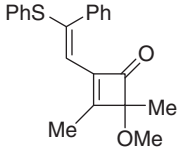


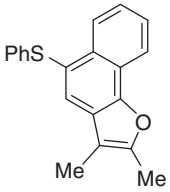




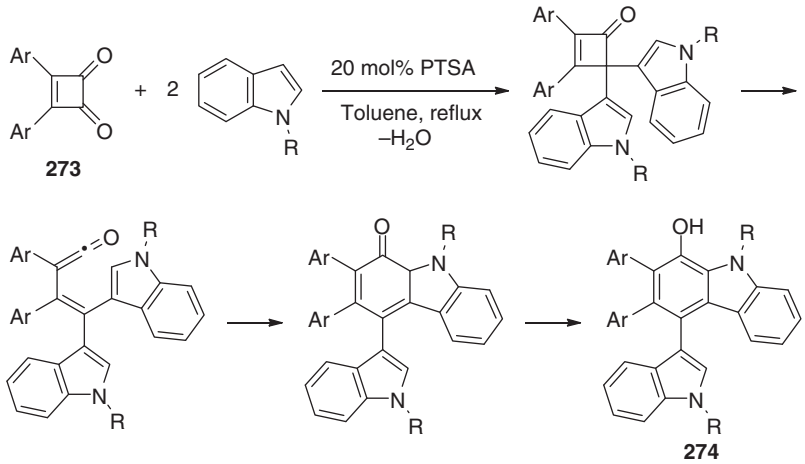








4-(1-Pyrrolyl)-4-siloxycyclobutenone **302** thermally rearranged to 5-hydroxy-8-siloxyindolizine **303**, which was oxidized to the indolizine-5,8-dione **304** (Scheme 119).[141] When the reaction was performed in the presence of dimethyl acetylenedicarboxylate, the indolizine precursor were trapped by an [8 + 2] cycloaddition to give pyrroloindolizine **305**.



5.16.4.2 [4 + 2] Annulation

Heteroatom-substituted alkynes undergo thermal benzannulation to afford phenols. The vinylketene-based benzannulation strategy developed by Danheiser et al. proceeds via a cascade process involving four successive pericyclic reactions (Table 13).

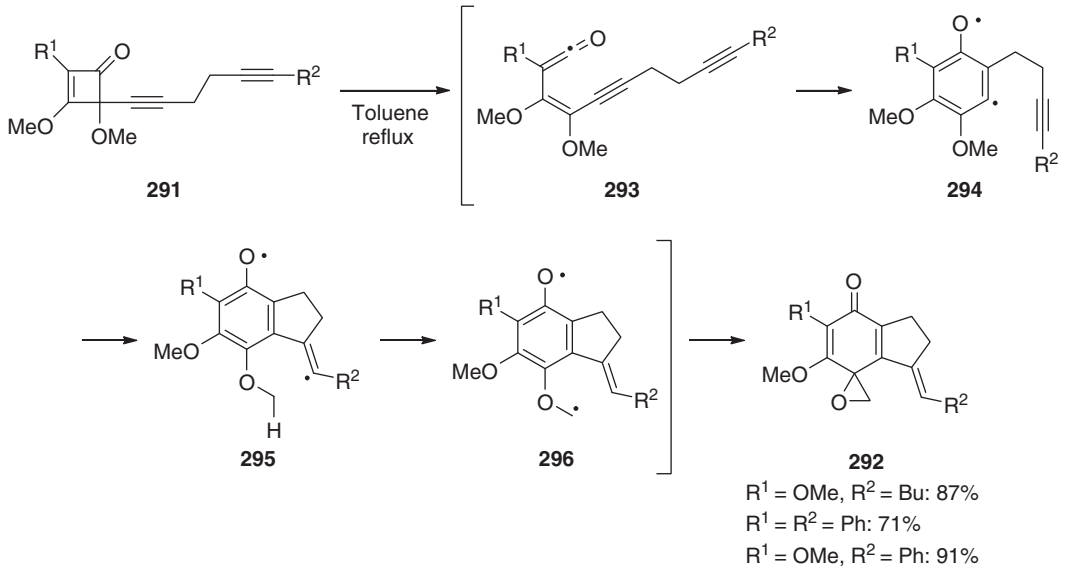
Heating of a cyclobutenone derivative of the general type **306** at temperatures greater than 80 °C induces an electrocyclic ring opening to generate vinylketene **307**, which undergoes a regiospecific [2 + 2] cycloaddition with the ketenophilic acetylene derivative **308** (X = OR, SR, NR_2).[142,143] Ring opening of the resulting 4-vinylcyclobutenone **309** then furnishes dienylketene **310**, which undergoes a 6π electrocyclization to afford a cyclohexadienone. Tautomerization finally yields the highly substituted phenol **311**. Either thermal or photochemical activation prompted benzannulation of ynamides.[144] Microwave irradiation could be also used for the benzannulation.



The synthesis of the sesquiterpene phenol (–)-ascochlorin was based on the [4 + 2] annulation strategy (Scheme 120).[145] A solution of the cyclobutenone **312** and the alkoxyacetylene **313** was initially irradiated, and then briefly heated to complete conversion to the desired aromatic product.

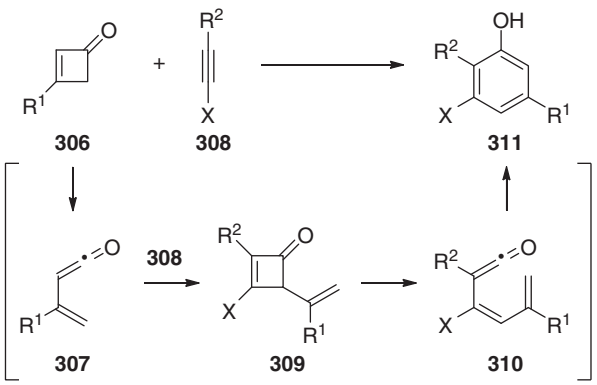
Intermolecular annulation of the cyclobutenone **314** with siloxyacetylene **315** afforded phenol **316**, which was then desilylated and methylated (Scheme 121). Treatment of the resulting diene **317** with the Grubbs catalyst led to the corresponding paracyclophane by head-to-tail cyclodimerization. Heterogeneous hydrogenation followed by cleavage of the methyl ether with BBr_3 completed the synthesis of (–)-cylindrocyclophane F.[146]

The cyclobutenone **318** reacted with (η^3-indenyl)Co(PPh_3)$_2$ to give the η^4-vinylketene complex **319**. The following reaction with alkynes produced phenols **320** (Scheme 122).[147]



The [4 + 2] annulation of cyclobutenones has also been catalyzed by a nickel(0) complex (Table 14). The reaction of cyclobutenones **321** and internal alkynes **322** occurred even at 0 °C to afford phenols **323** in good yields.[148] Poor regioselectivity was observed with unsymmetrical alkynes. 3,4-Disubstitution was allowed on the cyclobutenones. The vinylketene [4 + 2] cycloaddition with boryl-substituted alkynes provided an entry to boryl-substituted phenols.[149] Excellent regioselectivity was observed in most cases when such boryl-substituted alkynes were used.

Although the [4 + 2] annulation reaction catalyzed by Ni(cod)$_2$ failed to occur with a 2,3-disubstituted cyclobutenone, it became viable with a rhodium catalyst to afford a phenol in a moderate yield (Scheme 123).[150] Even electron-deficient alkenes participated in the rhodium-catalyzed reaction. The initially produced cyclohexenones were oxidized to phenols through hydrogen transfer to the alkenes (Scheme 124).

The thioketal derivatives of 2-silylcyclobutenone such as **324** readily underwent electrocyclic ring opening to generate reactive silyl(vinyl)ketene, which further reacted with TCNE to afford the corresponding [4 + 2] cycloadduct **325** (Scheme 125).[151]

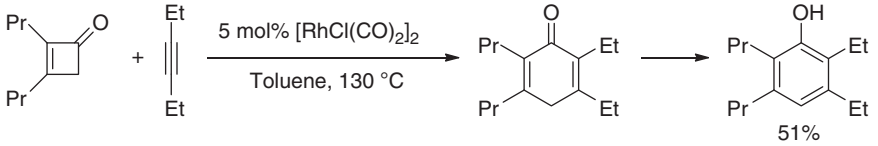
5.16.4.3 [2 + 2] Cycloaddition

When 4-allyl-4-arylcyclobutenones **328** were heated, [2 + 2] cycloaddition and 6π electrocyclization could occur in a competitive manner (Table 15). The selectivity between the two pathways varied according to the substituents. The naphthol **329** resulted in preference to the bicyclo[3.2.0]heptenone **330** from 4-allyl-2-hexynylcyclobutenone. This preference was reversed for 4-allyl-2-phenylcyclobutenone. A bicyclo[3.2.0]heptenone was exclusively formed from 2-*t*-butyl-4-methallylcyclobutenone.



3-(3-Butenyl)-2-isobutenyl-4-siloxycyclobutenone **331** underwent torquoselective electrocyclic ring opening, giving the vinylketene intermediate **332** (Scheme 127).[153] Subsequent intramolecular [2 + 2] cycloaddition with the allylic double bond afforded **333**. Treatment of this compound with aqueous acid resulted in the formation of the corresponding aldehyde with a diastereomeric ratio of 10:1. After reduction of the formyl group to a methyl group, vinyllithium was added to the ketone to

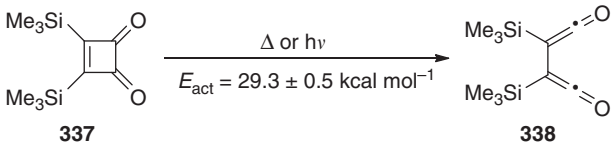
induce an oxy-Cope ring expansion. The resulting enolate was trapped as its diphenyl phosphate derivative to afford **334**. Exposure of **334** to $AlMe_3$ in the presence of catalytic $Pd(PPh_3)_4$ provided (±)-precapnelladiene (**335**).

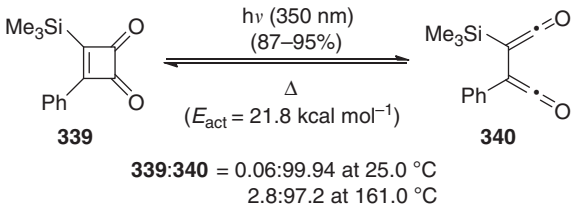
5.16.5 Cyclobutenediones



The photoinduced ring opening reaction of cyclobutene-1,2-diones giving 1,2-bisketenes was discovered in 1961.[154] However, 1,2-bisketenes facilely undergo thermal ring closure back to the cyclobutene-1,2-diones. Hence, 1,2-bisketenes have been observed only at low temperatures, mostly in matrices. Tidwell et al. found that bissilyl bisketenes were thermodynamically more stable than the cyclobutenediones at r.t. This finding led them to extensively study the spectroscopic and chemical properties of 1,2-bisketenes.

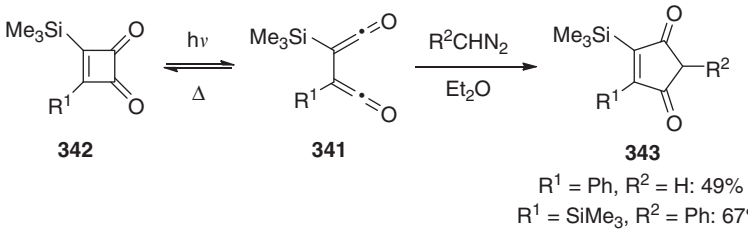
The irradiation of a variety of substituted cyclobutene-1,2-diones in the presence of cyclopentadiene led to the formation of 1:1 adducts.[155] They result from the cycloaddition of the photochemically generated bisketenes with cyclopentadiene and the following rearrangement of the α-ketenylcyclobutanones **336** (Scheme 128).

Ab initio calculations indicated that bisketene is less stable than cyclobutenedione by only 6.9 kcal mol^{-1}, and that electropositive substituents exert large stabilizing influences on ketenes to favor the acyclic bisketene structure. Heating of 3,4-bis(trimethylsilyl)cyclobutenedione (**337**) at 100 °C for 1 h gave complete conversion to bissilyl bisketene **338** (Scheme 129).[156] Irradiation of **337** with light of 350 nm wavelength for 12 min also formed **338** in 70% yield. Degassed bissilyl bisketene **338** in $CDCl_3$ remained unchanged after 45 days at 2 °C. The kinetics of the conversion of **337** to **338** on heating in



Scheme 128 [2 + 2] Cycloaddition of photochemically generated bisketenes with cyclopentadiene.

Scheme 129 Ring opening of 3,4-bis(trimethylsilyl)cyclobutenedione (**337**).

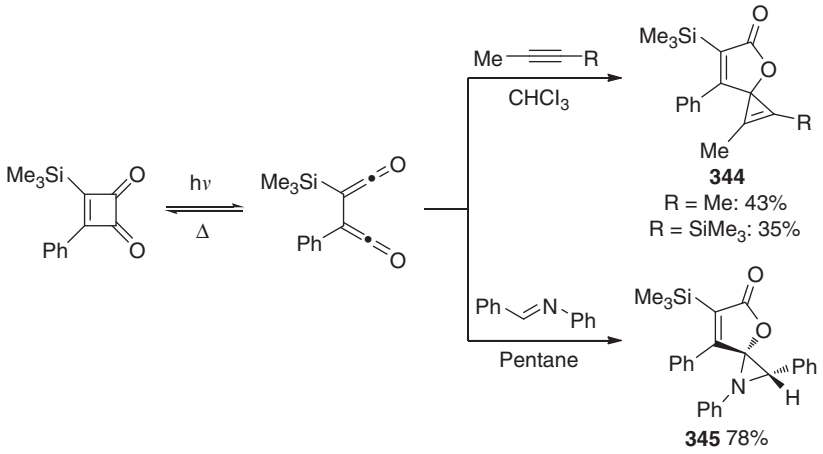


$CDCl_3$ in a sealed tube were monitored by ^1H NMR, which allowed the energy of activation to be determined as $E_{act} = 29.3 \pm 0.5$ kcal mol^{-1}.

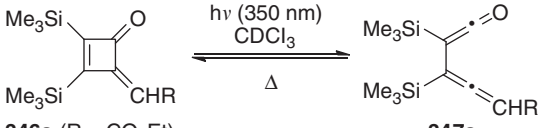
The interconversion of cyclobutenediones **339** with the corresponding bisketenes **340** was studied experimentally and theoretically (Scheme 130).[157]

Scheme 130 Interconversion of cyclobutenediones **339** with bisketenes **340**.

[4 + 1] Cycloaddition reactions of bisketenes **341**, generated on photochemical treatment of the corresponding cyclobutenediones **342**, with diazomethanes at r.t. led to the formation of cyclopent-4-ene-1,3-diones **343** (Scheme 131).[158]

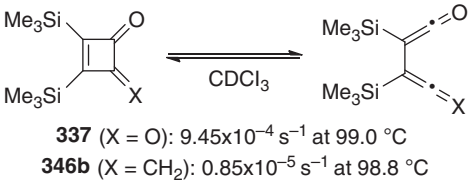


Scheme 131 [4 + 1] Cycloaddition reaction of bisketenes **341** with diazomethanes.



Irradiation of cyclobutenedione with light of 350 nm wavelength at 5 °C for 1 week in the presence of 2-butyne or 1-(trimethylsilyl)propyne furnished the spirocyclic cyclopropenes **344** (Scheme 132).[163] A photochemical reaction of cyclobutenedione formed bisketene, which then reacted with an imine to give spirocyclic aziridine **345** in good yield.[159]

Irradiation of 2,3-bis(trimethylsilyl)-substituted alkylidenecyclobutenones **346** caused quantitative conversion to the allenylketenes **347** which were stable enough to be isolated at r.t. (Scheme 133).[160] As predicted by molecular orbital calculations, the alkylidenecyclobutenones **346** underwent thermal equilibration with the corresponding allenylketenes **347** at 100 °C. The equilibrium constants **346a**:**347a** and **346b**:**347b** were 1.0 and 0.029, respectively. The measured rate constant for the ring opening of the bissilylcyclobutenedione **337** to form the bisketene **338** at 99.0 °C was 9.45×10^{-4} s^{-1} (Scheme 134). It was 110 times greater than that for the ring opening of **346b** at 98.8 °C.



The photochemical reaction of benzocyclobutenedione **348** produceed the bisketene **349** and the carbene **350** (Scheme 135). Benzyne was ultimately produced under matrix conditions. Irradiation of **348**, with light of 290 nm wavelength produced **349**, which was isolated in Ar matrix at 11 K[161]; the isomerization is photoreversible. Thus, photolysis of **349** at $\lambda > 320$ nm regenerated

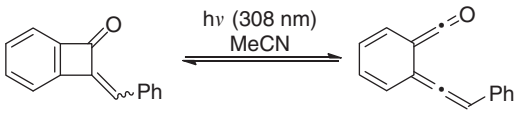

Scheme 134 Ring opening of bissilylcyclobutenedione **337** and alkylidenecyclobutenone **346b**.

Scheme 135 Photochemical reaction of benzocyclobutenedione **348**.

348. It could be repeated several times before the bisketene was finally converted to benzyne. The carbene **350** lived for about 20 μs in toluene and could be trapped by typical carbene scavengers such as alcohols.[162]

A stereoisomeric mixture of the benzylidenebenzocyclobutenone **351** underwent photoinduced isomerization via the intermediate ketene-allene **352**, which had a lifetime of ~26 μs (**Scheme 136**).[163]

351 **352**

Scheme 136 Photoinduced isomerization of benzylidenebenzocyclobutenone **351**.

Glossary

Cascade/Domino reactions A consecutive series of reactions, wherein each step generates the functionality required for the following reaction.

Density functional theory (DFT) A quantum mechanical modeling method, often used to investigate the electronic structure of molecules computationally.

Electrocyclization, electrocyclic reaction A type of pericyclic reaction, wherein the two termini of a linearly conjugated polyene form a new σ-bond at the expense of a π-bond.

endo*/*exo Stereochemical descriptors that refer to the face a particular substituent lies on in polycyclic ring systems. The convex face, or the side bearing the smaller bridge in bicyclic systems is generally denoted as *exo*, whereas *endo* is commonly used to describe the concave face or the side possessing the larger bridge in bicyclic systems.

Pericyclic reaction A reaction that occurs with a cyclic transition state and simultaneous, concerted bond-breaking/bond-forming events.

Torquoselectivity The rotational stereoselectivity (inward vs. outward directed rotation) of substituents in controtatory or disrotatory electrocyclic reactions.

Woodward–Hoffmann rules A set of rules based on orbital symmetry that allow, inter alia, for predicting the stereochemical course of pericyclic reactions.

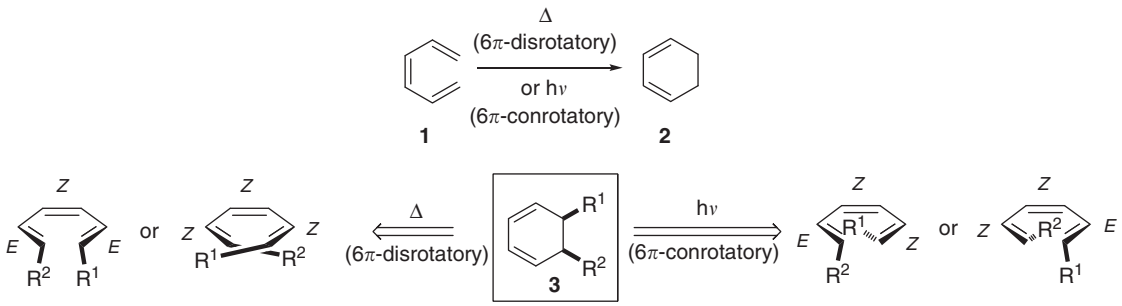
5.17.1 Introduction

An important subclass of pericyclic reactions, 6π electrocyclizations can be used to form six-membered rings with predictable stereochemistry and high levels of selectivity. Of historical significance, the reaction's discovery was implicated in the formulation of the Woodward–Hoffmann rules,[1] but only in more recent years has this reaction class begun to enjoy a more prominent role in organic synthesis. Since the vital role played by pericyclic reactions in vitamin D biosynthesis was elucidated,[2] numerous examples of electrocyclic reactions participating in biosynthetic pathways have been identified,[3] often seen in reaction cascades that rapidly generate molecular complexity.

This review aims to underscore the growing significance of this reaction class as a useful synthetic tool for six-membered ring formation, and does not cover electrocyclic ring-opening reactions. It is organized by first examining all-carbon systems, discussing general reactivity and stereoselectivity, before moving on to cases that include oxygen and nitrogen. Finally, since higher order 8π electrocyclizations are often followed by 6π electrocyclic ring closure, these reaction cascades will receive special attention, highlighting their proposed involvement in the biogenesis of various natural products. While this chapter is certainly

not a comprehensive account on 6π electrocyclization reactions, the reader is referred to a number of excellent reviews already published on this topic.[4] The rules of the conservation of orbital symmetry will not be detailed here either, instead the authors wish to provide a simple reminder of the stereochemical course of thermal and photochemical electrocyclization reactions in the ground and first excited states (Table 1).

Table 1 Summary of rotational stereoselectivity in electrocyclization reactions



Number of electrons	*Thermal*	*Photochemical*
4π	Conrotatory	Disrotatory
6π	Disrotatory	Conrotatory

5.17.2 6π Electrocyclizations of 1,3,5-Hexatrienes

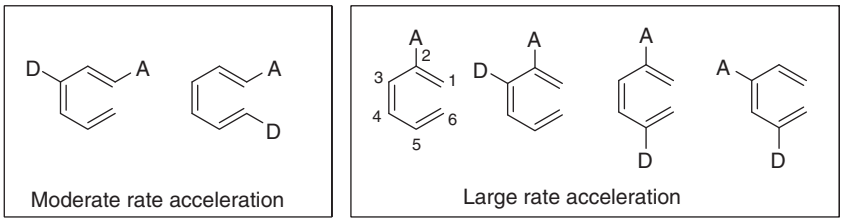
5.17.2.1 General Reactivity of 1,3,5-Hexatriene Systems

In its simplest form, 6π electrocyclic ring closure is the isomerization of a (3*Z*)-1,3,5-hexatriene **1** to a 1,3-cyclohexadiene **2** either thermally or photochemically, generating a σ–bond at the expense of a π–bond (Scheme 1). Retrosynthetically, a simple unsymmetrical 1,3-cyclohexadiene **3** can potentially arise from any of four different 1,3,5-hexatriene geometric isomers, all possessing a (*Z*)-configured central alkene, depending on the reaction conditions employed (thermal or photochemical) and on the torquoselectivity.[5] This powerful transformation, which forms six-membered rings with high stereochemical fidelity, has been underused in target-oriented synthesis compared to other pericyclic processes, such as the Diels–Alder reaction (*see* Chapters 5.09, 5.10, 5.11, 5.12, and 5.21) or sigmatropic rearrangements.[6] Since the discovery of 6π electrocyclizations in the early 1960s,[7] the limited development of related synthetic methodologies has been ascribed to the difficulties associated with preparing 1,3,5-hexatrienes with stereochemically defined alkene geometries, as well as the high thermal barrier of the ring-closing reaction (often requiring >150 –200 °C), bringing with it problems concerning functional group tolerance and competing pericyclic side-reactions, chiefly [1,5]- and [1,7]-hydrogen shifts.[4,8] In recent decades, however, the problem of olefin geometry control has been largely overcome with the advent of modern transition-metal mediated cross-coupling reactions, enabling numerous studies that have culminated in an understanding of several factors that accelerate thermal ring closure.

Scheme 1 The 6π electrocyclization manifold.

The discovery of various 1,3,5-hexatriene systems that undergo facile ring closure (*vide infra*) has provided the impetus for theoretical investigations into the rate-enhancing effects of substituents that perturb the electronics of the triene system.[9] In congruence with experimental evidence, the results of several computational studies using density functional theory (DFT) and MP2 methods have identified that introducing an electron-withdrawing substituent (CO_2Me, NO_2, SO_2Ph or $C{=}N^+Me_2$) at the 2-position has a profound effect on the rate of cyclization, capable of decreasing the activation energy barrier by up to 7–25 kcal mol^{-1}.[10] Furthermore, tactical positioning of electron acceptor/donor groups has been forecasted to drastically increase the rate of 6π electrocyclization, predicting that ring closure could occur even at room temperature in some cases. This acceleration has been attributed to a captodative[11] effect, which results in favorable electronic interactions that are stronger in the transition state than in the reactant structure (Figure 1).[9]

A steric or geometric bias that stabilizes or preorganizes the reactive triene s-*cis* conformation can significantly improve the rate of electrocyclization, as observed in 8π-6π reaction cascades that take place under relatively mild conditions, as well as in some extreme cases of steric confinement, where even symmetry disallowed electrocyclizations (i.e. thermal 6π conrotatory) have been observed due to geometrical constraints preventing the normal symmetry-allowed pathway from occurring.[12] Additionally,



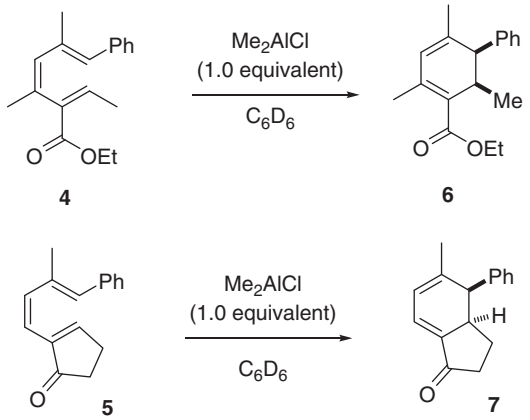


Figure 1 Substituent effects on 6π electrocyclizations of 1,3,5-hexatrienes. Reproduced from Yu, T.; Fu, Y.; Lei, L.; Guo, Q. *J. Org. Chem.* **2006**, *71*, 6157.

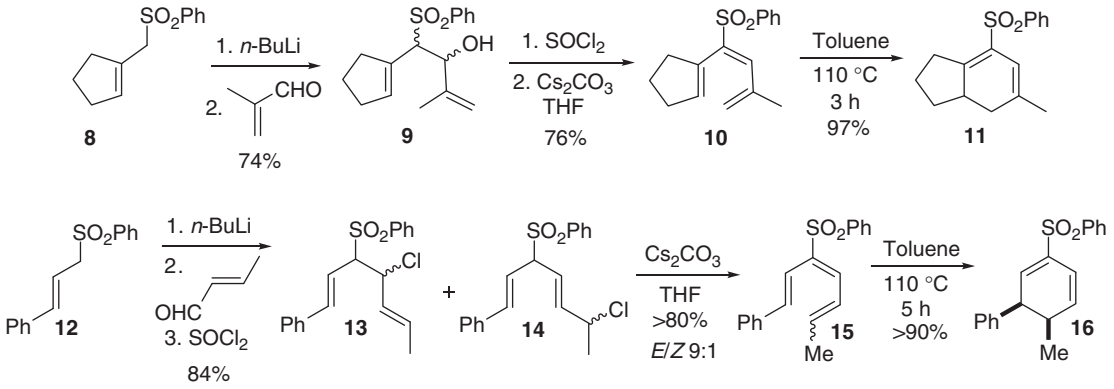
reactions that either liberate strain energy or gain in aromatic stabilization energy on ring closure often proceed at lower temperatures.[4a] Conversely however, it has been demonstrated that substitution at the termini of 1,3,5-triene systems typically results in reduced reaction rates by raising the kinetic barrier toward cyclization, energetically disfavoring the reactive conformation and in some cases facilitating alkene isomerization via [1,7]-H shifts.[4a]



A number of potential avenues exist for catalyzing 6π electrocyclizations of 1,3,5-hexatrienes.[13] One theoretical study using the B3LYP/6–311G* method predicted a significant drop in activation energy (>10 kcal mol^{-1}) for the electrocyclic ring closure of 1,3,5-hexatriene **1** to 1,3-cyclohexadiene **2** by Li^+ complexation through an electrostatic interaction that was proposed to stabilize the transition state.[14] Transition metals have also proven capable of directly complexing the transition states of related pericyclic reactions.[15] For 1,3,5-hexatriene systems that bear substituents, catalysis by Lewis/Brønsted acids or hydrogen-bonding catalysts are viable concepts. Proof of principle was only recently demonstrated by using an aluminum Lewis acid to accelerate the ring closure of 2-carboxy substituted trienes **4** and **5**.[10c] Specifically, in the presence of one equivalent of Me_2AlCl, rate enhancements of 13- and 55-fold were observed for the formation of cyclohexadienes **6** and **7** respectively, each arising from the expected thermal disrotatory pathway (Scheme 2). Varying the Me_2AlCl concentration gave evidence of catalytic turnover, but catalyst loadings of at least 17 mol% were required to increase the reaction rate. Somewhat more recently, a screening of Lewis acid additives revealed that $MeAlI_2$ promotes the same electrocyclization of triene **5** with a 600-fold rate increase over the uncatalyzed reaction.[16] This study also established the first example of a catalytic asymmetric carba-6π electrocyclization by exposing triene **5** to a chiral Lewis acid, albeit only modest enantioselectivities were observed (57–77% *ee*). Still, there is room for development and these preliminary findings have provided a starting point for the design of practical catalytic asymmetric methodologies.

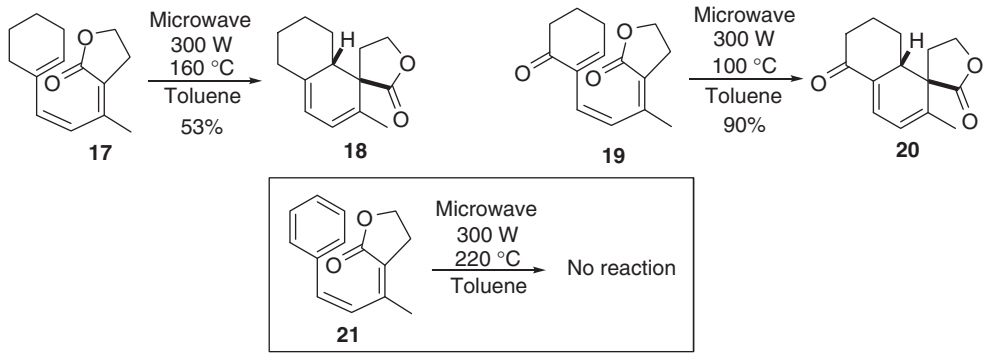
5.17.2.2 Electrocyclization as a Tool for the Synthesis of Six-Membered Rings

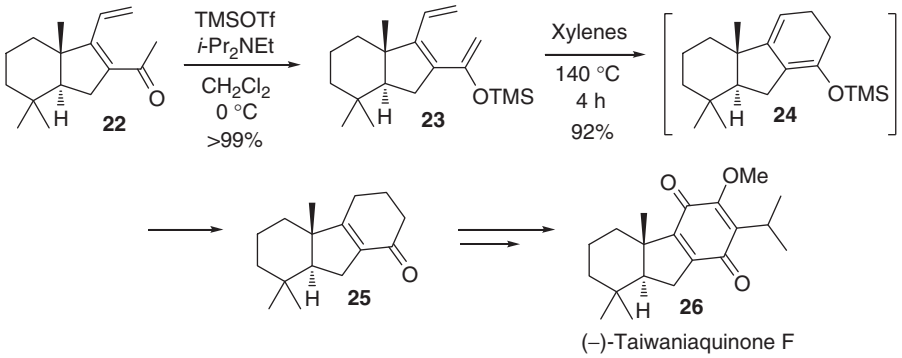


6π Electrocyclizations, although not as powerful as the Diels—Alder reaction, do provide a versatile and practical approach to functionalized six-membered rings, provided the precursor triene can be efficiently constructed. In a recent example, the phenylsulfonyl substituent acts as a versatile synthetic handle that serves a multipurpose role for the construction of six-membered carbocycles via 6π electrocyclizations.[17] In a manner reminiscent of Julia-Lythgoe olefination, (3*E*)-3-phenysulfonyl hexatrienes **10** and **15** with excellent isomeric purity for the central alkene ($>98\%$) were synthesized by α-lithiation of the corresponding allyl sulfones **8** and **12**, followed by trapping with an α,β-unsaturated aldehyde and subsequent dehydration (Scheme 3). The resulting triene systems **10** and **15** were sufficiently activated by the phenylsulfonyl group to afford 6π electrocyclization adducts **11** and **16**

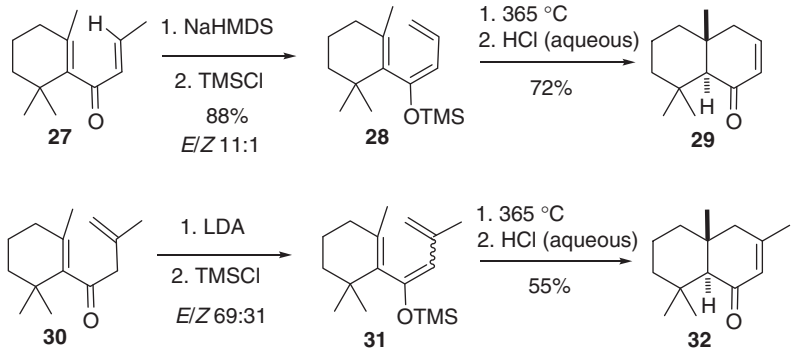
Scheme 3 6π electrocyclization of 3-sulfonyl-1,3–5-hexatrienes. Reproduced from Brändage, S.; Leijonmarck, H. *Chem. Commun.* **2004**, 292.

in superb yields under relatively mild conditions in refluxing toluene. The products are 1,3-cyclohexadienes that are susceptible to further regioselective manipulations, possessing two electronically differentiated alkenes and a flexible, easily modified functional group.[18]

A clear manifestation of electronic effects can be seen from the attempted 6π electrocyclization of various 1,3,5-hexatrienes with an incorporated γ-lactone moiety (Scheme 4).[19] Lactone **17** successfully underwent thermal disrotatory electrocyclization to 1,3-diene **18** in modest yield by microwave irradiation at 160 °C, whereas inclusion of an electron-withdrawing group at the 2-position, as in enone **19**, led to a drastic rate improvement, requiring only 100 °C to deliver 1,3-diene **20** in 90% yield. However, lactone **21**, in which the triene system is embedded within an aromatic ring, did not engage in electrocyclic ring closure, even when submitted to forcing conditions (thermally at 220 °C, flash vacuum pyrolysis at up to 600 °C or photochemically by irradiation at 254 nm, with or without I_2 present). This was presumably due to the unfavorable energetics concordant with a loss of aromaticity.

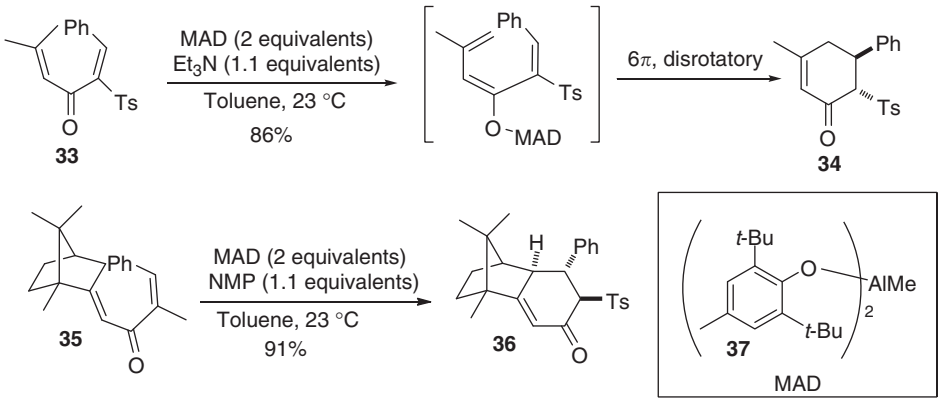


Scheme 4 Formation of 2-oxospiro[4.5]decanones by 6π electrocyclization. Reproduced from Pouwer, R.; Schill, H.; Williams, C.; Bernhardt, P. *Eur. J. Org. Chem.* **2007**, 4699.



One simple solution to constrain the requisite central *cis*-alkene geometry is to include the double bond within a cyclic system. Such an approach was utilized for the synthesis of several taiwaniaquinoids that featured a 6π electrocyclization as the key step (Scheme 5).[20] Dienone **22**, derived from the chiral pool building-block (+)-sclareolide, was transformed into silyl enol ether **23**, which smoothly underwent electrocyclic ring closure in refluxing xylenes to give enone **25** via 1,3-diene **24**, indicating that compounds possessing a strong electron donor at the 2-position can also undergo electrocyclization with reasonable reaction rates, provided the triene is preorganized.

Similarly, γ-deprotonation of the divinyl ketone **27** or α-deprotonation of the allyl vinyl ketone **30** can give rise to 3-oxo-substituted 1,3,5-hexatrienes **28** and **31** respectively, with modest to good *E*/*Z* selectivity (Scheme 6).[21] Pyrolysis of the silyl enol ethers **28** and **31** in a quartz tube at 365 °C led to electrocyclic ring closure and upon acidic aqueous workup, *trans*-decalones **29** and **32** could be isolated in moderate yield. In contrast to the relatively facile 6π electrocyclization of the 2-oxo-1,3,5-hexatriene **23** (Scheme 5), the cyclization of 3-oxo-1,3,5-hexatrienes **28** and **31** required much higher reaction temperatures, underscoring the importance of substituent effects in these systems.



In contrast to the previous example, exceptionally rapid 6π electrocyclizations are observed for 3-oxidohexatrienes bearing an electron-withdrawing group in the 2-position, which can be produced from 2-sulfonylated divinyl ketones **33** and **35** by γ-deprotonation (Scheme 7).[22] Using a bulky aluminum Lewis acid (**37**) and a weak amine base to ensure formation of the required *E*-enolate, disrotatory 6π electrocyclic ring closure proceeded with remarkable efficiency at room temperature, furnishing *trans*-enones **34** and **36** after diastereoselective protonation during the aqueous workup. Alternatively, similar 3-oxidotriene

Scheme 5 Synthesis of the taiwaniaquinoids using a 6π electrocyclization strategy. Adapted from Alvarez-Manzaneda, E.; Chahboun, R.; Cabrera, E.; *et al. Chem. Commun.* **2009**, 592, and Alvarez-Manzaneda, E.; Chahboun, R.; Cabrera, E.; *et al. Org. Biomol. Chem.* **2009**, *7*, 5146.

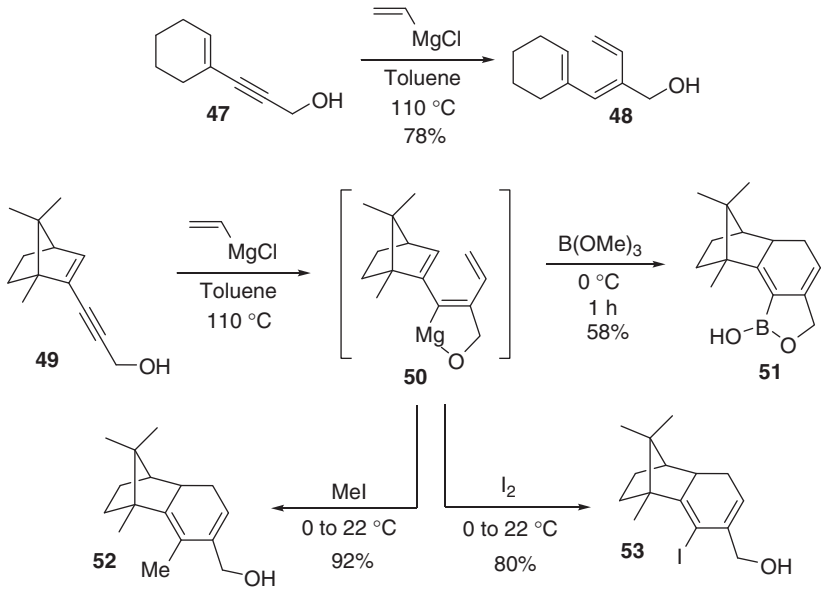
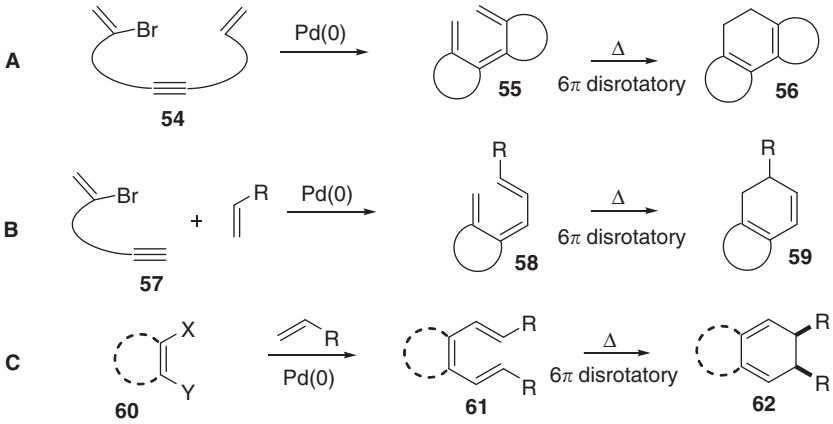


Scheme 7 6π electrocyclization of 2-sulfonyl-3-oxidohexatrienes generated via γ-deprotonation. Reproduced from Magomedov, N.; Ruggiero, P.; Tang, Y. *Org. Lett.* **2004**, *6*, 3373.

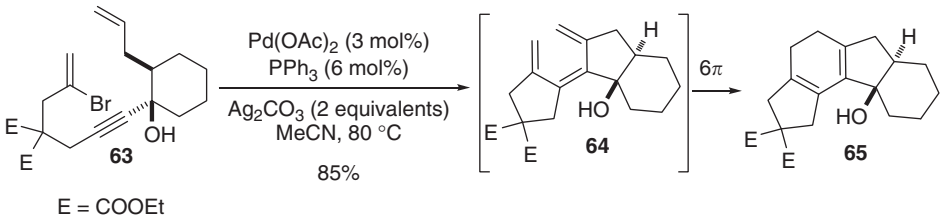
intermediates of type **39** can be generated *in situ* by addition of an appropriate nucleophile to cyclobutenone **38**, triggering a conrotatory 4π electrocyclic ring-opening (*see* Chapter 5.16) driven by the release of ring strain, occurring with outward rotation of the oxide group to form the desired (*E*)-enolate (Scheme 8).[23] Intermediate 3-oxidotriene **39** can be anticipated to undergo facile 6π electrocyclic ring closure since it would lead to 1,3-diene **40**, which is the more stable enolate anion. Notably, the presence of an electron-withdrawing group is essential for the 6π cyclization to occur, evidenced by the addition of β-(*E*)-lithiostyrene to cyclobutenone **38**, wherein the reaction cascade stops after the cyclobutene ring-opening step. Protonation of the intermediary enolate **40** then gives access to various substituted cyclohexenones **41**, overall using very mild conditions. Interestingly, it was found that substrates bearing allylic hydrogens *trans* to the electron-withdrawing group, as in enolate **46**, preferentially underwent a [1,7]-H shift over 6π electrocyclization. The exception to this was cyclopropane **42**, where a [1,7]-H shift would have produced a highly strained methylenecyclopropane.



Scheme 8 Conversion of cyclobutenones to cyclohexenones using a 4π/6π electrocyclization cascade. Reproduced from Magomedov, N.; Ruggiero, P.; Tang, Y. *J. Am. Chem. Soc.* **2004**, *126*, 1624.

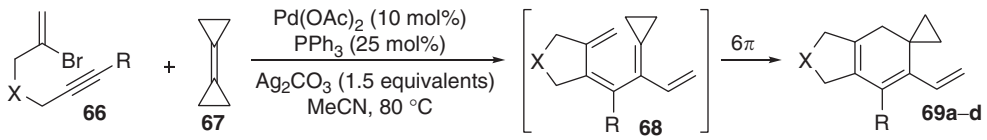
The carbomagnesation of 4-vinyl propargyl alcohols offers convenient access into 1,3,5-hexatrienes with complete control of the central alkene geometry. Treating propargyl alcohol **47** with vinyl magnesium chloride in refluxing toluene furnishes 1,3,5-hexatriene **48** in good yield; however, subsequent 6π electrocyclization proceeded rather inefficiently, requiring a reaction temperature of 250 °C (Scheme 9).[24] However, unusually facile cyclization was observed employing [2.2.1] bicyclic systems such as alcohol **49**, which underwent *in situ* 6π electrocyclic ring closure from the *exo* face via magnesium chelate **50** that afterward could be quenched with a variety of different electrophiles to afford functionalized 1,3-cyclohexadienes. The rapidity of the electrocyclization has been ascribed to the rigidity of the magnesium-chelated [2.2.1] bicyclic system. Additionally, the alleviation of ring strain from the norbornene-type system may play a role in enhancing the rate.

Scheme 9 Carbometallation with vinyl Grignard reagents as an entry to 1,3,5-hexatriene systems. Reproduced from Tessier, P.; Nguyen, N.; Clay, M.; Fallis, A. *Org. Lett.* **2005**, *7*, 767.



As a powerful $C(sp^2) - C(sp^2)$ bond forming method, the Heck reaction can be applied to construct 1,3,5-hexatriene systems for 6π electrocyclization using three general strategies (Scheme 10).[25] First, the all-intramolecular approach (**A**) starting from a bromodienyne **54** would, following oxidative insertion of Pd(0), proceed with *syn* carbopalladation of the alkyne to give the required *cis*-alkene geometry and lastly undergo an intramolecular Heck reaction to deliver bicyclic 1,3,5-triene **55**. This substrate class would be fixed in the s-*cis* conformation, a feature expected to greatly facilitate its electrocyclic ring closure. Second,

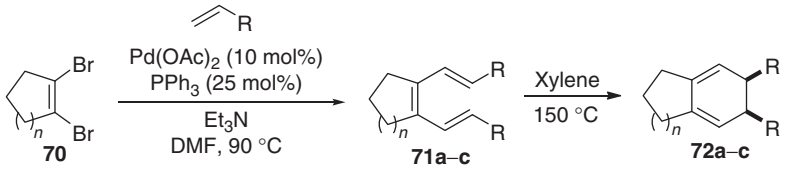
Scheme 10 Array of possible domino Heck reaction/6π electrocyclization cascades. Reproduced from de Meijere, A.; von Zezschwitz, P.; Bräse, S. *Acc. Chem. Res.* **2005**, *38*, 413.



an intra-intermolecular design (**B**) would involve termination of the cascade with an external Heck acceptor, yielding triene **58** with one newly formed ring. Finally, an all-intermolecular process would employ a 1,2-difunctionalized *cis*-alkene **60** that could either participate in a double Heck reaction or in two sequential Heck reactions to build up a 1,3,5-hexatriene of type **61**. Each of these approaches has been explored and will be highlighted in the following examples.

Exposure of vinyl bromide **63** to catalytic $Pd(OAc)_2/PPh_3$ resulted in an efficient threefold domino sequence, featuring two successive intramolecular Heck reactions and ending with a 6π electrocyclization (Scheme 11).[26] Most remarkably, the final cyclization was effected at only 80 °C, ascribed to the enforced s-*cis*/s-*cis* conformation of triene **64**. The addition of either a Ag(I) or Tl(I) salt was necessary to prevent palladium-mediated alkene isomerizations in triene **64** prior to the 6π electrocyclic ring closure.

Scheme 11 Intramolecular Heck cascade terminated by a 6π electrocyclization. Reproduced from Meyer, F. E.; Brandenburg, J.; Parsons, P. J.; de Meijere, *A. Chem. Commun.* **1992**, 390.



Employing very similar reaction conditions, vinyl bromides of type **66** underwent palladium-mediated cyclization and trapping by an external Heck acceptor, that is the highly strained methylenecyclopropane **67**, producing an intermediate triene **68** after cyclopropane ring-opening and β-hydride elimination (Scheme 12).[27] Again, facile 6π electrocyclization was observed, occurring at only 80 °C, owing to both the relative conformational inflexibility of the intermediate methylenecyclopropane **68**, as well as the significant liberation of strain energy upon ring closure to form spirocyclic cyclopropanes of type **69**.

The double Heck reaction of cyclic 1,2-dibromo alkenes **70** represents a general method to access 1,3,5-hexatrienes **71**, possessing *cis* central alkene geometry and identical groups at the termini of the triene system (Scheme 13).[28] In contrast to the previous two examples, due to the conformational flexibility of such hexatrienes **71**, higher temperatures (150 °C) were found to be required for their efficient electrocyclic ring closure.

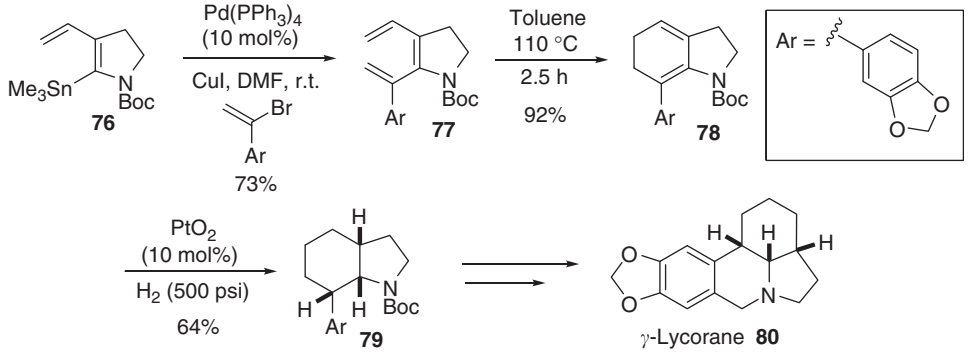
Scheme 13 1,3,5-Hexatriene synthesis by double Heck reaction of 1,2-dibromo alkenes. Reproduced from Voigt, K.; Lansky, A.; Noltenmeyer, M.; de Meijere, A. *Eur. J. Org. Chem.* **1998**, 1521.



Monocyclic 1,3,5-triene intermediates such as **74**, bearing similarities to methylenecyclopropanes **68** (Scheme 12), can be prepared transiently by the ruthenium-catalyzed coupling of a diyne **73** and an acyclic (*Z*)-alkene (Scheme 14).[29] The coupling is regioselective, provided the alkene substituents are sufficiently different, sterically and electronically. The relatively mild conditions needed for the subsequent electrocyclization to cyclohexadienes **75**, similar to the related examples already presented, is likely due to the geometry of the triene intermediates. Examples **75a–c** would be expected to exhibit particularly rapid electrocyclic ring-closing, since they possess both an electron acceptor in the 2-position and an electron donor in the 5-position of their triene **74** progenitors. Interestingly, when cyclic alkenes were used instead, a [2 + 2 + 2] mechanism was found to be operative that yielded isomeric 1,3-cyclohexadiene products.[30]

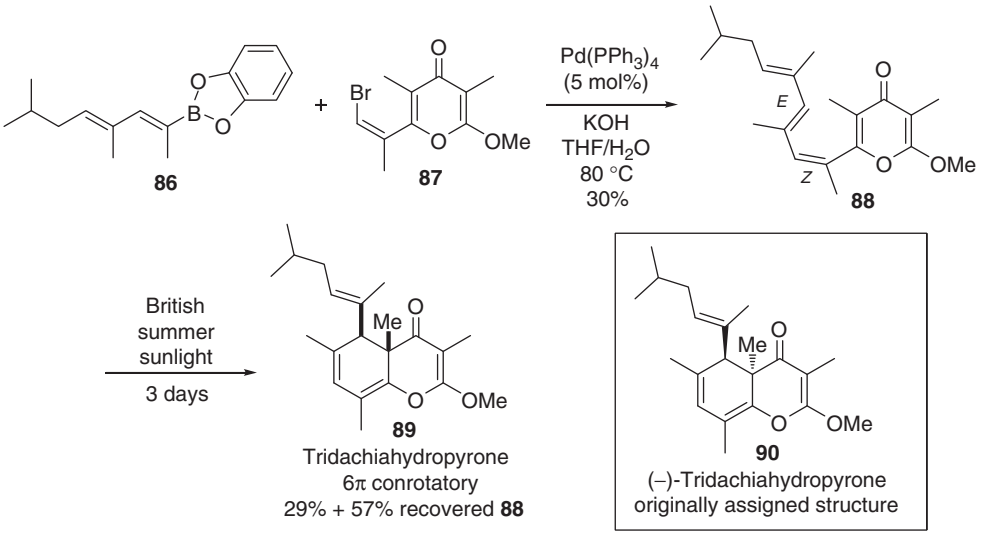
Tactical substrate design can render the 6π electrocyclization a valuable synthetic tool for 6-membered ring annulation, as seen in a recent total synthesis of γ-lycorane **80** (Scheme 15).[31] 3-Amino-1,3,5-trienes, such as **77**, conveniently accessible by Stille

Scheme 15 The total synthesis of γ-lycorane featuring a 6π electrocyclization as the key step. Reproduced from Huntley, R.; Funk, R. L. *Tetrahedron Lett.* **2011**, *52*, 6671.



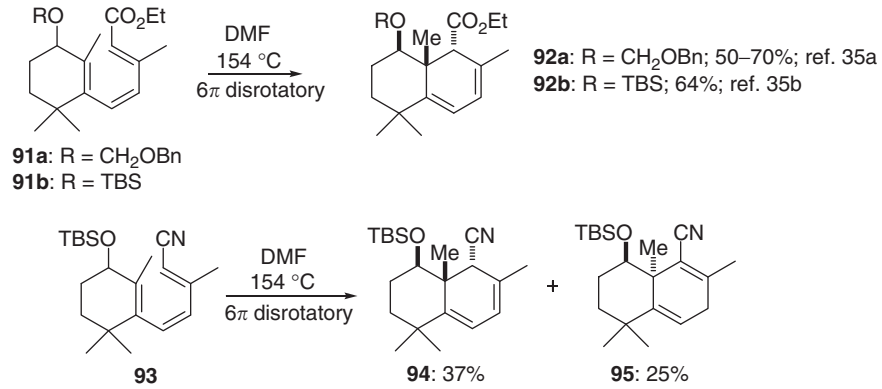
coupling between a vinyl stannane **76** and a vinyl bromide, have been found to undergo electrocyclic ring-closing under comparatively mild conditions (*vide infra*). Simply refluxing a toluene solution of amino-triene **77** for 2.5 h yielded 1,3-cyclohexadiene **78** in 92% yield. High-pressure hydrogenation afforded a single diastereomer of tetrahydroindole **78** that was later transformed into (±)-γ-lycorane **80** in two steps.

A family of γ-pyrone containing polyketide natural products, originating from molluscs of the order *Sacoglossa*, are proposed to feature various electrocyclization modes in their biosynthesis.[32] One natural product of this class, (±)-9,10-deoxytridachione **84**, was prepared in a highly convergent manner by a biomimetic cross-coupling/electrocyclization approach (Scheme 16).[33] Along these lines, a Suzuki coupling of vinyl boronate **81** and vinyl iodide **82** gave crude (*E*,*Z*,*E*,*E*)-tetraene **83**, which on heating in a benzene solution, underwent disrotatory 6π electrocyclic ring closure to afford the desired γ-pyrone natural product **84** in 31% yield. In addition, cyclohexadiene **85**, the product of alkene isomerization and a subsequent 8π/6π electrocyclization cascade, was also obtained from the reaction mixture in 15% yield and was later isolated as a natural product itself.

Scheme 16 The biomimetic synthesis of deoxytridachione and ocellapyrone A. Reproduced from Rodriguez, R.; Adlington, R.; Eade, S.; *et al. Tetrahedron* **2007**, *63*, 4500.

A unique member of the tridachiapyrone natural products, tridachiahydropyrone **89**, possesses a rearranged polypropionate skeleton and appears to result from a 6π electrocyclization that involves the γ-pyrone ring (Scheme 17).[34] Its structure was originally assigned as compound **90** (Scheme 17), the expected product from a thermal disrotatory 6π electrocyclic ring closure. However, a total synthesis of compound **90** called this structural assignment into question and instead suggested

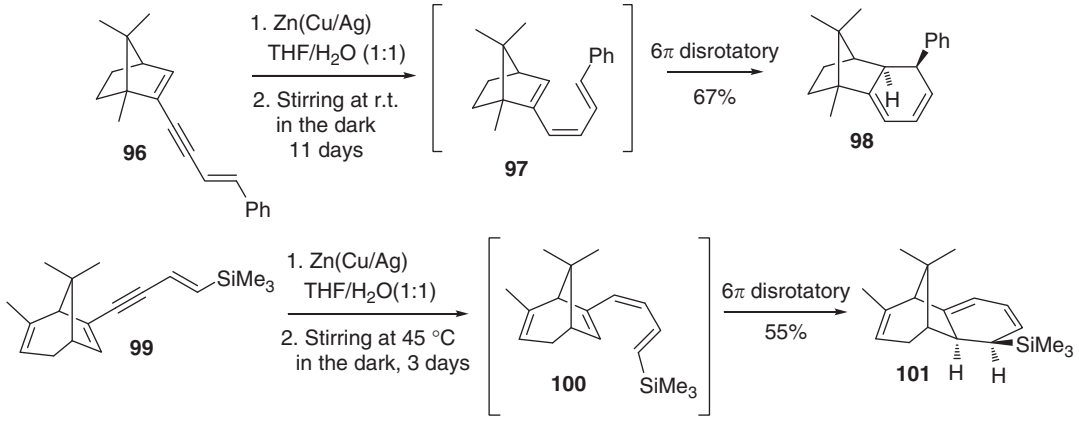
Scheme 17 The biomimetic synthesis and structural revision of tridachiahydropyrone. Reproduced from Sharma, P.; Griffiths, N.; Moses, J. *Org. Lett.* **2008**, *10*, 4025.



tridachiahydropyrone **89** as the true structure. This was later successfully confirmed by a total synthesis relying on a photochemical conrotatory 6π electrocyclization of γ-pyrone **88**, which was assembled in modest yield via the Suzuki coupling of vinyl boronate **86** with vinyl bromide **87**.

5.17.2.3 Asymmetric Reactions: Induced Diastereoselectivity

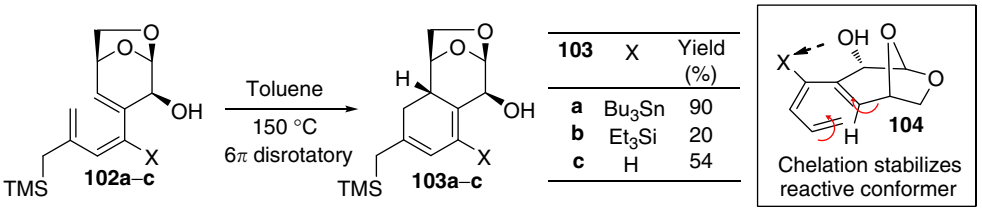
5.17.2.3.1 Thermochemical processes



Compared to other pericyclic reaction manifolds, the development of enantioselective 6π electrocyclization methodologies has received scant attention, especially the all-carbon 1,3,5-hexatriene systems. By contrast, the diastereoselectivities of these reactions has received much more attention. Although the simple diastereoselectivity is governed by the Woodward–Hoffmann rules and can be predicted with high fidelity, the induced diastereoselectivity is more involved. Although there remains no general method for stereocontrol of such reactions, it is an active area of research with valuable potential applications in synthesis.

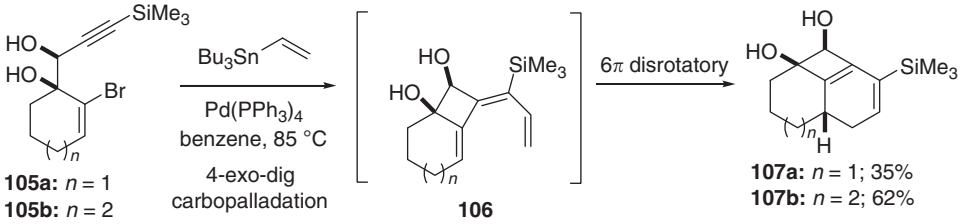
The electrocyclization products of β-ionone-derived esters **91a** and **91b** were obtained as single diastereomers and have served as building blocks for natural product synthesis,[35] demonstrating that torquoselective 6π electrocyclic ring closure can be directed by a stereocenter with a sufficiently bulky substituent at the triene terminus (Scheme 18). However, when the analogous nitrile-substituted triene **93** was submitted to the same conditions, both 1,3-diene **94** and 1,4-diene **95** (from alkene migration postelectrocylization) were isolated in similar quantities, indicating the reaction had proceeded with very little diastereoselectivity. This lack of selectivity was attributed to the nitrile functional group possessing a much smaller steric footprint compared to the ethyl ester, highlighting the subtle nuances involved in the stereocontrol of these systems, which often must be considered on a substrate-to-substrate basis.

Scheme 18 Diastereoselective 6π electrocyclizations of β-ionone derivatives. Adapted from Venkataraman, H.; Cha, J. K. *J. Org. Chem.* **1989**, *54*, 2505, and Jung, M. E.; Min, S.-E. *Tetrahedron* **2007**, *63*, 3682.



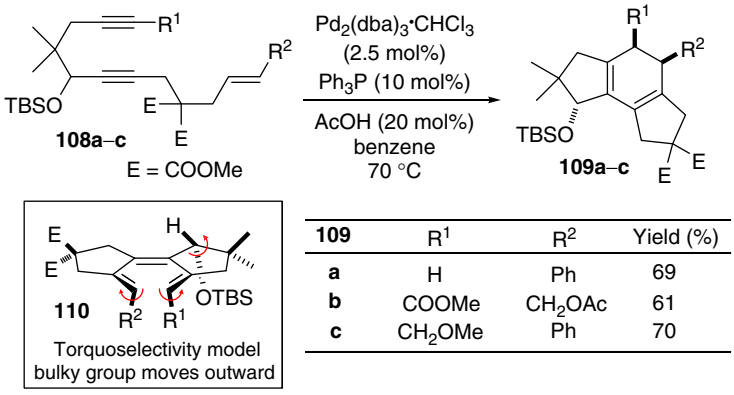
Annexing the 1,3,5-hexatriene motif with a chiral strained bicyclic alkene can allow for highly stereoselective 6π electrocyclizations, as in the case of the camphor-derivative **97** or the [3.2.1] bicycle **100** that were prepared by the stereoselective half-reduction of dienynes **96** and **99** respectively, using zinc activated by $Cu(OAc)_2$ and $AgNO_3$ (Scheme 19).[36] Strikingly, the ensuing electrocyclizations took place efficiently at room temperature, or at slightly elevated temperatures, but did require particularly long

Scheme 19 Strained bicyclic alkenes as a steric buttress for diastereoselective 6π electrocyclizations. Reproduced from Benson, C. L.; West, F. G. *Org. Lett.* **2007**, *9*, 2545.



reaction times. The bicycle likely imposes a rotational barrier on the appended carbon chain, thereby increasing the population of the reactive s-*cis* conformer. A possible cooperative driving force may be the release of ring strain in transitioning from an endocyclic alkene, such as **97**, to an exocyclic alkene **98**. In general, the 6π electrocyclization occurred from the *exo* face of the bicycle with complete diastereoselectivity in compliance with the expected mode of disrotatory ring closure.

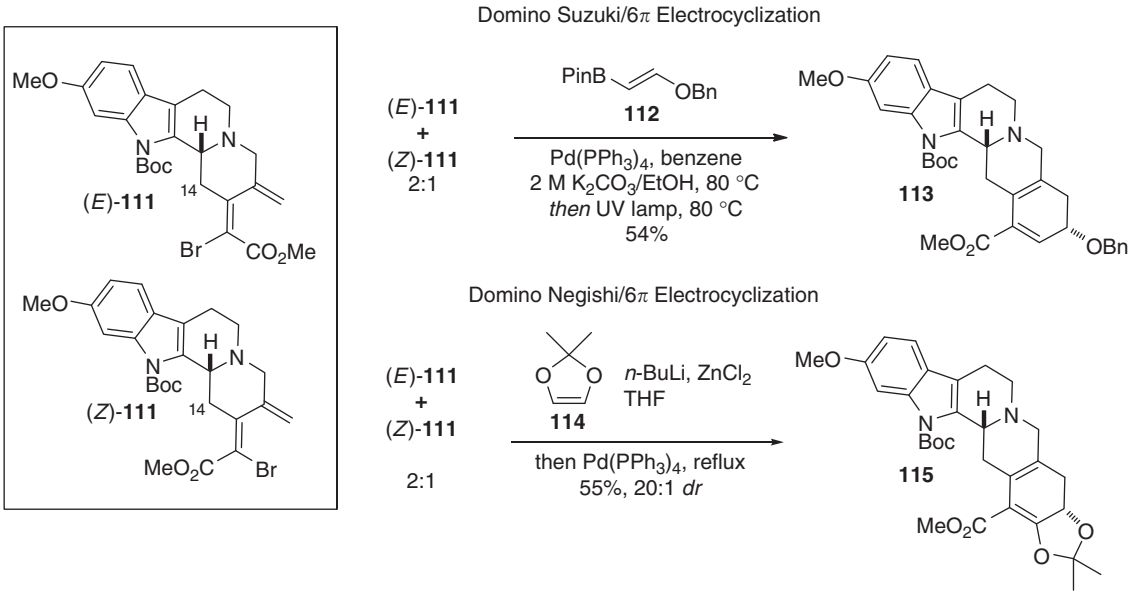
An interesting torquoselective 6π electrocyclic ring closure was employed in studies toward the asymmetric total synthesis of potent sodium channel blocker tetrodotoxin (Scheme 20).[37] Trienes **102a–c** were found to undergo electrocyclization stereoselectively from the *exo* face of the bicyclic acetal moiety. A chelation model **104** was suggested, since the nature of the substituent X neighboring the free alcohol had a profound effect on the reaction yield. It was proposed that when X = $SnBu_3$ (**102**), the free alcohol is able to form a rigid chelate, increasing the population of the s-*cis* conformer required for cyclization. Indeed, replacement by X = H (**102c**) negatively impacted the yield, whereas the use of a bulky nonchelating group that would be expected to disfavor the s-*cis* conformation, such as X = $SiEt_3$ (**102b**), resulted in a marked decline in reaction efficiency.



Scheme 20 Chelation-enhanced reactivity of a 6π electrocyclization en route to tetrodotoxin. Reproduced from Bamba, M.; Nishikawa, T.; Isobe, M. *Tetrahedron* **1998**, *54*, 6639.

Other unusual strained cyclic systems have proven capable of controlling the stereochemical outcome of 6π electrocyclizations, such as bis-methylenecyclobutanes **106** that could be generated from vinyl bromides **105a** and **105b** via domino 4-*exo*-*dig*-carbopalladation/Stille coupling (Scheme 21).[38] It was proposed that trienes of type **106** are conformationally preorganized toward 6π electrocyclic ring closure, enabling the production of strained cyclobutene-diols **107a** and **107b** as single diastereomers at relatively low temperature in refluxing benzene.

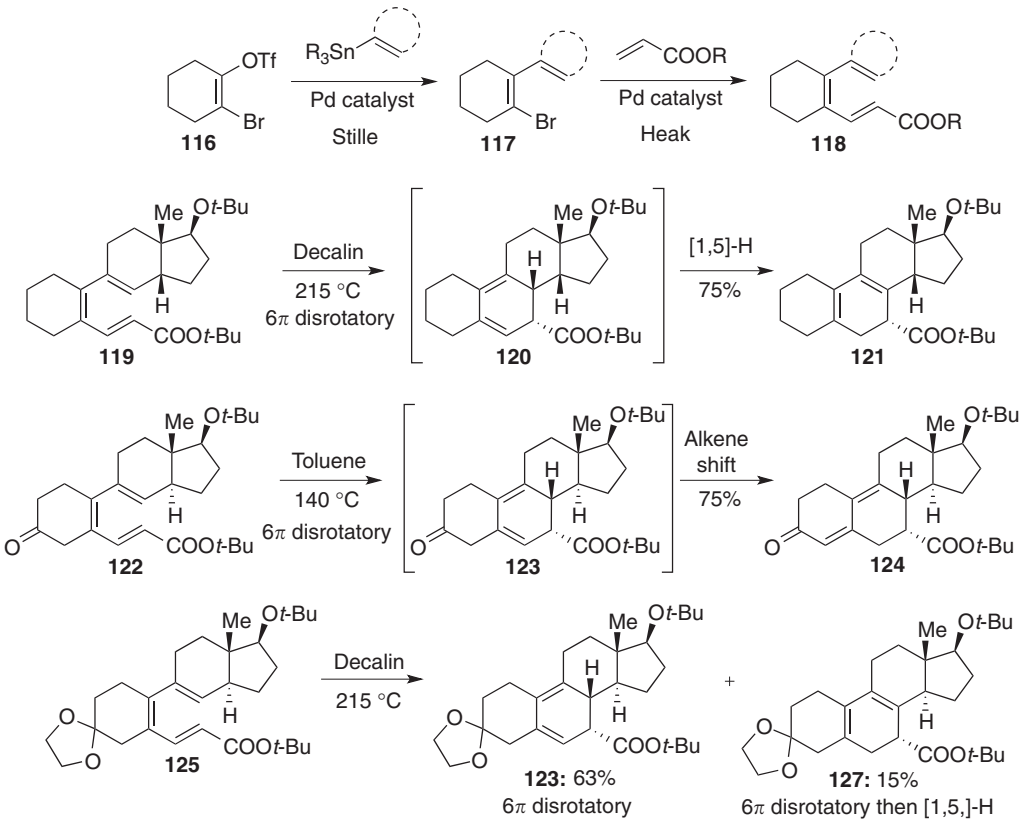
Scheme 21 The synthesis of strained cyclobutene-diols via a Pd-mediated cascade. Reproduced from Salem, B.; Klotz, P.; Suffert, J. *Org. Lett.* **2003**, *5*, 845.



Somewhat more subtle elements of substrate control can be operative, as is the case with the diastereoselective palladium-catalyzed cascade cyclization of enediynes **108a–c** (Scheme 22).[39] A lone remote stereocenter proved capable of directing the

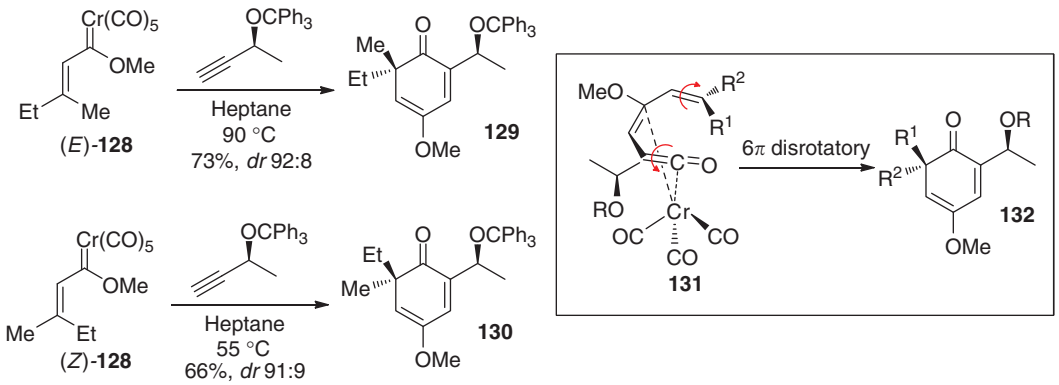
Scheme 22 Torquoselective cycloisomerization/Heck/6π electrocyclization cascade. Reproduced from Trost, B. M.; Shi, Y. *J. Am. Chem. Soc.* **1992**, *114*, 791.

stereochemical course of the reaction. The reaction cascade was initiated by the palladium-catalyzed cycloisomerization of an enediyne **108**, followed by an intramolecular Heck reaction to generate an intermediate 1,3,5-hexatriene **110**. Torquoselective disrotation occurred in an outward fashion, avoiding torsional strain between the bulky silyl group and the adjacent ring system (Scheme 22). As seen in previous examples within this chapter (Scheme 11), hexatrienes of type **110** are conformationally predisposed toward 6π electrocyclic ring closure, so it is perhaps unsurprising that tricyclic products **109a–c** are formed efficiently at only 70 °C.



In a related example, complete 1,6-stereoinduction was observed in a domino cross-coupling/6π electrocyclization approach to the reserpine alkaloids (Scheme 23).[40] The mixture of alkene geometric isomers (*E*)-**111** and (*Z*)-**111** was found to successfully undergo Suzuki coupling with vinyl boronate **112**, transiently producing a 1,3,5-triene intermediate. Subsequent irradiation of the reaction mixture with a UV lamp affected isomerization of the central alkene geometry, allowing for productive thermal 6π electrocyclic ring closure, giving 1,3-cyclohexadiene **113** as a single diastereomer. Alternatively, a Negishi coupling strategy proved equally effective, by generating the corresponding organozinc derivatives of alkene **114** via deprotonation and transmetalation, followed by exposure to the mixture of vinyl bromides (*E*)-**111** and (*Z*)-**111** and a Pd(0) catalyst in refluxing THF. In this case, 1,3-cyclohexadiene **115** is formed with high diastereoselectivity, without requiring UV irradiation, attributed to Pd-mediated isomerization of the central alkene geometry. The observed remotely induced diastereoselectivity was proposed to arise from a steric interaction between the methyl ester and the C-14 methylene unit in the electrocyclic transition state.

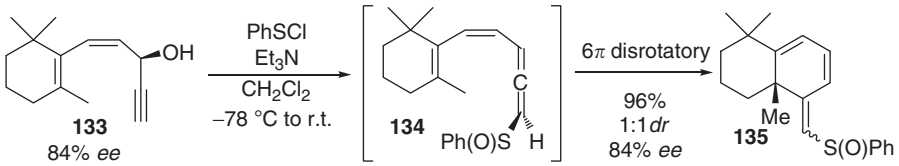
Scheme 23 A diastereoselective 6π electrocyclization approach to the reserpine alkaloids. Reproduced from Barcan, G. A.; Patel, A.; Houk, K. N.; Kwon, O. *Org. Lett.* **2012**, *14*, 5388.



The double Heck reaction of (*Z*)-1,2-bromoalkenes already presented is a viable method to access symmetrical 1,3,5-hexatrienes with a (*Z*)-configured central double bond (Scheme 13), whereas, unsymmetrical 1,3,5-hexatrienes **118** can be conveniently prepared by the sequential cross-coupling of a 2-bromo-enol triflate **116** (Scheme 24).[41] This approach has been used for the diastereoselective synthesis of various substituted steroidal frameworks.[42] For example, *cis*-hydrindane-fused triene **119** underwent clean diastereoselective thermal 6π electrocyclization at 215 °C for 45 min with outward disrotatory ring closure, followed by a [1,5]-hydrogen shift to yield diene **121**. Electrocyclization with outward rotation was also observed for *trans*-hydrindane-fused triene **122**, proceeding at lower temperature to transiently form diene **121** that isomerized to enone **124** under the reaction conditions. The reaction outcome appears to be governed by thermodynamics, as heating of ketal-protected triene **125** at 215 °C for 45 min gave a separable mixture of the 6π electrocyclization product **126** and diene **127**, arising from [1,5]-hydrogen shift post electrocyclization, in a 4:1 ratio. Re-subjecting the rearranged diene **127** to the reaction conditions returned a similar mixture of dienes **126** and **127**, indicating the [1,5]-hydrogen shift is reversible and that diene **126** is the thermodynamic product. In light of this, it is generally difficult to predict the exact reaction outcome in these systems, as the thermodynamic profiles of each substrate/product mixture must be considered individually.

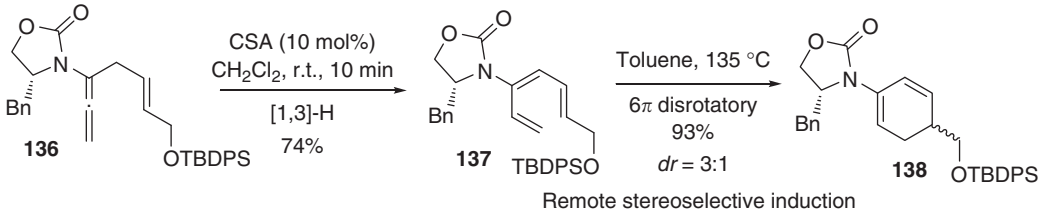
The diastereoselective synthesis of cyclohexadieneones from the union of a chromium Fischer carbene complex (*see* Chapter 5.25) and a chiral alkyne has been proposed to occur via the disrotatory 6π electrocyclization of a chromium–ketene complex **131** (Scheme 25).[43] The resulting products **132** possess a quaternary carbon center derived from 1,4-stereoinduction. Overall, the transformation was found to be stereospecific, since starting from either chromium complex (*E*)-**128** or its geometric isomer (*Z*)-**128** yields the diastereomeric dienones **129** and **130** respectively, each with comparable diastereoselectivity. Interestingly, the

Scheme 24 The synthesis of steroid scaffolds by torquoselective 6π electrocyclization. Adapted from Sünnemann, H. W.; Banwell, M.; de Meijere, A. *Eur. J. Org. Chem.* **2007**, 3879; Sünnemann, H. W.; de Meijere, A. *Angew. Chem. Int. Ed.* **2004**, *43*, 895, and Sünnemann, H. W.; Hofmeister, A.; Magull, J.; de Meijere, A. *Chem. Eur. J.* **2007**, *13*, 3739.

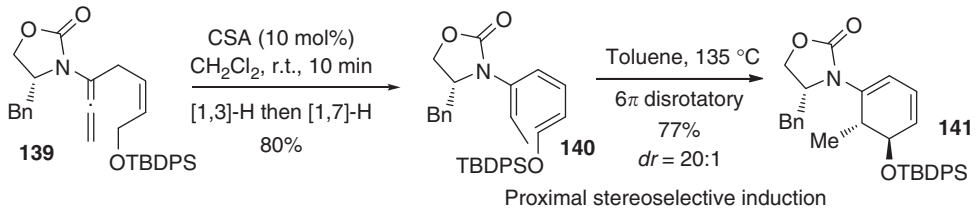


model for stereoinduction was suggested to involve an initial transfer of chiral information to the chromium coordination sphere, which directs outward disrotation of triene **131** to minimize disfavorable steric interactions between the R^1 substituent and the metal center.

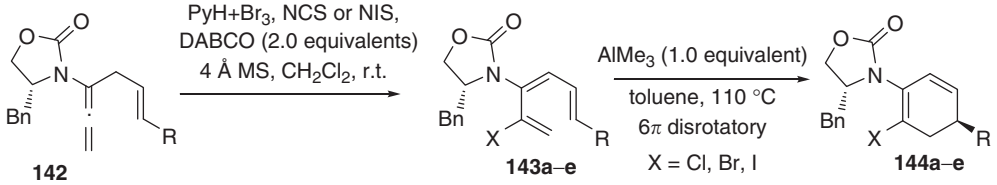
Scheme 25 Stereoselective cyclohexadieneone annulations using Fischer carbene complexes. Adapted from Hsung, R.; Wulff, W. *J. Am. Chem. Soc.* **1994**, *116*, 6449, and Hsung, R.; Quinn, J.; Weisenberg, W.; *et al. Chem. Commun.* **1997**, 615.

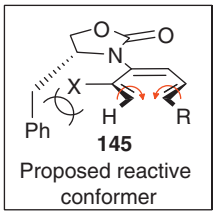


One of the earlier reported examples of a diastereoselective 6π electrocyclization to yield an enantiomerically enriched product involved the stereospecific chirality transfer from allene **134**, generated *in situ* from enantioenriched alcohol **133** by a [2,3]-sigmatropic rearrangement (Scheme 26) (*see* Chapter 5.21).[44] The chiral allene **134** underwent disrotatory electrocyclic ring closure at room temperature to yield 1,3-cyclohexadiene **135** as a 1:1 mixture of alkene isomers, but with no erosion of enantioenrichment.



It has also been demonstrated that the diastereoselectivity of 6π electrocyclizations can be controlled through the use of a removable chiral auxiliary. The acid-promoted [1,3]-hydrogen shift of chiral allenamides, such as **136**, affords chiral hexatriene





Scheme 26 Chiral allene directed diastereoselective 6π electrocyclic ring closure. Reproduced from Okamura, W. H.; Peter, R.; Reischl, W. *J. Am. Chem. Soc.* **1985**, *107*, 1034.

137 selectively with respect to the central alkene geometry (Scheme 27).[45] Heating of hexatriene **137** at 135 °C in toluene resulted in the highly efficient electrocyclic ring closure to diene **138** as a 3:1 mixture of diastereomers, an impressive level of selectivity considering it represents 1,6-stereoinduction. Counter to allenamide **136**, its olefinic isomer allene **139**, when treated with acid to trigger a [1,3]-hydrogen shift, further rearranged via [1,7]-hydrogen shift to triene **140**, fortuitously bearing the chiral auxiliary closer to the hexatriene terminus. In this case, thermal disrotatory electrocyclization produced diene **141** with significantly greater diastereoselectivity. More effective 1,6-stereoinduction could be achieved by steric buttressing of the auxiliary with a halogen

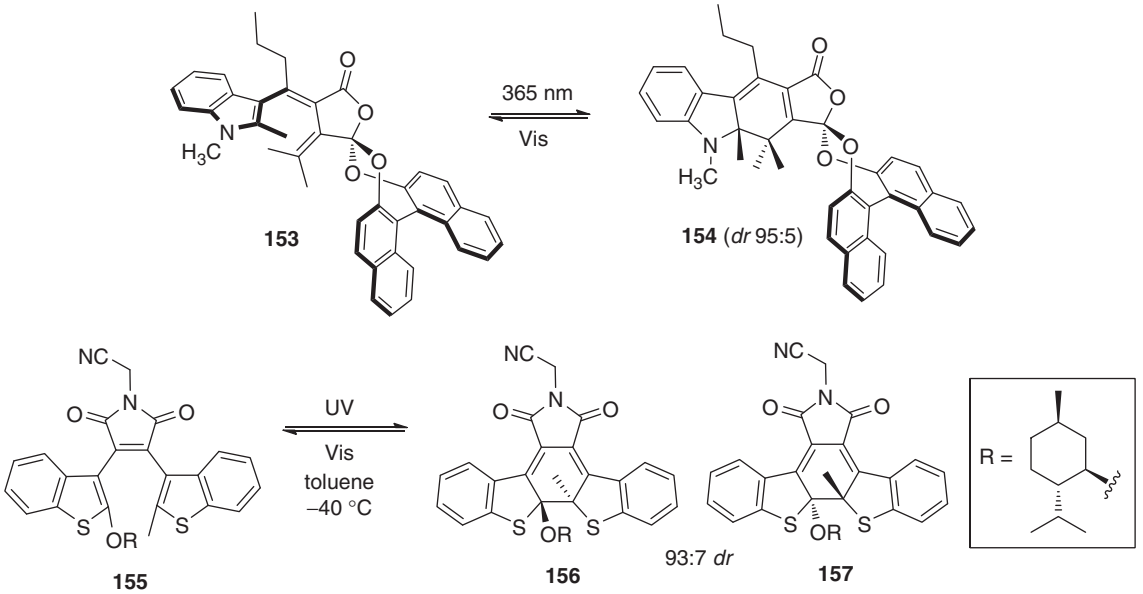
substituent, as was the case with trienes **143a-e**, which smoothly underwent 6π electocyclization in the presence of $AlMe_3$ to uniformly give synthetically useful levels of diastereoselectivty (approximately 9:1 *dr*).[46] A model **145** was put forward to rationalize the observed selectivity (Scheme 27), invoking that inward disrotation would be expected to minimize disfavorable steric interactions with the benzyl group of the auxiliary. It is worth noting that halogenated hexatrienes bearing a substituent at the C-5 position, such as bromo-triene **146**, were prone to oxidative aromatization under the reaction conditions.

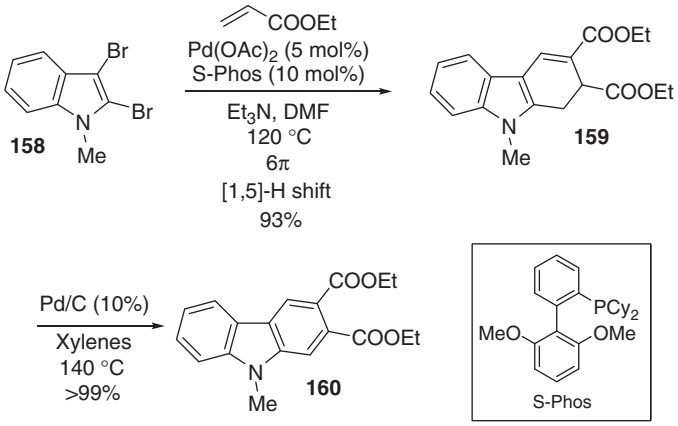


5.17.2.3.2 Photochemical processes

Photochemical 6π electrocyclizations have seen far less use in recent target-oriented syntheses than their thermal counterparts. Occurring with conrotatory ring closure and often at much lower reaction temperatures, the photochemical variant tends to exhibit torquoselectivity that reflects the relative population of conformers in the starting material's ground state.[47] For instance, this was noted in the total synthesis of ikarugamycin,[48] wherein phosphonium salt **148** and aldehyde **149** were used to prepare the advanced triene intermediate **150** with modest *Z*/*E* selectivity (Scheme 28). Subsequent irradiation of triene **150** at low temperature resulted first in the requisite *E* to *Z* alkene isomerization, followed by a 6π conrotatory electrocyclization to yield dienes **151** and **152** as a 4:1 ratio of diastereomers. It was proposed that this ratio is indicative of the inherent bias for the left-handed helical conformer of (*Z*)-triene **150** over its right-handed form.

Scheme 28 The photochemical 6π electrocyclization key step from ikarugamycin's total synthesis. Reproduced from Whitesell, J.; Minton, M. *J. Am. Chem. Soc.* **1987**, *109*, 6403.

It follows logically that it should be possible to affect the stereochemical outcome of photochemical 6π electrocyclizations using a chiral auxiliary. The feasibility of such an approach has been demonstrated by studies on chiral photochromic switches, which are compounds that interconvert between two isomers on irradiation with different wavelengths of light (Scheme 29).[49]



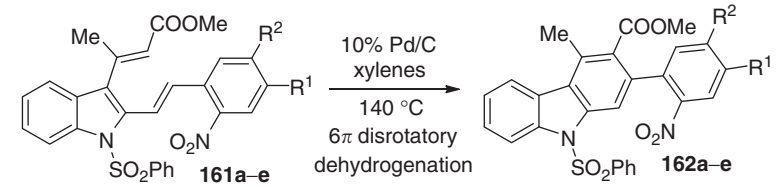
Scheme 29 Diastereoselective 6π electrocyclizations of chiral photochromic switches. Adapted from Yokoyama, Y.; Uchida, S.; Yokoyama, Y.; Sugawara, Y.; Kurita, Y. *J. Am. Chem. Soc.* **1996**, *118*, 3100, and Yamaguchi, T.; Uchida, K.; Irie, M. *J. Am. Chem. Soc.* **1997**, *119*, 6066.

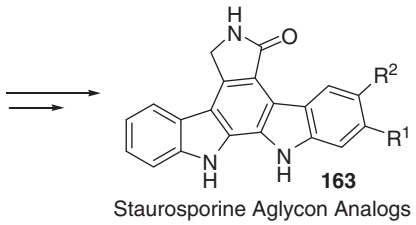
A large subset of photochromic switches rely on photochemical 6π electrocyclizations, typically employing 1,3,5-triene systems with one or more of the alkenes embedded within a (hetero)aromatic ring. For example, indolylfulgide **153**, possessing an appended (*R*)-BINOL motif, preferentially adopts one helical conformation that undergoes photochemical conrotatory ring-closing by irradiation at 365 nm, leading to cyclohexadiene **154** as virtually a single diastereomer.[50] Cycloreversion was also possible by simply exposing cyclohexadiene **154** to visible light. Similarly, it was possible to diastereoslectively photoisomerize diarylethene **155** bearing a menthyl auxiliary, which gave a 93:7 ratio of diastereomers at the photostationary state.[51] Perhaps unsurprisingly, diastereoselectivity in these systems often proves sensitive to solvent and reaction temperature, factors which also effect the relative populations of conformers in the ground state.

5.17.2.4 Electrocyclization as a Benzannulation Strategy

5.17.2.4.1 Thermochemical processes

The 1,3-cyclohexadiene products of 6π electrocyclizations are often easily further transformed into aromatic rings, either by the action of an external oxidant or autoxidation, particularly when fused to other aromatic or conjugated systems. For example, a general two-step benzannelation methodology for a number of 1,2-dibromoarenes and 1,2-dibromoheteroarenes,[52] including dibromoindole **158**,[53] has been developed, featuring an initial double Heck/6π electrocyclization cascade (**Scheme 30**). The transiently formed 1,3-cyclohexadiene undergoes a final [1,5]-hydrogen shift *in situ*, restoring aromaticity to the indole system **159**. Dehydrogenation of indole **159** was effected using palladium on carbon in refluxing xylenes, affording carbazole **160** in excellent yield.

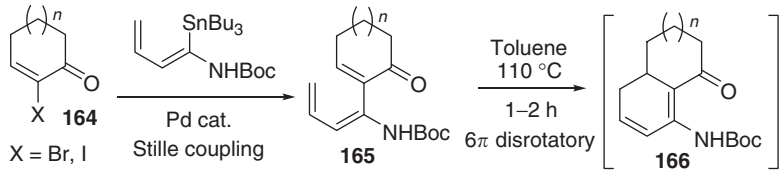




Scheme 30 Benzannealation of 1,2-dibromoarenes via 6π electrocyclization. Reproduced from Hussein, M.; Tengho Toguem, S.-M.; Ahmad, R.; *et al. Tetrahedron* **2011**, *67*, 5304.

In recent years, 6π electrocyclizations have become increasingly prominent as a tactic to prepare aromatic rings that are either sterically-crowded or possess otherwise difficult-to-access substitution patterns. Since many of the required triene precursors are now conveniently accessible through cross-coupling methodologies, numerous examples of this strategy have appeared in target-oriented synthesis within the past decade. For instance, the synthesis of several staurosporine aglycon analogs **163**, posessing a fully-substituted benzene core, were addressed using this approach (**Scheme 31**).[54] Highly substituted divinylindoles **161a-e** were treated with palladium on carbon in refluxing xylenes, triggering a 6π electrocyclic ring closure with concomitant dehydrogenation, efficiently producing various substituted biphenyls **162a-e**.

An unconventional retrosynthetic disconnection of 3,4-disubstituted indoles **169** along the lines of a 6π electrocyclization leads back to triene carbamtes **165**, which are easily prepared via the Stille coupling of an α-halo-enone **164** and an appropriate amino-vinyl stannane (**Scheme 32**).[55] Triene carbamates **165** undergo facile 6π electrocyclic ring closure, in accord with the substituent electronic effects already discussed (**Figure 1**). The cyclohexadiene intermediates **166** were not isolated, but rather treated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to effect oxidative aromatization, delivering protected anilines **167** and **168**, each in exceptional yield. Further elaboration to the indole nucleus was efficient and needed only two additional steps. This particular method was used in an approach to the total synthesis of the natural product welwistatin, wherein the structurally complex triene carbamate **170** underwent electrocyclic ring closure/oxidative aromatization without incident and was later converted into indole **172**, demonstrating the level of substrate intricacy tolerated by this methodology.[56] Additionally, an approach to the natural product dragmacidin E using this indole formation strategy has been reported.[57] Similar reaction conditions were successful at converting triene carbamate **173** into the protected arene **174**, which was also later transformed into a fused indole.



A related approach to *cis*-trikentin B **179** builds the indole benzenoid nucleus using a 6π electrocyclization (**Scheme 33**).[58] Relying again on a Stille reaction, vinyl stannane **175** was coupled with an enol triflate, allowing for the expedient synthesis of

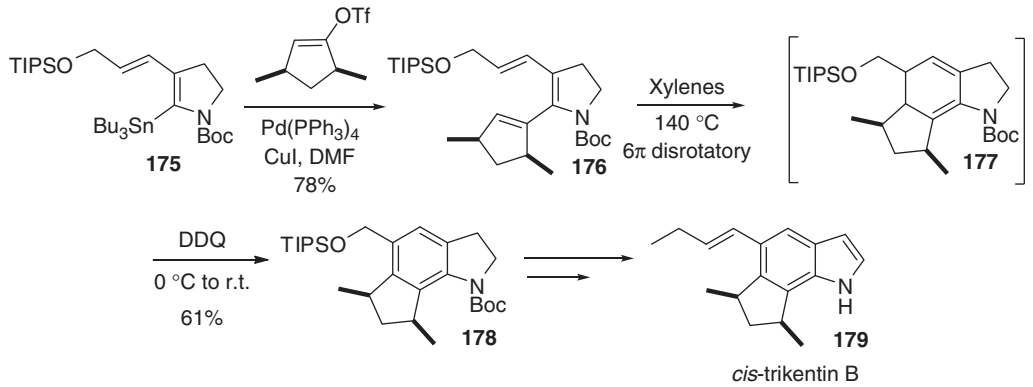
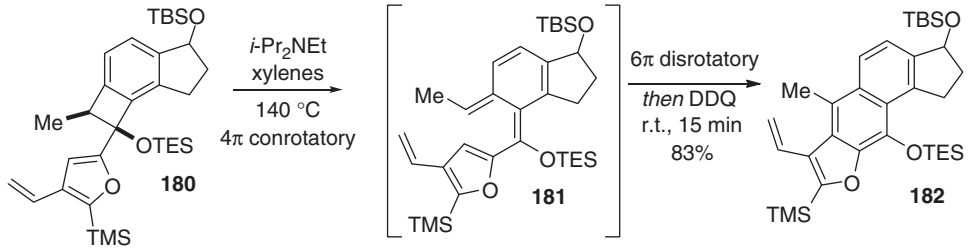


Scheme 32 Indole synthesis by the 6π electrocyclization of triene carbamates. Adapted from Greshock, T.; Funk, R. L. *J. Am. Chem. Soc.* **2006**, *128*, 4946; Greshock, T.; Funk, R. L. *Org. Lett.* **2006**, *8*, 2643, and Huntley, R. J.; Funk, R. L. *Org. Lett.* **2006**, *8*, 4775.

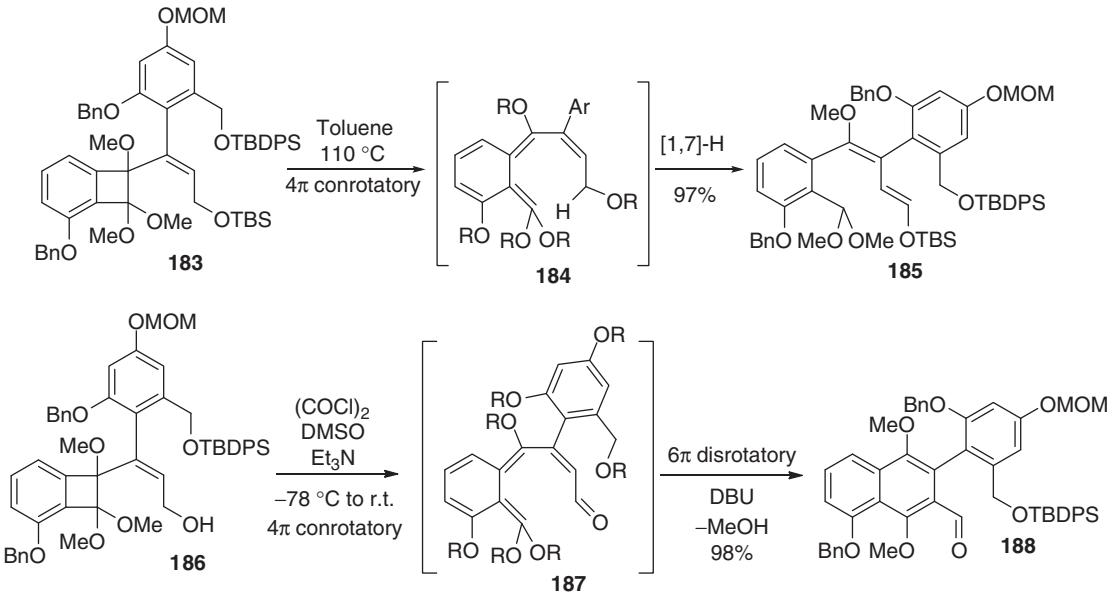


triene carbamate **176**. In turn, electrocyclic ring closure of triene **176** required slightly higher temperatures than triene carbamates **170** and **173** shown in the previous example, possibly due to the absence of the electron-accepting ketone in the former case. Subsequent *in situ* oxidation with DDQ at 0 °C furnished protected indoline **178**, which was successfully transformed into *cis*-trikentin B in four steps.

The synthesis of highly substituted naphthalenes has also merited from the 6π electrocyclization/benzannulation strategy, as seen in an excerpt from the total syntheses of viridin, a furanosteroidal antibiotic, and of the antibiotic TAN-1085. In the case of

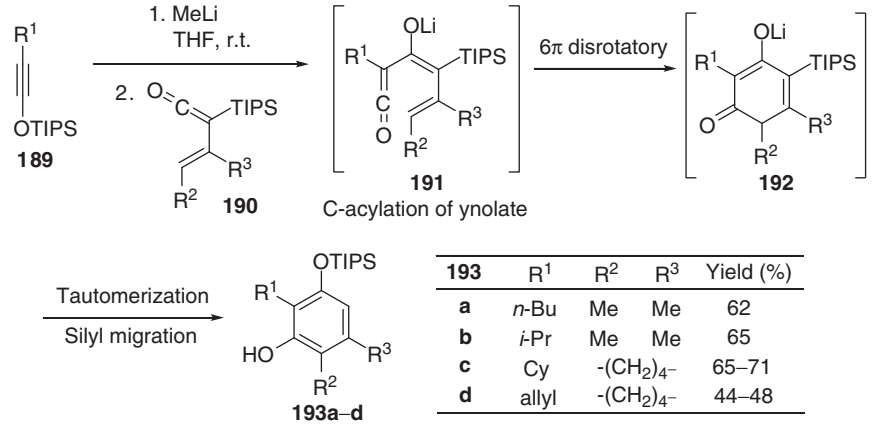
Scheme 33 The total synthesis of *cis*-trikentin B. Reproduced from Huntley, R. J.; Funk, R. L. *Org. Lett.* **2006**, *8*, 3403.

viridin, a substituted benzocyclobutene **180** was used to generate the intermediate 1,3,5-triene **181** via thermal 4π electrocyclic ring-opening (*see* Chapter 5.16) at 140 °C in xylenes (Scheme 34).[59] It is typical of triene systems such as **181**, which is an *o*-quinone dimethide, to undergo 6π electrocyclization at relatively low temperatures, driven by the formation of an aromatic ring upon ring closure.[4] Following the 6π electrocyclization, oxidative aromatization with DDQ gave tetracycle **182** in 83% yield, which is particularly efficient for a threefold domino reaction of this nature.



Scheme 34 Electrocyclization/aromatization cascade from the total synthesis of viridian. Reproduced from Anderson, E.; Alexanian, E.; Sorenson, E. *Angew. Chem. Int. Ed.* **2004**, *43*, 1998.

The total synthesis of TAN-1085 also included the 4π electrocyclic ring-opening (*see* Chapter 5.16)/6π electrocyclic ring-closing by design (Scheme 35). However, even though the initial 4π electrocyclic ring-opening of benzocyclobutene **183** in refluxing toluene proceeded without incident, the resulting triene system **184** instead underwent a remarkably high-yielding [1,7]-hydrogen shift, producing 1,4-dienol ether **185**.[60] A simple, yet astonishingly effective solution to this problem was to render the [1,7]-hydrogen shift pathway inoperative by oxidizing allylic alcohol **186** to the aldehyde under Swern conditions.[61] This modified the substrate electronics, such that the electrocyclic ring-opening/ring-closing cascade took place below room temperature, ultimately forming the sterically congested benzaldehyde **188** in exceptionally high yield after aromatization via base-mediated elimination of methanol.



The 6π electrocyclization of *sp*-hybridized carbon containing triene systems, such as alkynes, ketenes or allenes often gives aromatic products directly by tautomerization, requiring no additional oxidation step.[4b] Accordingly, trialkylsilyl vinyl ketenes **190**, which are stable toward silica gel chromatography, can be used to prepare highly substituted phenols (Scheme 36).[62] Adding the lithium ynolate derived from silyl ether **189** to vinyl ketene **190** generates a new ketene **191** via C-acylation, eliciting 6π electrocyclization at room temperature and forming intermediate dienone **192**. Subsequent tautomerization to the phenol was accompanied by 1,3 carbon-to-oxygen silyl migration, giving access to various substituted phenols **193a–d** in moderate to good yield.[63]

Ketene 6π electrocylizations have also found application in an expedient synthesis of the chiral ligands VANOL and VAPOL.[64] In the latter case, phenylacetylene was heated in the presence of the enolizable acid chloride **194**, which underwent *in situ* ketene formation, followed by a thermal [2 + 2] cycloaddition (*see* Chapter 5.02) to give cyclobutenone **195** (Scheme 37). Subsequent 4π electrocyclic ring-opening (*see* Chapter 5.16) formed a second ketene **196** that engaged in 6π electrocyclization, followed by a tautomerization to the corresponding phenol **198**. A high temperature oxidative dimerization provided racemic VAPOL **199** that could be separated into its constituent enantiomers by means of a classical resolution.

In analogy to ketenes, allene containing 1,3,5-triene systems also participate in thermal 6π electrocyclizations with typical activation energies that are significantly lower than the parent 1,3,5-hexatriene manifold. One particularly convenient method for the preparation of allenes, base-mediated isomerization of a propargyl ether,[65] was used to trigger allene 6π electrocyclizations in

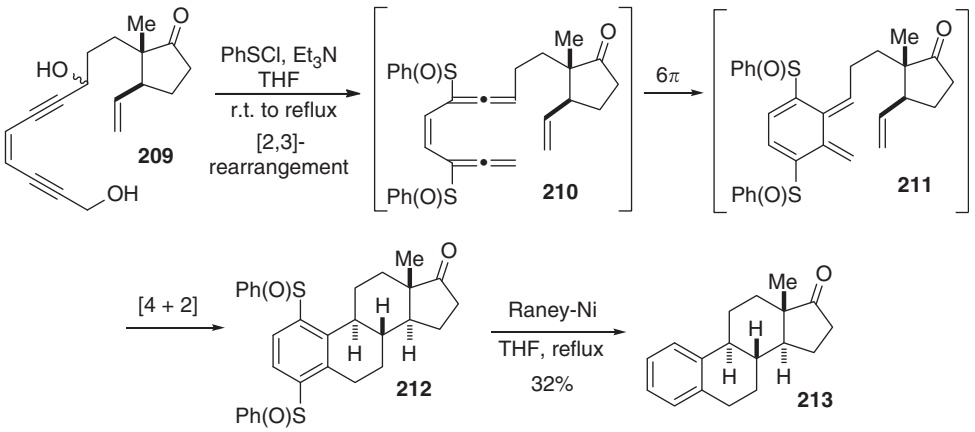
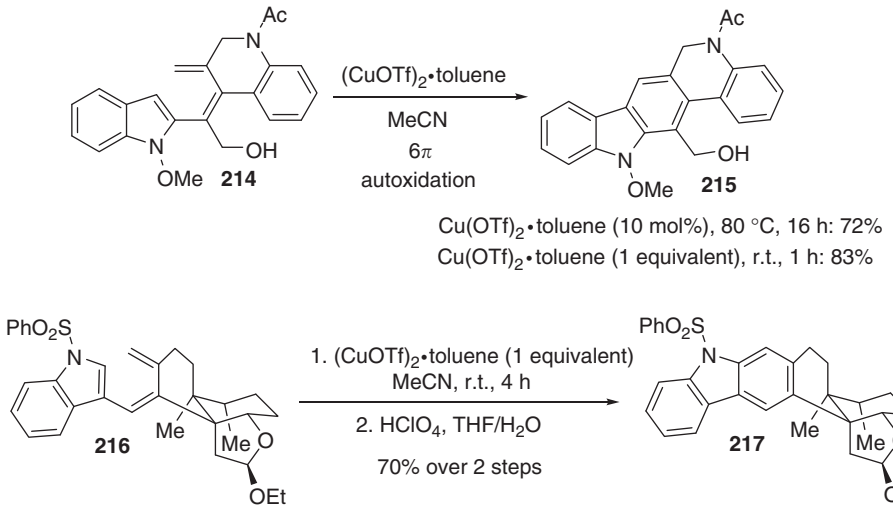
the total syntheses of calothrixin B and carbazomadurin A (Scheme 38). Along these lines, propargyl ether **200** was treated with potassium *tert*-butoxide in THF at 90 °C, leading to the efficient production of arene **202** possessing a fully-substituted central aromatic ring.[66] The same reaction conditions were not successful using propargyl ether **203**, an intermediate from the carbazomandurin A synthesis, but changing the base to tetra-*n*-butylammonium fluoride (TBAF) resulted in isomerization to allene **204** and successful electrocyclic ring closure to highly substituted arene **205**, albeit in modest yield.[67]

Scheme 38 Allene 6π electrocyclizations in the synthesis of calothrixin B and carbazomandurin A. Reproduced from Yamabuki, A.; Fujinawa, H.; Choshi, T.; *et al. Tetrahedron Lett.* **2006**, *47*, 5859.

Using other heteroatoms to promote alkyne-to-allene isomerizations to initiate 6π electrocyclization has also been investigated. Simple dieneynes **206** incorporating a propargylic oxygen, nitrogen or sulfur atom were readily accessible using cross-coupling chemistry (Scheme 39).[68] Treating these substrates with an amine base at slightly elevated temperatures was sufficient to educe isomerization to allene **207** and drive the subsequent 6π electrocyclization forward. Isotopic labeling studies showed that the isomerization occurs predominantly with transfer of deuterium, resulting in a high degree of deuterium incorporation in the product arene **208**. A large number of 1,2,4-trisubstituted arenes of type **208a–c** were accessible in good yield using this methodology.



Scheme 39 Heteroatom assisted alkyne-to-allene isomerization accompanied by 6π electrocyclization. Adapted from Zhou, H.; Xing, Y.; Yao, J.; Chen, J. *Org. Lett.* **2010**, *12*, 3674, and Zhou, H.; Xing, Y.; Yao, J.; Lu, Y. *J. Org. Chem.* **2011**, *76*, 4582.



Including two allenes in a 1,3,5-triene system can result in 6π electrocyclization to generate an *o*-quinone dimethide. This has been demonstrated by the formation of intermediate ene-diallene **210** from the sulfur-promoted double [2,3]-sigmatropic rearrangement (*see* Chapter 5.21) of bis-propargyl alcohol **209** (Scheme 40).[69] The ensuing 6π electrocyclic ring-closing begat *o*-quinone dimethide **211**, which underwent an intramolecular Diels–Alder reaction to terminate the cascade. Erasure of the sulfoxide substituents from the rapidly assembled steroidal framework **212** could be accomplished by treatment with Raney-nickel, giving ketone **213** in 32% overall yield from propargyl alcohol **209**.

During the course of studies on the total synthesis of calothrixins A and B, the conversion of 1,3,5-triene **214** to arene **215** was met with difficulty, failing under both forcing thermal and photochemical conditions (Scheme 41).[70] This prompted a screening of additives aimed at promoting the reaction,[71] revealing that a copper(I) salt was effective in catalyzing the 6π electrocyclization at elevated temperature in MeCN. Furthermore, using a stoichiometric quantity of the copper(I) salt caused the reaction to

proceed efficiently at room temperature. Although the exact mechanism of rate enhancement is unclear, it has been proposed the copper species acts as a Lewis acid. These conditions were later applied in another total synthesis, that of tubingensin A,[72] wherein 1,3,5-triene **216** was transformed into carbazole **217** by a copper-mediated 6π electrocyclization/aromatization followed by acetal hydrolysis.

5.17.2.4.2 Photochemical processes

As seen thus far, 6π electrocyclization followed by oxidative aromatization is a particularly effective strategy for making carbazoles. This is true for photochemical electrocyclic ring closure as well, especially when the substrate bears a suitable chromophore and is not susceptible to alkene isomerizations. The total synthesis of the telomerase inhibitors dictyodendrin B, C and E made use of such a transformation. Irradiation of enol ether **218** using a 250 W mercury lamp, followed by aromatization of the initially formed adduct by the addition of palladium on carbon and nitrobenzene gave pyrrolocarbazole **219** in good yield (Scheme 42).[73]

Photochemical 6π electrocyclizations can also be engineered into cascade sequences, enabling the rapid synthesis of polycyclic aromatic structures. For example, 3-chloroisoquinolone **220** undergoes homolytic C–Cl bond cleavage on irradiation with UV light, generating a carbon-centered radical that undergoes a 5-*exo-dig* cyclization with concomitant chlorine radical trapping to afford intermediate vinyl chloride **221** (Scheme 43).[74] A light-induced alkene isomerization to vinyl chloride **222** results in spontaneous 6π electrocyclization to amide **223**, followed by autoxidation, giving access to a number of benzo[*a*]phenanthridein-5-ones **224a–d**.

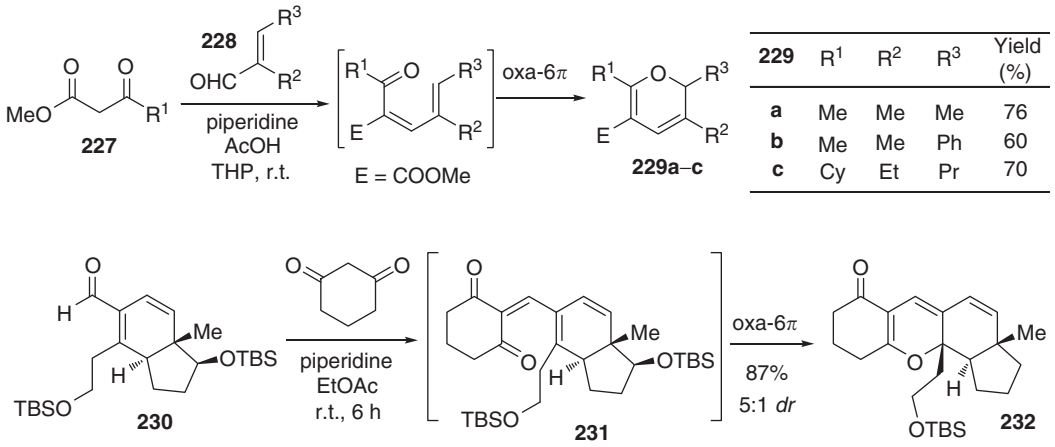
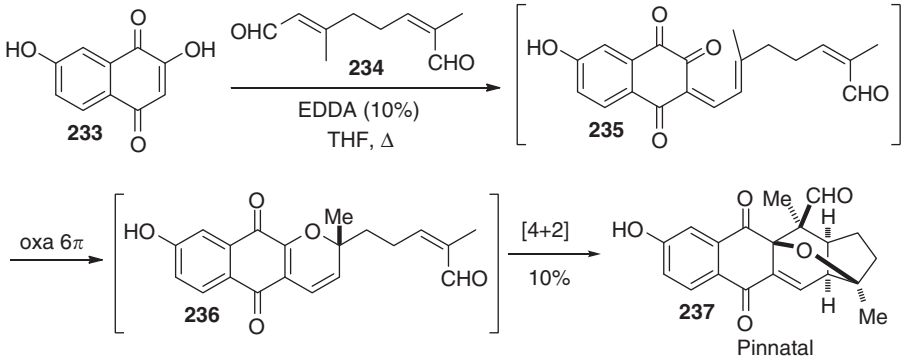
5.17.3 Oxa-6π Electrocyclizations



Replacing a terminal carbon in a 1,3,5-hexatriene with an oxygen atom, as in dienone **225**, drastically perturbs the system, significantly decreasing the activation energy barrier toward 6π electrocyclization (Equation 1).[4] The reason for this has been cited as a combination of the decreased steric demand of oxygen compared to a substituted carbon, as well as the direct participation of the oxygen nonbonding lone pairs in the electrocyclic process. Reactions of this type, where bonding and nonbonding orbitals exchange roles have been termed 'pseudopericyclic' and have been the subject of theoretical studies.[75] The oxa-6π electrocyclization interconverts an oxatriene system **225** with the corresponding α-pyran **226**, and has been predicted to be essentially thermoneutral.[4a] Therefore, the equilibrium between the two forms is sensitive to relatively small offsets in energy (1–3 kcal mol^{-1} for K = 10–100), which can be determined by numerous factors such as the steric/electronic nature of substituents, conformational bias or strain energy. The reaction produces one new stereocenter, but selectivites are often governed by thermodynamics, due to the reaction's reversibilty. It is however, a relatively common process in biosynthesis,[3] and many natural products have been found that include either a dihydropyran motif, or a derivative thereof. Several biomimetic syntheses and related studies have been carried out that support the involvement of pericyclic reaction cascades in a number of biosynthetic pathways (*vide infra*).



(1)

One of the more common and versatile strategies for constructing substituted dihydropyrans is via domino Knoevenagel/6π electrocyclization (Scheme 44).[76] For instance, acyclic acetoacetates **227** may be condensed with enals **228** bearing a C2

substituent ($R^3 \neq H$) to favor 1,2-addition with (*E*)-selectivity, granting access to dihydropyrans **229a–c** in good yield at ambient temperature.[77] Several natural product syntheses have employed similar domino sequences, among them being an approach to the cortistatins,[78] wherein enal **230** was condensed with cyclohexane-1,3-dione under Knoevenagel conditions to give diketone **231** that spontaneously cyclized to dihydropyran **232** in 5:1 dr with respect to the newly formed stereocenter. This type of sequence has been proposed to occur in various biosynthetic cascades, and has been used in biomimetic approaches to natural products. An illustrative example is provided by the condensation of naphthoquinone **233** with dialdehyde **234** in the presence of ethylenediamine diacetate (EDDA) (Scheme 45).[79] The initial condensation product, triketone **235**, underwent an oxa-6π electrocyclic ring closure, followed by an intramolecular hetero Diels–Alder reaction (*see* Chapter 5.10) to afford the natural product pinnatal **237** in low yield. Significantly higher yields could be obtained starting from the same naphthoquinone **233** by executing stepwise transformations rather than the threefold domino process.

An interesting method to generate the requisite oxatriene system includes the nucleophilic cycloisomerization of diketone **238** (Scheme 46).[80] To this effect, nucleophilic conjugate addition of 1,4-diazabicyclo[2.2.2]octane (DABCO) to enone **238** and subsequent intramolecular conjugate addition of the resulting enolate to the alkyne acceptor formed the Baylis–Hilman-like zwitterion **239**. Elimination of DABCO unmasked the oxatriene **240**, which then underwent facile oxa-6π electrocyclization to give (+)-harziphilone.

Chromenes, which are present in a variety of natural products, are often prepared by oxa-6π electrocyclization onto an aromatic ring. However, it has also been demonstrated that both rings of a chromene **246** may be constructed simultaneously (Scheme 47).[81] Combining enyne **242** with Fischer carbene **243** (*see* Chapter 5.25) resulted first in benzannulation to form phenol **244**, which readily ejected the silyl ether to give *o*-quinone methide **245** that engaged in 6π electrocyclic ring closure to restore aromaticity. The corresponding chromium arene complex (not shown) of **246** was then treated with an iron (III) salt to oxidatively remove chromium, enabling the isolation of chromene **246** in excellent yield.

The Claisen rearrangement of propargyl vinyl ethers, either thermal or metal-catalyzed,[82] represents an additional avenue for the generation of oxatriene systems, particularly when the vinyl terminus bears a suitable electron-withdrawing group as in propargyl ether **247** (Scheme 48). Activation of the alkyne moiety with a silver(I) salt elicited a propargyl-Claisen rearrangement, giving rise to allene **248**. Subsequent base-promoted isomerization to the oxatriene system **249** was facilitated by the presence of the ethyl ester, after which 6π electrocyclization led to the efficient production of various substituted dihydropyrans **250a–e**.

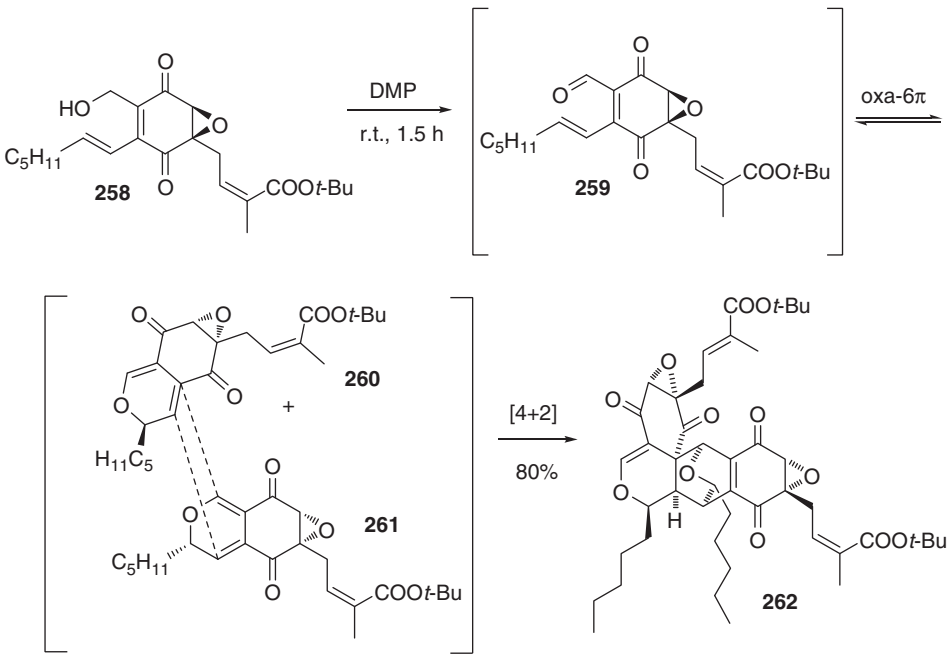
A powerful diastereoselective Stille coupling/oxa-6π electrocyclization methodology was borne out of an approach to the polycyclic pyran core of the natural product saudin.[83] The cross-coupling of racemic 2-stannyl-enone **252** and vinyl iodide **251** in the dark (to prevent alkene isomerization) at room temperature efficiently furnished dihydropyrans **254a–c** as single diastereomers via a



pentadienone **253** (Scheme 49).[84] Reversing the coupling partner's polarities, using a vinyl stannane **255** and a 2-iodo enone **256** led to comparable reaction yields, making this a highly versatile entry into bi/tricyclic pyran-containing scaffolds.[85]

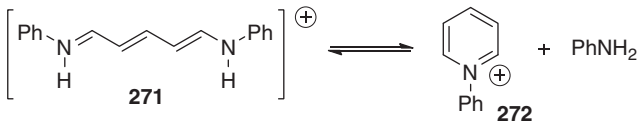
Several dimeric natural products have been discovered which incroporate oxa-6π electrocyclizations into their biosynthetic pathways. For example, the epoxyquinone natural product (+)-torreyanic acid has been proposed to originate from the Diels–Alder heterodimerization (*see* Chapter 5.09) of two diastereomeric 2*H*-pyrans **260** and **261**, which in turn are formed by a nondiastereoselective oxa-6π electrocyclic ring-closing (Scheme 50).[86] This hypothesis has been verified by synthesis, whereby

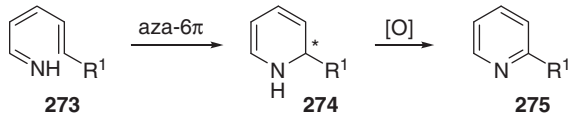
Scheme 50 The biomimetic total synthesis of (+)-torreyanic acid. Adapted from Li, C.; Johnson, R. P.; Porco, J. A., Jr. *J. Am. Chem. Soc.* **2003**, *125*, 5095, and Kleinke, A. S.; Li, C.; Rabasso, N.; Porco, J. A., Jr. *Org. Lett.* **2006**, *8*, 2847.

enantiomerically pure allylic alcohol **258** was oxidized with Dess–Martin periodinane, initiating the cascade via aldehyde **259**. The ensuing unselective oxa-6π electrocyclization gave a mixture of 2*H*-pyran diastereomers **260** and **261** that underwent Diels–Alder cross-dimerization to deliver the *tert*-butyl ester of (+)-torreyanic acid **262** as a single diastereomer in good yield. The selectivity appears to stem from an *endo*-selective Diels–Alder that orients the alkyl side chains *anti* to each other and occurs with facial selectivity *anti* to the epoxide.



In the same vein, a biomimetic approach to the epoxyquinols A **268**, B **269**, and C **270**, as well as epoxytwinol **267** was established based on a similar reaction sequence (Scheme 51).[87] Selective oxidation of allylic alcohol **263** under mild conditions allowed for the isolation of pentadienal **265**, which on stirring in toluene at room temperature underwent a nondiastereoselective oxa-6π electrocyclization and then various modes of dimerization to yield a mixture of the epoxyquinols A-C and epoxytwinol **267**, all of which had also been previously isolated from the same soil fungus. Epoxyquinol C **270** is known to be formed from epoxyquinol A **267** by microwave irradiation,[88] and epoxytwinol **267** gradually converts to epoxyquinol B **269** on standing, which suggests the reactions are reversible and the observed product mixture is a consequence of thermodynamics. The high selectivity and spontaneous reactivity of the oxa-6π/dimerization manifold hints that enzymes are unlikely to be involved in the process.

Scheme 51 Dimerization modes of epoxy-2*H*-pyrans. Reproduced from Shoji, M.; Kishida, S.; Kodera, Y.; *et al. Tetrahedron Lett.* **2003**, *44*, 7205.

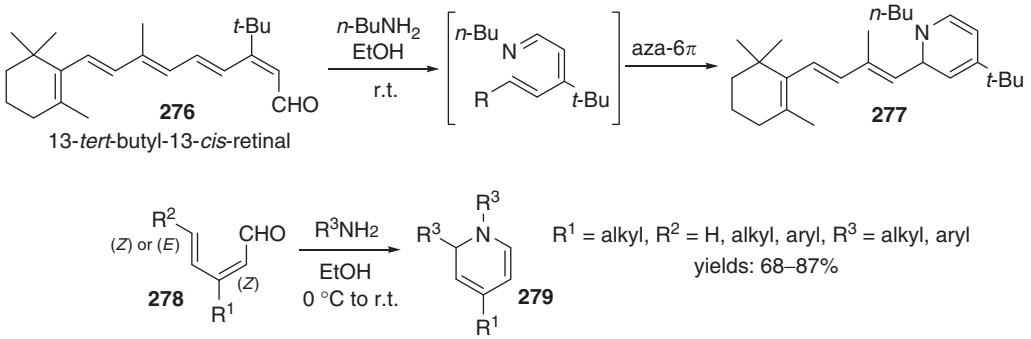


5.17.4 Aza-6π Electrocyclizations

Useful synthetic reactions involving aza-6π electrocyclizations of 1-azatrienes have been known for over a century, predating the mechanistic understanding of such processes. Of particular note is the ring-opening/ring-closing of König's salts **271** and pyridinum cations, that were studied by Zincke,[89] as well as Marvell (Equation 2).[90]

(2)

In general, aza-6π electrocyclic ring closure of 1-azatrienes **273** to 1,3-dihydropyridines **274** is exothermic, barring any additional substituent effects that might strongly perturb the system (Equation 3).[4a] The products are often easily oxidized to pyridines **275**, which has in many cases been used as an efficient route to such compounds. Aza-6π electrocyclizations tend to possess lower activation energy barriers than their 1,3,5-hexatriene counterparts, but usually occur at lower rates than oxa-6π electrocyclizations. Substitution at the *N*-terminus can have a profound effect on reaction rates for (*E*)/(*Z*) configurationally stable imines or oximes, where (*E*)-substrates normally cyclize more rapidly due to sterics.[4] There are three possible isomeric azatriene systems, all of which are able to participate in electrocyclic reactions,[4] but 1-azatrienes are the most well-studied and will be the main focus of this section.

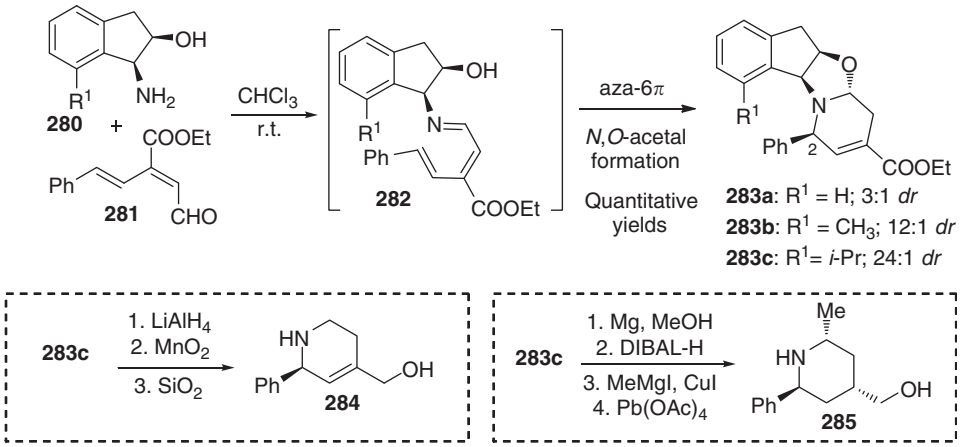


(3)

5.17.4.1 Formation of 1,2-Dihydropyridines

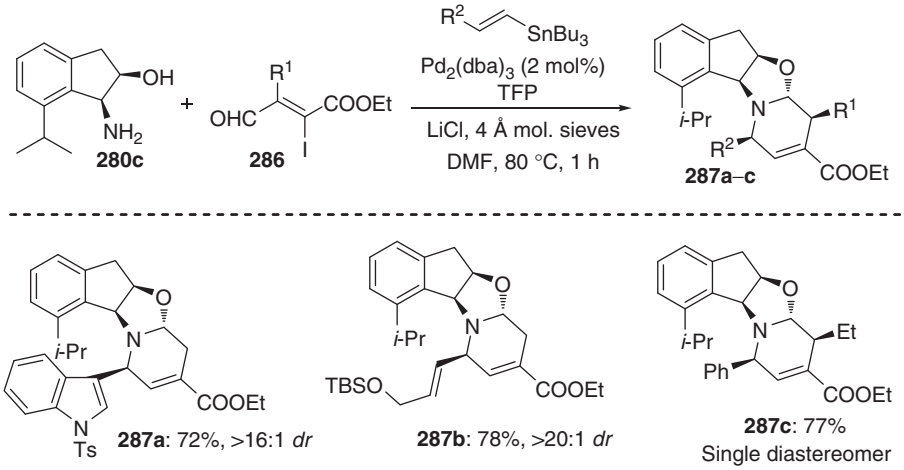
5.17.4.1.1 Thermochemical processes

In the late 1980s, it was discovered that 13-*tert*-butyl-13-*cis*-retinal **276** condenses with *n*-butylamine to form 1,3-dihydropyridine **277** quantitatively at room temperature (Scheme 52).[91] This provided the inspiration for studying the formation of simple 1,3-dihydropyridines **279** by the condensation reaction between a dienal **278** and a primary amine.[92] In the early report, the investigators expressed curiosity toward the propensity of 13-*cis*-retinal **276** to undergo aza-electrocyclization so readily, while the parent oxa-system does not cyclize to the corresponding 1,3-dihydropyran. A likely explanation is that the oxa- and aza-electrocyclizations both occur, but are reversible and the more thermodynamically stable product predominates in each case. Kinetic parameters for the general aza-6π-electrocyclization were measured, and the activation energies were found to be in the range of 17.5–22.5 kcal mol^{-1}, which is approximately 5–10 kcal mol^{-1} lower than typical all-carbon 1,3,5-hexatriene systems. The methodology is also quite useful, and efficiently produces substituted 1,3-dihydropyridines **279** provided a (2*Z*)-dienal **278** is employed.



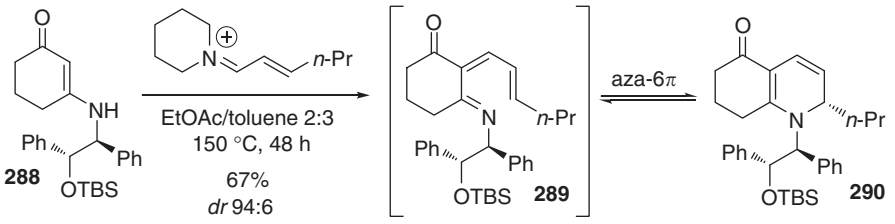
Scheme 52 Formation of 1,3-dihydropyridines by condensation/6π electrocyclization. Adapted from De Lera, A. R.; Reischl, W.; Okamura, W. H. *J. Am. Chem. Soc.* **1989**, *111*, 4051; Maynard, D.; Okamura, W. H. *J. Org. Chem.* **1995**, *60*, 1763, and Tanaka, K.; Mori, H.; Yamamoto, M.; Katsumura, S. *J. Org. Chem.* **2001**, *66*, 3099.

Condensing a chiral amine with a dienal can allow for diastereoselective aza-6π electrocyclizations and removable chiral auxiliaries have been used with some success. For example, 2-aminoindanol chiral auxiliaries **280** were shown to readily condense with dienal **280**, forming the corresponding 1-azatrienes **282** that undergo aza-6π electrocyclic ring-closing accompanied by tautomerization/*N*,*O*-acetal formation to give tetrahydropyridines **283a–c** in moderate to good diastereoselectivity with respect to the 2-position (Scheme 53).[93] The products are essentially 1,3-dihydropyridine synthons and can be easily modified to give useful synthetic building blocks. Auxiliary removal can be accomplished by treating the product *N*,*O*-acetal **283c** in series with $LiAlH_4$ and then MnO_2, followed by silica gel to afford the enantioenriched tetrahydropyridine derivative **284**. Additionally, substituted piperidines **285** can be synthesized asymmetrically in good overall yield by stereoselective conjugate reduction of unsatutared ester **283c** with Mg in methanol, ester reduction with diisobutylaluminum hydride (DIBAL-H), ring-opening of the *N*,*O*-acetal by Grignard addition and finally oxidative cleavage of the aminoindanol auxiliary with $Pb(OAc)_4$.



Using the 2-aminoindanol auxiliary **280c** deemed to be optimal in the previous example, it was possible to streamline the methodology, making it a multicomponent reaction featuring the Stille coupling of a *β*-iodo-enal **286** and an appropriate vinyl stannane (Scheme 54).[94] The R^2 substituent was limited to attachment via a non-sp^3 hybridized carbon, but alkenes could be used such as in tetrahydropyridine **287b**, which were later reduced to install an alkyl side chain. The value of this method has been exemplified by its use in the total synthesis of several piperidine alkaloids.[95]

Vinylogous amides **288** bearing a removable chiral auxiliary have also been used to direct stereoselective aza-6π electrocyclic ring closures (Scheme 55).[96] Using an iminium ion as the electrophile rather than an enal promoted selective 1,2-addition with loss of piperidine to give chiral 1-azatriene **289** that underwent reversible 6π electrocyclization to give 1,3-dihydropyridine **290** as the more thermodynamically stable diastereomer. Subsequent removal of the auxiliary was possible via palladium-catalyzed hydrogenolysis of the benzylic C–N bond.



Repositioning the chiral functional group to the *C*-terminus of the imminium ion **291** was somewhat less effective, typically resulting in lower levels of diastereoselectivity (Scheme 56).[97] Generally, during the aza-electrocyclization step, bulkier *C*-terminal and *N*-terminal substituents exhibited a trade-off of higher selectivity at the cost of a lower yield, whereas using smaller

Scheme 53 Aza-6π electrocyclization using a 1,2-aminoindanol-derived chiral auxiliary. Reproduced from Tanaka, K.; Kobayashi, T.; Mori, H.; Katsumura, S. *J. Org. Chem.* **2004**, *69*, 5906.

substituents sacrificed diastereoselectivity for increased yields. It was possible to thermally equilibrate a 1:1 mixture of lactone **293b** to favor the major diastereomer, but doing so required significantly higher temperature (250 °C) compared to that of the reaction temperature, suggesting that thermodynamics may not be the determining factor in reaction selectivity and some element of kinetic control may be operative.

As seen earlier in this chapter in Scheme 48, the propargyl-Claisen rearrangement of propargyl vinyl ethers **294** bearing a suitable electron-withdrawing group at the vinyl terminus offers convenient entry into 1-oxatriene systems via base-mediated isomerization of allene intermediates **295** (Scheme 57). The Claisen rearrangement (*see* Chapter 5.20) can be carried out

Scheme 56 Torquoselective 6π electrocyclization of 1-azatrienes with *C*-terminal chiral substituents. Reproduced from Sydorenko, N.; Hsung, R.; Vera, E. *Org. Lett.* **2006**, *8*, 2611.

thermally under microwave irradiation at elevated temperature,[98] or at room temperature in the presence of a gold(I)/silver(I) catalytic system.[99] The normal mode of oxa-6π electrocyclization can be intercepted by a primary amine, generating a 1-azatriene intermediate **296** that undergoes aza-6π electrocyclic ring-closing to give substituted 1,3-dihydropyridines **297a–d**.

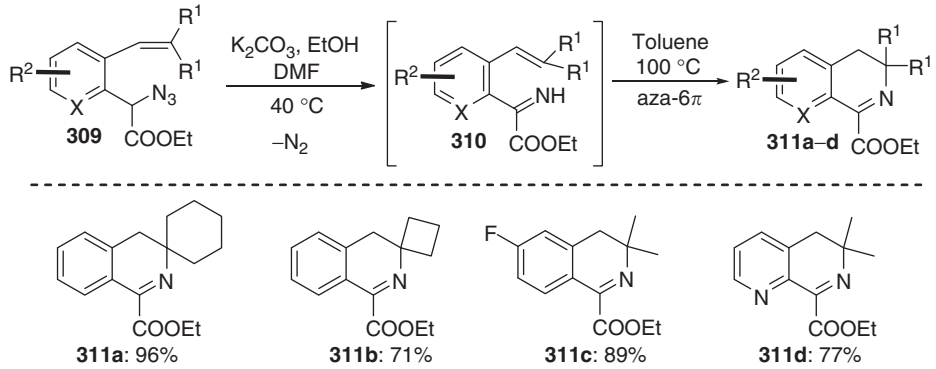
The rhodium(I)-catalyzed β-C–H bond activation (*see* Chapter 5.32) of α,β-unsaturated imines **298** and subsequent addition across alkynes can be used as a means of access to fully-substituted 1-azatrienes **299** that undergo *in situ* aza-6π electrocyclization to 1,3-dihydropyridines **300** (Scheme 58).[100] The 1,3-dihydropyridine **300** can be isolated, or tautomerized to the iminium species **301** using acetic acid, followed by reduction with a borohydride reagent to yield single diastereomers of various fully-substituted tetrahydropyridines **302a–d** in good yield.

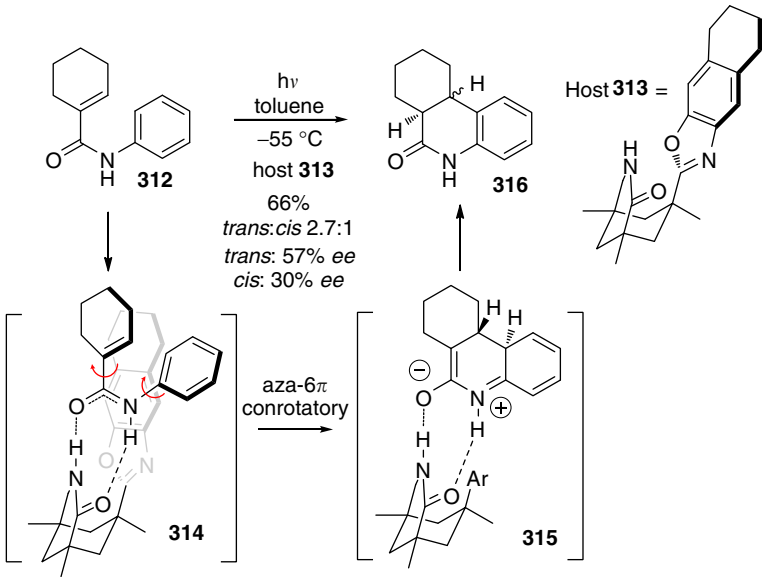
When the alkyne functionality is instead tethered to the α,β-unsaturated imines through the nitrogen, unusual strained bicyclic 1,3-dihydropyridine systems **308** can be obtained by rhodium(I)-catalyzed cycloisomerization/aza-6π electrocyclization (Scheme 59).[101] The proposed catalytic cycle begins with bidentate coordination of the metal center to the chiral imine **303** via its alkyne and imine lone pair to give complex **304**. The rhodium center is then posited to undergo C–H insertion with the proximal alkene to form the rhodium-hydride complex **305**, which is followed by intramolecular hydrorhodation of the alkyne to afford

Scheme 58 Tetrahydropyridine synthesis by C–H activation/aza-6π electrocyclization/reduction. Reproduced from Duttwyler, S.; Lu, C.; Rheingold, A. L.; Bergman, R. G.; Ellman, J. A. *J. Am. Chem. Soc.* **2012**, *134*, 4064.

10-membered rhodacycle **306**. Subsequent reductive elimination to triene **307** and aza-6π electrocyclization would give rise to the strained *anti*-Bredt enamine **308** as a single diastereomer.



Scheme 59 Synthesis of anti-Bredt bicyclic enamines by Rh-catalyzed cycloisomerization/6π electrocyclization. Reproduced from Yotphan, S.; Bergman, R. G.; Ellman, J. A. *J. Am. Chem. Soc.* **2008**, *130*, 2452.



An additional mode of entry to 1-azatriene systems is the base-mediated decomposition of α-azido esters **309** (Scheme 60).[102] Gentle heating of such azides **309** with a mild base was found to induce elimination of N_2 to form 1-azatrienes of type **310**. Dilution of the reaction medium with toluene and increasing the temperature to 100 °C permitted aza-6π electrocyclic ring closure that was followed by tautomerization to give dihydroisoquinolines **311a–d**. It is noteworthy that electrocyclizations of *N*-H imines are quite rare.[103]

5.17.4.1.2 Photochemical processes

A number of studies have been conducted aimed at developing enantioselective photochemical aza-6π electrocyclizations using a host–guest inclusion strategy,[104–106] but so far have mostly led to only modest levels of asymmetric induction. For instance, irradiation of anilide **312** in the presence of the chiral host **313** at −55 °C in toluene produces *trans*- and *cis*-tricycle **314** in a 2.7:1 ratio with 57% and 30% *ee* respectively (Scheme 61).[104] The selectivity model entails a host–guest complex **314** that is held together by a bidentate hydrogen-bonding interaction. The guest's cyclohexene moiety is proposed to reside in the host's chiral pocket and torquoselective outward conrotation is proposed to minimize unfavorable steric interactions with the host's axial tetrahydronaphthalene substituent, rendering the cyclohexene Si-face susceptible to attack from the aromatic ring. Finally, the

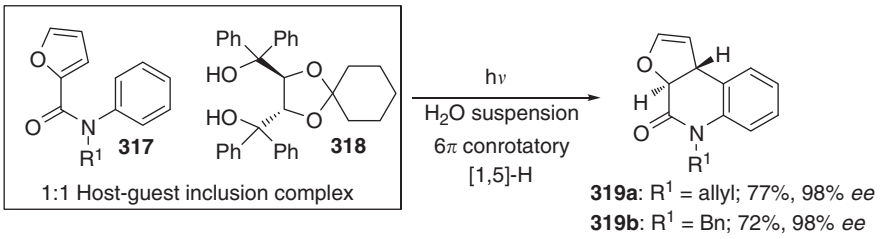
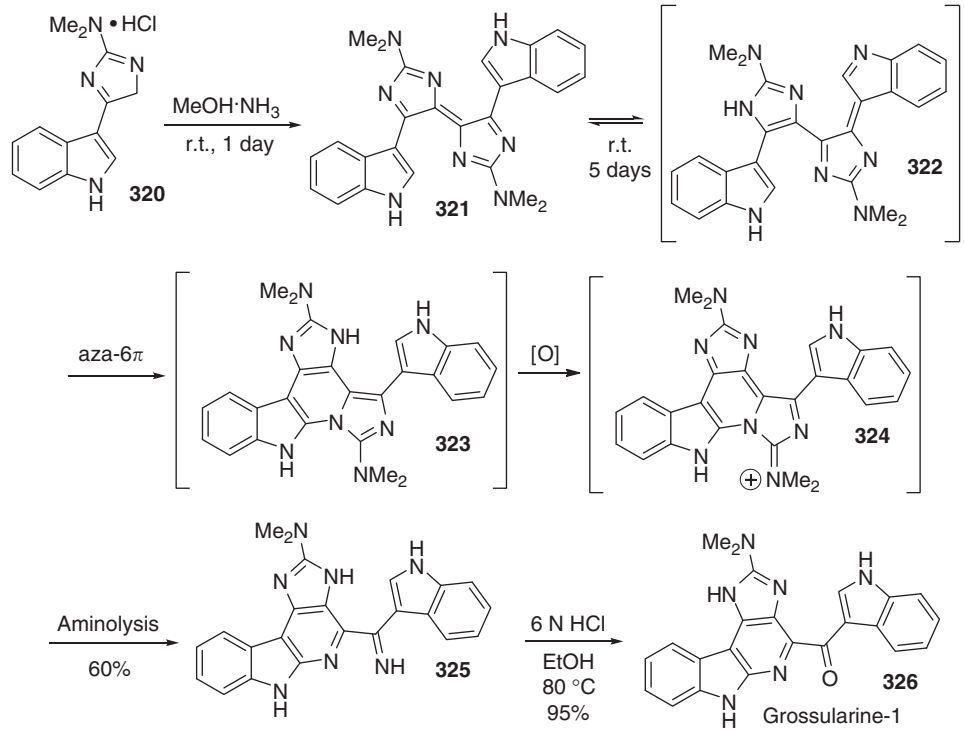


Scheme 61 Solution phase asymmetric photochemical aza-6π electrocyclization in a host-guest inclusion complex. Reproduced from Bach, T.; Grosch, B.; Strassner, T.; Herdtweck, E. *J. Org. Chem.* **2003**, *68*, 1107.

tricyclic product **316** is liberated from the host by diastereoselective protonation of intermediate **315**, providing a reason for the observed disparity in enantiomeric excesses between the *cis* and *trans* products.

The solution phase photochemical conversion of acrylanilides **312** to the corresponding tricyclic amides **316** has been known for some time and occurs readily,[107] presenting a challenge for the development of an asymmetric process since the background reaction leading to racemic product is relatively facile. Very high levels of asymmetric induction have been observed, however, for the solid phase photochemical conversion of aryl and furyl carboxyanilides **317** to tricyclic amides **319** by irradiation of a crystalline 1:1 host–guest complex suspended in water.[105] The reaction is believed to proceed by conrotatory ring closure dictated by the chirality of the inclusion complex, followed by a suprafacial [1,5]-hydrogen shift driven by the gain in aromatic stabilization energy. The solid-state structures of various related host–guest complexes have been studied and some were characterized by X-ray crystallography (Scheme 62).[106]

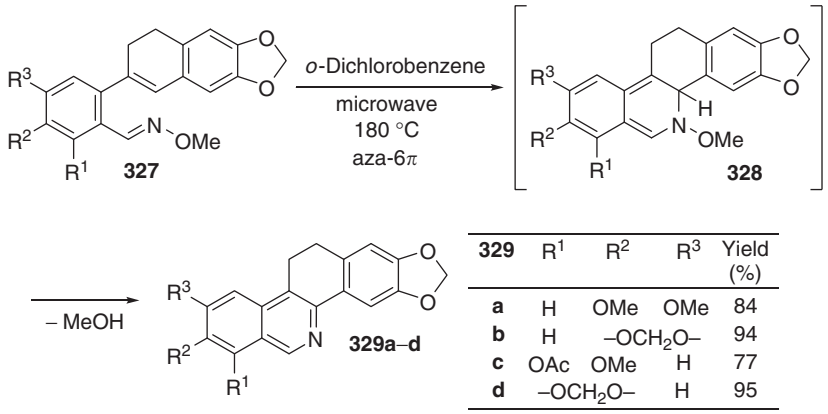


5.17.4.2 Aza-6π Electrocyclizations as a Method to Access Pyridines

As with all-carbon 1,3,5-hexatriene systems, 1-azatrienes offer a point of entry to aromatic compounds via 6π electrocyclization and subsequent oxidation. This sequence was proposed to be involved in the biosynthesis of grossularine-1 **326**, an α-carboline metabolite that exhibits pronounced effects against human tumor cell lines.[108] This proposal was confirmed by an elegant synthesis of grossularine-1 **326** in two steps from indole **320** (Scheme 63).[109] To this effect, indole **320** upon standing in methanol saturated with ammonia, underwent oxidative dimerization to bis-indole **321** that tautomerized to a 1-azatriene **322**,

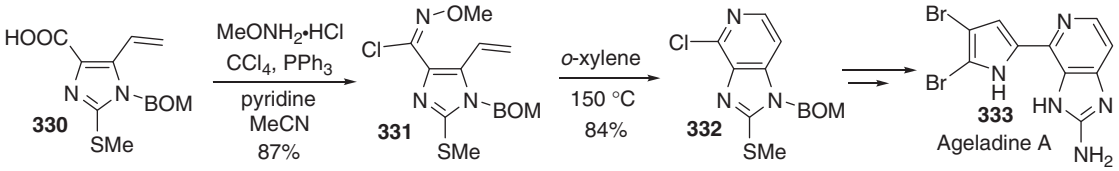
Scheme 62 Solid phase asymmetric photochemical aza-6π electrocyclization in a host-guest inclusion complex. Reproduced from Toda, F.; Miyamoto, H.; Kanemoto, K.; *et al. J. Org. Chem.* **1999**, *64*, 2096.

which in turn participated in an aza-6π electrocyclization to form 1,3-dihydropyridine **323**. An oxidation event resulted in putative guanidinium cation **324**, which after aminolysis allowed for the isolation of *N*-H imine **325** in a remarkable 60% overall yield from indole **320**. Simple imine hydrolysis under acidic conditions gave the natural product grossularine-1 **326**.



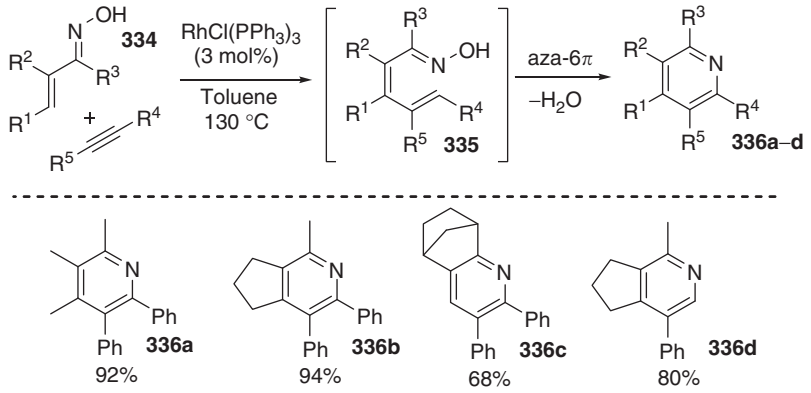
Scheme 63 Biomimetic synthesis of grossularine-1. Reproduced from Miyake, F.; Yakushijin, K.; Horne, D. *Angew. Chem. Int. Ed.* **2005**, *44*, 3280.

The subsequent oxidative aromatization step can be omitted from pyridine synthesis by including an appropriate leaving group on the triene *N*-terminus, as is the case with oximes and oxime ethers. A range of natural products have been synthesized using this particular strategy.[110] Of note is the preparation of a large number benzo[*c*]phenanthridine alkaloids, natural products possessing a wide range of interesting pharmacological properties,[111] starting from substituted oxime ethers **327** (Scheme 64).[112] Heating the latter to 180 °C with microwave irradiation results in aza-6π electrocyclization to a pentacycle **328**, which readily eliminates methanol to yield various phenanthridines **329a–d**.



The aza-6π electrocyclization of oxime ethers can provide expedient access to pyridines with substitution patterns that are more difficult to make by conventional cyclocondensation methods. In a total synthesis of ageladine A **333**,[113] a zinc matrixmetalloproteinase inhibitor, carboxylic acid **330** was directly converted into α-chloro oxime ether **331** (Scheme 65).[114] Thermal aza-6π electrocyclic ring closure by heating in *o*-xylene, followed by the elimination of methanol, gave pyridine **332**, which was later successfully used to assemble the natural product ageladine A **333**.

A number of related methodologies have been developed using the rhodium-catalyzed β-C – H bond activation of α,β-unsaturated imines and ketoximes for the synthesis of highly substituted pyridines (See also Scheme 58).[115] Using Wilkinson's catalyst, ketoximes **334** have been shown to undergo β-C – H bond functionalization and addition across alkynes to give pentadienyl oxime intermediates **335**, which are susceptible to aza-6π electrocyclization accompanied by dehydration under the reaction conditions (Scheme 66).[116]



329	R^1	R^2	R^3	Yield (%)
a	H	OMe	OMe	84

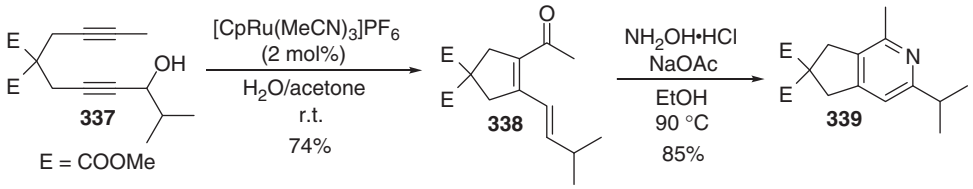
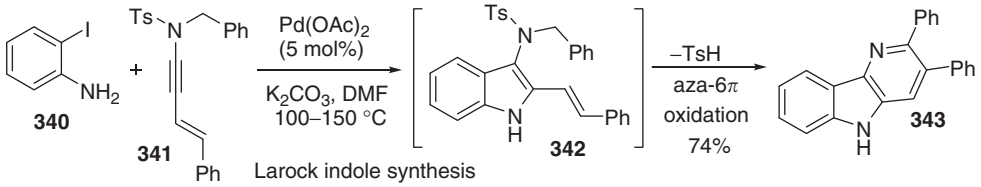


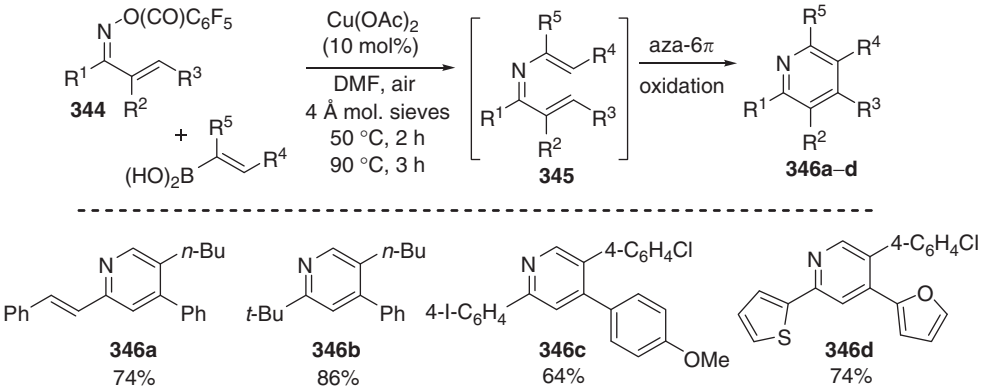
Scheme 65 Aza-6π electrocyclization of an α-chloro oxime ether. Reproduced from Kikugawa, Y.; Fu, L. H.; Sakamoto, T. *Synth. Commun.* **1993**, *23*, 1061.



Scheme 66 Rh-catalyzed one-pot synthesis of pyridines from ketoximes and alkynes. Reproduced from Parthasarathy, K.; Jeganmohan, M.; Cheng, C.-H. *Org. Lett.* **2008**, *10*, 325.

Direct condensation of hydroxylamine hydrochloride with a dienyl ketone **338** can result in the formation of a substituted pyridine **339** by oxime formation, aza-6π electrocyclization and dehydration (Scheme 67).[93,117] In this case, cyclic dienyl ketones **338** were prepared by the ruthenium-catalyzed cycloisomerization of diynol **337** and a range of five-membered ring-fused 2,3,4,6-substituted pyridines **339** could be prepared in only a few steps.[118]

The use of both 2- and 3-azatrienes to synthesize pyridines has been described as well, although to a much more limited extent.[4] Nevertheless, some interesting methodologies making use of these approaches have been reported, such as using *N*-tosyl-enynamines **341** as alkyne acceptors in the Larock indole synthesis (Scheme 68).[119] Along these lines, employing iodoaniline **340** as a coupling partner, intermediate indole **342** is produced, which undergoes base-mediated elimination of the *N*-tosyl group to form a 2-azatriene system (not shown) that engages in a 6π electrocyclization and concomitant autoxidation to yield δ-carboline **343**. This mechanistic proposal was based on the fact that both indole **342** and the aforementioned 2-azatriene intermediate could both be isolated from the reaction mixture when the reaction was performed at lower temperatures.



Scheme 67 Sequential Ru-catalyzed cycloisomerization and pyridine synthesis via ketoxime formation. Reproduced from Schiess, P.; Chia, H.; Ringele, P. *Tetrahedron Lett.* **1972**, *13*, 313.

Scheme 68 Synthesis of δ-carbolines by chaining the Larock indole synthesis with 2-azatriene 6π electrocyclization. Reproduced from Cao, J.; Xu, Y.; Kong, Y.; *et al. Org. Lett.* **2012**, *14*, 38.

Of additional note is the copper-catalyzed C–N coupling of an α,β-unsaturated ketoxime *O*-pentafluorobenzoate **344** with a vinyl boronic acid, which proceeds via 3-azatriene intermediate **345** to generate highly substituted pyridines **346a–d** by aza-6π electrocyclization and subsequent autoxidation (Scheme 69).[120] The reaction is remarkably functional group tolerant, and leaves aryl halides (including iodide), esters, nitriles and nitro groups untouched. The R^1 substituent is limited to groups that do not posses C(sp^3) – H bonds, since it enables [1,5]-hydrogen shifts that compete with the desired 6π electrocyclization.

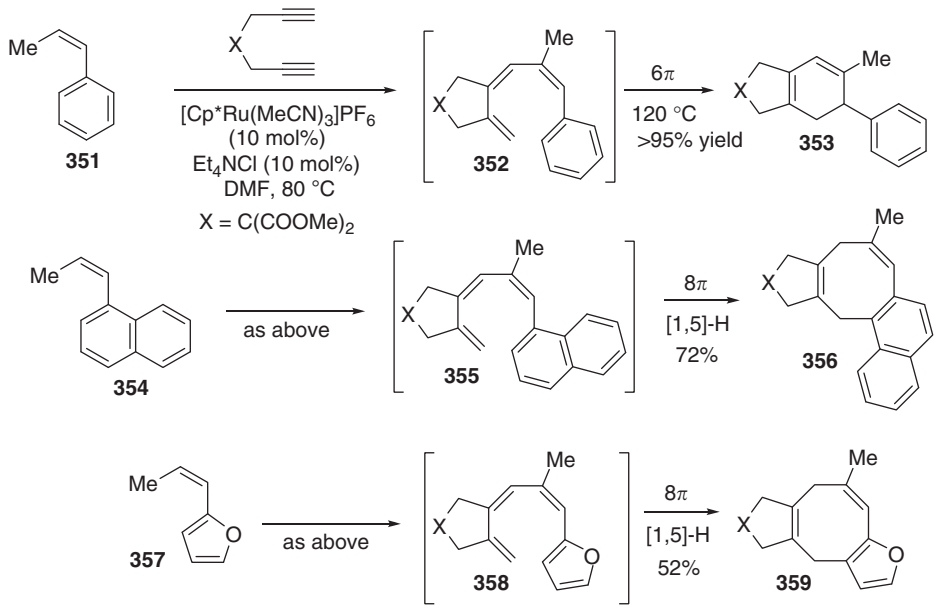
5.17.5 8π-6π Electrocyclization Cascades

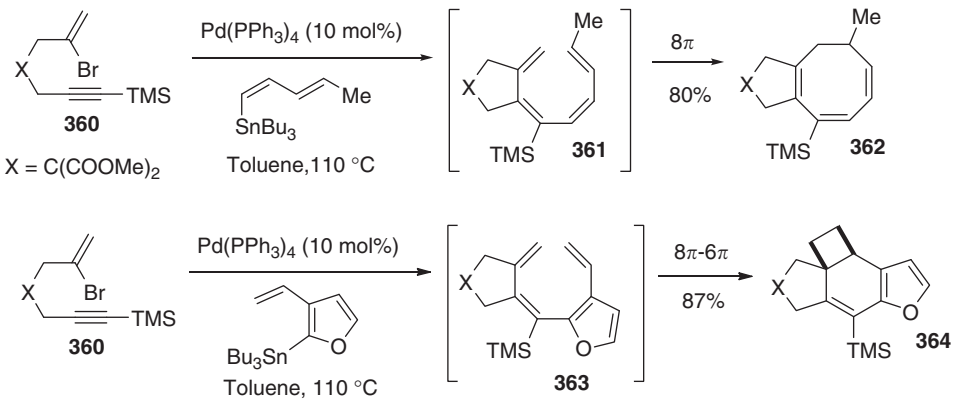
5.17.5.1 General Reactivity of 1,3,5,7-Octatetraene Systems



Conjugated tetraenes with (*Z*,*Z*)-substituted double bonds in their center, such as **347** or **348**, undergo rapid conrotatory 8π electrocyclization to afford cyclooctatrienes **349**, which is usually followed by a disrotatory 6π electrocyclization affording bicyclo[4.2.0]octa-2,4-diene products **350** (Scheme 70).[4] This unusually facile second ring closure is attributed to the fixed (*Z*)-alkene stereochemistry of the central double bond and the cyclic geometry, which brings the 1,3,5-triene termini into close proximity. Early on, it was recognized that 1,3,5-cyclooctatriene is in equilibrium with bicyclo[4.2.0]octa-2,4-diene at 80 °C via 6π electrocyclic ring-closing/ring-opening.[121] The conrotatory nature of 8π electrocyclizations has been firmly established, believed to occur by a Möbius aromatic transition state.[122] Its helical character has been proposed to account for the increased rate of cyclization over typical 6π processes, owing to a lack of strain and steric congestion in the transition state at the reacting termini of the tetraene.[123] It is worth noting that the same product (**349**) can arise from two different tetraene precursors whose two terminal

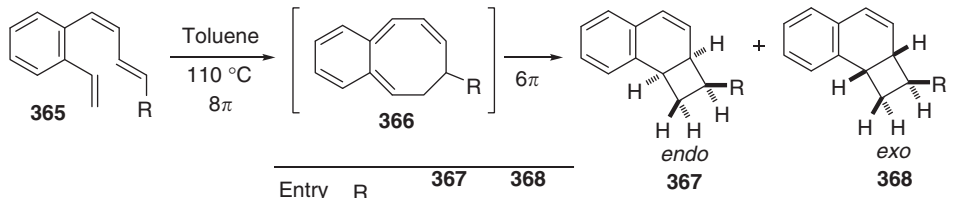
double bonds are both of opposite configuration (**347** vs. **348**). As with other electrocyclizations possessing low activation energy barriers, the 8π electrocyclization is also often reversible and thus under thermodynamic control, complicating the predictability of the various isomers resulting from such cascades.

Scheme 70 The 8π-6π electrocyclization cascade.



Although the 8π cyclization mode of 1,3,5,7-tetraenes tends to be significantly faster than 6π cyclization, there are certain cases where the two pathways compete, particularly under reaction conditions that allow for alkene isomerization,[4] since two (*Z*)-configured alkenes are required for the 8π cyclization. Interestingly, replacing one of the alkenes in the tetraene system with an aromatic ring can cause the two electrocyclization pathways to diverge, depending on the nature of the arene (Scheme 71).[124] For instance, the ruthenium-catalyzed cycloisomerization of diynes and addition to alkenes, such as styrene **351**, produces a 1,3,5,7-tetraene intermediate **352** that undergoes 6π electrocyclization at 120 °C to furnish 1,3-cyclohexadiene **353** in quantitative yield. Conversely, if the reaction is carried out with an arene other than benzene, as in naphthalene **354** or furan **357**, the intermediate tetraenes **355** and **358** preferentially react by 8π electrocyclization with concomitant [1,5]-hydrogen shift to restore aromaticity. This behavior has been attributed to the lesser degree of aromaticity in the latter substrates.

Scheme 71 Competition between 8π and 6π electrocyclizations decided by degree of aromaticity. Reproduced from García-Rubin, S.; Varela, J.; Castedo, L.; Saá, C. *Org. Lett.* **2009**, *11*, 983.

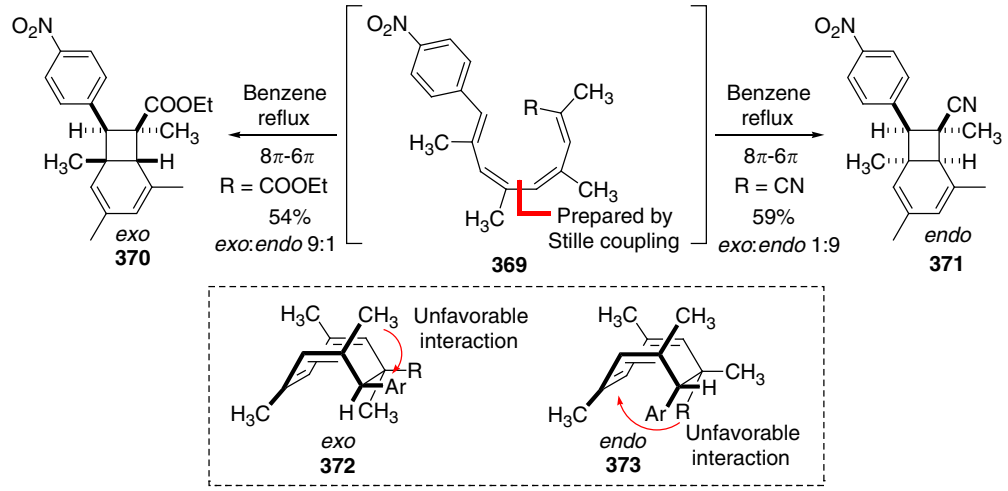


Even though 6π ring closure commonly succeeds 8π electrocyclizations, substrates with rings fused to the tetraene system can halt the cascade after the first step by imposing geometric constraints that disfavor the 6π ring-closing, or render competing processes operative, such as the [1,5]-hydrogen shift seen in the previous example. However, in some cases tetraene systems with fused rings can participate in 8π-6π cascades if there is a sufficient driving force for the second step. To illustrate, tetraene **361**, generated from the domino 5-*exo-dig* carbopalladation/Stille coupling of enyne **360**, undergoes facile 8π electrocyclization to 1,3,5-triene **362** without subsequent 6π ring-closing (Scheme 72).[125] By contrast, exchanging the Stille coupling partner gives rise

to tetraene **363** with an embedded furan ring, which engages in an 8π-6π cascade that is driven by rearomatization of the furan and proceeds in high efficiency despite forming a strained cyclobutane **364**.

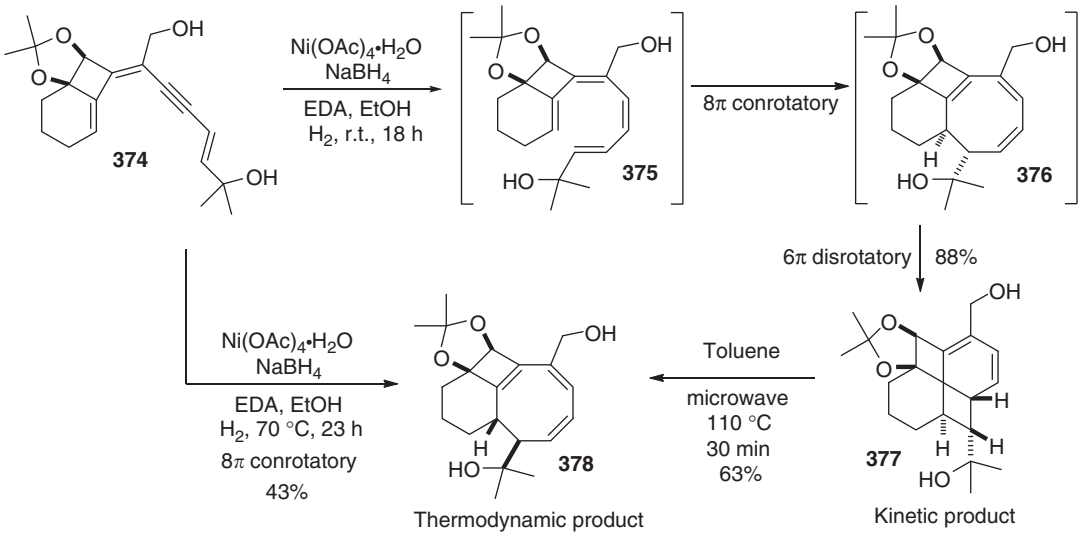
Scheme 72 An 8π-6π cascade driven by a gain in aromaticity. Reproduced from Kan, S. B. J.; Anderson, E. A. *Org. Lett.* **2008**, *10*, 2323.

When an aromatic ring is incorporated at the 3,4-position of a tetraene system rather than at the terminus, the 8π-6π cascade mode is strongly favored. Heating 3,4-benzo-fused tetraene **365** induces 8π cyclization to the triene system **366**, which is also an *o*-quinone dimethide, that undergoes a second electrocyclization to restore aromaticity and give bicyclo[4.2.0]octa-2,4-diene products **367**/**368**, with bulkier substituents leading to preferential formation of the *endo* product (Scheme 73).[126]



Entry	R	367 (%)	368 (%)
a	Me	33	11
b	Ph	73	–
c	2-furyl	56	–

Scheme 73 The 8π-6π cascade cyclization of [3,4]-benzo-octatetraenes. Reproduced from Skorić, I.; Pavoševic, F.; Vazdar, M.; *et al. Org. Biomol. Chem.* **2011**, *9*, 6771.

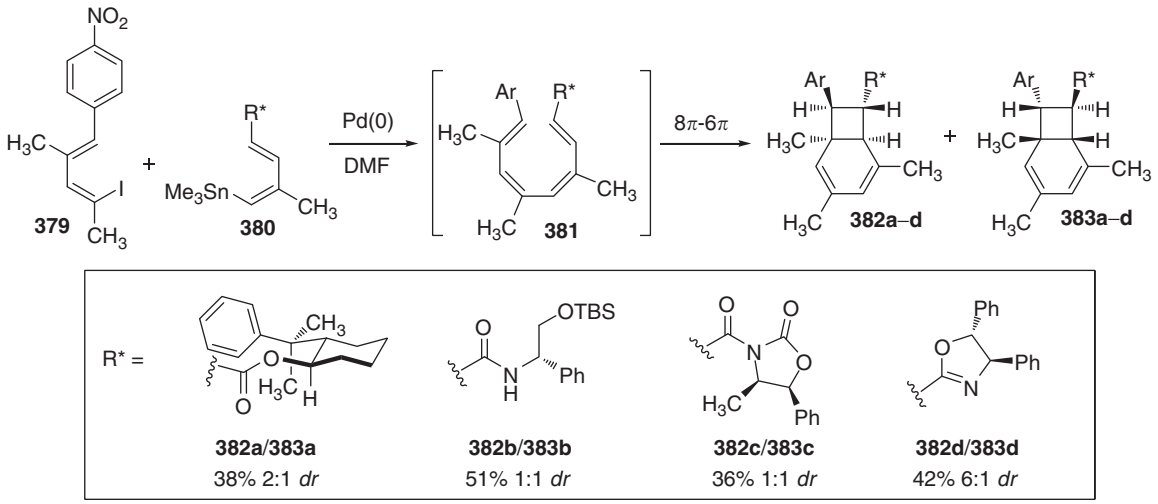


If the tetraene system has different substituents at its termini, diastereomeric *endo*/*exo* bicyclo[4.2.0]octa-2,4-diene products can be generated from the 6π electrocyclization step. The selectivity outcome can sometimes be difficult to predict, since it depends on the substituent interrelationships and can exhibit dramatic switches in *endo*/*exo* product distribution (Scheme 74).[127] For example, tetraene **369**, that was prepared *in situ* by Stille coupling, underwent 8π electrocyclization with subsequent *exo* selective 6π ring closure to bicyclo[4.2.0]octa-2,4-diene **370** when R═COOEt, but when R═CN, the 6π cyclization favored the *endo* bicyclo[4.2.0]octa-2,4-diene **371** instead. To account for this, a simple qualitative model was proposed based on the presumed conformer leading to 6π electrocyclization. The *exo* mode of cyclization **372** is presumed to incur an unfavorable steric interaction between the aryl group and the adjacent methyl substituent, making the *endo* mode **373** generally preferred for this type of substrate unless the R group is relatively large, in which case the R group prefers to be oriented outward from the cyclic system. In this example, the reduced steric demand of a nitrile substituent favors the *endo* product **371**, whereas the energetic benefit of orienting the ester substituent outward in *exo*-**372** outweighs the unfavorable aryl/methyl interaction and results in the predominant formation of *exo*-**370**.

Although induced stereoselectivity in 8π-6π cascades is little understood and has not been sufficiently studied, there are some examples where a high degree of substrate control was observed. An example in the synthesis of strained [4.6.4.6]-fenestradiene **377**, wherein enyne **374** was reduced with nickel boride at room temperature to give intermediate tetraene **375** (Scheme 75).[128] The ensuing 8π conrotatory/6π disrotatory ring closure yielded the product fenestradiene **377** as a single diastereomer. The initial conrotatory 8π cyclization was proposed to occur via a Möbius aromatic *M*-helical transition state, with the tetraene oriented on the same convex face as the acetonide moiety, which was supported by DFT calculations.[129] Further mechanistic studies revealed that fenestradiene **377** is actually the kinetic product, as reduction of enyne **374** at higher temperatures led to the formation of

Scheme 74 Control of bicyclo[4.2.0]octa-2,4-diene *endo*/*exo* selectivity by choice of substituent. Reproduced from Parker, K. A.; Lim, Y.-H. *Org. Lett.* **2004**, *6*, 161.

triene **378** instead, which was assigned as the thermodynamic minimum in this particular system. The cascade was shown to be reversible, since microwave heating of fenestradiene **377** also induced conversion into triene **378**.



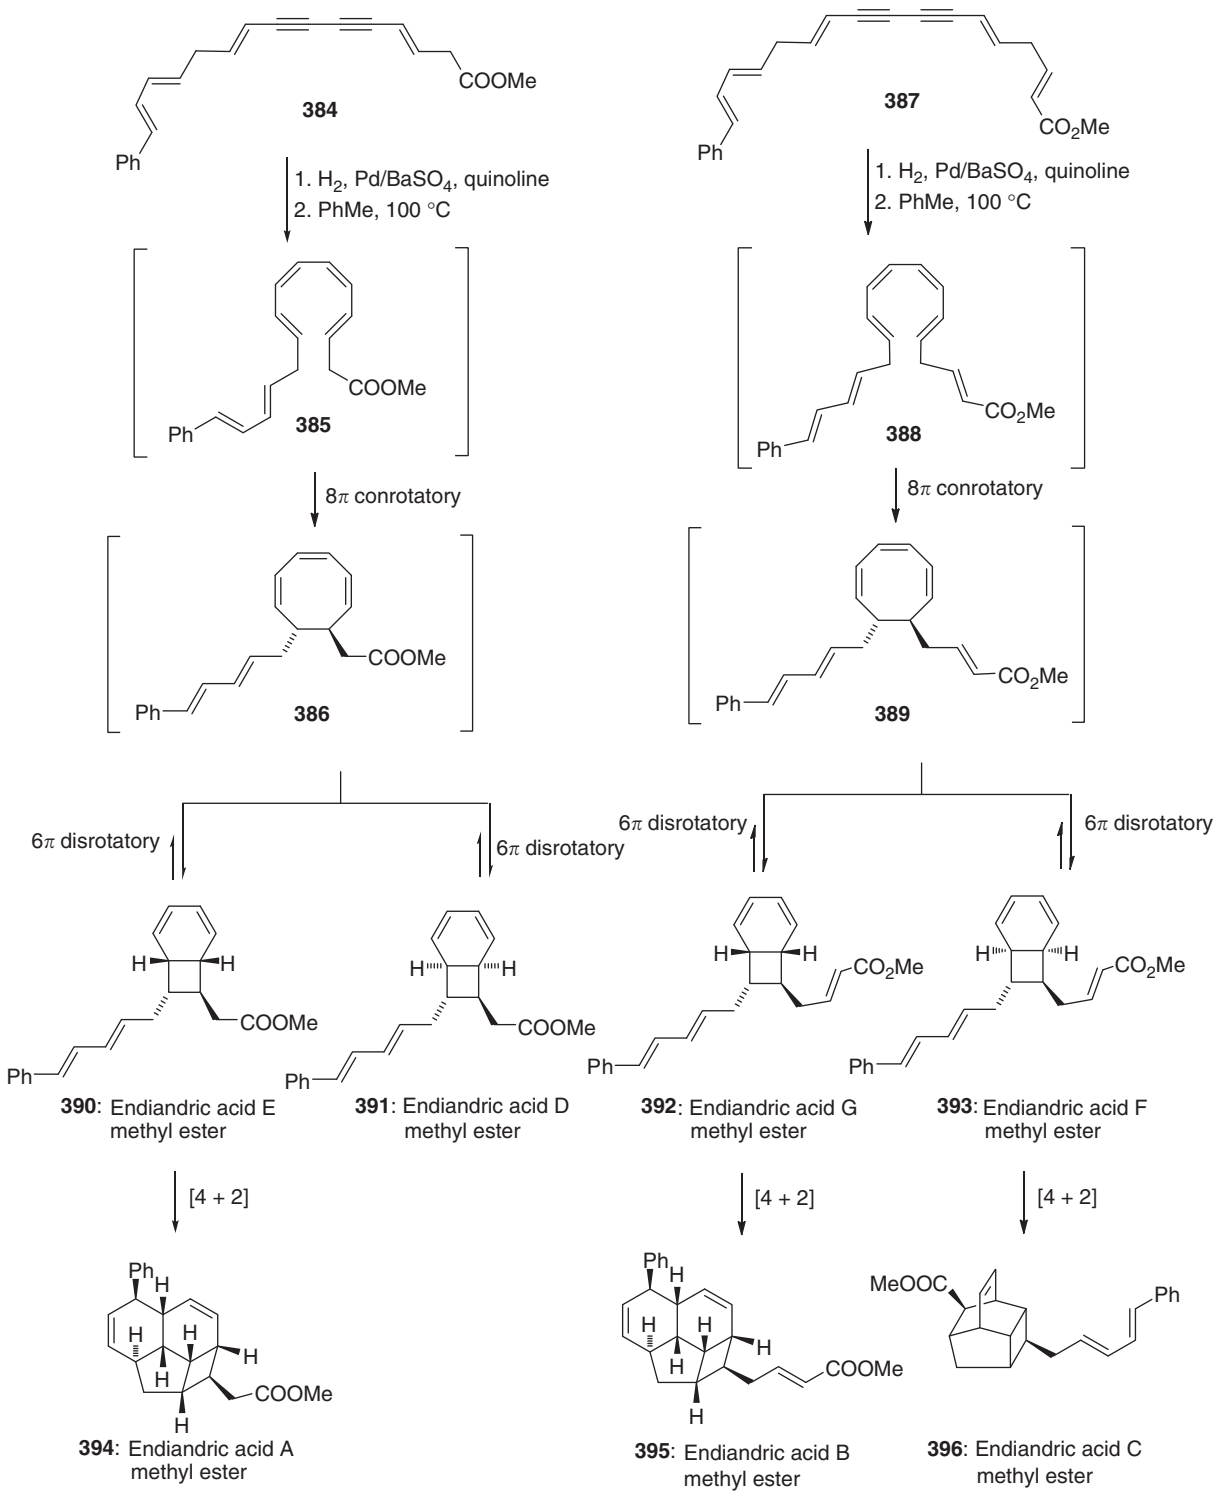
Scheme 75 Synthesis of fenestradienes base on an 8π-6π electrocyclization cascade. Reproduced from Hulot, C.; Blond, G.; Suffert, J. *J. Am. Chem. Soc.* **2008**, *130*, 5046.

Inducing asymmetry in 8π-6π electrocyclizations through the use of a removable chiral auxiliary has been met with very limited success. The Stille coupling of vinyl iodide **379** to a small range of chiral vinyl stannanes **380** with subsequent 8π-6π electrocyclization to form diasteromeric bicyclo[4.2.0]octa-2,4-dienes **382a–d**/**383a–d** was used as a test system to screen for asymmetric induction (Scheme 76),[130] since tetraenes of this type are known to undergo *endo*-selective 6π electrocyclization (Scheme 74). Although modest levels of selectivity were observed using the menthol-based auxiliaries **382a**/**383a** at the tetraene terminus, oxazoline **382d**/**383d** gave synthetically useful levels of stereoinduction.

5.17.5.2 Biomimetic 8π-6π Reaction Cascades

In what is now considered a classic example, the feasibility of 8π-6π cascades in biomimetic synthesis was first demonstrated by a synthesis of the endriandric acids in the early 1980s (Scheme 77).[131] This family of natural products includes members such as endriandric acid methyl esters A **394** and B **395**, which each possess eight stereogenic centers, but occur in nature as racemates.

Scheme 76 Asymmetric induction in 8π-6π electrocyclization cascades with a removable chiral auxiliary. Adapted from Parker, K. A.; Wang, Z. *Org. Lett.* **2006**, *8*, 3553, and Kim, K.; Lauher, J. W.; Parker, K. A. *Org. Lett.* **2012**, *14*, 138.

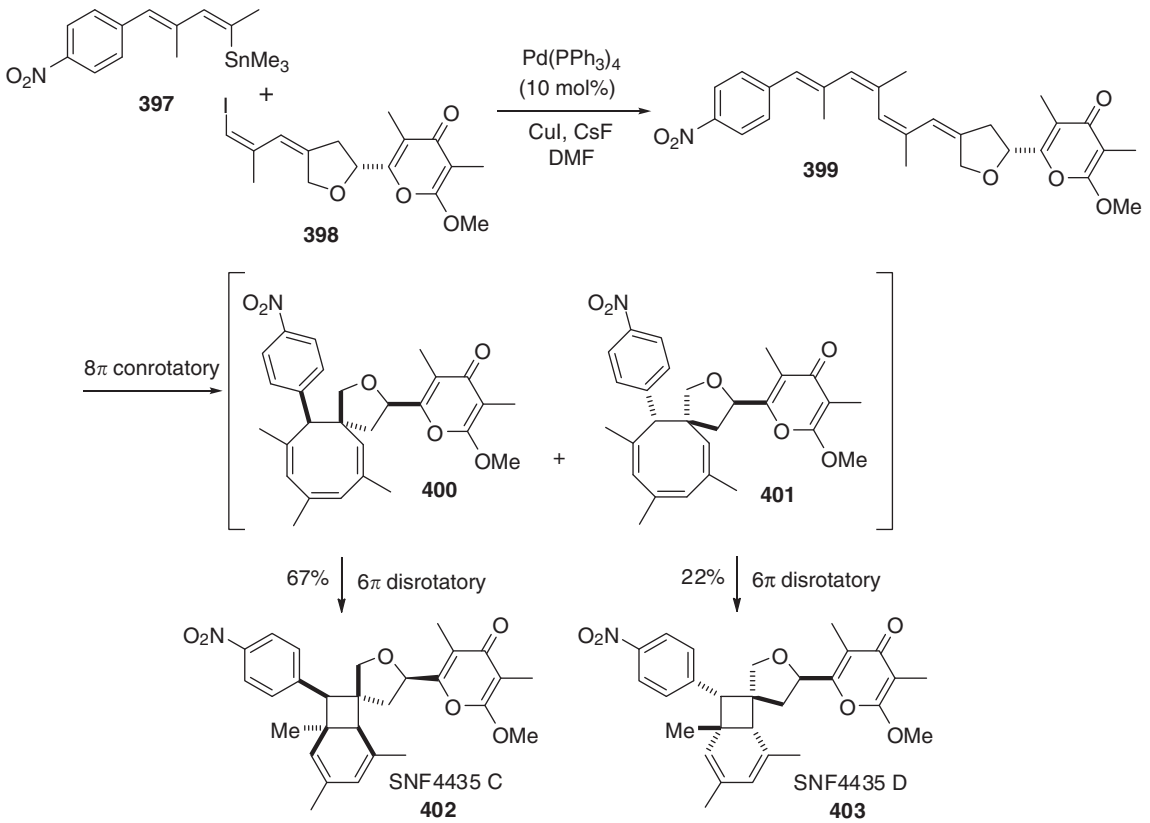


This observation led to the original hypothesis that an 8π-6π electrocyclization/Diels–Alder cascade (*see* Chapter 5.11) was involved in their biosynthesis, starting from achiral polyenes **385**/**388**, without the intervention of enzymes.[131] This spawned an elegant biomimetic synthesis, wherein (*Z*)-selective hydrogenation of diynes **384**/**387** at room temperature resulted directly in the formation of endriandric acid methyl esters E **390**, D **391**, G **392** and F **393** via the 8π-6π electrocyclization cascade (Scheme 77). Alternatively, heating a mixture of endriandric acid methyl esters G **392** and F **393** to 100 °C gave endriandric methyl esters B **395** and C **396**, arising from an intramolecular Diels–Alder reaction. Similarly, endriandric acid methyl esters E **390** and D **391** converged to endriatic acid methyl ester A **394** upon heating the mixture to 100 °C. It is worth noting that endriatic acid methyl ester A **394** cannot be formed directly by endriandric acid methyl ester D **391**, implying the 6π electrocyclization is reversible and that **391** first converts to endriandric acid methyl ester E **390**, funnelling the entire mixture through the intramolecular Diels–Alder pathway. This conjecture was further supported by the conversion of endriandric acid methyl ester E **390** to and equilibrium mixture of E **390**/ D **391** by heating at 70 °C in toluene.

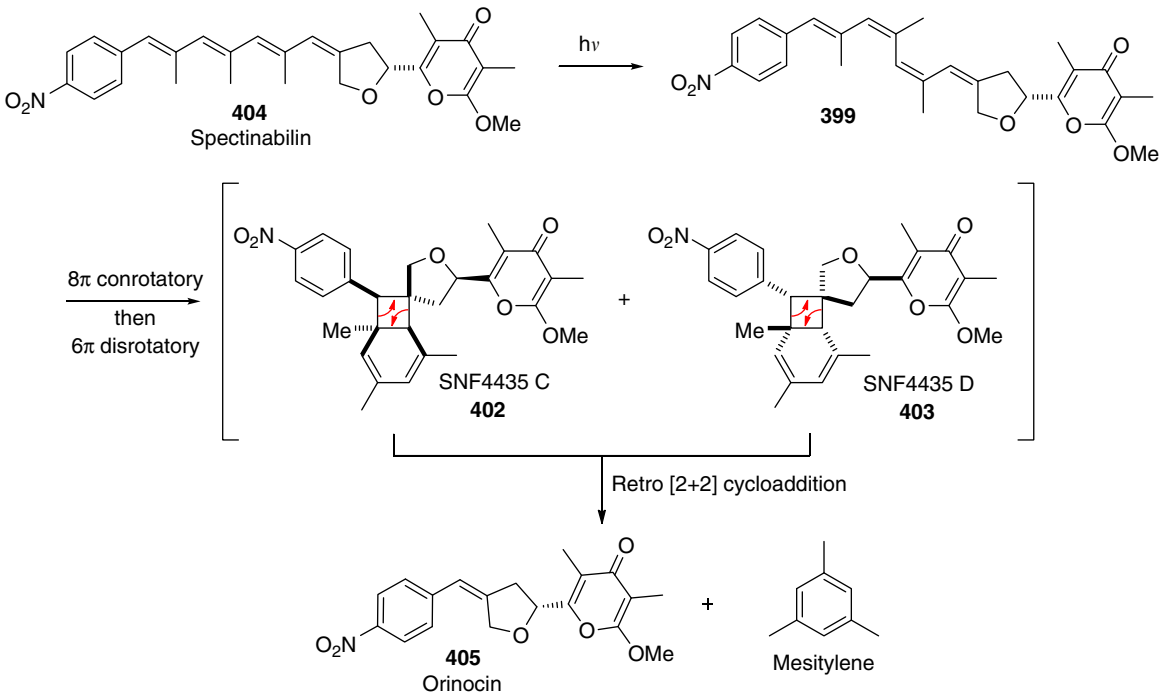
Since this landmark achievement, several additional natural products believed to originate from 8π-6π cascades have been identified, some of which have been targeted by synthetic chemists. In particular, diastereomeric polyketides SNF4435 C **402** and D **403**, isolated from a culture broth of *Streptomyces spectabilis*,[132] have been the subject of a number of synthetic studies (Scheme 78).[133] In contrast to the endriandric acid family, the SNF4435 compounds were isolated as single enantiomers, which were proposed to result from the partially diastereoselective 8π ring-closing of chiral γ-pyrone **399** to form 1,3,5-triene diastereomers **400** and **401**. The subsequent 6π electrocyclization was expected to be completely *endo*-selective, since the corresponding *exo* isomers were not detected in the original isolation study. Indeed, the generation of γ-pyrone **399** from the Stille coupling of vinyl stannane **397** and vinyl iodide **398** ultimately delivers SNF4435 C **402** and D **403** in 67% and 22% yields respectively, which resembles the ratio of the mixture isolated from nature.

Further speculation into the biosynthetic origin of SNF4435 C **402** and D **403** led to re-examining the metabolic profile of *S. orinoci*, an organism that produces spectinabilin **404** under various sets of conditions (Scheme 79).[134] It was postulated that intermediate *E*,*Z*,*Z*,*Z*-tetraene **399**, from the total synthesis of SNF4435 C **402** and D **403**, arises biosynthetically from the photoisomerization of spectinabilin **404**, followed by the 8π/6π electrocyclization cascade depicted in Scheme 79. Indeed, when fermentation and workup of *S. orinoci* was carried out in the dark, no SNF4435 C **402** or D **403** were detected. However, exposure of either the culture or pure spectinabilin **404** to daylight resulted in the formation of SNF4435 C **402** and D **403**, along with small amounts of an additional metabolite orinocin **405**, which appears to be produced from the SNF4435 natural products via retro [2 + 2] cycloaddition. It was also possible to detect mesitylene in the mixture using gas chromatography/mass spectroscopy, providing additional support for the involvement of this mechanism. These studies indicate that the SNF4435 compounds owe their biogenesis to a nonenzymatic alkene photoisomerization of spectinabilin **404** and put forth that mesitylene is in fact a natural product, which can be traced back biosynthetically to an 8π/6π electrocyclization/retro [2 + 2] cycloaddition cascade.

Polyketide natural products isolated as single enantiomers from the marine fungus *Emericella variecolor*, the shimalactones A **411** and B **412**, are also believed to be the consequence of a biosynthetic pathway featuring a moderately torquoselective 8π electrocyclization, followed by a highly diastereoselective 6π electrocyclization (Scheme 80).[135] This too is supported by a synthetic study, in which the enantiomerically enriched alcohol **406** was cross-coupled with oxabicyclo[2.2.1]heptane **407**, resulting in a spontaneous 8π-6π cascade at room temperature that afforded the two diasteromeric shimalactone natural products **411** and **412** in a 5:1 ratio.

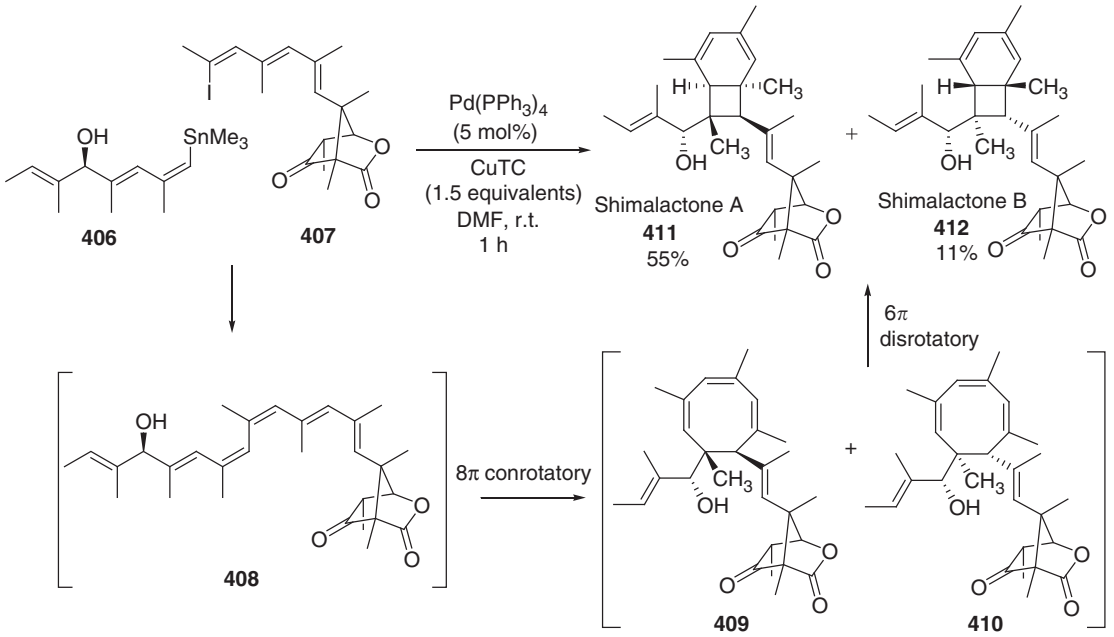


The bicyclo[4.2.0]octane motif present in the sesquiterpene natural product (–)-coprinolone **416** has led to speculation that an 8π-6π cascade is involved in its biogenesis (Scheme 81). Preliminary investigations have demonstrated that trienone **413** can



Scheme 77 Biomimetic synthesis of the endriatic acids. Reproduced from Beaudry, C.; Malerich, J.; Trauner, D. *Chem. Rev.* **2005**, *105*, 4757.

transiently form a 1,3,5,7-tetraene system **414** via keto–enol tautomerism in methanol at 110 °C, which undergoes 8π-6π electrocyclization in modest yield.[136] The product enone **415** possesses the same relative stereochemistry as the natural product (–)-coprinolone **416**, lending some support to the biosynthetic hypothesis.



The Bcl-xL/Bak interaction inhibitor kingianin A **417**,[137] a natural product isolated from the bark of the Malaysian *Endiandra kingiana* Gamble, has been proposed to form biosynthetically from an *endo*-Diels–Alder dimerization of the corresponding homochiral bicyclo[4.2.0]octa-2,4-diene *endo*-**418** (Scheme 82).[138] The natural product was isolated as a racemate, suggesting that

Scheme 82 Approach to kingianin A based on a speculated biosynthesis involving 8π-6π electrocyclization/dimerization. Reproduced from Sharma, P.; Ritson, D. J.; Burnley, J.; Moses, J. E. *Chem. Commun.* **2011**, *47*, 10605.

an enzyme may not be involved in its biosynthesis. A synthetic study aimed to verify this hypothesis, forming the requisite (*E*,*Z*,*Z*,*E*)-tetraene **421** from the Stille coupling of vinyl bromide **419** and vinyl stannane **420** at 110 °C in toluene.[139] The ensuing electrocyclization cascade occurred with an unselective 6π step, leading to a 1:1 separable mixture of *endo*-**422** and *exo*-**423** diastereomers. Counter to the proposed biosynthesis, various forcing conditions (195 °C) were unsuccessful at promoting the formation of kingianin A **417** from either *endo*/*exo* diastereomer of nitriles **422**/**423** or amides **424**/**425**. It was demonstrated that the 6π electrocyclization is reversible in this case, as prolonged heating of either bicyclo[4.2.0]octa-2,4-diene diastereomer **424**/**425** converged to a 1:1 equilibrium mixture. Therefore, it does not rule-out that the dimerization of a homochiral bicyclo[4.2.0]octa-2,4-diene **418** is somehow implicated in the biosynthesis of kingianin A **417**, raising the interesting question of how such a dimerization could occur *in vivo*.

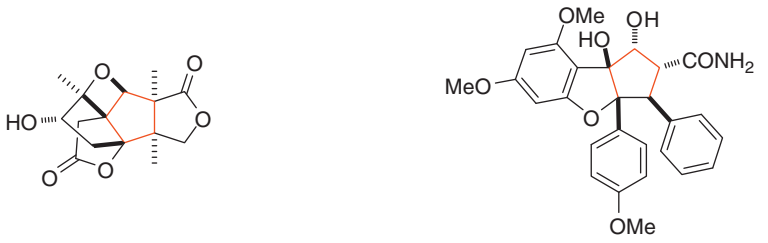
Glossary

Chirality transfer Creation of one or more new stereocenters/axes if chirality in a molecule under the influence of a preexisting stereocenter/axis of chirality, with simultaneous destruction of the original stereocenter/axis of chirality.
Electrocyclization A pericyclic, orbital symmetry-controlled cyclization of an extended π-system, forming a new σ-bond and a new ring.
***endo* isomer** A diastereomer of a bridged bicyclic compound in which the substituent(s) in question is (are) located *syn* to the longest bridge.
***exo* isomer** A diastereomer of a bridged bicyclic compound in which the substituent(s) in question is (are) located *anti* to the longest bridge.
Organocatalysis Enhancement of the rate of a reaction through the addition of a nonmetallic catalyst (typically a small organic molecule).
Oxyallyl cation A delocalized allylic cation bearing oxygen substitution at the central carbon (C-2).
Pericyclic reaction An orbital symmetry-controlled reaction involving a cyclic transition state with concerted bond formation and cleavage.
Torquoselectivity A preference for one of two possible directions of rotation during either electrocyclic opening or closure.
Vinylogous A structure or process that through the addition of one or more π bonds permit conjugation of two moieties that were directly attached in the original version.
Wagner–Meerwein rearrangement A cationic rearrangement, common in polycyclic ring systems, involving the 1,2-migration of hydrogen, alkyl, or aryl substituents to a carbocationic center from the neighboring atom.

5.18.1 Introduction

The Nazarov cyclization[1] has emerged as an effective means for converting divinyl ketones to cyclopentenones since its discovery in 1903 by Vorländer,[2] with later structural correction in 1955.[3] It gained popularity following the investigations by Nazarov et al. into the hydration of dienynes with mercury salts to form cyclopentenones in the 1940s and 1950s (Scheme 1).[4]



Scheme 1

Since this time, studies have effectively elucidated the mechanism of this transformation, developed means to control regioselectivity in the elimination event, intercepted the oxyallyl cation, and showcased new methods to access the pentadienyl cation intermediate.[1] The Nazarov cyclization has also been shown to be effective in the synthesis of numerous natural products. Highlights of these syntheses include the synthesis of (±)-merrilactone A, where the Frontier group used a Nazarov cyclization to form the C-ring (Figure 1–1).[5] The Frontier group also used an oxidative entry to the Nazarov cyclization in their synthesis of (±)-rocaglamide (Figure 1–2).[6] Furthermore, Williams utilized a Nazarov cyclization to form the cyclopentenone present in (+)-fusicoauritone (Figure 1–3),[7] whereas Tius utilized the reaction in his synthesis of (+)-mandinoline A and its cyclopentendione epimer (+)-mandinoline B (Figure 1–4).[8]

5.18.1.1 Mechanism and Activation

The mechanism for the Nazarov cyclization was covered in detail in the previous edition of Comprehensive Organic Synthesis, and will therefore be addressed only briefly.[1a] In its conventional form, the reaction begins with activation of a cross-conjugated dienone (5) forming a pentadienyl cation (6) (Scheme 2).[3,9] This cation is a conjugated 4π system capable of undergoing an electocyclization,[10] closing the ring in a stereospecific conrotatory fashion. This electrocyclization forms a 2-hydroxycyclopentenyl cation (7), which then undergoes proton elimination and enol tautomerization to form a cyclopentenone (8).

Activation of divinyl ketones has traditionally been done with stoichiometric amounts of strong Brønsted or Lewis acids,[1b] limiting the scope of dienones to those that could tolerate such harsh conditions. Recent findings by the Greaney group have shown that cyclization can occur in the absence of acid, instead mediated by higher reaction temperatures and the use of a microwave reactor.[11] By subjecting dienones with substituents at both α-positions, conversion to cyclopentenones can be seen in good to excellent yield (equation 1). The solvent choice was shown to be imperative, as only dimethylacetamide and the ionic liquid 1-ethyl-3-methylimidazolium tetrafluoroborate ($EMImBF_4$) were successful solvents.

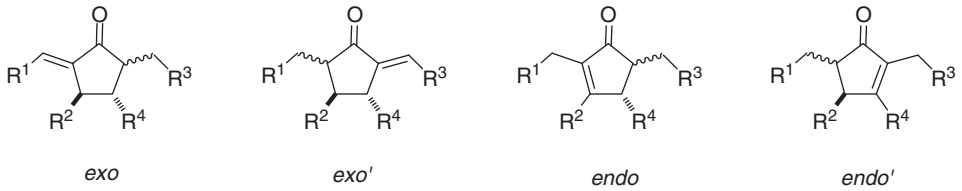
5.18.1.1.1 Photochemical activation

The Nazarov cyclization can also be initiated by photolysis. When dienones are subjected to photolytic conditions, the ring closure occurs via a disrotatory electrocyclization, setting the *β*-position stereocenters in the opposite *syn*/*anti* relationship to that of the thermal conditions.[10] The Giannis group showcased a photochemical Nazarov in their synthesis of 16-*epi*-terpendole E. The enone was irradiated with 350 nm light, forming the desired cyclopentenone in 80% yield, before being carried out through four more steps to get to the target molecule (Scheme 3).[12]

Scheme 3

5.18.1.2 Directing Groups

For a long time, a major issue inhibiting the widespread utilization of the Nazarov cyclization in synthesis lay in its final mechanistic step, the elimination. For an unsymmetrical dienone, there are four possible elimination options, leaving the alkene in either an *endo* or an *exo* disposition, and on either side of the ring (Figure 2).



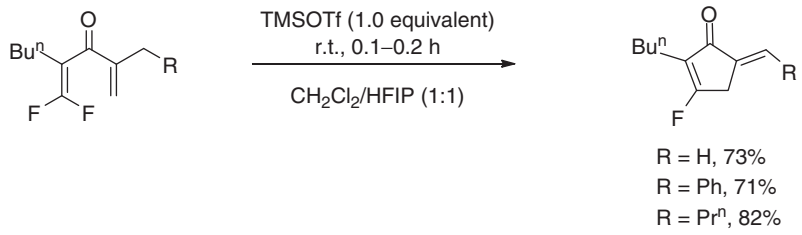


Figure 2 Possible alkene regioisomers.

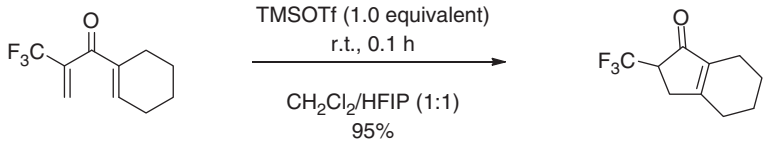
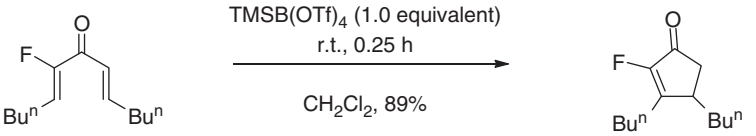
To address the regioselectivity problem, Denmark et al. developed the silyl-directed Nazarov reaction. The results of these studies, as well as their tin-based counterparts, have been discussed in detail in the previous edition of Comprehensive Organic Synthesis.[1a]

5.18.1.2.1 Effects of fluorine

In contrast to the directing effect of silicon, which installs the alkene selectively with concomitant loss of the silyl group, fluorine was shown by Ichikawa et al. to have a β-destabilizing effect, and directed the elimination to the other side of the ring.[13] By subjecting β-difluoro substituted dienones to trimethylsilyl trifluoromethansulfonate (TMSOTf), elimination was found to occur on the opposite side of the ketone from the fluorines and exclusively in an exocyclic manner. The sequence concluded with elimination of one of the fluorides to afford a second C=C bond (equation 2).



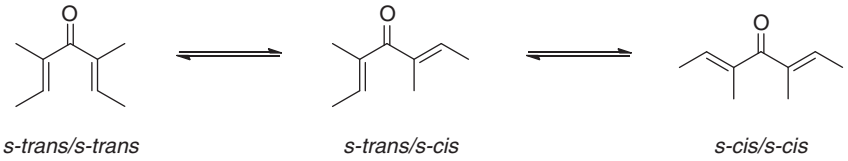
(2)



R = H, 73%
R = Ph, 71%
R = Pr^n, 82%

Ichikawa also showed that fluorine atoms at the α-position of the dienone can exert useful directing effects. Placement of a trifluoromethyl group at an α-position led to reactivity analogous to the β-substituted case, directing the elimination to the other side of the ring.[14] However, in these cases, elimination was shown to favor the endocyclic alkene, and elimination of a fluorine to

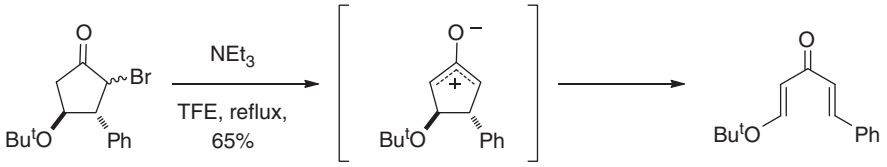
form the second double bond was not observed (equation 3). Placement of fluorine at the α-position of the dienone reversed the selectivity of the elimination as fluorine has an α-stabilizing effect on cations.[15] In this case, elimination occurred toward the fluorine atoms to afford 2-fluorocyclopentenone in high yield (equation 4).



(3)

(4)

5.18.1.3 Substituent Effects

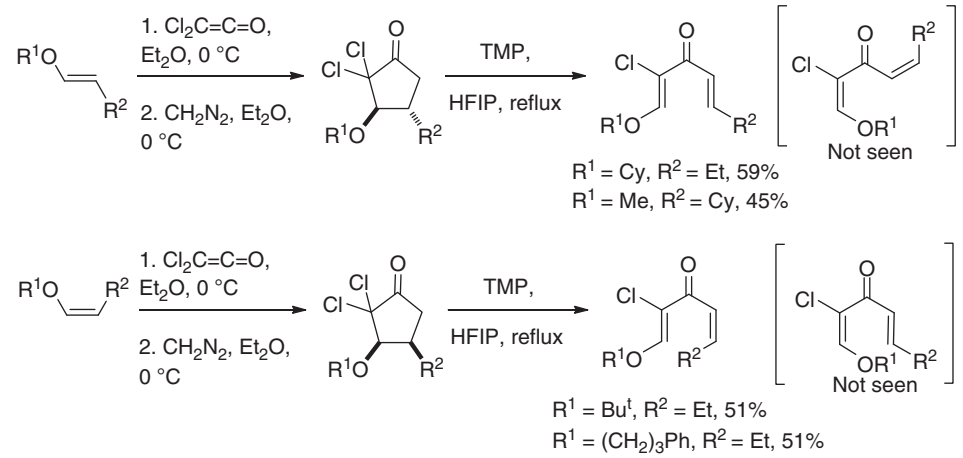


The degree of substitution on dienone substrates has significant effects on the Nazarov cyclization. Alkyl substitution at positions 2 and 4 of the dienone is especially important. Substitution with an alkyl group at either of these positions is believed to increase the population of the reactive *s-trans/s-trans* conformer, facilitating cyclization (Scheme 4).[16] When a hydrogen occupies the α-position, the s-*cis* conformers dominate, leading to diminished reactivity.

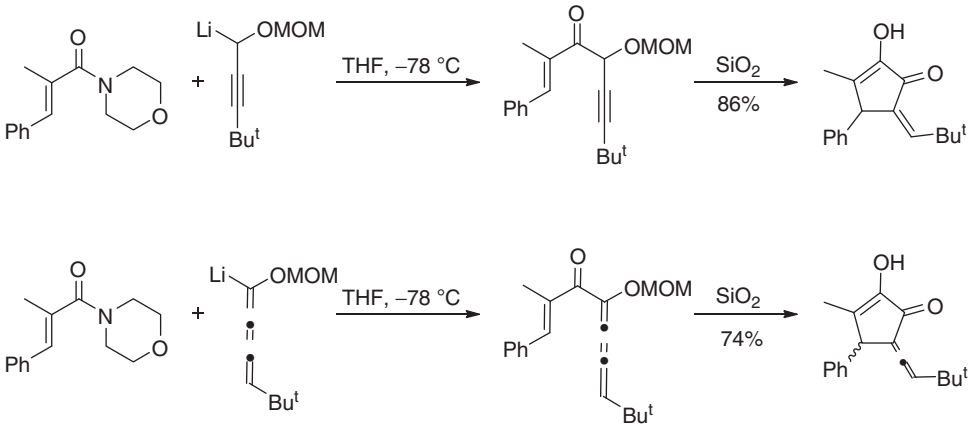
Scheme 4

5.18.1.3.1 The retro-Nazarov

β-Electron-donating substituents such as alkoxy groups stabilize the pentadienyl cation intermediate, leading to an increase in the activation barrier for electrocyclization, consequently reducing the rate of cyclization. A particularly germane case of this phenomenon is seen in the Harmata group's discovery of the retro-Nazarov reaction.[17] When α-bromo cyclopentanones bearing β-alkoxy groups were subjected to a base such as triethylamine in refluxing trifluoroethanol, an acyclic dienone results presumably through the intermediacy of a 2-oxidocyclopentenyl cation that undergoes retrograde Nazarov reaction (Scheme 5).



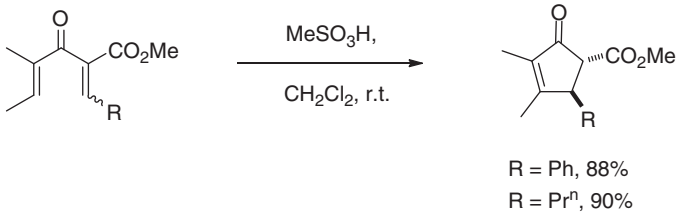
Scheme 5



The Harmata group developed this methodology further, finding that vinyl ethers could be selectively transformed through two steps to either the *syn*- or *anti*-cylopentanones with *gem*-dichloro substitution.[18] When these were subjected to retro-Nazarov conditions, they observed remarkable torquoselectivity, forming a single dienone in each case. Each substrate favored the dienone with a (*Z*)-alkoxychloro alkene (i.e., with the alkoxy group *trans* to the ketone), with no detectable quantity of the (*E*)-conformer (Scheme 6).

5.18.1.3.2 Electron-donating groups

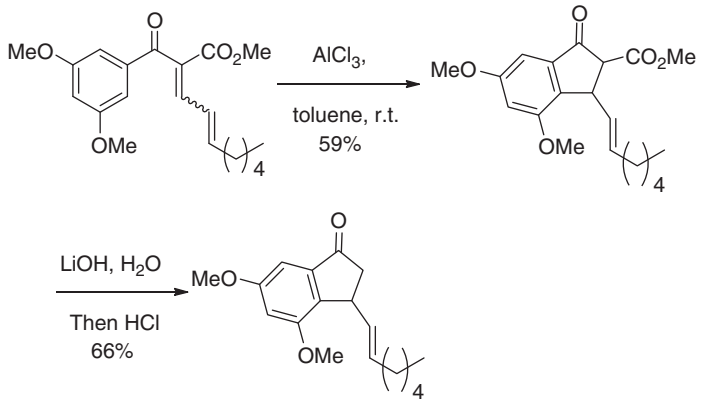
Electron-releasing groups at C-2 seem to increase the reactivity of dienones, a phenomenon thought to result from stabilization of the intermediate cyclopentenyl cation.[16] Tius and coworkers have exploited this phenomenon to synthesize a variety of compounds from alkoxy-allene[19] and – cumulene[20] substrates under exceedingly mild conditions (e.g., elution through silica gel) (Scheme 7).



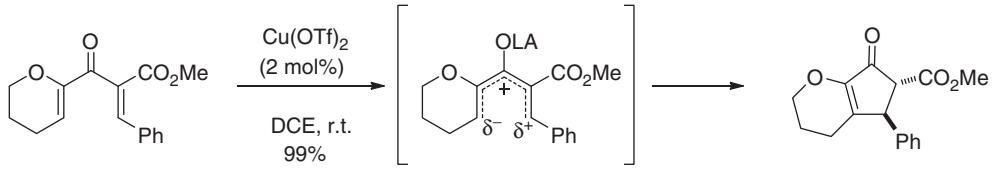
Scheme 6

Scheme 7

5.18.1.3.3 Electron-withdrawing groups



Electron-withdrawing groups at C-2 or C-4 can effectively control the regiochemistry of the elimination (equation 5).[21] The presence of such a group on the intermediate allyl cation should promote greater positive charge density at the opposite terminus, leading to selective elimination on that side. The Sarpong group also showed that esters in the α-position can be easily removed after cyclization and replaced with hydrogen, accessing substrates that were not accessible from the appropriate dienone due to the *s-trans* conformer being favored (Scheme 8).[22]



(5)

5.18.1.3.4 Polarized substrates

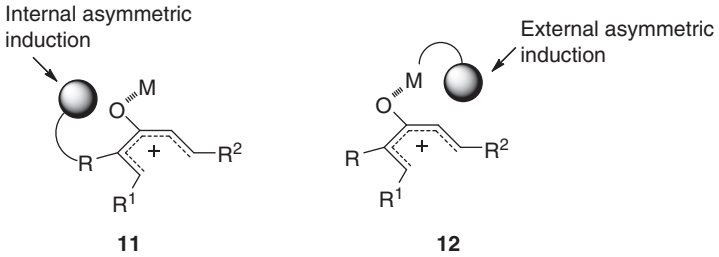
The Frontier group described the additive effect of electron-donating and -withdrawing groups at C-2 and C-4, permitting Nazarov cyclization under unusually mild conditions.[23] These 'polarized' dienones were shown to complex to copper and iridium catalysts and convert to cyclopentenones in excellent yields (Scheme 9).

Scheme 8

Scheme 9

5.18.2 Asymmetric Nazarov Cyclization[1i,24]

As noted above, the Nazarov reaction is a pericyclic reaction in which the relative configuration at newly formed stereocenters in the cyclized products is governed by the preservation of the orbital symmetry.[10] In the absence of any stereochemical bias, the reaction proceeds with equal amounts of clockwise and counterclockwise conrotation, resulting in a racemic mixture. Recent research efforts have been devoted to the control of absolute configuration by imparting a specific direction of conrotation through the introduction of internal or external asymmetric induction (Figure 3). In Section 5.18.2.1, the development of methodologies and strategies in this field will be discussed.



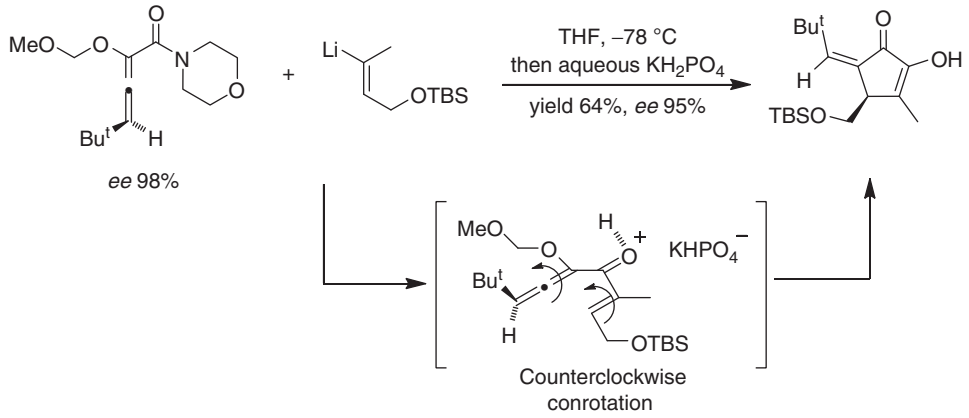


Figure 3 Approaches to asymmetric induction.

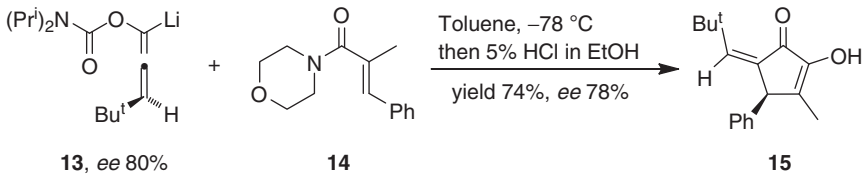
5.18.2.1 Internal Asymmetric Induction

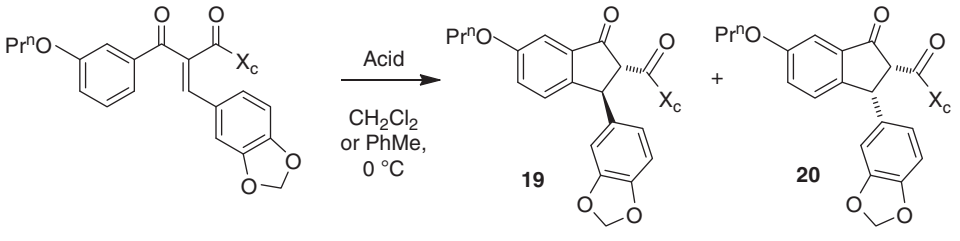
5.18.2.1.1 Chirality transfer



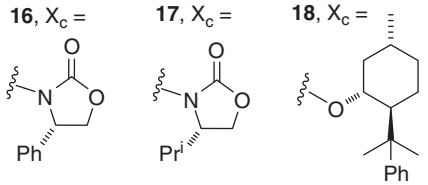
Denmark et al. first demonstrated chirality transfer via silicon-directed Nazarov reaction of a substrate on which the silyl group resides on a stereogenic center.[25] The stereogenic silicon substituent directs the counterclockwise conrotation of the pentadienyl cation by providing continuous electronic stabilization that is not feasible in the clockwise rotation owing to geometrical constraints. Their pioneering work was covered in the previous edition of Comprehensive of Organic Synthesis and will not be discussed further.[1a] Although the early Denmark example employed asymmetric induction from an sp^3 hybridized carbon center, Tius and coworkers described another promising example where high level of axial-to-tetrahedral chirality transfer was observed during cyclization of a chiral allenyl ketone. The sense of rotation was dictated by the steric bias on the distal allene moiety.

As exemplified in Scheme 10, the *tert*-butyl group prefers to rotate away from the pentadienyl system, thus giving a *Z-exo*-olefin as the major isomer plus near-perfect transfer of asymmetry from the allene.[26] However, the nontrivial task of enantioselective preparation of chiral silanes or allenyl amides has limited their further applications.

Scheme 10



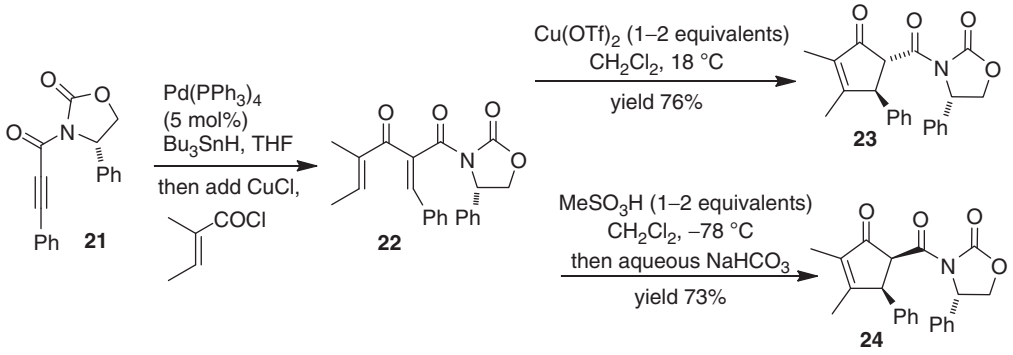
In 2001, Hoppe and coworkers reported an efficient enantioselective synthesis of allenyl carbamates by *n*-BuLi/(−)-sparteine-mediated isomerization of the corresponding alkynes, which can nicely apply to the asymmetric Nazarov reaction described above. Along the same line, Hoppe, Grimme, Tius, and coworkers published an alternative approach to optically active 5-alkylidene-2-cyclopentenones (e.g., **15**) featuring the addition of lithiated chiral allenyl carbamate **13** to the unsaturated amide **14** followed by treatment with protic acid (equation 6). With the same efficiency of chirality transfer, this method proves to be a superior choice in terms of synthetic ease than its previous version.[27]



(6)

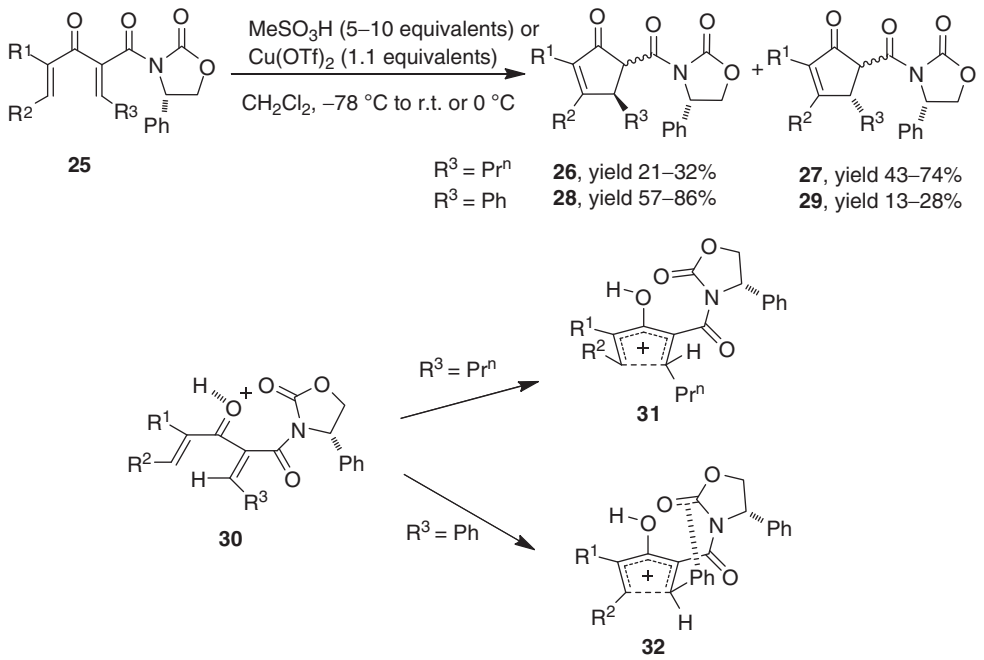
5.18.2.1.2 Chiral auxiliaries

Pridgen et al. reported the first apparent example of asymmetric 4π-electrocyclization controlled by a pendent chiral auxiliary in 1999 (Scheme 11). In the presence of tin tetrachloride, the cyclization of phenyl oxazolidinone **16** is more stereoselective than its analog **17**. Also, attachment of an 8-phenylmenthoxy group, as in compound **18**, offers a slightly more efficient asymmetric



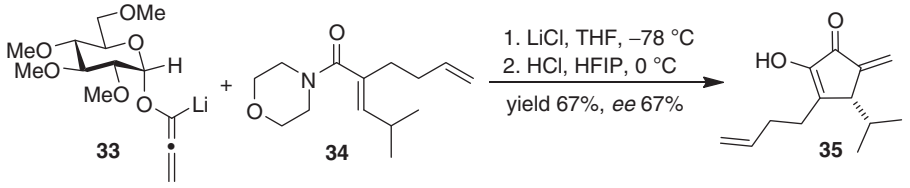
Substrate	Acid (equivalent)	yield (%)	Product ratio (**19**:**20**:other)
16	$SnCl_4$ (1.1)	85	88:12:0
16	$MeSO_3H$ (2)	88	85:15:0
16	$TiCl_4$ (1.1)	60	70:30:0
17	$SnCl_4$ (1.1)	74	71:16:14
18	$SnCl_4$ (1.1)	90	92:4:4

Scheme 11



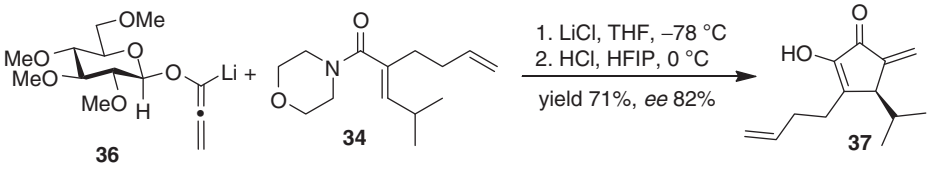
induction, implying that proper modifications of this component may further increase the diastereoselectivities of the cyclization. Comparable results with Lewis and Brønsted acid argues against the intermediacy of a rigid chelate.[28]

Flynn and coworkers reported a modular synthesis of cross-conjugated dienones substituted with Evans' chiral oxazolidinone by a palladium-mediated hydrostannylation/cross-coupling sequence, which represents a synthetically useful extension of Pridgen's work (Scheme 12).[21b] Different acid catalysts were examined, with results indicating that the Nazarov cyclization of **22** could be diverged to give *cis*- or *trans*-cyclopentenones in good yields and excellent diastereoselectivities. The exclusive formation of *cis*-**24** by reaction of **22** with triflic acid at low temperature is presumed to result from kinetic control. This protocol offers a convenient approach to access either of two diastereomeric products **23** and **24** in enantiomerically enriched form.



Scheme 12

Subsequent to their preliminary studies, Flynn and coworkers extensively explored the scope of the auxiliary controlled Nazarov reaction.[29] Initially, an evaluation of different auxiliary groups shows that chiral phenyloxazolidinone imposes the best torquoselectivity during cyclization. Additionally, they found that both the steric and electronic nature of the substitutients on the dienone **25** affect the stereoselectivity significantly in this system. Evidence for this can be seen in the reversal of torquoselectivity with differing R^3 groups (Scheme 13). When R^3 = alkyl, it is anticipated that the oxazolidinone-oriented perpendicular to the plane of the pentadienyl cation would avoid steric repulsion to the alkyl substitution, thus favoring the clockwise rotation (see transition state **31**). For R^3 = Ph, the authors rationalize the switched stereochemistry by a favorable secondary orbital interaction between the phenyl group and the carbamate moiety in a counterclockwise rotation, leading to transition state **32**. Nevertheless, several examples in this work exhibit poor to moderate stereoselectivities, albeit the combined yields of isomeric products are generally high.



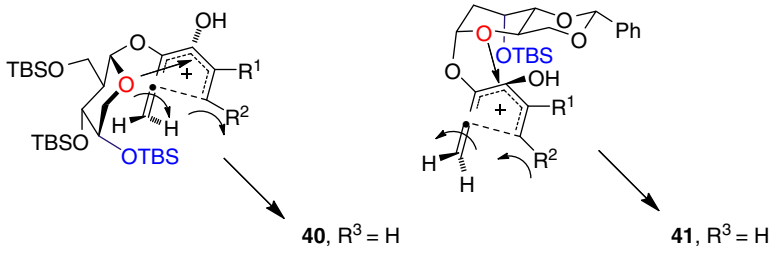
Scheme 13

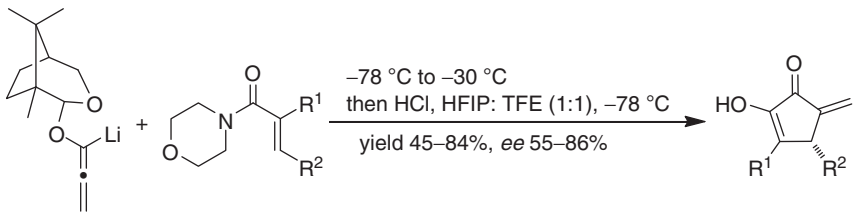
In 2000, Harrington and Tius described an asymmetric Nazarov reaction of allenyl vinyl ketones, where a D-glucose-derived chiral auxiliary is attached to the proximal allenyl carbon.[30] In comparison with the earlier axial→tetrahedral chirality transfer approach, this method does not require the presence of a substituent on the distal allene carbon (required for a stereogenic allene). In this method, an additional step to remove the chiral auxiliary is not necessary because it is lost during the course of cyclization, in contrast to the related oxazolidinone-based protocols. Notably, the use of the lithiated β-anomeric allene **36** altered the absolute sense of electrocyclization, providing even higher enantioselectivity (equation 8). These findings permit a simple way to synthesize both enantiomers **35** (equation 7) and **37** (equation 8) from readily available D-glucose.

(7)

(8)

With extensive modifications over years, Banaag and Tius disclosed their optimized chiral auxiliaries and reaction conditions for the allenyl version of the Nazarov reaction that offers excellent control on both directions of conrotatory electrocyclization.[31] A coherent mechanistic proposal for the origin of stereoselectivity was fully elucidated, highlighting the donor–acceptor interaction between the ring oxygen and pentadienyl cation, which enhance the proximity of the auxiliary to the developing carbon–carbon bond, and the face-blocking function of axial substituents during cyclization (**Figure 4**). Notably, the enantioselective installation of a quartenary center to the cyclopentenoid products could be accomplished in good yields by employing the fully substituted conjugated amide as a coupling partner (**Scheme 14**).





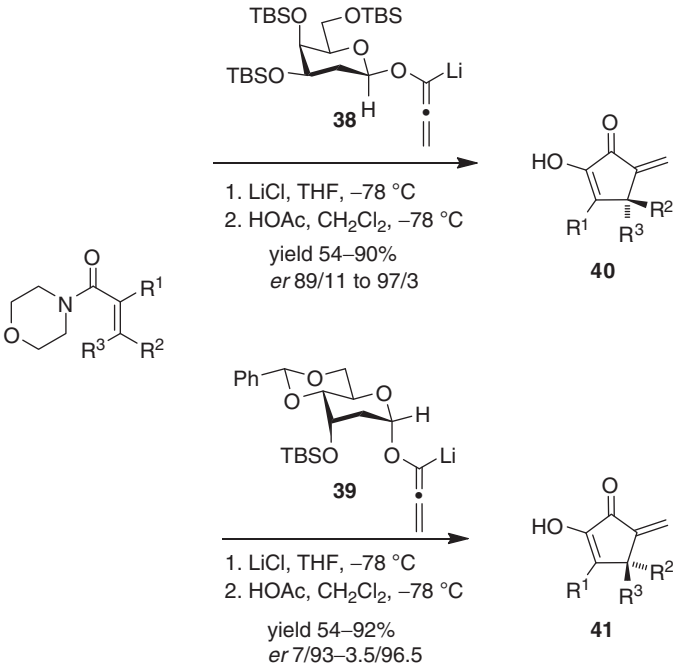


Figure 4 Models for torquoselectivity.

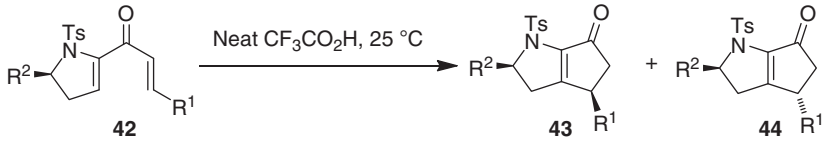
The Tius group explored another type of traceless auxiliary derived from camphor in the context of an enantioselective total synthesis of roseophilin employing an asymmetric Nazarov cyclization as a key step.[32] Later, the scope of that process was examined in detail. However, the control of torquoselectivity during the cyclization in this system is moderate compared to the reaction of exhaustively optimized **38** or **39** (**Scheme 14** versus equation 9).[33] An alternative role of the camphor-derived auxiliary group was demonstrated in the diastereoselective interrupted Nazarov reaction of allenyl ketone substrates. Further discussions on that topic will be given later in the chapter.

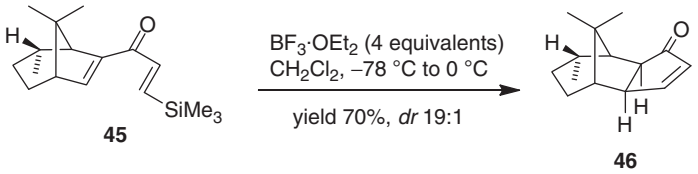
(9)



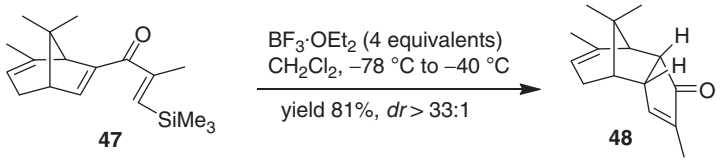
Scheme 14

5.18.2.1.3 Diastereoselective Nazarov reaction of nonracemic substrates

Encasing a portion of the dienone nucleus within a ring containing one or more stereocenters offers another strategy for control of the absolute sense of conrotatory electrocyclization. Early examples of this approach are discussed in the previous edition of Comprehensive Organic Synthesis.[1a] As a general observation, the steric bulk exhibited by the substituent(s) on the stereogentic center and its distance from the developing tetrahedral centers are the two major factors determining the level of torquoselectivity.



More recently, Occhiato et al. examined the diastereoselective Nazarov reaction of enantiopure dihydropyrrole derivatives **42** in the presence of neat trifluoroacetic acid (Scheme 15).[34] The remote stereocenter located on the heterocycle was able to provide good torquoselective control, albeit in moderate chemical yields. The major product **43** is believed to originate from counterclockwise conrotation in which steric clash between R^2 and the developing cyclopentenyl cation is minimized, consistent with earlier examples[1a] where the steric repulsion between R^2 and pentadienyl cation would be minimized during the course of cyclization.

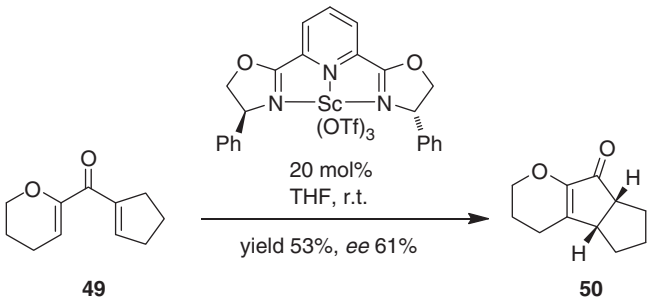


R^1 = Me, R^2 = CH_2OH, yield 42%, *dr* 10:1
R^1 = Pr^i, R^2 = Me, yield 40%, *dr* 1:0 (only diastereomer)
R^1 = Pr^i, R^2 = CH_2OH, yield 27%, *dr* 7:1
R^1 = Pr^i, R^2 = $(CH_2)_2CH = CH_2$, yield 43%, *dr* 1:0 (only diastereomer)

Scheme 15

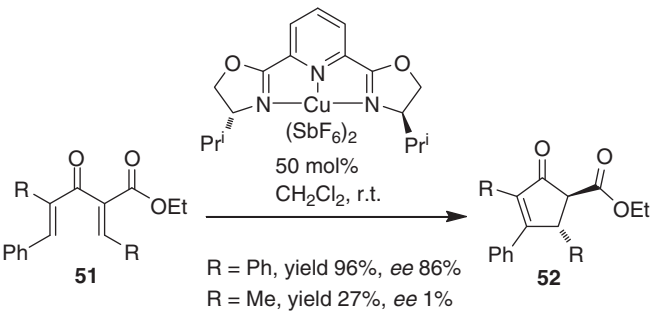
West and coworkers examined the silicon-directed Nazarov reaction of chiral divinyl ketones where one olefin is embedded in a bridged bicyclic system.[35] The observed *exo* selectivity in the formation of **46** from **45** is consistent with known preferences for electrophilic attack on related bicyclic alkenes (equation 10). Correspondingly, a homologous system, bridged bicyclic 1,3,5-trienes, displayed complete selectivity in favor of electrocyclization from the *exo* face.[36] However, an unexpected reversal of torquoselectivity to afford the *endo* product **48** was found in the reaction of **47** (equation 11). The authors attributed this profound stereochemical effect of a remote olefin to conformational preferences within the six-membered ring of the bicyclic system.

(10)



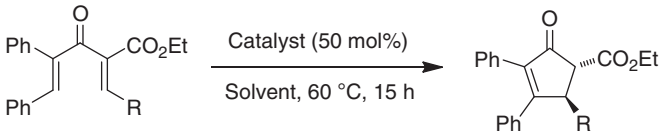
(11)

5.18.2.2 External Asymmetric Induction[1j,37]



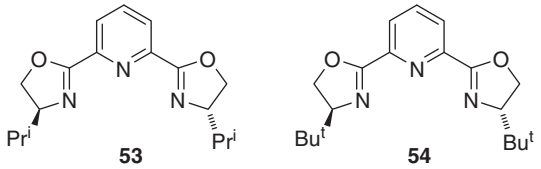
5.18.2.2.1 Metal Lewis acid asymmetric induction

Conventionally, the Nazarov cyclization of cross-conjugated dienones is subject to Brønsted or Lewis acid catalysis. This mechanistic feature offers a platform for the development of catalytic asymmetric versions of the reaction. However, it is somewhat surprising that the first such achievement was reported only recently, six decades after Nazarov's pioneering research. Trauner and coworkers employed 20 mol% of a Sc(III)/PyBOX (2,6-Bis[(4R)-4-phenyl-2-oxazolinyl]pyridine) complex to catalyze the cyclization of **49** to afford the tricyclic product **50** with moderate enantioselectivity (equation 12).[37] The authors speculated that the dihydropyran oxygen fulfilled two critical roles. First, substitution of an ether oxygen at the 2-position of the pentadienyl system should stabilize the intermediate cyclopentenyl cation through resonance. Second, chelation of the scandium ion by both the ether and the carbonyl oxygens should enhance the transmission of stereochemical information from the PyBOX ligand to the developing cyclopentenyl cation.



(12)

Shortly after Trauner's report, Aggarwal and Belfield described the use of Cu(II)/PyBOX complexes to promote Nazarov cyclization of 2-acyldienones (equation 13).[38] For these substrates, the yield and enantioselectivity of cyclization were found to be extremely sensitive to the substitution pattern of the dienones, as seen in the large difference for **51** when R = Ph versus Me. Overall, the high catalyst loading of this reaction underscored the central issue of product inhibition for the development of a catalytic transformation.



(13)

To broaden the library of metal Lewis acids capable of promoting the asymmetric Nazarov cyclization, Kawatsura and Itoh et al. screened various combinations of iron or cobalt salts, chiral PyBOX ligands, and solvents (**Scheme 16**).[39] The authors concluded that the Fe(II)/PyBOX Lewis acid complex is superior to the Co(II)/PyBOX catalyst for most 2-carboxydienones in terms of yield and enantioslectivity. The results also revealed that the electron density of the β-aryl group has significant impact on the overall performance of the cyclization that clearly limited the substrate scope. Nevertheless, this process still suffered from the demand of high catalyst loading, consistent with Aggarwal's earlier observation[38] for systems of this type.

Substrate	Catalyst	Solvent	Yield (%)	*ee* (%)
R = 4-$MeOC_6H_4$	$Co(ClO_4)_2{\cdot}6H_2O$/**53**	CH_2Cl_2	70	8

Scheme 16

Tang and coworkers explored the suitability of tris(oxazoline) ligands to amplify the asymmetric environment around the electrocyclization transition state of polarized dienones such as **55**. Their design allowed for two possible binding modes, via either chelation by both carbonyls (**58**) or chelation by the dienone carbonyl and the dihydropyran ring oxygen (**59**) (Figure 5).[40] In the event, the complex of copper (II)/*tris*(oxazoline) ligand **57** was the most efficient asymmetric catalyst for the Nazarov reaction of **55**, furnishing **56** in high yields and enantioselectivities (Scheme 17). It is notable that this process tolerated a range of R substituents at C-5, although electron-poor arenes and alkyl groups required extended reaction times.

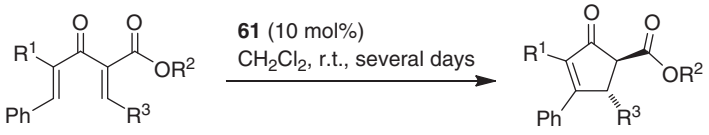
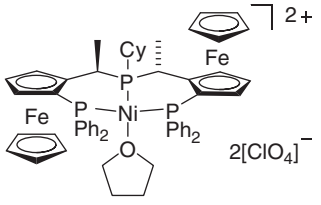


Scheme 17



The first vanadium-catalyzed Nazarov reaction was reported for dialkylidene β-keto esters by Togni and coworkers, with remarkable turnover frequencies.[41] As an extension to their own work, a preliminary attempt to utilize a chiral vanadium salen complex **60** for asymmetric catalysis was not fruitful, resulting in racemic cyclopentenone products (equation 14). Nonetheless, the high catalytic activity of these V(IV) complexes offers a strong impetus to carry out further optimization studies of the asymmetric process.

(14)

The known Lewis acidic behavior of the Ni(II)/Pigiphos complex in mediating various types of reactions inspired Walz and Togni to pursue its application in the catalytic asymmetric Nazarov reaction.[42] An examination on the substituent effects indicated that varying the steric and electronic properties of the ester moiety (R^2) would cause the erosion of both yields and enantioselectivities. Moreover, electron-rich aryl groups R^3 are beneficial to the overall process (Scheme 18). The requirement for extremely long reaction times with the Ni(II)/Pigiphos catalyst **61** identifies an area for further improvement of this promising system.

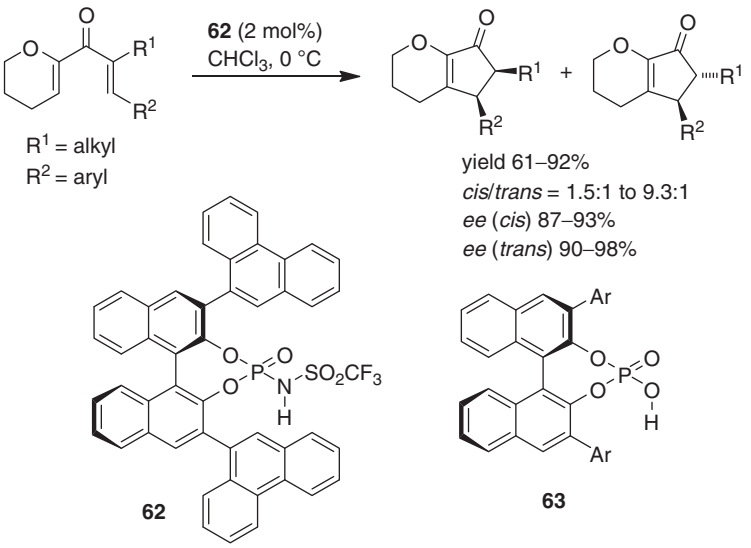
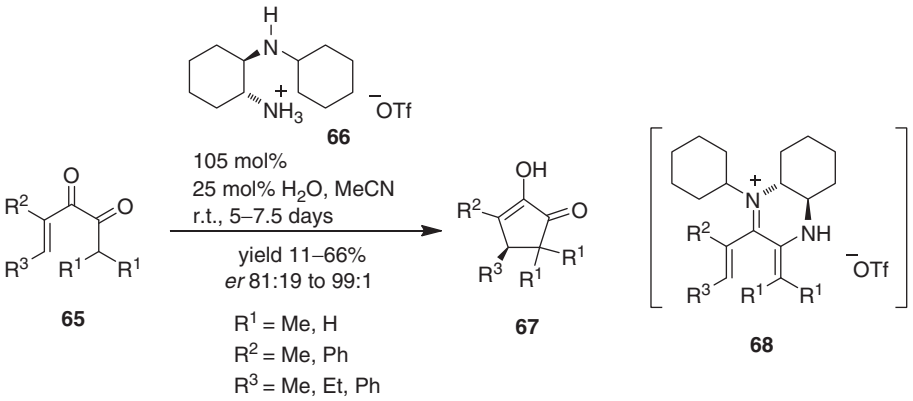
Scheme 18

5.18.2.2.2 Organocatalytic asymmetric induction



Rueping et al. demonstrated that the sense of conroratory electrocyclization could be controlled using asymmetric organocatalysis, presumably via a chiral ion-pair mechanism.[43] Although several chiral BINOL phosphate-derived Brønsted acids were evaluated for the Nazarov reaction of various dihydropyran-containing dienones, *N*-triflyl phosphoramide **62** was found to be more stereoselective than the corresponding phosphoric acid **63**. As an alternative to the metal-catalyzed process, this method features lower catalyst loadings and excellent enantiocontrol; however, only moderate *cis*/*trans* diastereoselectivities were obtained (Scheme 19).

Blanchet and coworkers explored a dithio analog **64** of BINOL phosphoric acid **63** as a new organocatalyst for the asymmetric Nazarov reaction, where the acidity of the promoter was postulated to be essential to both reactivity and enantioselectivity (equation 15).[44] In the event, the level of torquoselectivity using **64** was disappointingly low, although the *cis*/*trans* diastereoselectivity was somewhat higher than that obtained with **62**.

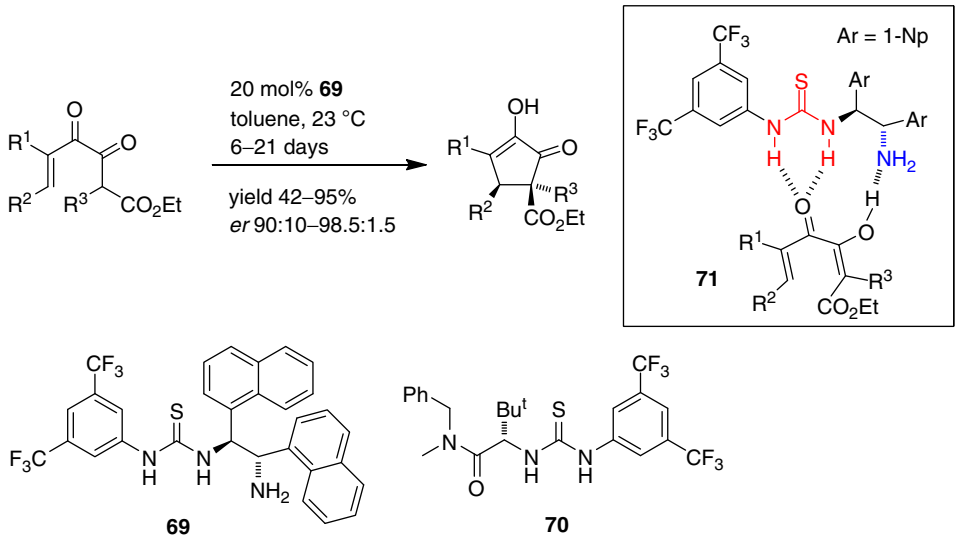


64, Ar = 3,5-$(CF_3)_2C_6H_3$

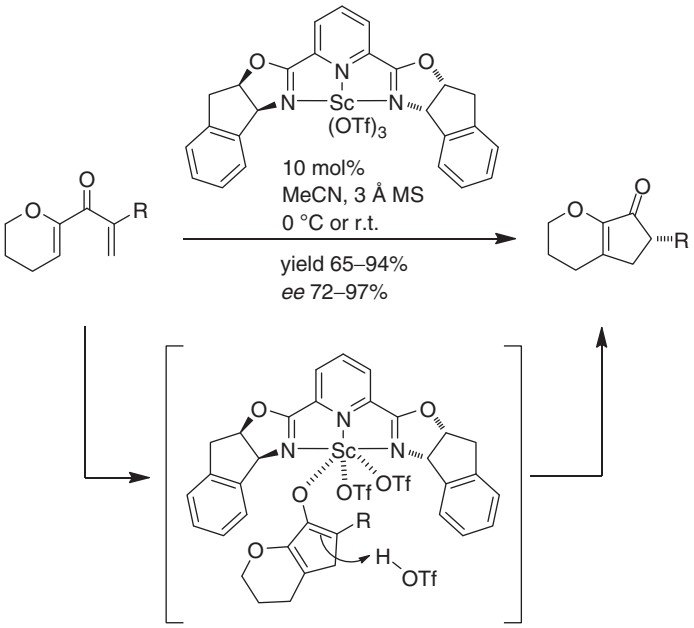
(15)

Scheme 19

Tius and coworkers disclosed a novel approach for controlling the absolute sense of electrocyclization through the generation of a presumed enamine–iminium intermediate **68** from α-diketone **65** and stoichiometric diamine monotriflate **66** (Scheme 20).[45] The cyclized covalent intermediate, a transpositional enamine-iminium species, was hydrolyzed during aqueous workup to release an α-hydroxycyclopentenone **67** in remarkable optical purity. The chemical yields of this relatively slow process varied from 11% to 66%.

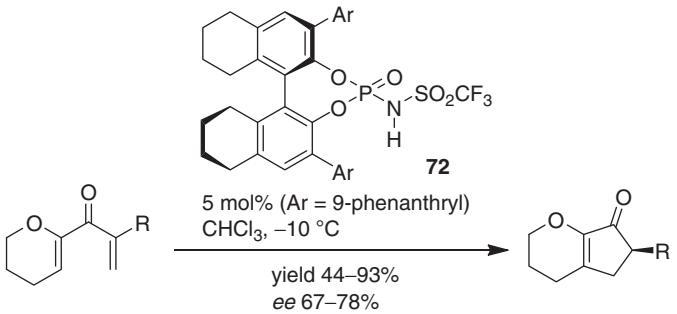


Scheme 20



Tius and coworkers devised thiourea-derived bifunctional catalysts for the Nazarov reaction of enolic diketoesters to provide highly functionalized cyclopentenones in moderate to good yields and in enantiomeric ratios that range from 90:10 to 98.5:1.5 (Scheme 21).[46] A notable advantage of this protocol is that two contiguous stereogenic centers, one of which is a quartenary center, could be readily installed. The fact that catalyst **70** lacking a basic amine group was not an effective catalyst highlighted the cooperative function between acidic thiourea moiety and basic primary amine residing in **69**, as indicated in the model **71**.

5.18.2.2.3 Electrocyclization/enantioselective protonation



Enantioselective protonation[47] is a common means for establishing absolute configuration in biosynthetic pathways. Liang and Trauner described a new strategy toward asymmetric Nazarov reactions where the enantioselectivity was determined during the final protonation of the enolate intermediate instead of the electrocyclization step (Scheme 22).[48] The yields and enantiomeric ratios obtained in this process are promising, but currently the substrate scope is limited to highly reactive dihydropyran-containing dienones. Rueping and Ieawsuwan described a strategy similar to Liang and Trauner's, using the partially reduced *N*-triflylphosphoramide organocatalyst **72** (equation 16).[49]

Scheme 21

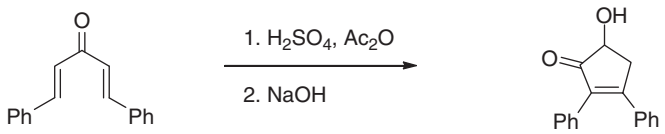
(16)

5.18.3 The Interrupted Nazarov Reaction

Although the conventional Nazarov reaction has considerable value for the construction of cyclopentenones, recently there has been growing interest in utilizing the unique reactivity of various intermediates occurring during the process to form additional strategic bonds. Specifically, the 2-oxidocyclopentenyl cation **7** (Scheme 1) formed on electrocyclization can participate in a variety of nucleophilic trapping or cycloaddition reactions. However, the dienol or dienolate species resulting from elimination can react with a range of electrophiles. This concept of diverting the Nazarov process from its normal path with an added reagent has been labeled the interrupted Nazarov reaction.

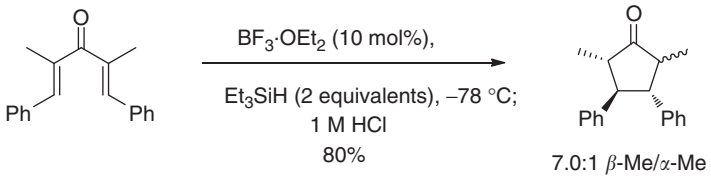


5.18.3.1 Early Interrupted Nazarov Reactions

The first examples which intentionally exploited 2-oxido-cyclopentenyl cation reactivity were observed during photo-Nazarov cyclizations. Trapping of the oxyallyl intermediate **74** generated from photochemical Nazarov cyclization of 4-pyranone **73** was found to occur in a bimolecular fashion with hydroxylic solvent[50,51] or in [4+3] cycloadditions with furan (Scheme 23).[50] West et al. demonstrated the corresponding intramolecular process using pendent hydroxyl traps to form fused bicyclic products.[52] They also found that carbon-based nucleophiles such as olefins, arenes, and dienes could be tethered to 4-pyranones to generate bi- and tricyclic ring systems.[53–55] The photo-Nazarov methodology had a relatively limited scope and required the use of a polar, nonnucleophilic solvent such as trifluoroethanol.

Scheme 23

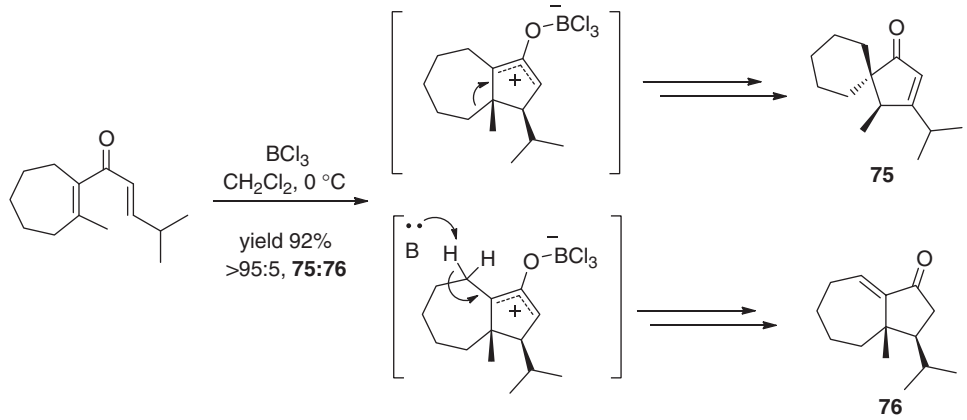
The similarity of the intermediate in conventional Nazarov reactions and that formed in the photochemical process suggested the possibility of generalizing this trapping strategy beyond a specialized class of 4-pyranone substrates. In fact, long before the mechanism of the Nazarov reaction was understood, Vorländer and Schroedter observed a ketol product from treatment of dibenzylideneacetone with acetic anhydride and sulfuric acid (equation 17), which was most likely the result of trapping of the cyclopentenyl cation intermediate with water, bisulfate, or acetate. Although not appreciated at the time as an example of the interrupted Nazarov reaction, this process offered clear evidence in support of the notion that the Nazarov intermediate could be trapped with nucleophiles.[2] Section 5.18.3.2 will highlight some of the recent advances in domino and tandem processes resulting in interception of the intermediates formed in thermal Nazarov cyclizations. For an in-depth discussion the reader is referred to a review published by West and coworkers.[1g]



(17)

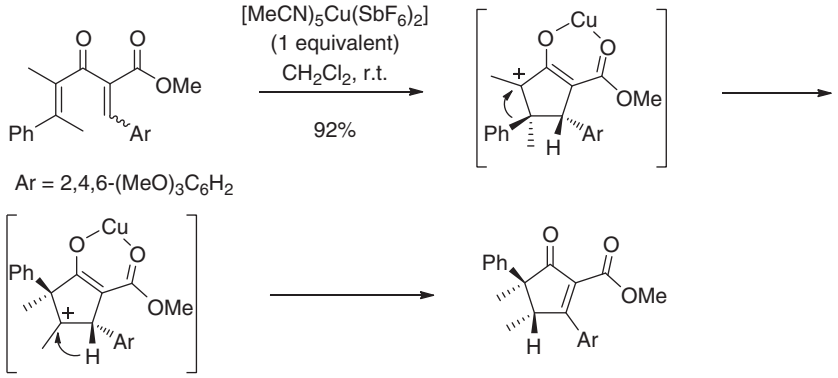
5.18.3.2 Reductive Nazarov Reaction

An important advantage of the interrupted Nazarov cyclization is the retention of the two stereocenters formed in the electrocyclization step to make functionalized cyclopentanones. Giese and West utilized triethylsilane as a Lewis acid-tolerant hydride source to trap the 2-oxido-cyclopentenyl cation and form cyclopentanones in good yields (equation 18).[56] Nazarov cyclization was followed by a regioselective delivery of hydride at the less substituted end of the 2-oxido-cyclopentenyl cation, rationalized by the preferred formation of a more substituted enolate. Hydride addition favors addition from the seemingly more hindered face to afford a *trans–trans* relative stereochemistry.[57] The reductive Nazarov reaction efficiently captured the oxyallyl cation intermediate



conserving the newly formed stereocenters. Another important observation was the capability to carry out the reaction using catalytic amounts of Lewis acid.

(18)

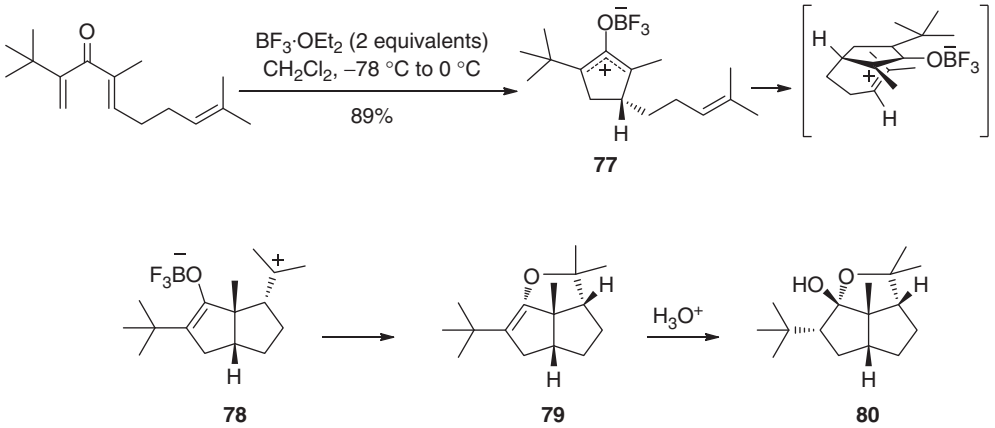


5.18.3.3 Tandem Nazarov Cyclization – Skeletal Rearrangments

Although exploring the synthesis of hydroazulene ring systems using the Nazarov reaction, Chiu and Li found that they could also access spiro[4.5]decanones resulting from Wagner–Meerwein rearrangment of the 2-oxido-cyclopentenyl intermediate.[58] However, this methodology appears to be limited to the formation of spiro[4.5]decanones, as the corresponding spiro[4.4]nonanones are formed as a mixture with the classical Nazarov product (Scheme 24).

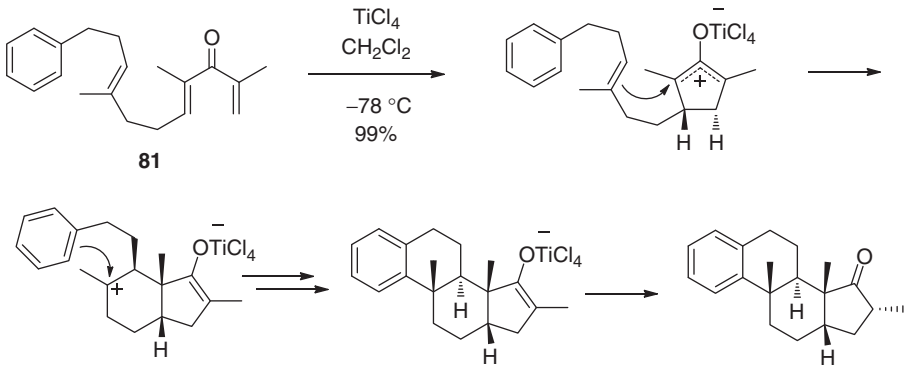
Scheme 24

Frontier and coworkers have also developed a methodology utilizing [1,2]-shifts to intercept the oxyallyl cation formed following Cu(II) promoted Nazarov cyclization to prepare highly substituted cyclopentanones.[59] Simple dienones bearing an electron-withdrawing substituent on one of the α-carbons can undergo Nazarov cyclization followed by two sequential chemoselective and stereospecific [1,2]-migrations to cyclopentenone products. The chemoselectivity of the migrations can be predicted based on the migratory aptitude of the substituents, although steric demand also plays a role, as seen in the preferential migration of hydride rather than the bulky 2,4,6-trimethoxyphenyl (TMP) group. (Scheme 25). By employing a bis(oxazoline) ligand, the reaction could be performed enantioselectively. Additionally, the Frontier group showed that when one of the dienone alkenes was part of a cyclohexene, the resulting 1,2-shift led to a ring contraction and formation of a spirocyclic ring junction at the α-position.[60]



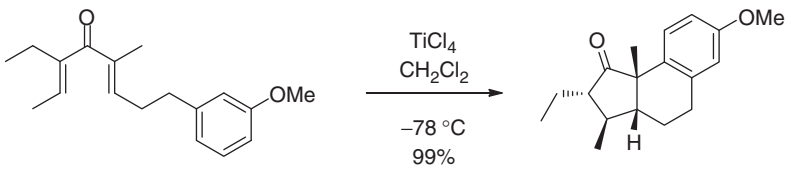
Scheme 25

5.18.3.4 C–C Bond Formation



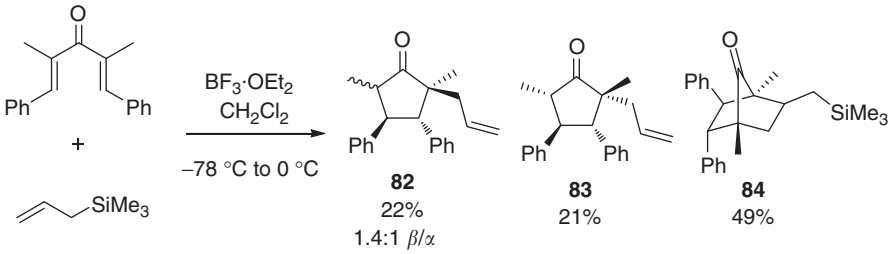
5.18.3.4.1 Intramolecular olefin trapping

In 1998, West and coworkers reported the first intentional interception of the 2-oxidocyclopentenyl cation intermediate generated by a thermal Nazarov cyclization.[61] In this process cross-conjugated dienones bearing an olefin tether were treated with $BF_3{\cdot}OEt_2$ to form a single polycyclic hemiketal product, with consequent formation of two new carbon–carbon bonds and four or five new stereocenters. The products observed were the result of 4π-conrotatory Nazarov cyclization generating a 2-oxidocyclopentenyl cation intermediate **77** (Scheme 26), which underwent cationic cyclization to the tethered olefin resulting in tertiary carbocation **78**. Trapping of this cation by the boron enolate would give the strained enol ether **79**, the hydrolysis of which leads to the observed hemiketal diquinane product **80**.



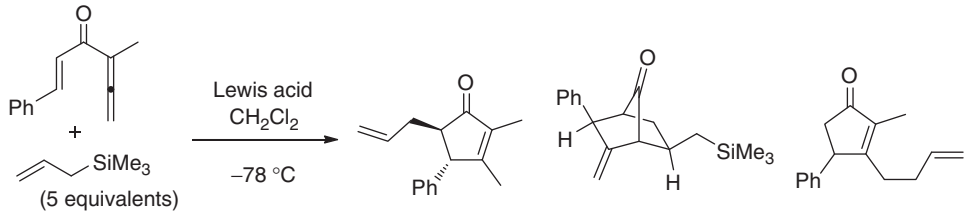
Scheme 26

Cascade polycyclizations with aryl-terminated trienones such as **81** are also possible.[62] Initial trials using protic acid or $BF_3{\cdot}OEt_2$ furnished only simple Nazarov cyclization or truncated monocyclization products. Lower reaction temperatures and stronger Lewis acid were used in an effort to increase the lifetime of the carbocation intermediates with hopes of achieving the polycyclization cascade. In the event, $TiCl_4$ at −78 °C was found to successfully convert the aryltrienone substrate to the desired tetracyclic product in 99% yield with complete diastereoselectivity (Scheme 27). Tethered arenes could also be used to directly trap the Nazarov oxyallyl cation intermediate (equation 19),[63,64] affording benzohydrindenones in good yields.



Scheme 27

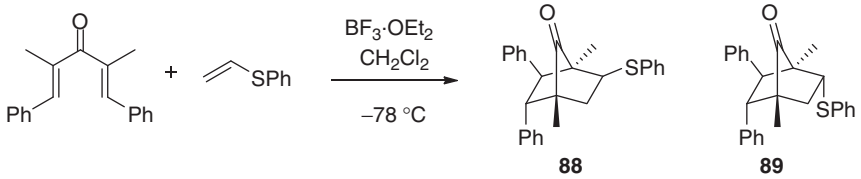
(19)



5.18.3.4.2 Intermolecular olefin trapping

The success of intramolecular trapping by π-nucleophiles spurred investigation of the corresponding bimolecular processes. Initial studies employed simple allylsilanes, chosen for their known nuclophilic reactivity and Lewis acid stability. Dibenzylidene-3-pentanone was treated with $BF_3{\cdot}OEt_2$ in the presence of allyltrimethylsilane to afford a diastereomeric mixture of allylated cyclopentanones **82** and **83**, along with the bicyclo[2.2.1]heptanone product **84** derived from [3+2] cycloaddition (equation 20).[65] Products **83** and **84** are thought to arise from the same silicon-stabilized carbocation, which can be trapped by the enolate or undergo silyl elimination. Formation of the [3+2] product could be maximized by using a less labile allylsilane, such as allyltriisopropylsilane. In the case of unsymmetrical dienones, nucleophilic attack occurred exclusively at the less substituted end of the oxyallyl cation intermediate to provide the more stable enolate. Interestingly, complementary diastereoselectivity could be obtained by using a different Lewis acid.

(20)

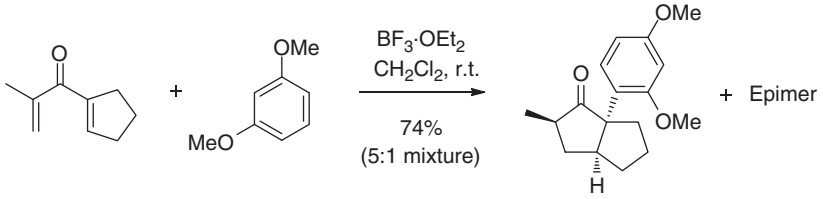


More recently, an allenyl vinyl ketone substrate was shown by Marx and Burnell to undergo efficient trapping with allylsilanes (Scheme 28).[66] Mixtures of allylated cyclopentenone **85** and [3+2]-adduct **86** were formed using $BF_3{\cdot}OEt_2$. However when $Cu(OTf)_2$ or $InCl_3$ were used to promote the Nazarov cyclization, an allylated product **87** arising from exocyclic trapping of the extended cationic intermediate was also formed.

	85	86	87
$BF_3{\cdot}OEt_2$	27%	54%	–
$Cu(OTf)_2$	20%	10%	42%
$InCl_3$	22%	–	56%

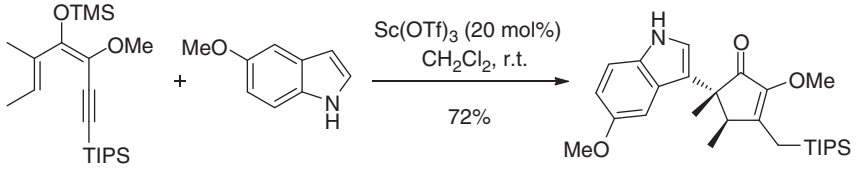
Scheme 28

Recently, a variety of other electron-rich olefins with enolate-like reactivity have been used to trap the Nazarov oxyallyl intermediate. Mahmoud and West observed exclusive [3+2] trapping with vinyl sulfides to generate sulfide-substituted bicyclo[2.2.1]heptanones (equation 21) with no evidence of trapped cyclopentanone products.[67] In contrast, nucleophilic silyloxyalkenes were used to generate 1,4-dicarbonyl systems containing highly substituted cyclopentanones and up to five new stereocenters in what was termed a 'homologous Mukaiyama reaction.'[68] When simple divinyl ketone substrates were treated with, $BF_3{\cdot}OEt_2$ in the presence of silyl enol ethers, silyl ketene acetals, or mixed ketene *S*,*O*-acetals, trapping occurred such that the more stable enolate was formed on interception of the oxyallyl cation (equation 22). Similar reactivity involving an allyl vinyl ketone and enol ethers was observed by Marx and Burnell.[66]



(21)

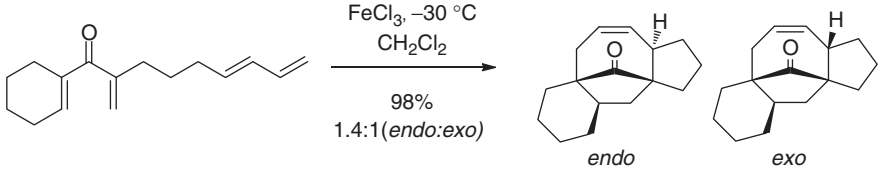
(22)



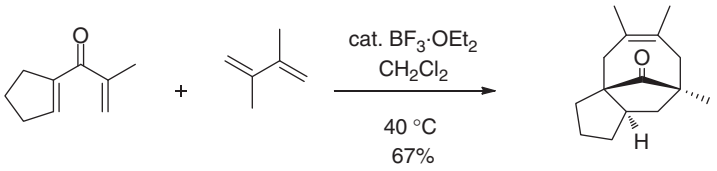
5.18.3.4.3 Intermolecular arene trapping

In 2008, West and coworkers found that similar enolonium-type reactivity could be observed for Nazarov intermediates containing at least one fused cyclopentane ring. Treatment of the corresponding dienones with $BF_3{\cdot}OEt_2$ in the presence of electron-rich arenes furnished products resulting from electrophilic aromatic substitution onto the cyclized 2-oxidiocyclopentenyl Nazarov intermediate.[69] Furans, thiophenes, protected pyrroles, protected indoles,[70] and electron-rich benzene rings were all efficiently trapped. The regioselective attack at the bridgehead (equation 23) is attributed to the formation of the less strained enolate on trapping of the oxyallyl cation. Consistent with the intramolecular studies, less electron-rich aromatic rings failed to undergo the domino process, and instead simple eliminative Nazarov products were isolated.

(23)



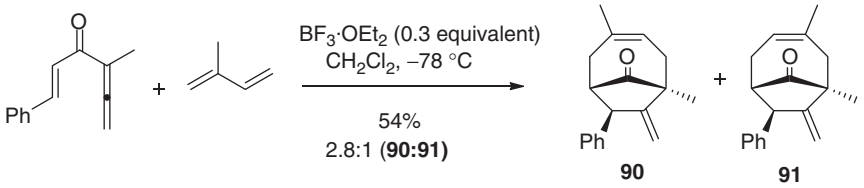
In the same year, Tius and coworkers reported conceptually related work utilizing unprotected indoles as aromatic nucleophiles.[71] In the study, enediyne substrates were cyclized in the presence of catalytic $Sc(OTf)_3$. The resulting cationic Nazarov intermediate was trapped by a variety of indoles at the nuclophilic C-3 position (equation 24). The trapping was reasonably efficient, provided the indoles were electron-rich and sterically unencumbered.



(24)

5.18.3.4.4 [4+3]-Cycloaddition reactions

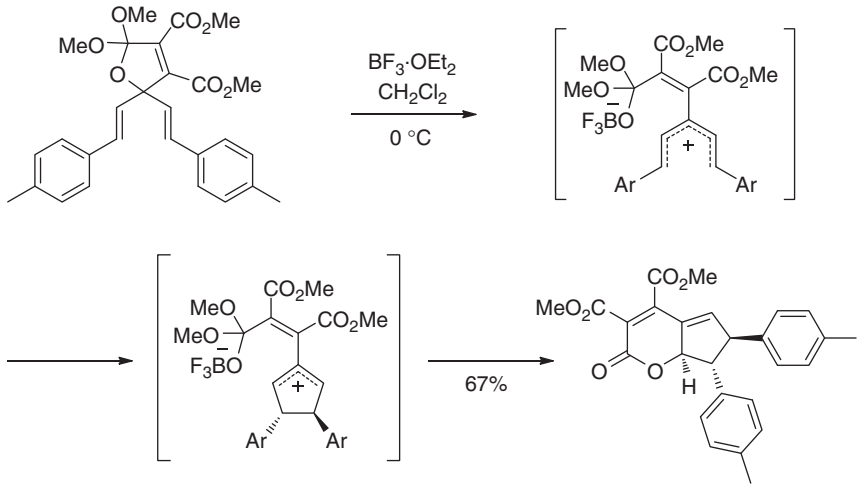
An alternative mode of trapping the oxyallyl intermediate to the nucleophilic processes described above would be through concerted [4+3]-cycloaddition utilizing the oxyallyl intermediate as a dieneophile. This [4+3]-cycloaddition can also be considered to be a formal [4+4]-cycloaddition given that the reactive 2-oxidocyclopentenyl cation intermediate is enclosed within a ring, furnishing a keto-bridged cyclooctene product. West and coworkers tested this concept using a series of divinyl ketones bearing diene tethers. Treatment with $FeCl_3$ at low temperature led to the desired polycyclic products in excellent yield as a mixture of diastereomers (equation 25).[72] Although exclusive approach of the diene from the more accessible face of the cyclopentenyl cation was seen, reaction via either *endo* or *exo* transition states was possible, and both products were typically obtained. The analogous intermolecular [4+3]-cycloaddition process is also efficient (equation 26).[73] Catalytic activation of simple dienones by $BF_3{\cdot}OEt_2$ in the presence of simple cyclic and acyclic dienes formed the [4+3]-cycloadducts in good to excellent yield with complete facial selectivity.



(25)

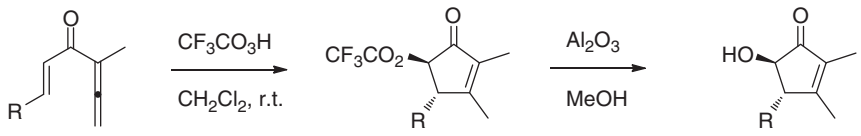
(26)

Marx and Burnell examined the [4+3] reactivity of an allenyl vinyl ketone, and found that efficient trapping was seen using $BF_3{\cdot}OEt_2$ at low temperatures in the presence of simple dienes (equation 27).[66] In cases employing more substituted dienes, [3+2] trapping products were observed as the major products. This was attributed to low populations of the *s-cis* conformation required for a concerted [4+3]-cycloaddition process.



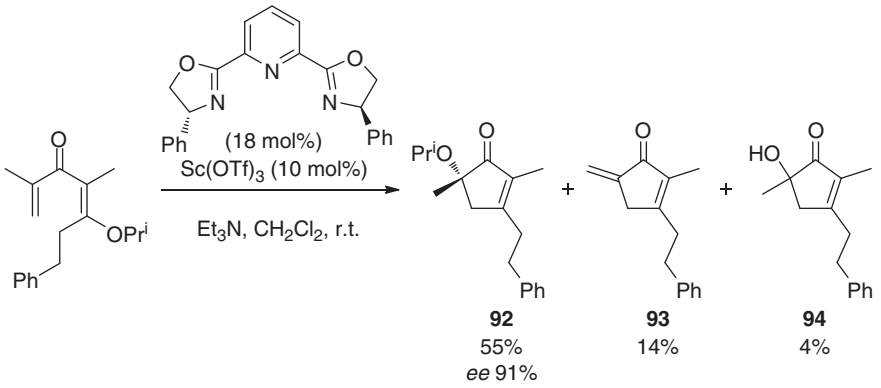
(27)

5.18.3.5 Heteroatom Trapping



5.18.3.5.1 Oxygen nucleophiles

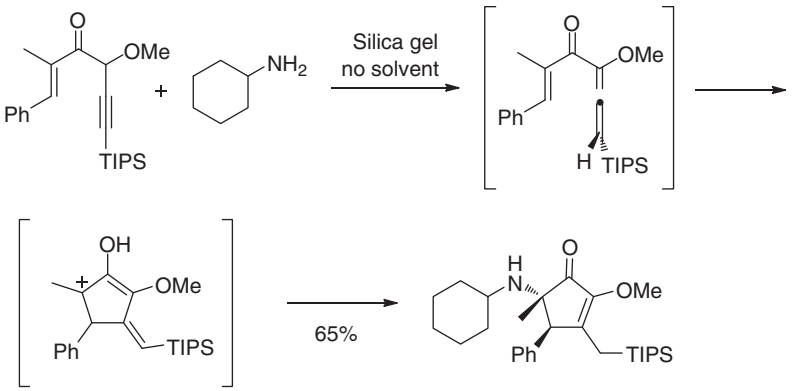
In 2002, Nair et al. used nontraditional *gem*-divinyl dihydrofuran substrates in an intramolecular oxygen interrupted Nazarov reaction (Scheme 29).[74] When the substrates were treated with $BF_3{\cdot}OEt_2$, a cascade was initated by ring opening to generate a pentadienyl cation that underwent Nazarov cyclization to form the cyclopentadienyl cation intermediate. Subsequent trapping by the *ortho* ester borate oxygen gave the complex bicyclic lactone products and three new stereocenters.



Scheme 29

Marx and Burnell observed that efficient trapping of the cyclopentenyl cation generated by acid promoted Nazarov cyclization of select allenyl vinyl ketones with trifluoroacetic acid. The resulting trifluroacetate esters could be smoothly converted to α-hydroxycyclopentenones on elution through basic alumina (Scheme 30).[75] However, some allenyl vinyl ketones failed to undergo trapping, generating the simple Nazarov product, or underwent Michael addition into the allene before cyclization could occur.[76]

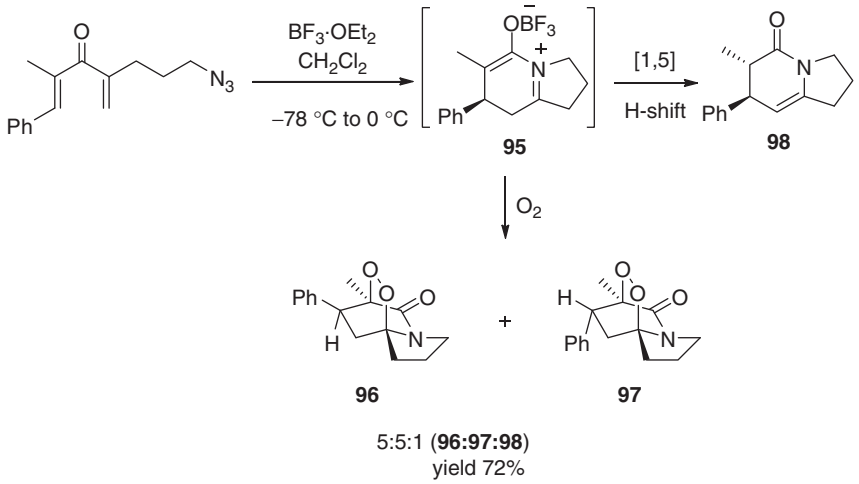
Scheme 30



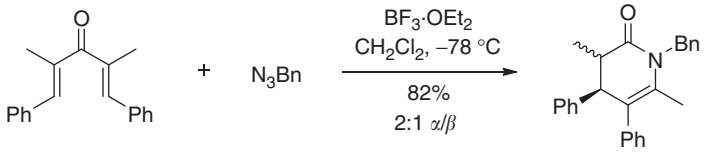
In 2009, Yaji and Shindo reported an asymmetric interrupted Nazarov reaction catalyzed by a $Sc(OTf)_3$–Pybox complex to generate enantioenriched α-alkoxy cyclopentenoes with good yield and moderate ee (equation 28).[77] Deuterium labeling was used to support intermolecular delivery of the alkoxy nucleophile rather than an intramolecular [1,3]-shift.

(28)

5.18.3.5.2 Nitrogen nucleophiles

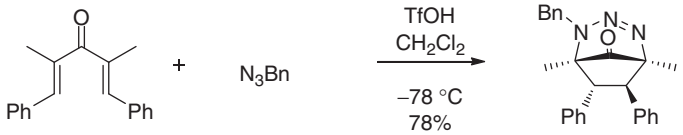


In 2005, Dhoro and Tius reported the first examples of nitrogen as a nucleophile for the interrupted Nazarov reaction.[78] Silica gel was used to promote Nazarov cyclization of *in situ*-formed allenyl vinyl ketones in the presence of a variety of primary and secondary amines (equation 29). Under solvent-free conditions the highly reactive cyclopentadienyl cation could be trapped by the amine, notable due to the readily available elimination pathways that are not seen even in the presence of basic amine. The success of this reaction can be attributed to the high reactivity of the allene ether species, and its close proximity to the nucleophilic amine in the solvent-free conditions. By employing a camphor-based chiral auxiliary on the allene ether, control of the torquoselectivity in the conrotatory cyclization was seen.[79]



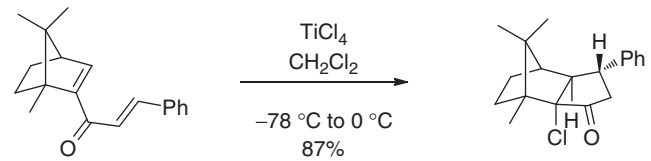
(29)

West and coworkers demonstrated the use of azides to intercept the 2-oxido-cyclopentenyl cation Nazarov intermediates.[80–82] Initial studies focused on intramolecular reactivity, using azide-tethered dienones (**Scheme 31**).[80] Treatment with $BF_3{\cdot}OEt_2$ at low temperature furnished indolizidine endoperoxides **96** and **97** as the major products, along with trace amounts of **98**. The authors suggest that all of these products arise from the 1,4-dipolar intermediate **95**. Careful exclusion of oxygen from the reaction allowed the exclusive formation of **98**. However, the reaction was optimized to favor the peroxy-bridged products by performing the reaction in the presence of oxygen, providing an additional useful handle for further transformations.

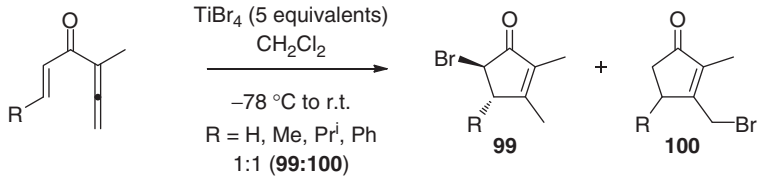


Intermolecular azide trapping of 2-oxidocyclopentenyl cations generated from simple dienones has also been studied.[81] On treatment with $BF_3{\cdot}OEt_2$, Nazarov cyclization followed by azide attack and domino ring expansion produced substituted dihydropyridones from simple starting materials (equation 30). *Trans*-dihydropyridones were the major or exclusive product; however, the lack of complete stereospecificity at the α-carbonyl position argued against a concerted [1,5]-hydrogen shift mechanism, and an alternative pathway was proposed. In contrast to the intramolecular study, no evidence of peroxy-bridged products was seen. In a more recent study an alternative mode of intermolecular azide trapping was observed.[82] When simple dienones were instead treated with strong Brønsted acid in the presence of azides, products resulting from apparent [3+3]-cycloaddition were observed, generating bridged bicyclic triazines, in contrast to the Schmidt-type products observed in the earlier studies (equation 31).

Scheme 31



(30)

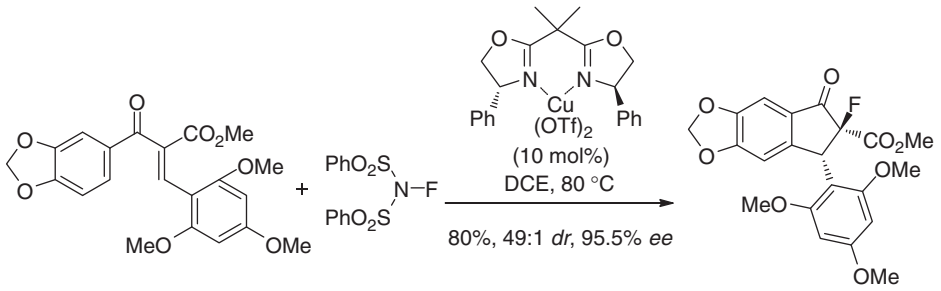


(31)

5.18.3.5.3 Halide nucleophiles

The first examples of nuclophilic halide trapping of the Nazarov oxyallyl cation were reported by White and West in 2005. When bridged bicylic dienones were treated with stoichiometric titanium(IV) chloride, Nazarov cyclization occurred and the resulting oxyallyl cation was trapped with Lewis acid-derived chloride (equation 32).[83] However, this methodology appears to be limited to hindered bicyclic dienones. Additionally, alkyl shift pathways have been found to compete with the halide trapping step. In 2009, Burnell and coworker reported a low yielding inadvertent halide trapping of the Nazarov 2-oxidocyclopentenyl cation intermediate by incorporation of chloride from $AuCl_3$.[75] Subsequent work sought to generalize the halide trapping process.[84] It was found that allenyl vinyl ketones underwent Lewis acid-mediated Nazarov cyclization, followed by halide trapping in the presence of excess Lewis acid. Moderate to low yields of regioisomeric mono-halogenated cyclopentenones were observed (equation 33).

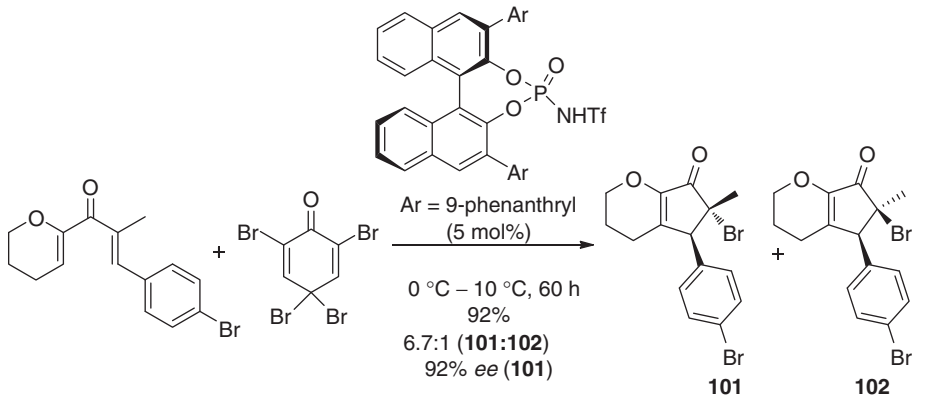
(32)



(33)

5.18.3.6 Electrophilic Trapping

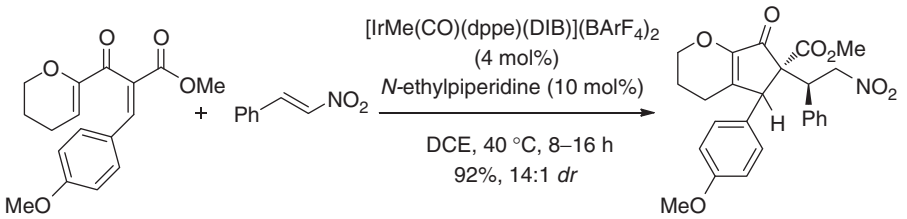
All examples discussed so far have involved the interception of the cyclopentenyl cation formed immediately following Nazarov cyclization. The enolate formed on elimination can also be used in domino processes by interception with suitable electrophiles.



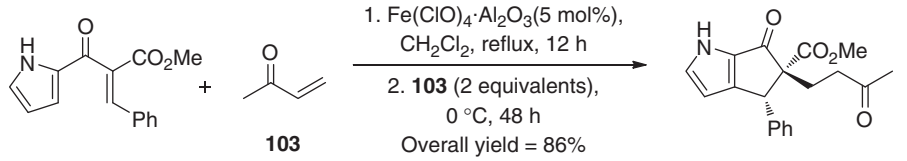
5.18.3.6.1 Trapping with electrophilic halogen sources

Ma and coworkers reported the synthesis of fluorinated indanones in a catalytic Nazarov cyclization/electrophilic fluorination sequence.[85] Alkylidine β-ketoesters were treated with a copper(II) Lewis acid in the presence of *N*-fluorobenzenesulfonimide (NFSI). Nazarov cyclization was followed by elimination with rearomatization, and the resulting copper enolate was then captured with electrophilic fluorine to give the fluorinated 1-indanone. The reaction was also studied using an asymmetric copper(II)-bis(oxazoline), which provided the desired products with moderate enantioselectivity. The same group has also published related methodology for trapping with electophilic fluorine,[86] chlorine, and bromine.[87] In these studies, a one-pot Knoevenagel condensation/Nazarov cyclization/halogenation sequence generates the halogenated 1-indanone products from β-ketoesters. Itoh and coworkers used a Nazarov cyclization/electrophilic fluorination strategy similar to that described above. Divinyl ketones bearing an α-ester were treated with an iron(II) Lewis acid in the presence of NFSI to give rise to fluorinated cyclopentenones.[39]

(34)



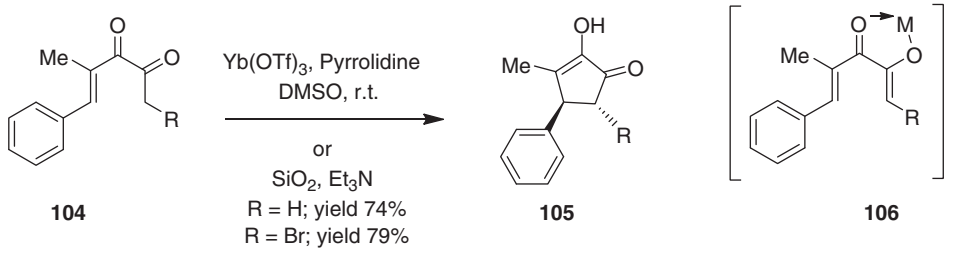
Recently, a conceptually related study by Rueping and Ieawsuwan gave rise to enantiomerically enriched α-halocyclopentenones via an asymmetric Brønsted acid-catalyzed Nazarov cyclization/electrophilic halogenation sequence.[88] Polarized dienone substrates were treated with a chiral BINOL-based *N*-triflylphosphoramide in the presence of the electrophilic bromine source 2,4,4,6-tetrabromocyclohexa-2,5-dienone. Torquoselective Nazarov cyclization followed by elimination led to an enol that was diastereoselectively captured by bromine from the opposite face as the β-substituent. The process was moderate to high yielding with synthetically useful enantiomeric excess, although long reaction times at low temperature were required.



(35)

5.18.3.6.2 Trapping with Michael acceptors

The enolate intermediate of the Nazarov process has also been successfully utilized in conjugate additions. Frontier and coworkers reported the first examples of a tandem Nazarov cyclization/Michael addition (equation 36).[89] When polarized push–pull dienones were subjected to catalytic iridium(III) and amine base in the presence of nitro-alkenes, Nazarov cyclization and elimination occured, followed by Michael addition of the resultant enolate into the nitro alkene. In the process three new stereocenters were formed. The Michael addition is relatively fast, suggesting activation of the nitroalkene by coordination to the Lewis acid. In a similar study, Itoh and coworkers found that pyrrole-containing dienones could undergo Nazarov cyclization in the presence of alumina-supported iron(III) perchlorate, and subsequent Michael addition of the enolate into α,β-unsaturated ketones and aldehydes to generate the desired cyclopentenone Michael adducts (equation 37).[90]

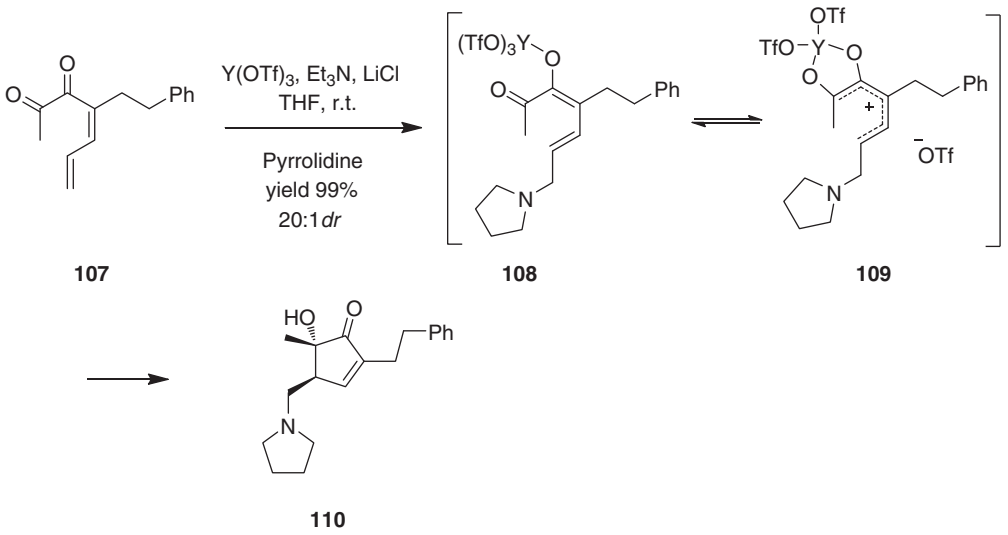


5.18.4 Alternative Activation Strategy

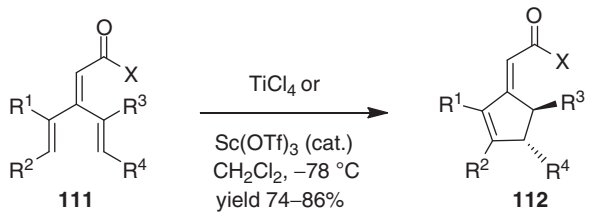
In its traditional format, the Nazarov reaction proceeds via activation of a cross-conjugated dienone with Lewis or Brønsted acid, followed by conrotatory electrocyclization of the resulting pentadienyl cation. However, some possible applications are precluded by limitations in substitution pattern or reagent compatibility. As a result, there has been considerable recent activity focused on alternative routes to the key pentadienyl cation.

5.18.4.1 Activation Through Diketones

α-Diketones are potential pentadienyl cation precursors via tandem enolization/carbonyl activation. α-Hydroxycyclopentenones were first reported to be formed from enediones in 1965 through a Nazarov-type cyclization of a chelated metalloenolate intermediate.[91] Later, Tius and coworkers described the cyclization of diketones **104** using $Yb(OTf)_3$ and pyrrolidine as base, which gave diosphenols **105** (Scheme 32).[92] The intramolecular Michael addition of the metal enolate derived from **104** is precluded by poor orbital overlap (a 5-*endo-trig* ring closure disfavored by Baldwin's rules). Instead, an electrocyclic ring closure involving the internally chelated metalloenolate **106** analogous to the Nazarov cyclization could better account for the formation of **105**.



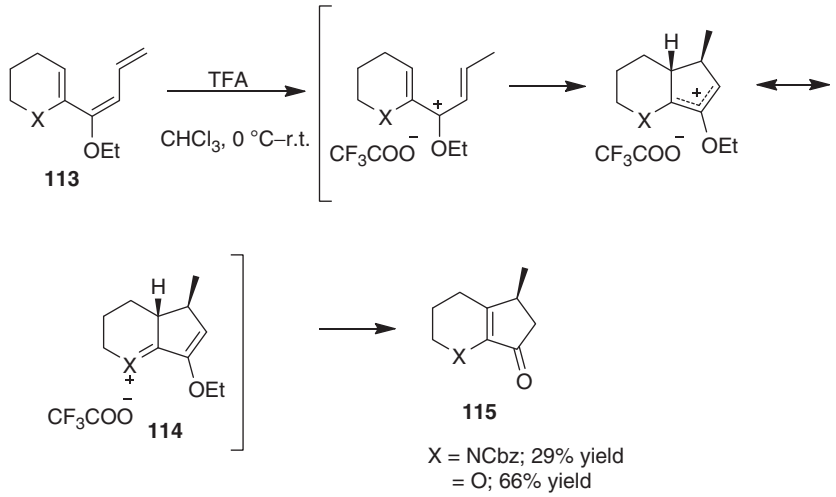
Scheme 32



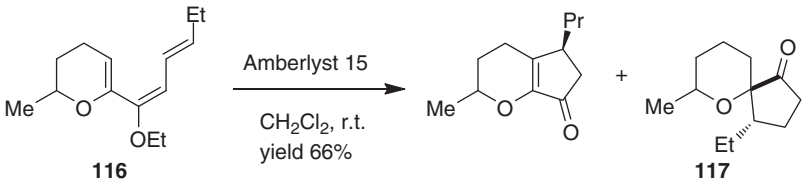
However, the Frontier group found that treatment of dienyl diketone **107** under similar conditions provided α-hydroxycyclopentenone **110** with installation of the pyrrolidine moiety in the molecule (Scheme 33).[93] In the proposed mechanistic rationale, a Lewis acid-promoted conjugate addition of the nucleophile to the diketone **107** would form intermediate **108**. A pentadienyl cation **109** could then be formed through activation of the keto-carbonyl moiety, which then undergoes a Nazarov-type cyclization to give **110**.

5.18.4.2 Vinylogous Nazarov Reaction

The general convention for substrate activation in Nazarov cyclization is through complexation to a C-3 carbonyl moiety. Variation of substitution at C-3 position raises challenges with regard to initiation of the reaction. West and coworkers have demonstrated that a cross-conjugated trienes **111** can also undergo successful Nazarov cyclization in the presence of $TiCl_4$ or $Sc(OTf)_3$ to furnish the cyclized products **112** (equation 38).[94] Replacement of the carbonyl moiety with enoate, enamide, enone, or enal functionality did not impede cyclization. Notably, only a single diene regioisomer **112** was furnished with the endocyclic olefin being *trans* to the carbonyl group.



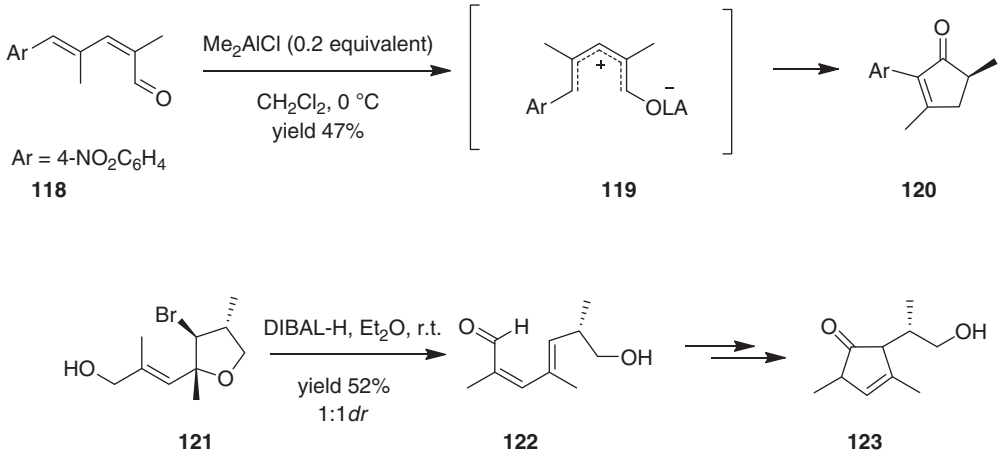
Scheme 33



(38)

5.18.4.3 Activation Through Trienes

The Occhiato group has highlighted that proper activation of electron-rich trienes such as **113** derived from the lactam or lactone triflates can also trigger an efficient Nazarov cyclization to construct N- and O-containing heterocycles **115** with high diastereoselectivity (Scheme 34).[95] The presence of the heteroatom in the ring is critical for the stabilization of the oxallyl cationic intermediate **114**, which also accounts for the mildness of the reaction conditions. A spirocyclic by-product **117** was also observed during the cyclization of the dihydropyran derivative **116** via competing protonation of the dihydropyran olefin (equation 39).[96]



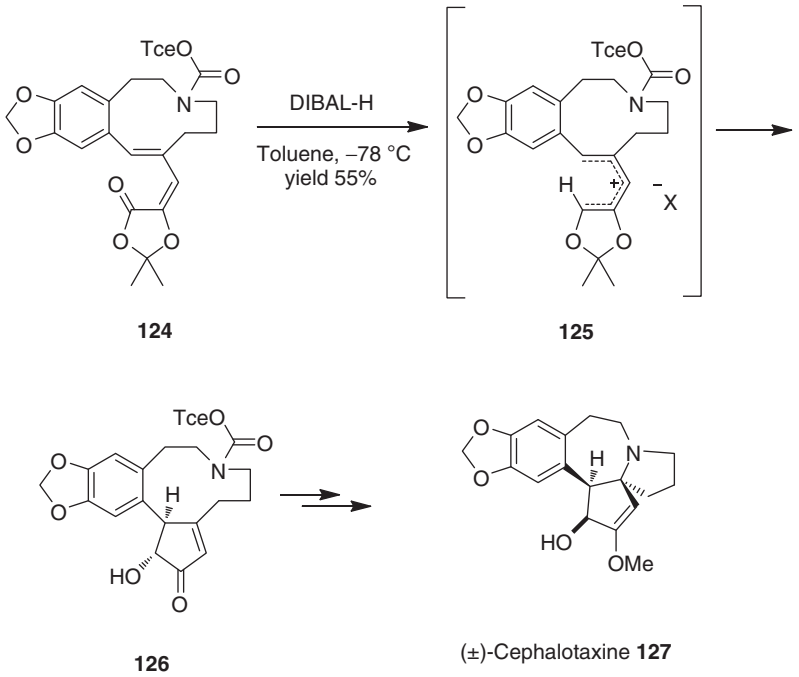
Scheme 34

(39)

5.18.4.4 Iso Nazarov

The electrocyclization of linearly conjugated dienals under Lewis acidic conditions, referred to as the iso-Nazarov reaction, has been studied recently. The Trauner group first reported the formation of cyclopentenone **120** from pentadienal **118** in the presence of a Lewis acid (Scheme 35).[97] The product **120** is assumed to form through a 4π electrocyclization of an oxy-pentadienyl cation **119**. An unusual rearrangement-cyclization of 2-alkenyl-3-bromotetrahydrofuran **121** under DIBAL-H reduction conditions was reported by the Jung group in 2007.[98] The cyclopentenone **123** is presumably formed via the iso-Nazarov cyclization of the activated form of dienal **122**. The acidic impurities from the DIBAL-H are most likely to catalyze this conversion.

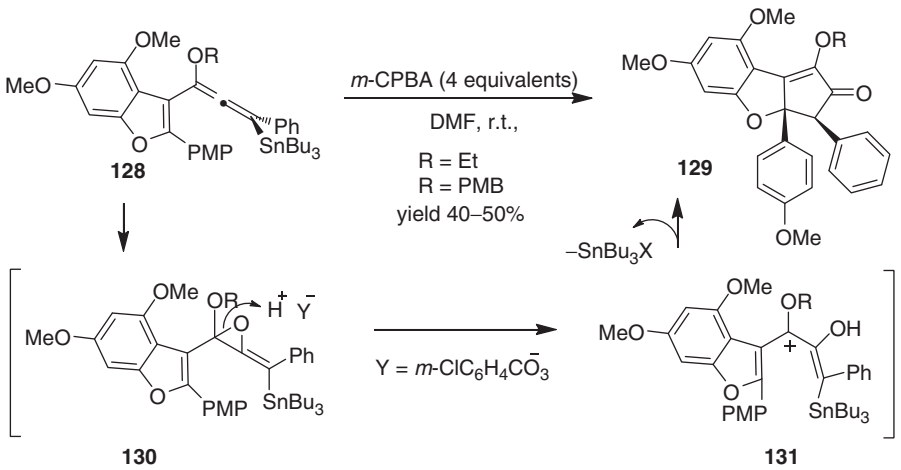
Scheme 35



A similar type of electrocyclization strategy (reductive oxy-Nazarov reaction) has been developed by the Li group in conjunction with their studies toward the natural product cephalotaxine **127** (Scheme 36).[99] This transformation involved DIBAL-H reduction of vinylalkylidene dioxolanone **124** to form a tethered 1,2-oxidopentadienyl cation **125**, which then underwent a conrotatory ring closure to give cyclopentenone **126** in a regio- and stereospecific fashion.

5.18.4.5 Alkoxy Allenes

Another potential route to pentadienyl cations involved electrophilic activation of vinyl allenes. In their recent approach to the natural product rocaglamide, Frontier and coworkers applied this strategy through oxidative activation. Treatment of the alkoxy allene **128** with excess *m*-CPBA gave the cyclized product **129** stereospecifically, but in moderate yield (Scheme 37).[6] This tandem sequence involved an initial regioselective epoxidation of allenol ether **128** to generate allene oxide **130**. Epoxide opening under acidic conditions unveiled the pentadienyl cation **131** which then underwent a conrotatory ring closure to form the fused tricyclic product **129**. This strategy has also been extended to simpler vinyl alkoxyallenes.[100]



5.18.4.6 Brønsted Acid Activation of Vinyl Allenes

Brønsted acid activation offers another method for accessing pentadienyl cations from vinyl allenes (Scheme 38).[101] Vinyl siloxyallene such as **133** formed *in situ* from enyne **132** were shown to undergo a 4π electrocyclization on Brønsted acid (TFA)-mediated activation to form cyclopentenones **134** and **135** in good yields. However, the regiocontrol for deprotonation at the termination step was poor.

5.18.4.7 Dihalocyclopropane Nazarov Reaction

Disrotatory electrocyclic ring opening of dihalocyclopropanes under thermal or silver-assisted conditions is quite well known. The resulting chloroallyl cations can undergo a variety of trapping processes. A dihalocyclopropane, when properly substituted with an

alkene unit, could potentially provide a novel route to a pentadienyl cation capable of undergoing Nazarov cyclization. Grant and West have demonstrated that alkenyl- and silyloxy-substituted cyclopropane **136**, in the presence of Ag(I), opens to pentadienyl cation **137**.[102] Subsequent 4π electrocyclic closure and elimination would then provide chlorocyclopentenones **138** or **139** (Scheme 39). Complete regioselectivity in the elimination step in favor of more substituted alkene product **138** was observed in cases lacking alkyl substitution on the cyclopropane.

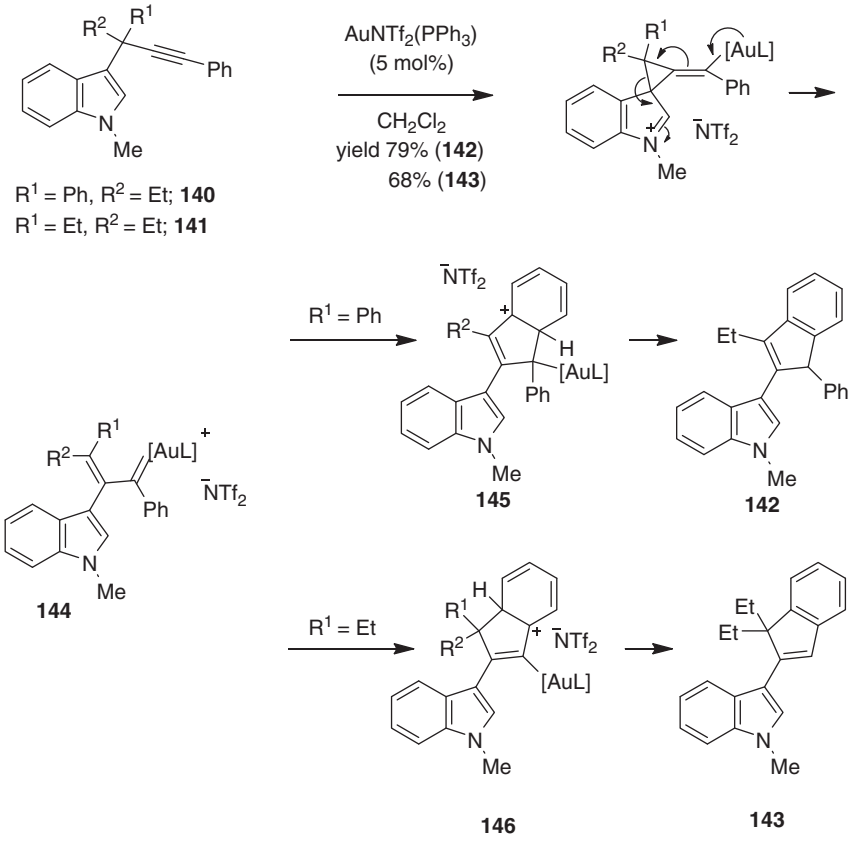
5.18.4.8 Cyclization via *In Situ* Generation of Nazarov Intermediate

Several different strategies have been developed over the past few years to access species bearing the pentadienylic moiety analogous to the Nazarov intermediate for cyclopentannulation.

5.18.4.8.1 Metal-mediated activation of alkynes

Divinylmetallocarbenes should be expected to display pentadienylic character analogous to Lewis or Brønsted acid-activated divinyl ketones. A common way of generating such type of metallocarbenes is through Au-mediated activation of alkynes. Sanz et al. reported the first gold-catalyzed tandem reactions of propargylated indoles triggered by a 1,2-indolyl migration.[103] Interestingly, propargyl indole **140** with an aryl group at the propargyl position gave **142** as the sole product whereas **143** was formed when **141** was the substrate (Scheme 40). Both products **142** and **143** are believed to be formed through a common intermediate **144** after a 1,2-indole migration.[103a,104] When there is an aryl group at the propargylic position, an intramolecular attack of the aryl group on the carbene carbon leads to the intermediate **145**. Finally, rearomatization and subsequent protodemetallation generates **142**. However, when there are two alkyl groups at the propargyl position, the carbene intermediate may involve in a Nazarov type cyclization to give **146**. Ultimately a similar rearomatization followed by protodemetallation gives the usual aura-Nazarov product **143**.[104]



An interesting domino cyclization of propargylic acetate **147** has been reported by the Malacria group using a gold(I) catalyst.[105] An initial [3,3]-rearragement of the acetate group of **147** leads to the intermediate **148** which then undergoes a metallo-Nazarov cyclization to generate a cyclopentenylidene gold complex **149** (Scheme 41). A subsequent cyclopropanation of **149** provides the tetracyclic product **150** as a single diastereomer in excellent yield. This methodology has been applied to a short total synthesis of capnellane.[105b] A similar domino protocol of [3,3] rearrangement and Nazarov cyclization of enynyl acetate **151** to cyclopentenone **153** has been studied by the Zhang group.[106] Best results were obtained using wet dichloromethane as solvent, prompting the authors to propose a water-assisted proton transfer via **152**.[106b]

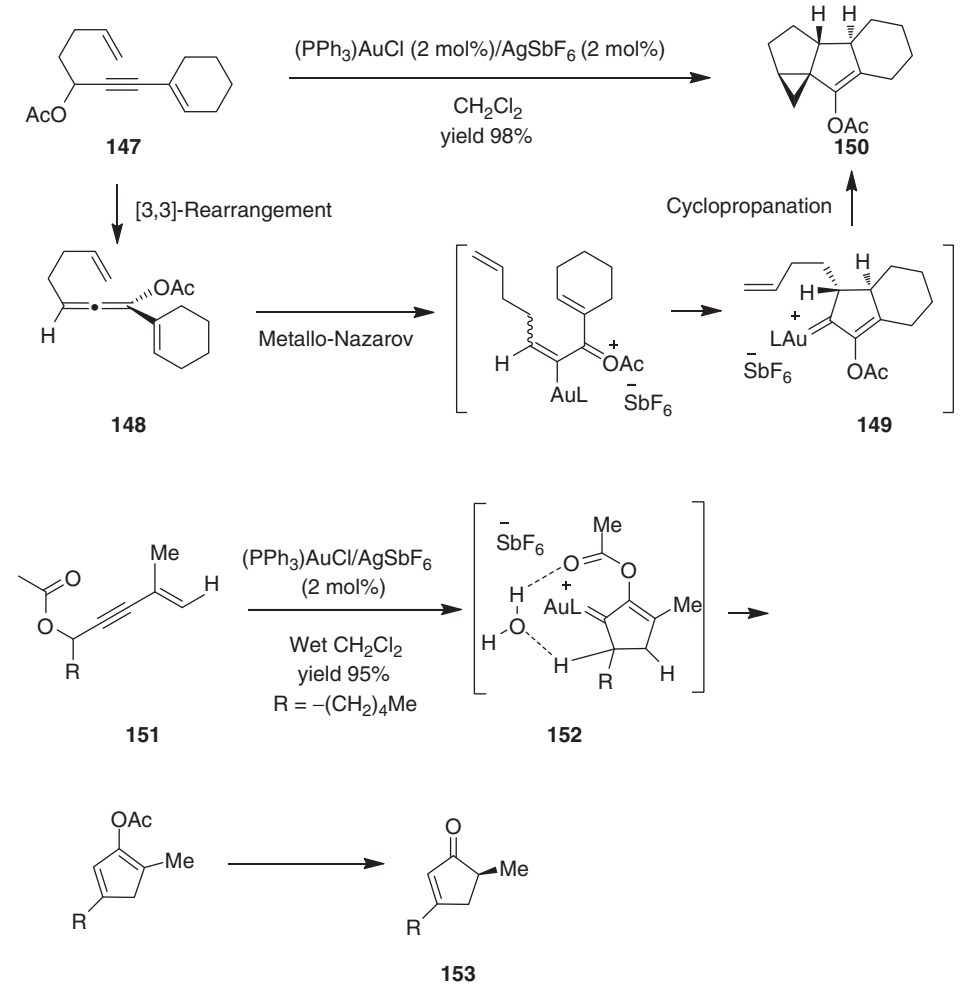
Vinylcarbenoid intermediates can also be generated by other transition metal catalysis. Indenes **155** and **156** have been formed from propargyl ester **154** by platinum or ruthenium-mediated activation.[107] Metal-mediated activation of the alkyne moiety in **154** with a subsequent 1,2-acetyl shift generated a vinylcarbenoid species **157** (Scheme 42). In the presence of a platinum catalyst, a mixture of isomers **155** and **156** were formed, whereas the use of a ruthenium catalyst yielded predominantly isomer **156**. An alternative reaction mechanism via metallacycle **158** has been proposed for the ruthenium-mediated reaction.

Gold-mediated activation of alkynes can also lead to a Nazarov-type cyclization via a pentadienyl cationic intermediate without involving a vinylcarbenoid species (Scheme 43).[108] The 1,6-yne-allene **159**, for example, undergoes a domino 6-*endo-dig* cyclization via Au(I)-π-alkyne intermediate **160** and a subsequent Nazarov cyclization to generate a tricyclic compound **161** in moderate yield. The $PtCl_2$/CO catalyst system has also been shown to be efficient in catalyzing 2-alkenyl-(1′-hydroxy-4-en-2-ynyl) benzenes **162** through a similar tandem process to generate cyclopentanaphthalene derivatives **163** regioselectively.[109]

Another method of generating the pentadienyl system **165** in the presence of a gold cation can be through heteroenyne metathesis of 1,3-enynyl carbonyls **164** (Scheme 44).[110] In this case, Au (III) activates the alkyne and carbonyl moieties simultaneously. The trienones **166** are generally formed in excellent yields with good olefin regioselectivity and also high diastereoselectivities.

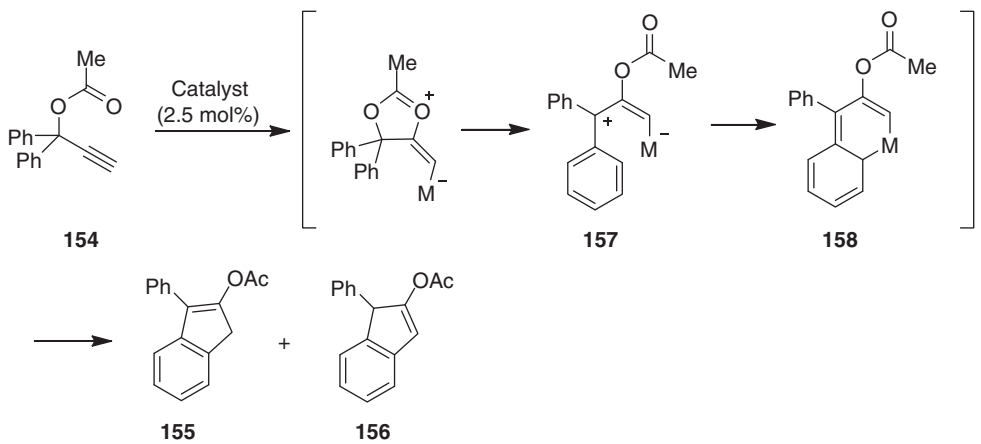
Various other ways of generating the 3-oxygenated pentadienyl cations have been reported in recent years. A tandem cyclization of diyne **167** and oxocarbenium ion **168** in the presence of $FeCl_3$ catalyst has been reported to provide highly functionalized indenes **169** (Scheme 45).[111] In this example, diyne **167** undergoes a [2+2] cycloaddition with the oxocarbenium ion **168** generated from benzaldehyde acetal by Lewis acid catalysis, to form oxete **170**. Ring opening leads to the pentadienyl cation **171**

Scheme 40



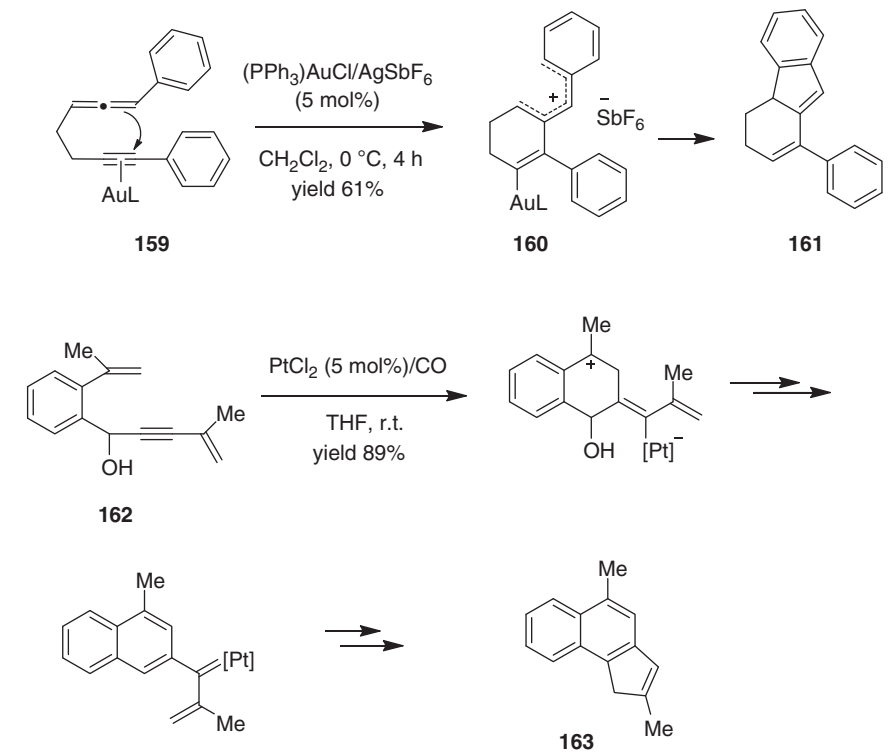
which subsequently undergoes a 4π electrocyclization to generate another oxocarbenium cation **172**. The tethered alkyne moiety then intercepts the oxocarbenium ion and subsequent attack by chloride ion provides the indene **169** as the final product.

5.18.4.9 *In Situ* Generation of Allenyl Vinyl Ketone



Nazarov cyclization of allenyl vinyl ketone is quite well developed and has been discussed in detail in Section 5.18.3.5.3. Tang and coworkers have developed a method for the *in situ* generation of allenyl vinyl ketone **175** and subsequent Nazarov cyclization (Scheme 46).[112] In this process the starting unsaturated diazocarbonyl compound **173** underwent a Wittig olefination with ketene **174** to provide the allenyl vinyl ketone intermediate **175**. Subsequent cyclization under acidic conditions gave the cyclopentenone **176**. This reaction provides an efficient one-pot alternative access to sensitive allenyl vinyl ketones which can then undergo a facile cyclization to provide cyclopentenone derivatives with high yield and excellent *Z* stereoselectivity.

5.18.4.10 Imino Nazarov



In 2001 Tius et al. first reported the formation of α-aminocyclopentenones **179** in a single operation from α,β-unsaturated nitriles **177** and allenyl nucleophiles **178** (Scheme 47).[113] The cyclopentannulation event was described by the authors as an imino Nazarov cyclization. The amines were converted to the corresponding acetamides **180** for ease of handling and storage. Theoretical calculations by the Smith group rule out the possibility of a classical imino Nazarov cyclization due to an unfavorable equilibrium for the cyclization.[114] However, the formation of the α-aminocyclopentenones **179** is favored by the irreversible loss of the methoxymethyl cation after the cyclization step. Cyclopent-2-imines **187** have been reported to be formed through an interesting tandem reaction sequence involving a gold-catalyzed activation of propargyl tosylates **181** followed by further reaction with activated aldimine **182** (Scheme 48).[115] According to the proposed reaction mechanism, an initial activation of the alkyne moiety by gold(I) leads to the 1,2-tosyl rearrangement inducing an alkyl migration to give **183**. A further elimination provides the diene **184** which then reacts with the activated aldimine **182** to form a highly strained azetine species **185**. Finally, a divinyl imine **186** is formed via the electrocyclic ring opening of **185**. In the presence of the gold complex, **186** then undergoes a Nazarov-like cyclization to give the cyclopentenyl imine product **187**. The formation of cyclopentimine products through the final Nazarov cyclization can also be termed as an imino Nazarov cyclization.

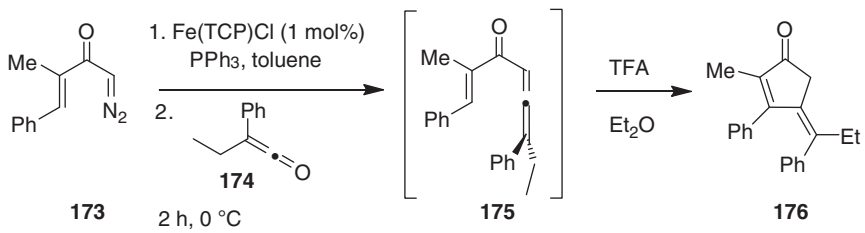
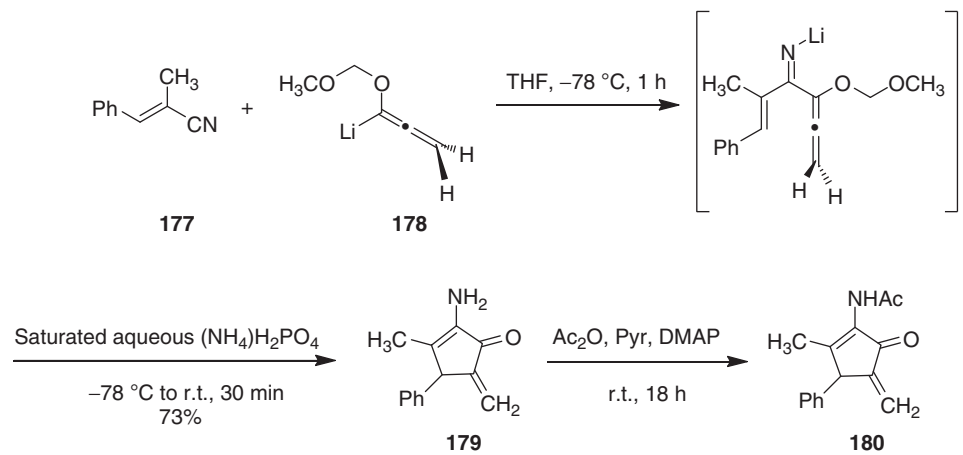
5.18.4.11 Aza-Nazarov

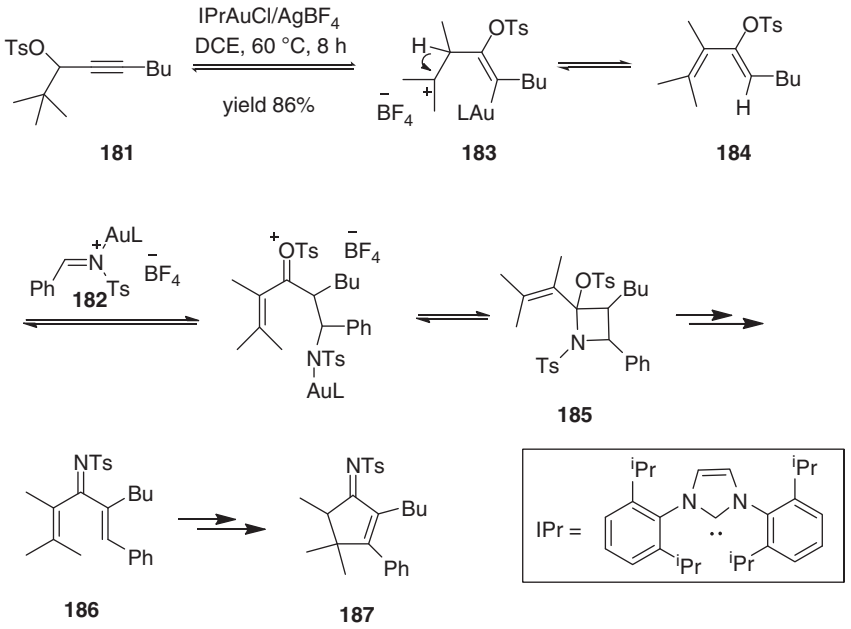


Replacement of 1,4-pentadien-3-ones with 1-aza-1,4-pentadien-3-ones can potentially lead to the formation of pyrroles. Ciufolini and Roschangar first coined the name aza-Nazarov reaction during their synthetic endeavor toward camptothecin where a quinoline-containing enone gave an indolizine product in the presence of $Yb(fod)_3$.[116] Later, the Würthwein group showed that hydrazones of type **188** having nitrogen in the 1-position undergo smooth cyclization to give **189** in accordance with their theoretical estimates (Scheme 49).[117] Compound **189** was generally trapped by acetylation to give **190**, due to its instability. Further studies were carried out with indoline **191**; it was found that indole **193** was an effective leaving group to produce the substituted 1*H*-pyrrole **192**.[118] Klumpp et al., however, reported the aza-Nazarov cyclization of 2-azapentadienone **194** to form a fused bicyclic product **196** (Scheme 50).[119] Although the presence of nitrogen at the 2-position was calculated to confer a high activation energy for cyclization, the reaction occurred smoothly when the substrates were *N*-acyliminium salts **194**, in the presence of acid catalysts.[119a] On the basis of theoretical calculations Klump and coworkers suggested that the formation of superelectrophilic species such as **195** is key to the success of these reactions.

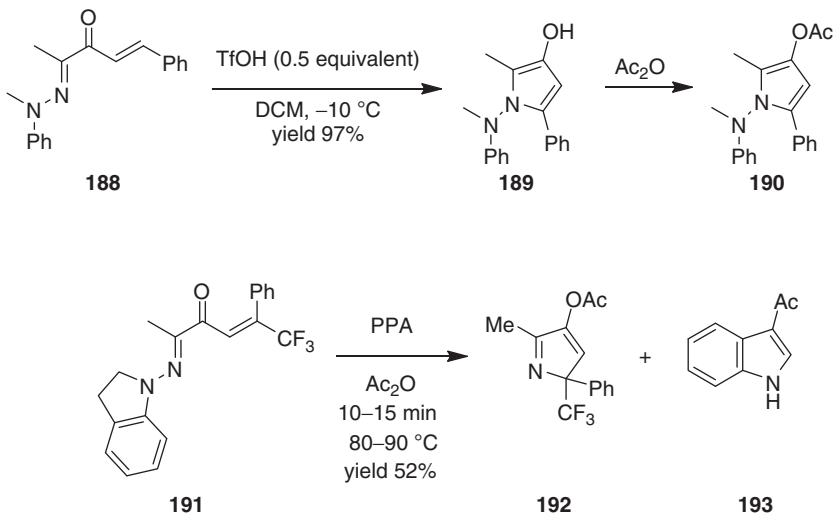
5.18.4.12 Cyclization of Pentadienyl Carbocation Generated through Dehydration



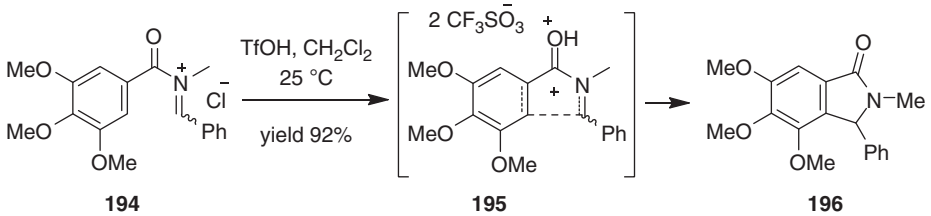
Another alternative route to a pentadienyl carbocation for a potential 4π-electrocyclization could be achieved via dehydration of a divinyl alcohol. An allenic version of this protocol has been reported by Malacria and Gandon to provide a direct route to benzofulvenes **199** or **200** starting from α-hydroxyallenes (Scheme 51).[120] In case of the monosubstituted α-hydroxyallene



Scheme 45

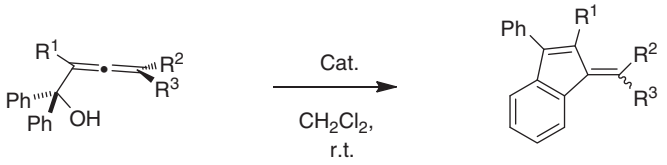


Scheme 46



Scheme 47

Scheme 48



Scheme 49

Scheme 50

substrate **197**, $ZnCl_2$ proved to be a superior catalyst, whereas for di- and tetrasubstituted allenes such as **198**, AgOTf, TfOH and phosphomolybdic acid (PMA) gave the best results. Interesting polycyclic scaffolds **202** have been synthesized in a similar fashion from diaryl alcohols **201** by the Panda group (Scheme 52).[121] The presence of an electron-donating group activates the cyclization of the pentadienyl carbocation, whereas lack of substitution leads to a sluggish cyclization and also allylic isomerization of the

product. 1,3-Diarylallylic alcohols **203** have been shown to provide 1-aryl-1-H-indenes **204** and **205** under similar Lewis acid-mediated conditions.[122] The reaction is proposed to proceed through dehydration of the alcohol to form the corresponding 1,3-diarylallylic carbocation. Presence of a substituent is necessary at the 2-position of the diarylallic alcohols **203** to attain the reactive conformation for 4π electrocyclization. A dehydrative cyclization was also observed by Rieder and West during their studies on the Meyer–Schuster rearrangement of alkynyl carbinols **206** under gold(III)-catalyzed conditions.[123] Exclusive formation of the cyclized alkyne **207** in good to excellent yields was observed when the reaction was carried out in the presence of molecular sieves. The stereochemical outcome of this dehydrative cyclization confirmed a Nazarov-type electrocyclization pathway. Zhou et al., however, have reported a sulfur-mediated dehydration of [2-(1-thio-vinyl)phenyl]alcohols **208** to generate the pentadienyl cation **209**, followed by Nazarov-type cyclization leading to 3-thio-1*H*-indenes **210**.[124]

5.18.4.13 Piancatelli Reaction

In 1976, Piancatelli et al. reported a protocol for the synthesis of various 4-hydroxycyclopentenones via acid-catalyzed rearrangement of 2-furylcarbinols.[125] The overall transformation is believed to proceed through a domino sequence that involves a 4π electrocyclic ring closure of a pentadienyl cation, closely resembling the Nazarov cyclization. However, the synthetic application of this rearrangement has been largely limited because of the requirement of stoichiometric amounts of acid as activator, dilute reaction conditions, and excess water.

In 2007, the Batey group reported the synthesis of 4,5-diaminocyclopent-2-enones **213** under Lewis acidic conditions from furan-2-carbaldehyde **211** and aniline **212** (Scheme 53).[126] Product **213** is formed with exclusive *trans* diastereoselectivity. The overall transformation is proposed to follow a domino pathway involving an initial condensation followed by ring-opening and electrocyclization, very similar to the Piancatelli reaction. In 2010, Alaniz and coworkers developed a mild catalytic aza-Piancatelli protocol for the synthesis of 4-amino-5-alkylcyclopentenones **216** from readily available 2-furylcarbinols **214** and aromatic amines **215**.[127] 5 mol% of $Dy(OTf)_3$ was optimal for the conversion with good yields and high *trans* diastereoselectivity. Generally, product isomerization is hard to control in the Piancatelli rearrangement which could be avoided in the present protocol due to the mild nature of $Dy(OTf)_3$. The aza-Piancatelli rearrangement has further been extended by the Alaniz group toward the synthesis of azaspirocycles **218** using 2-furylcarbinols with an aminoalkyl side chain **217**.[128] The Reddy group has recently reported a very similar aza-Piancatelli rearrangement to construct *trans*-4,5-disubstituted cyclopentenones under mild conditions using very low catalyst loading (0.03 mol% PMA).[129] The intramolecular aza-Piancatelli rearrangement also

Scheme 53

proceeds with good *trans* diastereoselectivity, consistent with a 4π electrocyclization. Substrates bearing an electron-donating group adjacent to the alcohol and an electron-withdrawing group on the nucleophilic nitrogen were most efficient in the intramolecular pathway. The intramolecular aza-Piancatelli rearrangement provides an efficient approach to the construction of challenging azaspirocycle motifs **218** by forming the tertiary stereocenter and the spirocyclic system in a single operation.

Glossary

Chiral auxiliary Covalently attached chiral residue that controls a desired diastereoselective bond-forming process.
Concerted reaction Reaction with a single transition state for bond breaking and bond making.
Domino reaction Transformation with multiple bond-forming processes run under identical reaction conditions, in which each subsequent reaction occurs at the functional group newly formed in the previous step.
Endo Space inside a vaulted, bicyclic structure.
Exo Space outside a vaulted, bicyclic structure.
Medium-size ring Carbo- or heterocyclic ring with 8–12 members.
Sigmatropic rearrangement Migration of a σ-bonded atom or group along a π-system.
Synchronous reaction Reaction with simultaneous bond breaking and bond making.

5.19.1 Introduction

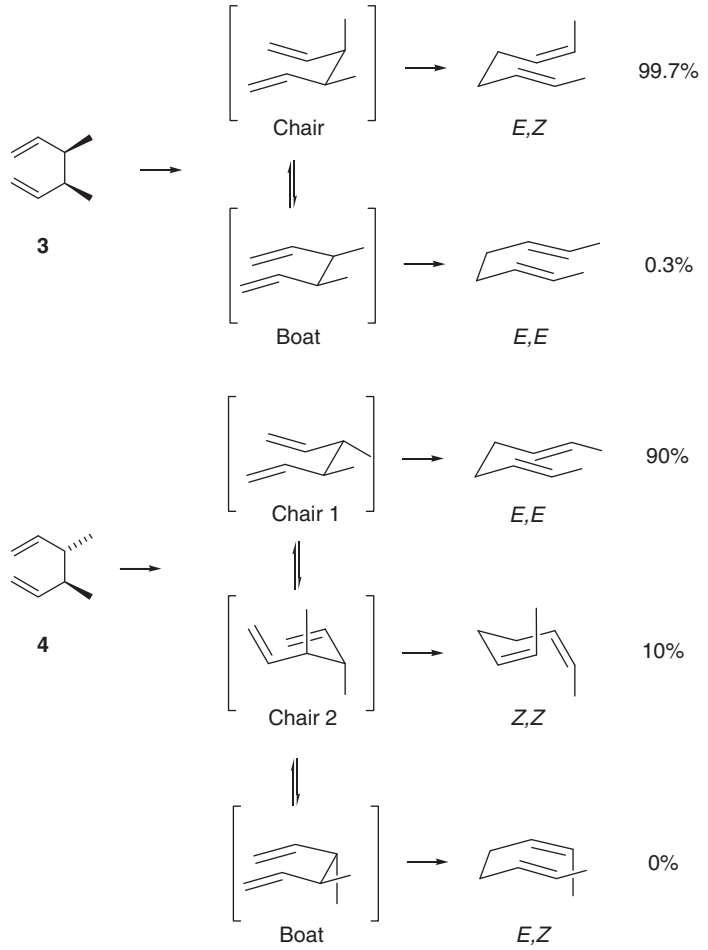
The all-carbon [3.3]-sigmatropic rearrangement of 1,5-dienes, serendipitously discovered by AC Cope and his group in 1940 during the distillation of the allylated malonic cyanoester **1** (equation 1),[1] comprises the suprafacial migration of an allyl fragment along a second allyl moiety with concomitant σ- and π-bond reorganization to arrive at the doubly conjugated

product **2**. In the course of this process one new σ-bond and two new π-bonds are predictably established at unambiguously defined locations within the product.

1 **2** (1)

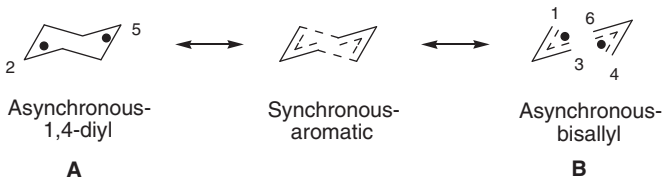
In contrast to the related Claisen rearrangement of allyl vinyl ethers that takes advantage of the formation of a carbonyl group in the course of the reaction, the Cope rearrangement is principally a thermoneutral and hence reversible process, which derives its driving force from interaction with the substituents attached. In particular, carbonyl and related substituents with the capacity to conjugate with the developing double bonds turned out early on to be well suited to shift the equilibrium to the product side. A breakthrough for the utility of the Cope rearrangement in synthetic organic chemistry came with the development of the oxy-Cope reaction, which benefits from an irreversible enol–keto tautomerization subsequent to the actual rearrangement. The discovery that a negative charge on the oxy substituent leads to dramatic rate accelerations in the anionic version of the oxy-Cope rearrangement further extended the applicability of this process. In addition, release of ring strain and aromatization of the product can contribute significantly to the ease and driving force of the Cope rearrangement.

This chapter will briefly outline the basic principles of this reaction and then focus primarily on recent developments since 1991. For additional information, the reader is referred to the respective chapter 7.1 in the first edition of this book and a number of excellent review articles.[2]



5.19.1.1 Transition State and Mechanism

The Cope rearrangement proceeds through a cyclic, strictly intramolecular, and concerted transition state with inversion of the migrating allyl group. The activation enthalpy for the reaction of the parent 1,5-hexadiene has been measured as 33.5 kcal mol^{-1} with an activation entropy of -13.8 cal mol^{-1} K.[3] Through a number of ingenious experiments, Doering and Roth discovered the exact transition state conformation for rearrangements of acyclic 1,5-dienes.[4] Thus, the Cope rearrangement of *meso*-3,4-dimethyl-1,5-hexadiene (**3**) furnished 99.7% of (2*E*,6*Z*)-2,6-octadiene and only 0.3% of the corresponding *E*,*E*-isomer on heating at 225 °C (Scheme 1). In addition, the C_2-symmetric stereoisomer **4** gave rise to 90% of the *E*,*E*-isomer, 10% of the *Z*,*Z*-isomer, and none of the *E*,*Z*-isomer. These observations reveal a highly stereospecific reaction pathway and suggest a chair transition state conformation which prevails over a boat-like structure by at least 5.7 kcal mol^{-1}.

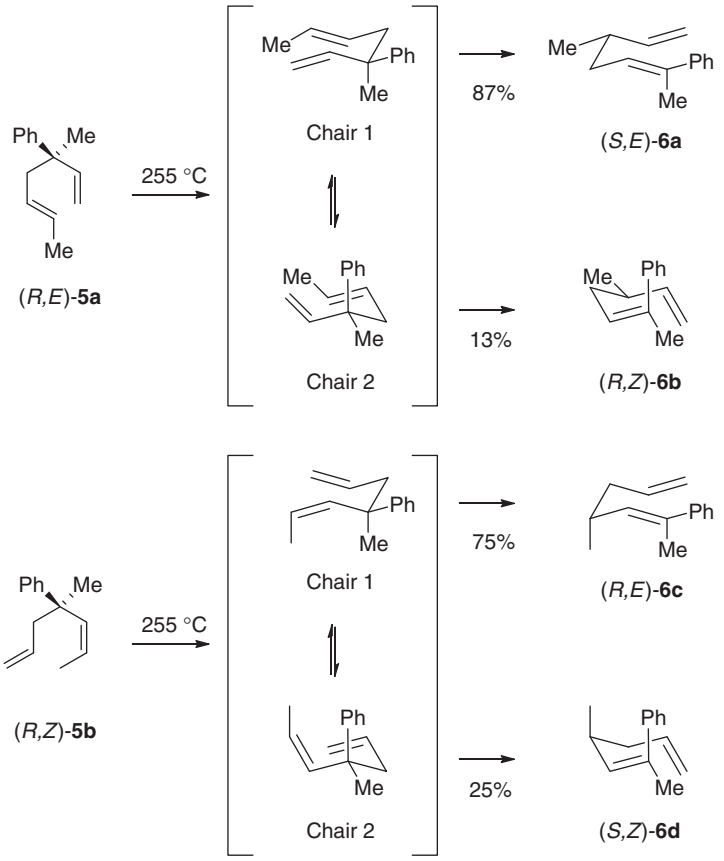


Although the preference for chair-like transition states holds true for acyclic and thus flexible 1,5-hexadienes, boat transition structures may energetically be accessible and even prevail in cyclic 1,5-dienes, which suffer from geometrical constraints. For example, in *cis*-1,2-divinylcyclopropanes, which rearrange spontaneously at ambient temperature, only a boat conformation with eclipsing substituents can bring the two vinyl groups in sufficiently close proximity such that bond formation can occur. For the same reason, most *cis*-1,2-divinylcyclobutanes rearrange through boat transition states too, whereas *cis*-1,2-divinylcyclopentanes can accommodate both conformations and *cis*-1,2-divinylcyclohexanes employ chair conformations exclusively.

The exact nature of the transition state of the Cope rearrangement has been a matter of intense debate in the course of time. Specifically the question whether it is a truly synchronous process with simultaneous bond making and bond breaking resulted in a host of theoretical studies.[5] Although a full discussion of this topic would be beyond the scope of this chapter, some important conclusions should be mentioned here:

(1) The Cope rearrangement of the parent 1,5-hexadiene involves a concerted, aromatic, and synchronous transition state as described above.
(2) Radical-stabilizing substituents such as phenyl and cyano groups located both at C2 and C5 within the 1,5-diene system lead to an asynchronous transition structure with advanced bond making between C1 and C6, which is best described by a cyclohexane-1,4-diyl biradical resonance structure **A** (equation 2).
(3) However, radical-stabilizing substituents at C1, C3, C4, and C6 within the 1,5-diene system result in very long interallylic bond lengths and a transition state that resembles two weakly interacting allyl radicals as depicted in resonance structure **B**. Here, bond breaking between C3 and C4 precedes bond making between C1 and C6. Doering described this phenomenon as a chameleonic transition structure of the Cope rearrangement,[5c] whereas Borden coined the term of a variable transition structure depending on the exact substitution pattern of the 1,5-hexadiene.[5d]

Scheme 1



(2)

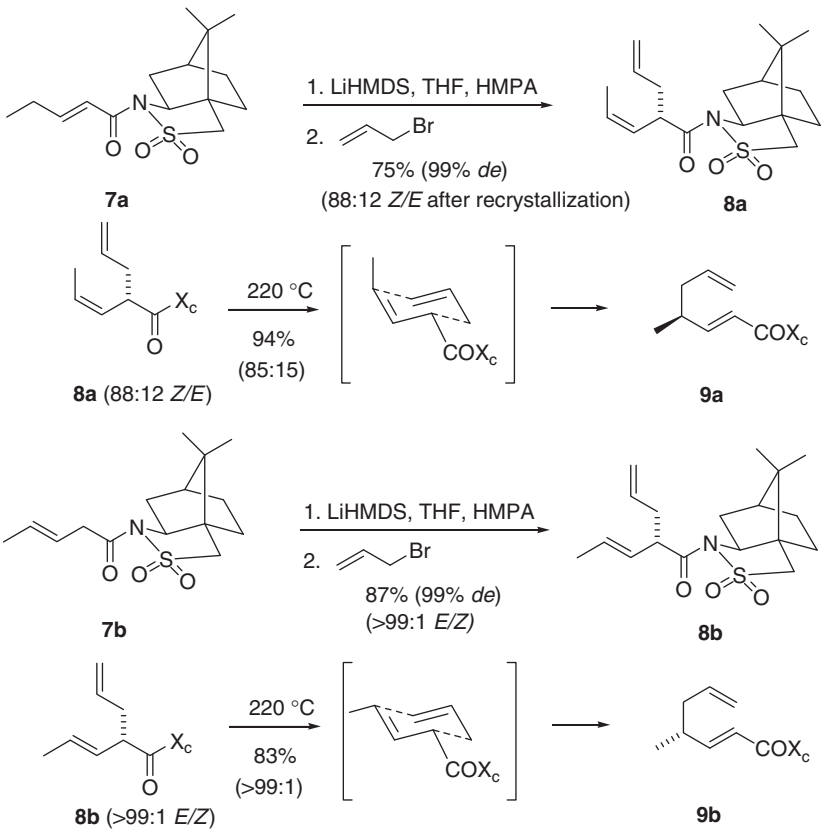
5.19.1.2 Double Bond Configuration and Chirality Transfer

Based on the preference for chair transition states, C3- and C4-substituents within the 1,5-diene strongly prefer equatorial positions, which results in the formation of *E*-configured Cope products accordingly. Thus, the thermal rearrangement of **4** furnished 90% of the *E*,*E*-configured diene originating from chair 1 with both methyl groups in equatorial positions and only 10% of the *Z*,*Z*-diene resulting from chair 2 with the methyl groups in the unfavorable axial positions (Scheme 1). The preference for the equatorial position of a given substituent and hence the formation of the *E*-alkene increases with the steric size of that substituent. Such A-values for the equatorial/axial preference of substituents in cyclohexanes are a good measure for estimating the proportion of the *E*-alkene in a stereoisomeric mixture of Cope products. If two substituents are attached to the same carbon atom, the larger of them will occupy the equatorial position in the preferred transition state. In oxy-Cope rearrangements, however, the polarity of the solvent and the existence of a charged species, such as in the anionic version, may affect the *E*/*Z* ratio of the product. In general, nonpolar solvents and the absence of charge increase the proportion of *E*-alkene in the stereoisomeric mixture of Cope products.

The stereospecificity of the Cope rearrangement has important implications for chiral 1,5-dienes carrying prochiral alkene groups. Hill et al.[6] first demonstrated unambiguously that the pair of stereoisomeric dienes (*R*,*E*)-**5a** and (*R*,*Z*)-**5b** rearranged on heating exclusively either to a mixture of (*S*,*E*)-diene **6a** and (*R*,*Z*)-diene **6b** or (*R*,*E*)-diene **6c** and (*S*,*Z*)-diene **6d**, respectively (Scheme 2). The two stereoisomers formed in each reaction resulted from the two competing chair-like transition states and consequently had opposite configurations at both the new chiral center and the double bond. No crossover stereoisomers were observed within the limits of detection, indicating stereospecificity of at least 97%. The equatorial preference of the larger phenyl substituent in the respective chair transition state 1 dictated the stereoselectivity of the Cope rearrangement in favor of the formation of *E*-alkenes (*S*,*E*)-**6a** and (*R*,*E*)-**6c**.

Scheme 2

This highly stereospecific reaction path and the unique ability to predictably relay the absolute configuration of an existing stereogenic center along the 1,5-diene via a chair-like transition structure to a prochiral sp^2 center have undoubtedly contributed to the significance and popularity of the Cope rearrangement in synthetic organic chemistry.

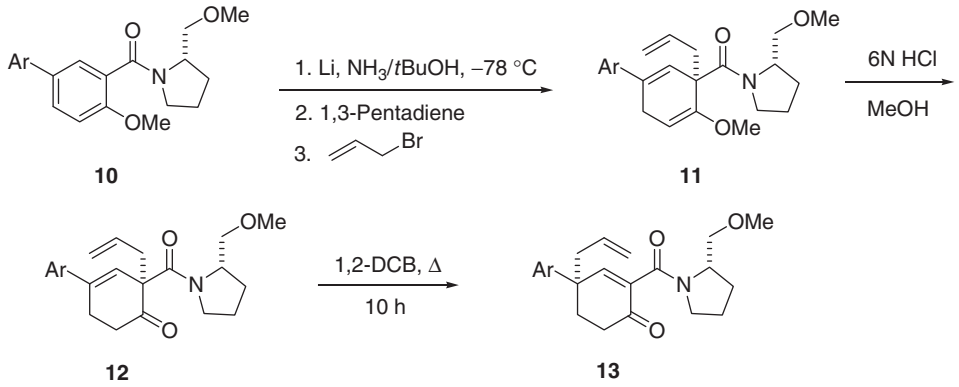


5.19.2 Thermal Cope Rearrangements

5.19.2.1 With Acyclic Unstrained 1,5-Dienes

The equilibria within Cope rearrangements are shifted toward the thermodynamically more stable 1,5-dienes, which may contain either more highly alkyl-substituted or resonance-stabilized alkenes. Rather drastic reaction conditions are typically employed in purely thermally induced processes with reaction temperatures ranging from 160 to 240 °C in most cases due to the high activation enthalpy. The reaction shown in equation (1) is the archetypical example of such a transformation and represents a very useful general strategy until today. An α,β-unsaturated carbonyl compound is converted into the corresponding dienolate by vinylogous enolization, which is alkylated with an allyl electrophile regioselectively at the α-carbon atom to generate the requisite 1,5-diene in one synthetic operation. This 1,5-diene now contains either one or even two carbonyl groups at C3 as a result of the deconjugative allylation process. In the course of the Cope rearrangement, one of the double bonds is shifted back into

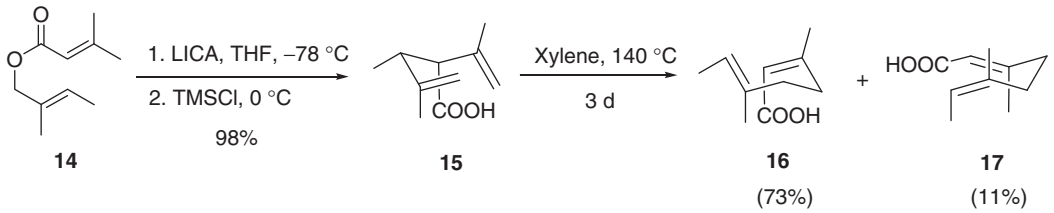
conjugation with the carbonyl group(s) which provides the driving force of the rearrangement. A compilation of instructive synthetic examples can be found in Chapter 7.1.2 of the first edition of this book.



Nakai and coworkers reported the first asymmetric version of this strategy employing a chiral auxiliary.[7] Vinylogous deprotonation of α,β-unsaturated imide **7a** and subsequent asymmetric allylation gave rise to the predominantly *Z*-configured 1,5-diene **8a** (88:12 *Z*/*E* after recrystallization) with >99% *de*. The Cope rearrangement was then effected by heating this diene to 220 °C in naphthalene, which furnished an 85:15 stereoisomeric mixture of products **9a** and **9b** in high yield (Scheme 3). Thus, an 88:12 mixture of *Z*/*E*-stereoisomers was almost stereospecifically converted into an 85:15 mixture of diastereomers. The large carboximide group apparently controlled the diastereoselectivity of this process by its strong preference for the equatorial position in the chair transition state. Likewise, asymmetric allylation of the stereochemically homogenous *E*-configured 1,5-diene **7b** yielded a single diastereomer of *E*-diene **8b**, which was rearranged under the same conditions to furnish Cope product **9b** in good yield, again as a single diastereomer. This study clearly reveals the power of combining an asymmetric enolate-based reaction with the highly stereospecific Cope rearrangement in the context of acyclic stereocontrol and specifically the facile switch of absolute product configuration by changing the corresponding alkene stereochemistry (for the corresponding asymmetric aldol-Cope-sequence see the silyloxy-Cope rearrangement of aldol products in Section 5.19.7.3).

Scheme 3

The combination of an asymmetric Birch reduction-allylation sequence with a thermal Cope rearrangement has been exploited by Malachowski et al. for the highly stereoselective synthesis of carbocyclic quaternary centers.[8] Auxiliary-controlled Birch reduction of a series of *o*-anisidic amides **10** generated dienolates *in situ*, which were trapped with allyl bromide to furnish 1,5-dienes **11** in typically good yields and excellent diastereoselectivity (Scheme 4 and Table 1). Acidic hydrolysis of the enol–ether moiety gave rise to the doubly activated 1,5-dienes **12**, which on heating in 1,2-dichlorobenzene for 10 h underwent a highly stereospecific Cope rearrangement to furnish the thermodynamically more stable isomers **13** in yields ranging from 50% to 80% and as single diastereomers. Microwave irradiation could shorten the reaction time significantly to only 1 h, and identical yields were obtained. The Cope products formed via this strategy were successfully further converted into the alkaloids (+)-mesembrine and (–)-lycoramine.



The Cope rearrangement can be coupled to an Ireland–Claisen rearrangement as shown by Kraft et al. in the context of a synthesis of a constitutional isomer of nerol with interesting olfactory properties.[9] Claisen rearrangement of allyl ester **14** under Ireland's conditions gave rise to the 1,5-diene **15**, which on refluxing in xylene furnished the conjugated acid **16** in 73% yield carrying the desired 2*Z*,6*E*-configuration along with 11% of its stereoisomer **17** with opposite double bond geometries (Scheme 5).

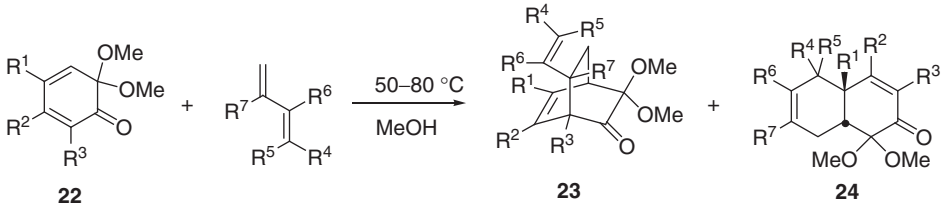
5.19.2.2 With Strained Bicyclic 1,5-Dienes

1,5-Dienes embedded within strained bicyclic compounds enjoy a natural driving force to undergo Cope rearrangements as they result in the release of ring strain. Therefore, processes involving vinyl-substituted bicyclo[2.2.1]heptenes and bicyclo[2.2.2]octenes, respectively, have been widely employed as suitable substrates for the Cope rearrangement, as long as the vinyl group is on the *endo*-side of the molecule so that a concerted rearrangement can occur. Oxy-Cope and anionic oxy-Cope rearrangements (AOC) make up for the most part of this category based on the facile synthetic accessibility of the requisite 3-oxy-1,5-dienes by highly *endo*-stereoselective organometallic vinyl group additions toward bicyclic ketones. However, regular 1,5-dienes are excellent substrates for this strategy as well.



Thus, 1,5-diene **18** with a bicyclo[2.2.1]heptene backbone, which was obtained through catalytic enantioselective Diels–Alder reaction as key step, underwent a highly stereoselective Cope rearrangement on heating at 160 °C for only 4 h to furnish *cis*-hydroindenone **19** in 71% isolated yield after decarboxylation.[10] **19** was subsequently converted into the plant growth regulator, gibberellic acid. Likewise, bicyclo[2.2.2]octenone **20** underwent a smooth thermal Cope rearrangement to deliver the corresponding *cis*-decalin **21** in moderate yield and as a single diastereomer (Scheme 6).[11]

Through inverse electron demand, Diels–Alder cycloadditions of cyclohexa-2,4-dienones and acyclic 1,3-dienes, vinyl-substituted bicyclo[2.2.2]octenones were generally accessible and then converted into *cis*-decalins via Cope rearrangement. In particular, *o*-benzoquinones **22**, masked as ketals, which were obtained through (diacetoxy)iodobenzene-mediated oxidation of the corresponding *o*-methoxy phenols, have been reacted with various 1,3-dienes to furnish mixtures of vinyl-substituted bicyclo[2.2.2]octenones **23** along with the desired *cis*-decalins **24** directly on heating at 50–80 °C (Scheme 7 and Table 2). The Diels–Alder adducts **23** were separated and heated at 200–220 °C in mesitylene for 1–2 h to deliver the Cope product **24** in typically good overall yields.[12]

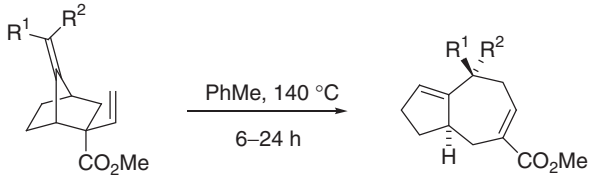
A number of natural products containing a *cis*-decalin structure were successfully synthesized according to this general scheme, including eremopetasidione, 3β-angeloyloxyfuranoeremophilane, and 3β-methacryloylfuranoeremophilane.[13]



The vinyl substituent may also be attached to the bridgehead atom of a norbornane skeleton to furnish a 1,5-diene, which undergoes a strain-release thermal Cope rearrangement (equation 3). In the course of synthesis of the tetracyclic core of CP-225,

917 the strained lactone **25** was submitted to a Cope rearrangement at 170 °C for 6 h to deliver the tricyclic lactone **26** in 95% yields.[14]

25 **26** (3)

2-*exo*-Vinyl-7-alkylidenenorbornanes **27** underwent facile Cope rearrangements in toluene at 140 °C to furnish hexahydroazulenes **28** in good to excellent yields (Scheme 8 and Table 3).[15] At first glance, this smooth rearrangement appeared unexpected, as significant molecular distortion was required on the side of the bridgehead alkylidene group in order to interact with the exocyclic vinyl group. This rearrangement additionally benefits, however, from the shift of the double bond into conjugation with the ester group. When the ester group was reduced to a hydroxymethyl group, incomplete conversions and low yields were observed even at elevated temperatures and extended reaction times. The starting 1,5-dienes **27** were readily prepared through Diels–Alder reaction of fulvenes and methyl acrylate with subsequent introduction of the *exo*-vinyl group via diastereoselective enolate alkylation and elimination of a suitable leaving group.

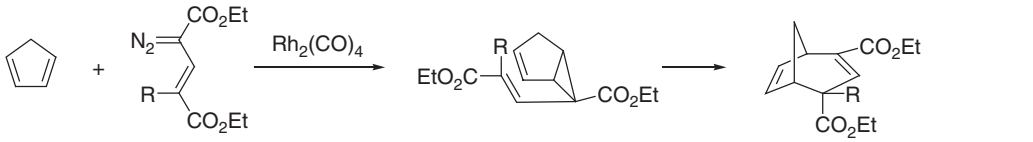
5.19.3 Ring Expansion of *cis*-1,2-Divinylcycloalkanes

5.19.3.1 *cis*-1,2-Divinylcyclopropanes



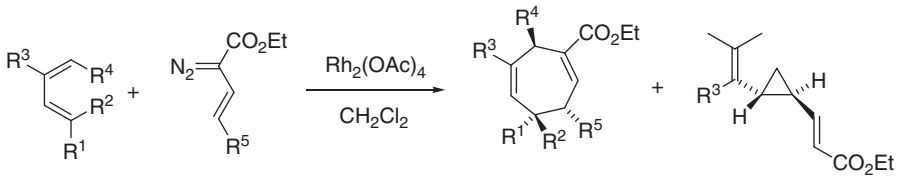
cis-1,2-Divinylcyclopropanes rearrange spontaneously to 1,4-cycloheptadienes at ambient temperature, as a good amount of the activation enthalpy is provided by the release of ring strain. The half-life of the parent *cis*-1,2-divinylcyclopropane toward rearrangement has been measured as being only 90 s at 35 °C and 25 min at 11 °C, so that most of the starting divinylcyclopropanes can only be isolated at low temperatures. Accordingly, any synthetic method for the preparation of *cis*-1,2-divinylcyclopropanes, which themselves require ambient or even elevated temperatures, will frequently furnish the rearranged 1,4-cycloheptadiene instead. Substituents on the double bonds, however, increase the activation barrier of the rearrangement so that elevated reaction temperatures may be necessary. The stereoisomeric *trans*-1,2-divinylcyclopropanes are completely inert toward the [3.3]-sigmatropic process and must be isomerized at higher temperatures to the *cis*-isomers in order for the Cope rearrangement to proceed. Calculations suggest a highly concerted reaction mechanism with only boat-like transition state conformations being accessible because of geometrical constraints.[16]

This process is among the most useful methods for the synthesis of seven-membered carbocycles and has been employed frequently in natural product synthesis. An illustrative example of the power of this strategy in the context of complex molecule synthesis is the straightforward preparation of the [5.4.0]-core structure of the natural product, phorbol (equation 4).[17]

(4)

By combining the actual Cope rearrangement with the preceding cyclopropanation, Davies and coworkers have been able to establish a very elegant domino-type strategy toward 1,4-cycloheptadienes in one synthetic operation. For example, the Rh(II)-catalyzed reaction of vinyldiazoacetate **29a** and cyclopentadiene gave rise to the bicyclo[3.2.1] system **31a** in 98% yield directly (Scheme 9). A highly *cis*-stereoselective cyclopropanation started the sequence furnishing the presumed *cis*-1,2-divinylcyclopropane **30a**, which spontaneously rearranged to **31a**.[18]

29a: R = H
29b: R = OMe



30a: R = H
30b: R = OMe (74%)

31a: R = H (98%)
31b: R = OMe (>95% yield)

Scheme 9

Supporting evidence for this mechanism was obtained from the reaction of the more highly substituted vinyldiazoacetate **29b**. Under otherwise identical reaction conditions, the *cis*-divinylcyclopropane **30b** was isolated in 74% yield, which resisted a spontaneous rearrangement most likely on the basis of steric effects. However, heating of a solution of **30b** in toluene under reflux initiated a quantitative Cope rearrangement to furnish the bicyclic compound **31b**.

This protocol could be successfully extended to acyclic 1,3-dienes as well (Scheme 10 and Table 4). In the case of unsymmetrical 1,3-dienes **32**, the cyclopropanation predictably occurred at the least substituted double bond and delivered 1,4-cycloheptadienes **33** in typically good yields. The stereoselectivity of the initial cyclopropanation step proved to be dependent on

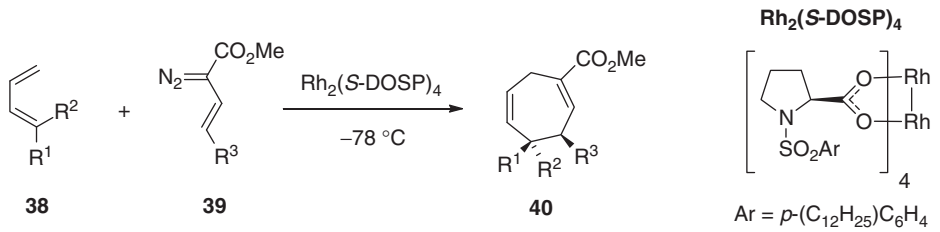
the vinyldiazoacetate employed. With **29a** ($R^5 = CO_2Et$) as vinylcarbenoid precursor, significant amounts of the *trans*-divinylcyclopropanes **34** were formed, which did not undergo the Cope rearrangement for geometrical reasons and were isolated as such. With **29c** ($R^5 = CH{=}CHPh$), however, a highly *cis*-stereoselective cyclopropanation occurred giving rise exclusively to the corresponding 1,4-cycloheptadienes **33** via the domino cyclopropanation/Cope rearrangement.



The concerted and highly stereospecific reaction pathway of the sigmatropic process was proven by the reaction of the stereoisomeric *E*- and *Z*-1,3-pentadienes, **32c** and **32d**, respectively, which exclusively furnished the stereoisomeric *cis*- and *trans*-cycloheptadienes, **33e** and **33f**, respectively (Table 4, Number 5 and 6). In the case of **32e** carrying two disubstituted alkenes, the cyclopropanation occurred chemoselectively at the *Z*-alkene moiety, whereas the *E*-alkene remained completely untouched (Number 7).

In contrast to reactions with alkyl-substituted 1,3-dienes, vinyldiazoacetate **29a** reacted with vinylketene silyl-*O,O*-acetals such as **35a** under $Rh_2(CO)_4$-catalysis with complete *cis*-stereoselectivity and furnished doubly oxygenated cycloheptadienes, which on acidic hydrolysis and oxidation gave rise to tropolone **36a** in excellent overall yield (Scheme 11). A fused tropolone **36b** was accessible as well via this strategy by embedding the vinyldiazoacetate double bond into the ring system of **29d**, whereas the corresponding reaction of **29e** with *E*-1-acetyoxy-1,3-butadiene (**35c**) directly furnished hydroazulene **37**.

Scheme 11

By developing an enantioselective cyclopropanation process, Davies and coworkers were able to obtain highly enantiomerically enriched 1,4-cycloheptadienes via this strategy. They employed the highly reactive rhodium(II) (*N*-dodecylbenzenesulfonyl)-*S*-prolinate (Rh_2(S-DOSP)$_4$) as chiral catalyst, which decomposed vinyldiazoacetates **39** in the presence of 1,3-dienes **38** even at temperatures as low as $-78\ ^\circ C$ to afford the corresponding 1,4-cycloheptadienes **40** in moderate to good yields and excellent enantioselectivities (Scheme 12 and Table 5).[18b] The diastereoselectivity of the cyclopropanation/Cope rearrangement was again governed by the double bond configuration of the starting 1,3-diene. The natural product 5-*epi*-vibsanin E was synthesized according to this strategy.[18c] An intramolecular version of this process furnished fused 1,4-cycloheptadienes in moderate selectivities.[18d]

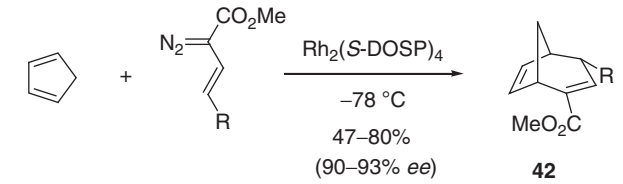
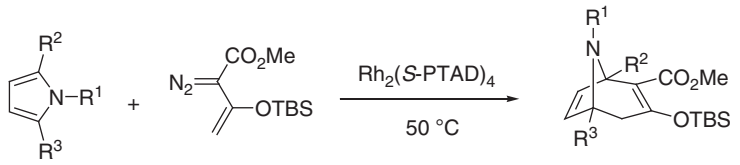
1,3-Dienes embedded into bicyclic systems furnished fused 5-6-7- and 6-6-7-tricyclic structures on reaction with 2-(silyloxyvinyl)diazoacetate **41** and the adamantyl glycine-derived catalyst Rh_2(*S*-PTAD)$_4$ (Scheme 13).[18e] Besides the additional functional group, which could be used advantageously for further synthetic manipulations, the silyloxyvinyldiazoacetate **41** generally provided much better stereodifferentiation in the cyclopropanation step than that by the parent vinyldiazoacetate. One of the reaction products was subsequently converted into the terpene natural products, (–)-barekol and (+)-barekoxide.



Scheme 13

Cyclic 1,3-dienes such as cyclopentadiene gave rise to bicyclo[3.2.1]octadienes **42**, which constitute formal [4 + 3]-cycloaddition products. In each case, the *endo*-stereoisomers were formed exclusively and the enantioselectivities ranged from 90% to 93% *ee* (Scheme 14). This reaction could be successfully extended to heterocyclic 1,3-dienes and delivered 8-oxabicyclo[3.2.1]octadienes from furans[18f] as well as the corresponding tropanes **43** from *N*-protected pyrroles and **41** with Rh_2(*S*-PTAD)$_4$ as the catalyst in 2,2-dimethylbutane as the solvent (Scheme 14 and Table 6).[18g]



Stoltz and coworkers developed an alternative strategy to access 5-7- and 6-7-bicyclic structures via the Cope rearrangement of *cis*-1,2-divinylcyclopropanes. With vinyl cyclopropyl diazoketones **44** as starting material, a silver-catalyzed Wolff rearrangement was initiated under carefully optimized reaction conditions. The ketene produced as intermediate engaged the vinylcyclopropane residue in the [3.3]-sigmatropic process *in situ* to generate bicyclo[5.3.0]decadienones **45** in excellent yields and as single stereoisomers (Scheme 15).[19] For terminal vinyl cyclopropanes as reaction partners for the ketene, a photochemical activation of the diazoketones was found to be superior.

Yet another elegant synthetic access to *cis*-1,2-divinylcyclopropanes relies on organoiron methodology. Addition of alkenyl Grignard reagents to the (1-methoxycarbonyl-pentadienyl)iron(1 +) cation **46** generates the corresponding (2-alkenylpent-3-en-1,5-diyl)iron complexes, which on ceric(IV) ammonium nitrate (CAN)-oxidation eliminate the metal fragment and furnish *cis*-divinylcyclopropanes **47**. Owing to the electron-withdrawing nature of the ester group which stabilizes the distal cyclopropane

ring bond, such *cis*-divinylcyclopropanes are frequently stable at ambient temperature and require heating up to 125 °C in order to rearrange to the corresponding 1,4-cycloheptadienes depending on the substitution. A milder and more general alternative includes $LiAlH_4$-reduction of the ester moiety at 0 °C, which directly gave rise to 1,4-cycloheptadienes **48** in generally good yields via the presumed hydroxymethyl-substituted cyclopropanes (Scheme 16 and Table 7).[20]

The capacity of cationic gold(I)-complexes to induce a 1,2-acyloxy migration of propargyl esters resulting in the formation of vinyl-substituted gold carbene complexes paved the way for an elegant gold(I)-catalyzed synthesis of seven-membered carbocycles with 1,3-dienes. Thus, reaction of propargyl acetates **49** with 1,3-dienes **50** under Au(I)-catalysis delivered *cis*-6,7-substituted 1,4-cycloheptadienes **51** via Cope rearrangement of the presumed *cis*-divinylcyclopropanes through a boat-like transition state conformation (Scheme 17 and Table 8).[21] This reaction could be rendered enantioselective using a chiral gold(I)-complex, which catalyzed the formation of 1,4-cycloheptadiene **51h** from the corresponding propargyl pivaloate and 1,3-diene in good yield and diastereoselectivity and with >90% *ee*. This bicyclic 1,4-cycloheptadienyl acetate represents a direct synthetic precursor of the natural product frondosin.

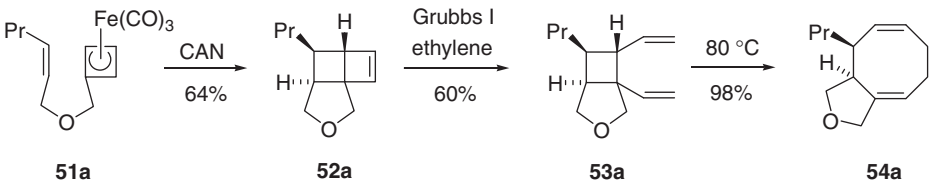
The Cope rearrangement of *cis*-1,2-divinylcyclopropanes can be extended to divinyl-substituted small ring heterocycles. A prominent example of this category is the [3.3]-sigmatropic rearrangement of *cis*-2,3-divinyl epoxides **49**, which required slightly higher reaction temperatures of 100–150 °C and again proceeded stereospecifically via boat-like transition structures. Highly valuable 4,5-dihydrooxepins **50** were formed as products in good yields. The double bond configuration of **49** determined which diastereomer of **50** was formed (Scheme 18).[22] *E*-configured substrates required higher reaction temperatures than that required by those with *Z*-double bonds.

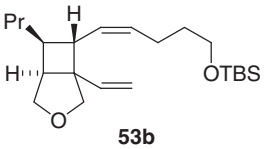


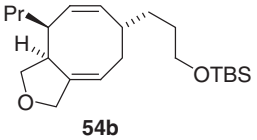
Scheme 18

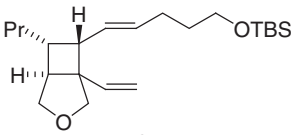
5.19.3.2 *cis*-1,2-Divinylcyclobutanes

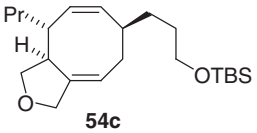
Cope rearrangements of *cis*-1,2-divinylcyclobutanes are almost as facile as those of *cis*-1,2-divinylcyclopropanes as can be estimated from the similar strain energy of the two small rings. However, the parent compound *cis*-1,2-divinylcyclobutane is actually stable at room temperature and requires heating at 120 °C to cleanly rearrange to *Z*,*Z*-1,5-cyclooctadiene.[23] As already seen with *cis*-1,2-divinylcyclopropanes, substituents on the double bonds retard the reaction.

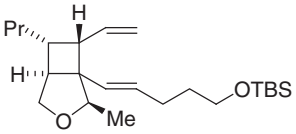
A very common synthetic strategy to furnish *cis*-1,2-divinylcyclobutanes in a highly straightforward manner is based on cycloadditions to assemble the four-membered ring. Snapper et al. have further built on that concept and developed an elegant procedure to synthesize fused cyclooctadienes. For example, the iron carbonyl complex of cyclobutadiene **51a**, which was tethered to an unactivated alkene, was oxidatively decomplexed and the liberated cyclobutadiene moiety underwent an instantaneous, intramolecular [4 + 2] cycloaddition to furnish the cyclobutene-containing 5-4-4 ring system **52a**. On a Ru-catalyzed ring-opening cross metathesis with ethylene, the requisite *cis*-1,2-divinylcyclobutane **53a** was obtained, which on heating gave rise to oxabicyclo[6.3.0]undecadiene **54a** in excellent yield as a single stereoisomer (Scheme 19).[24]

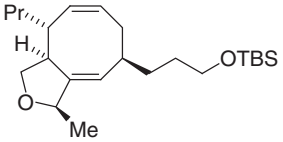


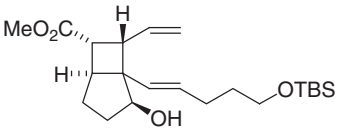


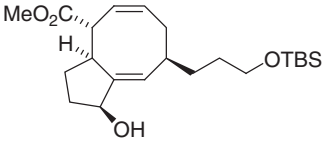


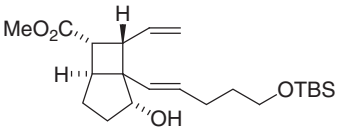


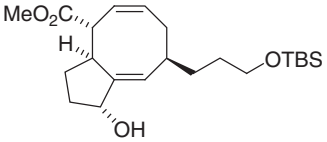


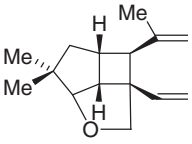


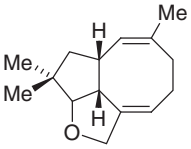












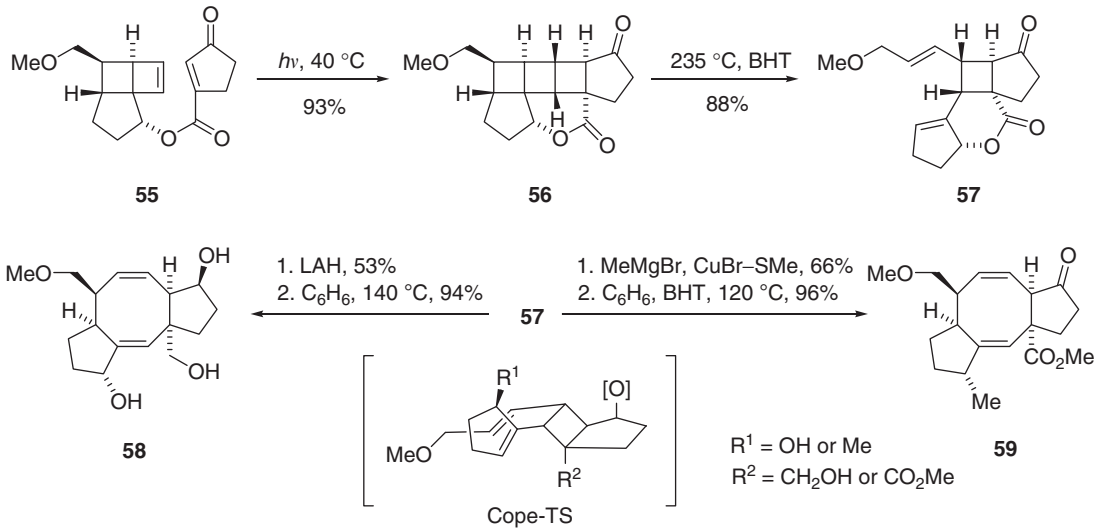
Scheme 19

To access more highly substituted and functionalized bicyclic cyclooctadienes, which possess greater value in the context of natural product synthesis, the ring-opening cross metathesis was also performed with unsymmetrical, substituted alkenes. The ring-opening metathesis (ROM) products were obtained with moderate to good levels of regiocontrol and excellent stereoselectivity furnishing exclusively the *E*-stereoisomers. On heating at 200 °C, the *cis*-1,2-divinylcyclobutanes **53b–f** underwent a stereospecific Cope rearrangement to furnish oxabicyclo[6.3.0]undecadienes, **54b–d**, and bicyclo[6.3.0]undecadienes, **54e** and **54f**, again as single stereoisomers in good to excellent yields (Table 9). The relatively harsh reaction conditions were required because of the highly substituted cyclobutane ring. Substrates lacking a β-alkyl substituent on the cyclobutane ring underwent the sigmatropic rearrangement in refluxing benzene in the same pot. This methodology was successfully applied in a total synthesis of the sesquiterpene natural product, asteriscanolide.[24c]

In a complimentary approach, [2 + 2] photocycloadditions were employed to install the requisite cyclobutane ring. Thus, irradiation of the cyclobutene–cyclopentenone system **55** using a medium pressure Hanovia Hg lamp with a Pyrex filter initiated an intramolecular [2 + 2] cycloaddition to furnish photoadduct **56** in almost quantitative yield (Scheme 20). Thermal fragmentation of the highly strained dicyclobuta[*a*,*c*]cyclobutane **56** at 235 °C gave rise to the desired *cis*-1,2-divinylbutane **57**, which was prevented from undergoing an instantaneous Cope rearrangement through the existence of the lactone bridge. LAH reduction of **57**, however, released the strained system; heating at 140 °C triggered a [3.3] sigmatropic rearrangement via the depicted boat-like transition state to generate dicyclopenta[*a*,*d*]cyclooctadiene **58** in excellent yield.[25] Alternatively, the lactone bridge was opened through an allylic substitution reaction with an organocopper reagent, and the resulting ester rapidly rearranged to cyclooctadiene **59** at 120 °C in 96% yield (Scheme 20).

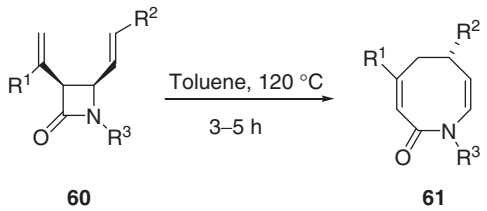
Table 9 Cope rearrangement of fused *cis*-1,2-divinylcyclobutanes **53** (200 °C, 1 h, benzene) (Scheme 19)[24]

No.	*Substrate*	*Product*	*Yield (%)*
1	 **53b**	 **54b**	70
2	 **53c**	 **54c**	97
3	 **53d**	 **54d**	90
4	 **53e**	 **54e**	96
5	 **53f**	 **54f**	99
6	 **53g**	 **54g**	74 (combined yield for ROM and Cope)



The ring expansion of 1,2-divinyl-substituted four-membered rings can also be performed on heterocyclic systems. Thus, azetidinone-tethered 1,5-dienes **60** smoothly rearranged to eight-membered lactams **61** on heating at 120 °C in a sealed tube in toluene (Scheme 21 and Table 10).[26] With optically pure *β*-lactam **60e**, obtained from asymmetric[2 + 2]cycloaddition of a ketene and an imine controlled by a chiral auxiliary on the lactam nitrogen atom, optically pure **61e** was produced as a single diastereomer (Number 5).

5.19.4 Ring Contraction of Medium Rings



5.19.4.1 1,5-Cyclononadienes

As medium size rings suffer from significant transannular strain but cyclopentanes are almost strainless, the thermal equilibrium between *cis*-1,2-divinylcyclopentane **63** and (*Z*,*Z*)-1,5-cyclononadiene (*Z*,*Z*-**62**) lies on the side of the smaller ring (95:5 in favor of **63** at 220 °C) (Scheme 22). On the basis of its configuration, *Z*,*Z*-**62** can only adopt a boat-like transition state conformation. However, due to the greater flexibility of five-membered rings, *E*,*Z*-configured 1,5-cyclononadiene, *E*,*Z*-**62**, can easily rearrange to **63** quantitatively as well, employing a chair transition state which requires significantly lower temperatures.[27]

E-Configured cycloalkenes are inherently planar-chiral compounds and their 8- and 9-membered congeners typically have racemization barriers high enough, so that the individual enantiomers can be separated. An interesting planar-to-central chirality transfer has been observed with cyclic ether **64**, which on Pd(II)-catalyzed Cope rearrangement (see Section 5.19.6) furnished

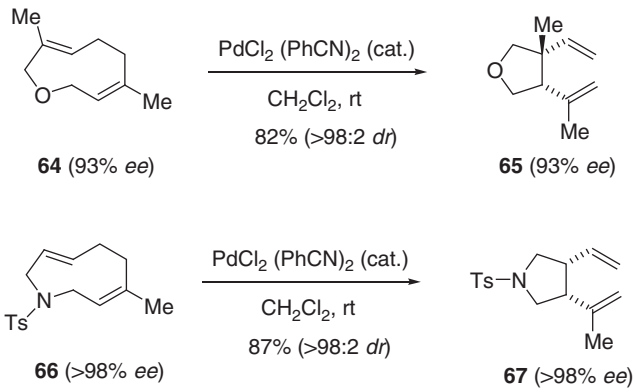
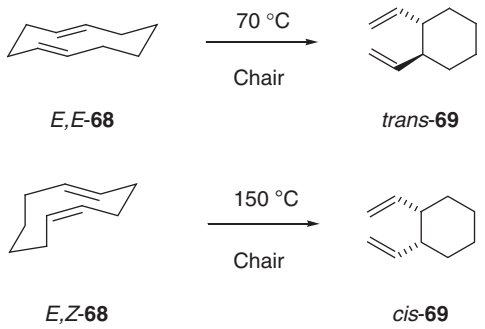


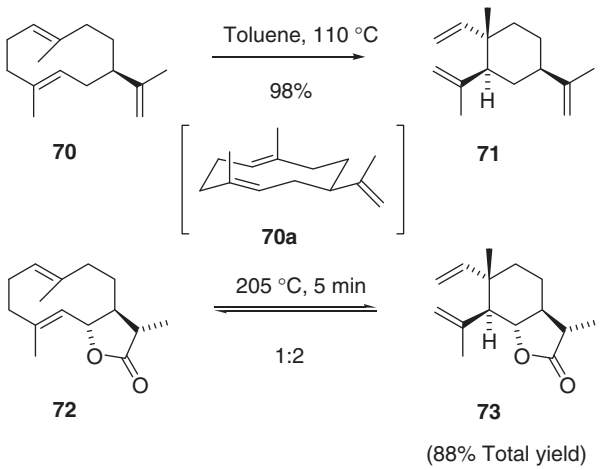
Scheme 22

cis-1,2-divinyl tetrahydrofuran (THF) **65** in good yield and complete chirality transfer (Scheme 23).[28a] Its aza-analogue **66** underwent this transformation in a similar manner delivering *cis*-1,2-divinyl pyrrolidine **67** in 87% yield as a single enantio- and diastereomer, which was further converted into the neurotransmitter stimulator, (–)-kainic acid.[28b]



5.19.4.2 1,5-Cyclodecadienes

1,5-Cyclodecadienes **68** rearrange quantitatively to divinylcyclohexanes **69** furnishing both stereoisomers stereospecifically depending on the configuration of the starting 1,5-diene. *E,E*-1,5-cyclodecadiene, *E,E*-**68,** rearranges exclusively to *trans*-1,2-divinylcyclohexane *trans*-**69** at 70 °C, whereas *Z,E*-**68** is converted into *cis*-**69** specifically at 150 °C.[29] In both cases, the rather

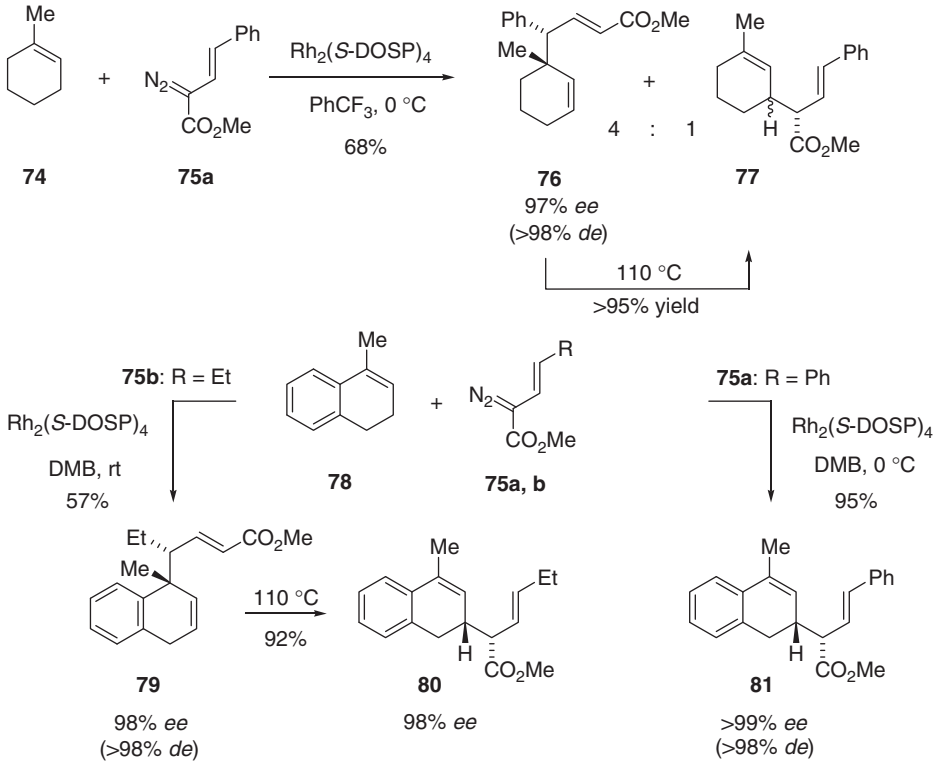


Scheme 23

flexible structure of the six-membered ring, which is formed in the course of the Cope rearrangement, allows the involvement of a favorable chair transition state conformation (Scheme 24).

Scheme 24

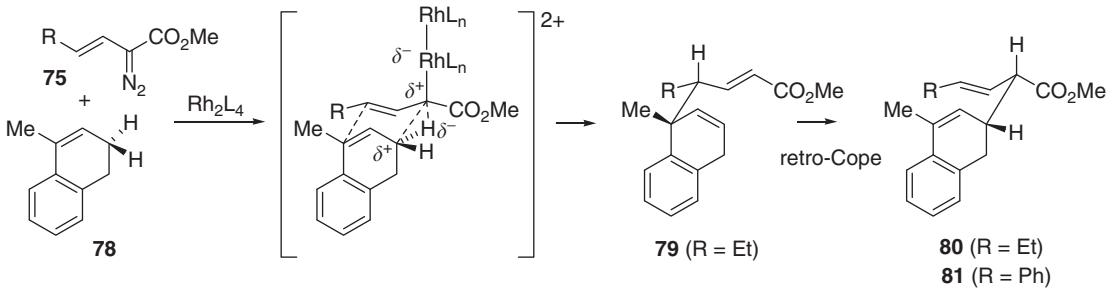
A prominent example where this rearrangement plays a major role is found in the sesquiterpene class of natural products named germacranes. They contain an *E,E*-1,5-cyclodecadiene skeleton as central structural motif and easily undergo thermal Cope rearrangements either during distillation or by gas chromatography analysis to furnish elemanes.[30] Thus, germacrene A (**70**) is readily converted to *trans*-*β*-elemene (**71**) in quantitative yield on refluxing the solution in toluene (Scheme 25). The isopropenyl group at the stereogenic center in **70** efficiently controls the diastereoselectivity of the rearrangement by its preference for the equatorial position in transition state **70a**. Likewise, many other germacrenes undergo Cope rearrangements in high yields during distillation to afford the corresponding elemenes.[30]



Scheme 25

More highly substituted cyclodecadienes may furnish, however, equilibrium mixtures of germacrenes and elemenes depending on the exact substitution pattern. In addition to some examples listed in Chapter 7.1.5.4 of the first edition of this book, this phenomenon was observed in a synthesis of (+)-vernolipin.[31a] Thus, thermal Cope rearrangement of germacrolide **72** produced an equilibrium mixture of elemanolide **73** and germacrolide **72** in a ratio of 2:1 on heating at 205 °C for 5 min in a sealed tube. The recovered germacrolide was used again in two more rounds, giving rise to elemanolide **73** in a total yield of 88% after three cycles (Scheme 25).

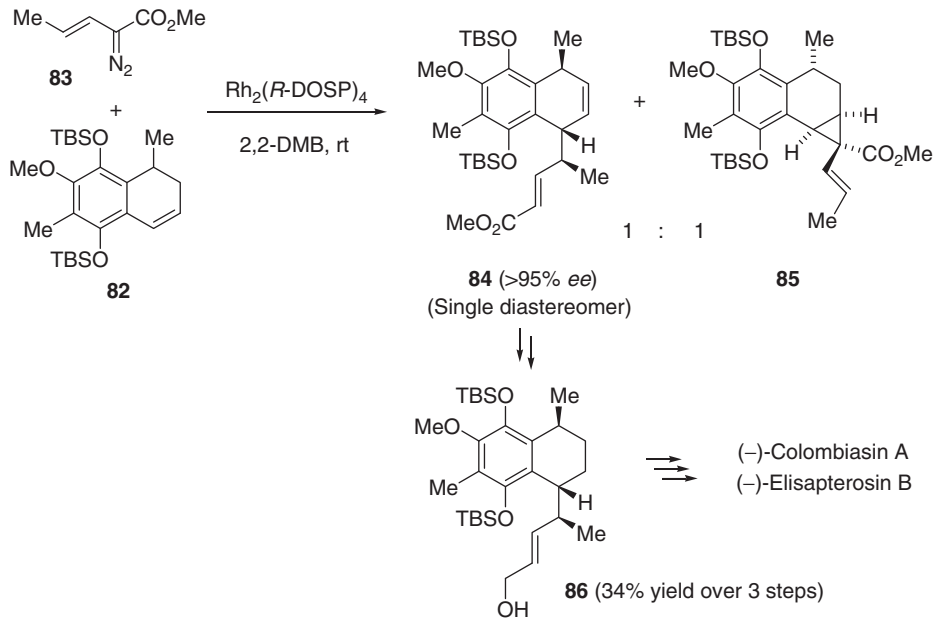
5.19.5 CH Activation/Cope Rearrangement



Electron-rich cycloalkenes, when treated with donor–acceptor-substituted diazo compounds, can undergo a very powerful and highly stereoselective Rh(II)-catalyzed combined CH activation/Cope rearrangement. Thus, the Rh_2(S-DOSP)$_4$-catalyzed reaction of 1-methylcyclohexene **74** and styryldiazoacetate **75a** furnished a 4:1 mixture of CH activation/Cope rearrangement product **76** and the apparent direct CH activation product **77** in 68% combined yield (Scheme 26).[32a] **76** was formed with outstanding levels of stereocontrol: a single diastereomer was produced with 97% *ee*. The apparent direct CH activation product was obtained as a mixture of two diastereomers, of which the major diastereomer was formed with 97% *ee*. However, a control experiment revealed that **77** was actually the thermodynamically more stable product, as heating of **76** in refluxing toluene cleanly and quantitatively converted **76** into **77**.

Scheme 26

However, reaction of 4-methyl-1,2-dihydronaphthalene (**78**) with **75a** (R=Ph) under otherwise almost identical reaction conditions furnished exclusively the apparent direct CH activation product **81** in excellent yield as a single diastereomer and enantiomer, whereas vinyldiazoacetate **75b** (R=Et), on reaction with **78**, delivered the CH activation/Cope rearrangement product **79** in moderate yield and again very high levels of diastereo- and enantioselectivity (Scheme 26).[32b] **79** could subsequently be converted into **80** in excellent yield and complete chirality transfer on heating in refluxing toluene for 6 h.

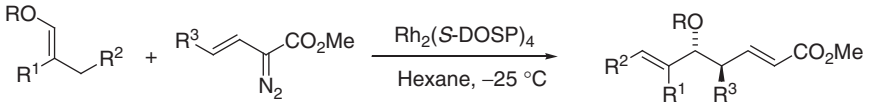


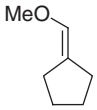
A detailed mechanistic analysis including density functional theory (DFT) calculations revealed a more complicated reaction course for the formation of the CH activation/Cope rearrangement products, **76** and **79**, respectively. It comprised a concerted, yet highly asynchronous hydride-transfer/vinylogous C–C bond-forming event as depicted in Scheme 27.[32c] The relative and absolute configuration found in **76** and **79** was fully consistent with a catalyst-controlled α-selective hydride transfer, and the C–C bond formation occurring in a typical chair transition state conformation. The apparent direct CH-activation products **77**, **80**, and **81** actually originated from a thermodynamically driven retro-Cope rearrangement of the initial CH insertion/Cope products. The discrepancy between the

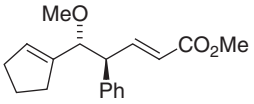
Scheme 27

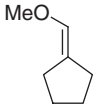
reactions of vinyldiazoacetates **75a** and **75b** with **78** was due to the exceptional ease with which the retro-Cope rearrangement took place in the case of **75a,** even at temperatures as low as 0 °C, delivering the more highly conjugated product, **81,** directly.

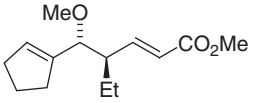
With chiral racemic 1-methyl-1,2-dihydronaphthalenes as the substrates, an enantiomer differentiation event was observed in this CH activation/Cope rearrangement sequence. Thus, in the course of the total syntheses of the diterpenes (–)-colombiasin A and (–)-elisapterosin B, Davies and coworkers reacted (*E*)-2-diazo-3-pentenoate (**83**) with 1-methyl-1,2-dihydronaphthalene **82** and catalytic Rh_2(*R*-DOSP)$_4$ to generate a 1:1 mixture of the CH activation/Cope rearrangement product **84**, which was formed as a single diastereomer with >95% *ee* along with cyclopropane **85** (Scheme 28).[32d] **84** was subsequently hydrogenated and reduced to alcohol **86**, which was purified by chromatography and 34% yield was obtained over three steps (68% yield in theory based on the racemic starting material). The two enantiomers of **82** apparently responded differently to the reaction with the chiral rhodium vinylcarbenoid, resulting very selectively in CH-activation for one enantiomer and cyclopropanation for the other. The selectivity of these reactions has been found to be markedly influenced by the nature of the chiral catalyst, vinyldiazoacetate and dihydronaphthalene.[32e] The same phenomenon has been employed advantageously in total syntheses of the diterpenes (+)-erogorgiaene[32f] and (+)-elisabethadione by the Davies group.[32g]

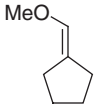


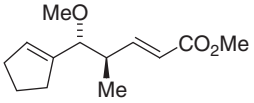


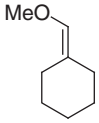


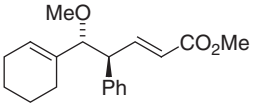


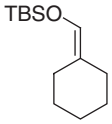


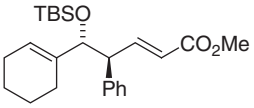


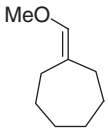


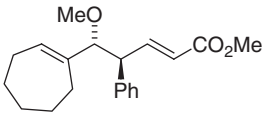


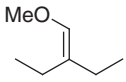


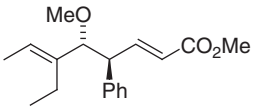






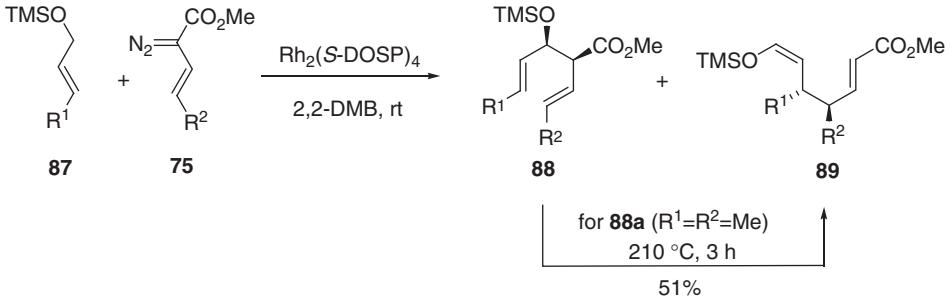






Scheme 28

This methodology was successfully extended to reactions of, for example, 4-silyloxy-1,2-dihydronapthalenes giving rise to chiral tetralones,[32b] 4-acetoxy-6,7-dihydroindoles, which furnished 4-substituted indoles,[32h] and vinyl ethers establishing a formal vinylogous Mukaiyama aldol process (Table 11).[32i] The latter reaction is especially remarkable as it provides an efficient surrogate for a fundamental C–C bond-forming reaction. Good yields and excellent diastereo- as well as enantioselectivity are attractive features of this process, which is currently, however, limited to symmetrical β-disubstituted vinyl ethers.



A closely related reaction developed by Davies et al. starts from allyl silyl ethers **87**, which on Rh_2(*S*-DOSP)$_4$-catalyzed reaction with vinyldiazoacetates **75** furnished mixtures of direct CH insertion products **88** and combined CH-activation/Cope

rearrangement products **89** (Scheme 29 and Table 12).[32k] Both products were formed as single diastereomers and with enantioselectivities of more than 90% *ee* for the styryldiazoacetate **75b** (but more moderate selectivities for alkyl-substituted vinyldiazoacetates). The similar selectivities observed for **88** and **89** pointed to a very similar pathway involved for both reaction manifolds. The purely 1,6-dialkyl-substituted 1,5-diene **88a** was subsequently converted into **89a** in a thermally induced silyloxy-Cope rearrangement (see Section 5.19.7.3).

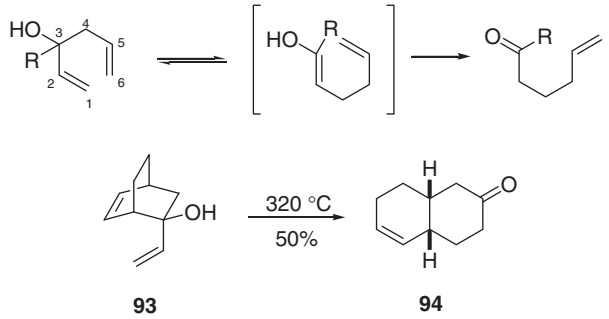
5.19.6 Metal-Catalyzed Cope Rearrangements

Palladium(II) salts have been known since 1966 to promote the Cope rearrangement at ambient temperature.[33a] In 1980, Overman et al. discovered that catalytic amounts of $PdCl_2(PhCN)_2$ were sufficient to convert 2-methyl-3-phenyl-1,5-hexadiene (**90**) into a stereoisomeric mixture of Cope products, **91a** and **91b,** in a 93:7 ratio and in 87% combined yield (Scheme 30).[33b] The reaction conditions were extremely mild and rate accelerations on the order of 10^{10} relative to thermal Cope rearrangements were observed.

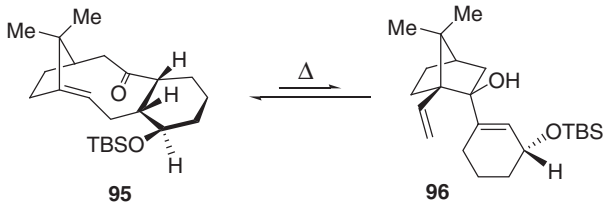


Scheme 30

This reaction does not follow a concerted mechanism but involves two discrete steps: the first one involves a rate-limiting Pd(II)-initiated cyclization to yield a 4-palladacyclohexyl cation intermediate **92**, which is followed by elimination of $PdCl_2(PhCN)_2$ to furnish the final Cope products in the second step (cyclization-induced rearrangement). The observation that exactly one cation-stabilizing substituent at either C2 or C5 of the 1,5-diene is required for the reaction to proceed is fully consistent with this mechanistic analysis, which was further substantiated through the kinetic analysis of the Cope rearrangement of various electron-deficient 2-aryl-1,5-dienes.[33c] With chiral 1,5-dienes, a complete transfer of chirality toward a prochiral sp^2 center was observed, indicating the same chair topology as in thermal Cope rearrangements. Accordingly, the Pd(II)-catalyzed Cope rearrangement has been successfully employed in synthetic organic chemistry as shown in Scheme 23. For example, chiral oxa- and aza-1,5-cyclononadienes were converted into 3,4-substituted THF and pyrrolidines, respectively, with full stereochemical control.[28] Also, the conversion of germacrone and germacranolides into elemenone and elemanolides, respectively, was facilitated under Pd(II)-catalysis.[31b,c]

Pd(0)-species such as $Pd(PPh_3)_4$ have been found to be able to catalyze the Cope rearrangement as well.[34a] Here, the rearrangement proceeds through bis(η^3-allyl)Pd(II)intermediates, however, which are generated by oxidative addition of Pd(0) into carbon–carbon σ-bonds. In addition, a Pd(0)-catalyzed domino allylation-Cope rearrangement of allyl 3-butenoates was achieved by decarboxylative sp^3–sp^3 coupling.[34b]

5.19.7 Oxy-Cope Rearrangement

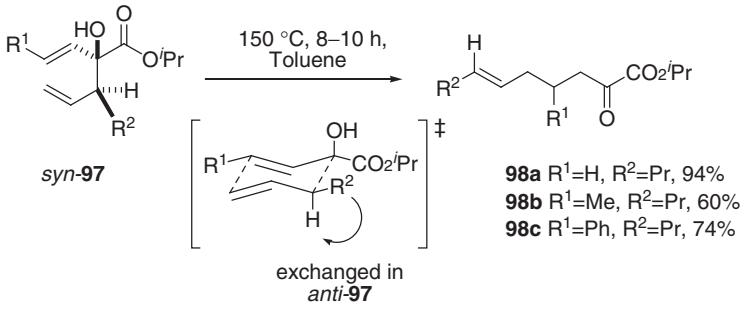


The discovery of the thermal oxy-Cope rearrangement greatly broadened the applicability of [3.3]-sigmatropic processes in the synthesis of complex structures. In analogy to the classical Cope rearrangement, a shift of double bonds occurs to generate new double bonds between C2 and C3 and C4 and C5, respectively (Scheme 31). As a hydroxyl group is attached to C3, the product of the rearrangement can undergo a facile and rapid enol–keto tautomerization to furnish a ketone or an aldehyde with a strong carbonyl bond. However, rather drastic thermal conditions are still necessary for the rearrangement to proceed. Berson and Jones

Scheme 31

discovered this reaction in 1964 while heating 2-*endo*-vinyl-2-*exo*-hydroxybicyclo[2.2.2]octene (**93**) at 320 °C to obtain *cis*-$\Delta^{5,6}$-octalone-2 (**94**), providing a facile entry into functionalized *cis*-decalins after hydrogenation.[35]

The first thermally induced retro-oxy-Cope rearrangement was reported by Paquette in 1991 (equation 5).[36] When a solution of **95** was refluxed in toluene for 5 days, 35% of **96** could be isolated along with 61% of recovered starting material. Subjecting **96** to identical reaction conditions resulted in the same distribution as observed before, proving that the oxy-Cope rearrangement was indeed reversible. Apparently, transannular strain in **95** provided enough driving force to partially compensate for the loss of binding energy of the carbonyl group.

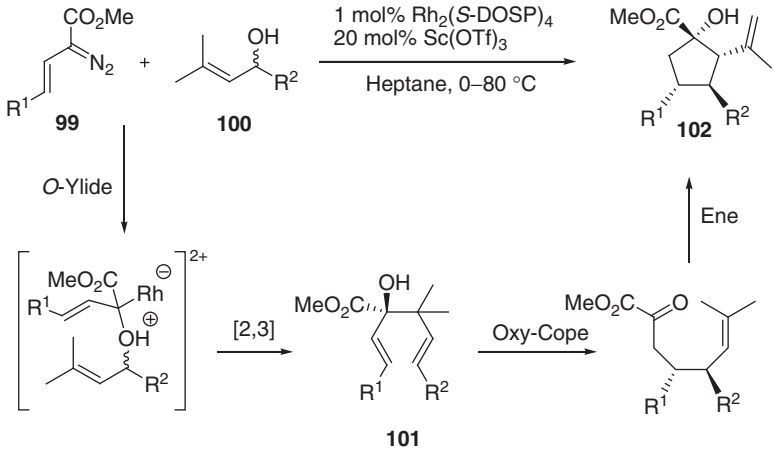


(5)

Although earlier studies of the oxy-Cope rearrangement dealt with investigations into the stereoselectivity of the reaction, geometry of transition states, kinetics, and substrate scope, in the past two decades the oxy-Cope rearrangement has witnessed a vast number of applications in complex molecule synthesis and cascade reactions to assemble polycyclic scaffolds.

5.19.7.1 Application in Synthesis – Acyclic Examples

Reports on the participation of acyclic 1,5-dienes in the oxy-Cope rearrangement are rare due to the lower driving force and selectivity when applying conformationally more flexible and less rigid systems. By heating 1,5-hexadienes *syn*-**97** in a sealed tube, Hiersemann could obtain α-keto esters **98** in good yields and *E*-diastereoselectivities (Scheme 32).[37]



Scheme 32

The high selectivities of the rearrangement could be explained with the advantageous chair-like transition state. When changing to the anticonfigured substrates, the additional axial substituent caused the selectivity and rate of the reaction to deteriorate drastically. Hiersemann later found that α-keto esters such as **98** underwent ene reactions with good to moderate selectivities when subjected to harsher conditions, giving functionalized cyclopentanes.[37]

A very elegant, asymmetric one-pot access to highly functionalized cyclopentanes **102** via similar intermediates was demonstrated by Davies and coworkers.[38] They developed a domino sequence in which styryldiazoacetates **99** and racemic allyl alcohols

100 underwent Rh(II)-catalyzed tandem oxygen ylide formation/[2,3]-sigmatropic rearrangement to give rise to highly enantioenriched dienols **101**, which underwent an oxy-Cope rearrangement on heating followed by ene cyclization to arrive at multiply substituted cyclopentanols with excellent diastereo- and enantioselectivity (Scheme 33 and Table 13).

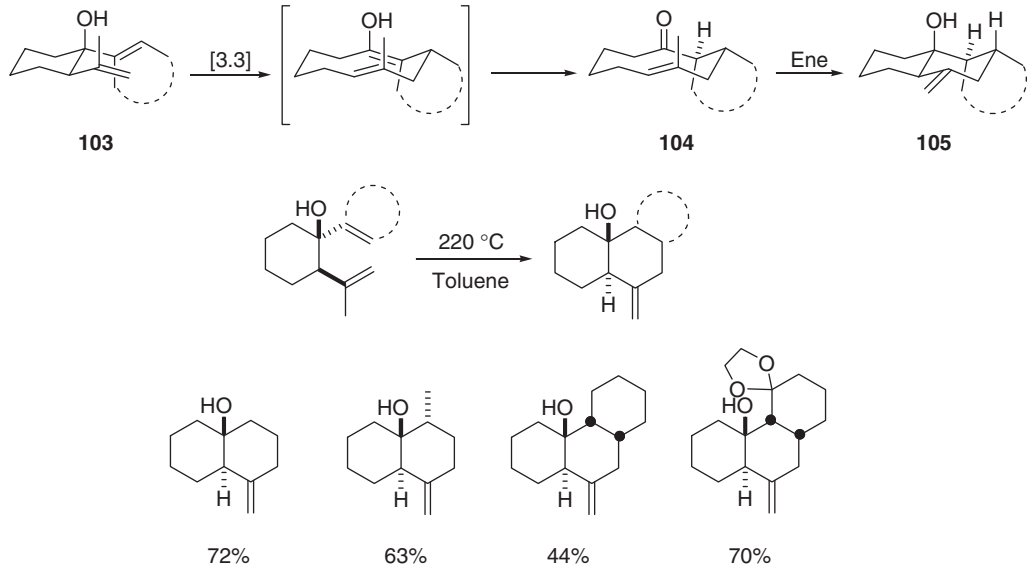
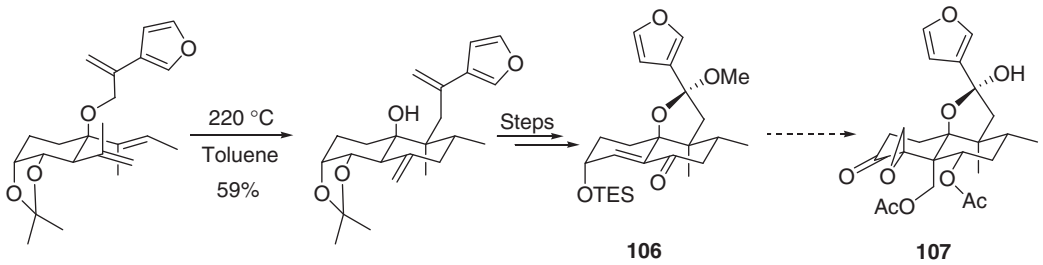
5.19.7.2 Application in Synthesis – Cyclic Examples



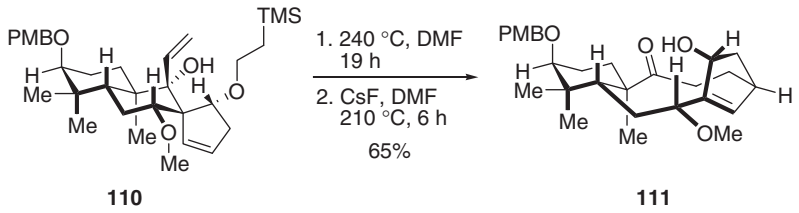
Barriault and coworkers applied the thermal oxy-Cope rearrangement of a variety of 1,2-divinylcyclohexanols **103** for the construction of polycyclic ring systems.[39] After the sigmatropic process, the intermediate ketones **104** underwent spontaneous transannular ene reactions with high diastereoselectivity to give polycycles **105** (Scheme 34). A number of functionalized decalins were successfully generated by this method, giving the products in moderate to good yields and with complete diastereoselectivity.

On extending this methodology, they assembled the *trans*-decalin core of the diterpenoid teucrolivin A **107** via a cascade oxy-Cope/Claisen/ene reaction with complete diastereoselectivity (Scheme 35). This cascade reaction was applied toward the synthesis of several other decalin scaffolds of natural products.



Mehta and coworkers constructed the 5,11-fused bicyclic framework present in dolabellane-type diterpenoids (equation 6).[40] Under thermal conditions, they could induce the sigmatropic shift in **108** to access the cycloundecadienone **109** as a single diastereomer. Attempts to employ the anionic variant of the oxy-Cope rearrangement failed.

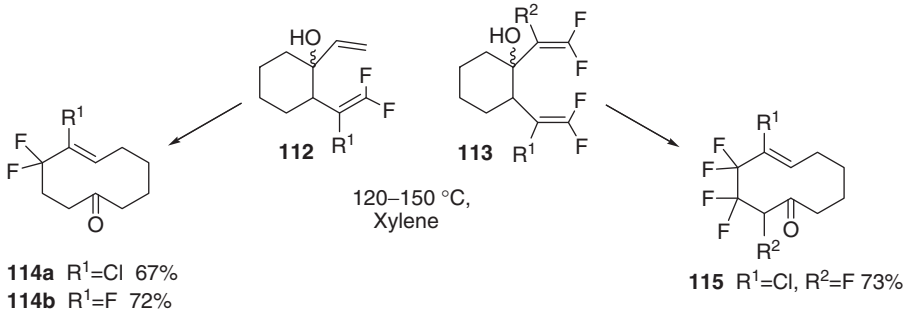
108 109 (6)



Scheme 34

Scheme 35

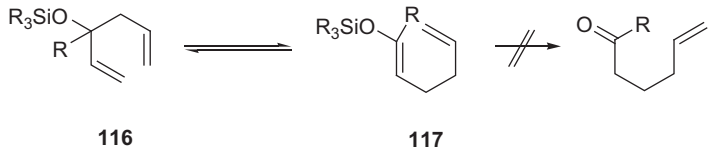
During the total syntheses of the diterpenoids (–)-*O*-methylshikoccin and (+)-*O*-(methylepoxy)shikoccin, Paquette and coworkers transformed **110** into **111** by an oxy-Cope rearrangement followed by *in situ* deprotection to give the target molecule in good yield as a single isomer (equation 7).[41]



(7)

Rearrangement of the highly fluorinated divinylcyclohexanols, **112** and **113**, under thermal conditions gave access to cyclodecenones, **114** and **115**, respectively, containing up to five fluorine atoms (Scheme 36).[42] The exceptional driving force for the oxy-Cope process strongly overrode the typically prevalent ring contraction of cyclodecadienes. This method by Percy constituted the first route toward the synthesis of cyclic fluoroketones, which were otherwise impossible to obtain.

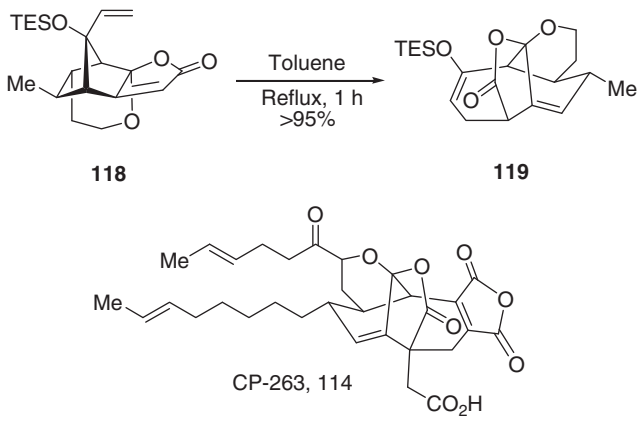
5.19.7.3 The Silyloxy-Cope Rearrangement



5.19.7.3.1 With cyclic substrates

One of the major drawbacks of the oxy-Cope rearrangement is the competing retro-ene fragmentation, which always occurs whenever it is geometrically possible. To avoid this side reaction, the hydroxyl group has been frequently protected as an ether or ester making the oxy-Cope rearrangement the exclusive pathway.[43] In a similar manner, the silyloxy-Cope rearrangement using 3-silyloxy-1,5-dienes **116** as substrates has been developed furnishing silyl enol ethers **117** as products, which cannot tautomerize to

Scheme 36

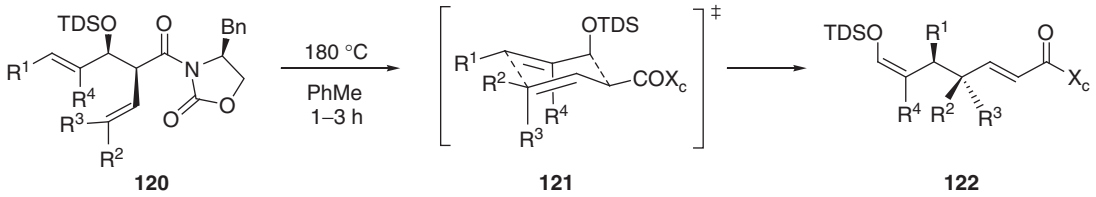


the corresponding aldehydes or ketones under the reaction conditions (Scheme 37). This process, however, still greatly benefits from the enol–ether conjugation in the product.

Scheme 37

The application of the silyloxy-Cope rearrangement in cyclic substrates is rarely documented and deals exclusively with the assembly of the core structure of the phomoidride family of natural products. The natural product, phomoidride B, also known as CP-263, 114, and derivatives thereof were found to be active against protein farnesyl transferase and hence might serve as lead structures in the design of anticancer drugs. Also, due to their challenging structure, their synthesis has generated considerable interest among synthetic chemists.

In an attempt to synthesize the tricyclic core structure of the phomoidrides, Leighton and coworkers found that heating of a solution of **118** in toluene led to smooth conversion to silyl enol ether **119** as a single compound (Scheme 38).[44] Remarkably, the reaction was completed within 1 h in refluxing toluene based on the embedded strain of the lactone spiroketal **118** that was released on rearrangement, despite the bridgehead double bond in the product. Subsequent reports applied similar approaches adding more substituents to the core structure and combining preceding reactions in a tandem fashion with the sigmatropic rearrangement.

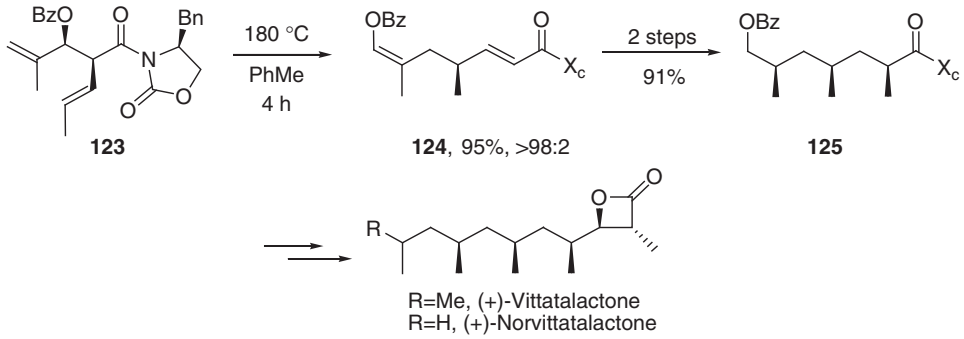


Scheme 38

5.19.7.3.2 With acyclic substrates

Chiral aldol products have been introduced as suitable substrates for the silyloxy-Cope rearrangement. First demonstrated by Schneider and coworkers, 3-silyloxy-1,5-dienes **120**, which were prepared via an Evans *syn*-aldol reaction with subsequent silylation, underwent rapid and highly stereoselective thermal Cope rearrangements on heating for 1–3 h at 180 °C in toluene in a sealed flask (Scheme 39 and Table 14).[45] Alternatively, microwave irradiation was applied, which sharply reduced the reaction

times to only 15–20 min in dimethylformamide as solvent.[45d] The exceptional diastereoselectivity arises from the chair-like transition state conformation **121**, in which the bulky carboximide substituent occupies the pseudoequatorial position, whereas the rather slim silyl ether favors the pseudoaxial position. The uncommonly high rate of this process presumably originates from the different electronic properties of the two allyl fragments, resulting in a highly dipolar transition structure with a resonance structure resembling an allyl cation and allyl anion couple.[46] Kinetic studies using aldol products with different oxy substituents and different carboxyl groups clearly revealed that strongly electron-releasing oxy groups and strongly electron-withdrawing carboxyl groups accelerate the Cope rearrangement substantially, whereas less electron-releasing oxy groups and less electron-withdrawing carboxyl groups retard the reaction. DFT calculations convincingly supported these results and predicted activation barriers very close to the experimental results. A broad range of different substituents could be accommodated in the aldol components, and the products **122** were typically obtained with excellent yields and diastereoselectivities (**Table 14**).



Scheme 39

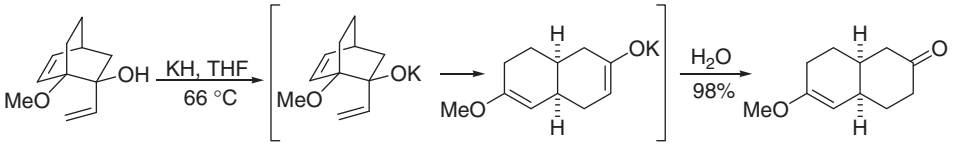
The straight-chain Cope products **122** have proven to be versatile synthetic intermediates due to their functional group pattern and have been successfully converted into optically pure and polysubstituted tetrahydropyrans, piperidines, terpenols, 1,3,5…-polyol chains, and highly functionalized cyclohexanes.[47]

A related oxy-Cope rearrangement of the benzoyl-protected aldol product **123** has been performed in the context of the first noniterative and straightforward synthetic approach toward polydeoxypropionate natural products. Enol benzoate **124** was obtained both in excellent yield and diastereoselectivity on heating **123** at 180 °C for 4 h. On the basis of the coordinating benzoate group, a highly diastereoselective catalyst-controlled hydrogenation with a chiral iridium catalyst delivered a dideoxypropionate building block which was further converted into trideoxypropionate **125** via an auxiliary-controlled enolate methylation (**Scheme 40**).[48] This methodology was successfully applied toward the asymmetric synthesis of the cucumber beetle pheromones, (+)-vittatalactone and (+)-norvittatalactone.

Scheme 40

Independently, Black and Nakai and their groups reported thermal Cope rearrangements of 3-silyloxy-1,5-dienes derived from aldol products as well. Although Black employed the same Evans-type substrates, Nakai took advantage of the Oppolzer sultam as a chiral auxiliary to obtain the *syn*-aldol product **126**. Again, the silyloxy-Cope rearrangement proceeded rapidly to give rise to Cope product **127** in excellent yield and stereoselectivity (equation 8).[49]



126 **127** (8)

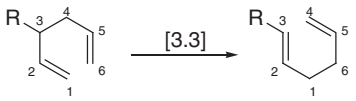
5.19.8 AOC

Until today, the AOC has been the most extensively investigated and synthetically employed variant of the Cope rearrangement. The majority of the literature that refers to the term 'oxy-Cope' in fact deals with the anionic variant. Owing to its mild reaction conditions and thus functional group tolerance, the AOC has been widely used for the assembly of complex, polycyclic scaffolds of natural products often in the context of cascade reactions with the AOC being only a part of the entire sequence. There have been more than 70 reports over the past 20 years employing the AOC as the key step in total syntheses. The subchapters of the AOC's synthetic applications can thus only scratch the surface of what has been published within the past two decades.

5.19.8.1 Rate Acceleration

Discovered in 1975 by Evans and coworkers, the AOC of **128** using potassium hydride (KH) as base to generate the corresponding potassium alkoxide resulted in observed rate accelerations of 10^{10}–10^{17} to afford the rearranged enolate **129**, which was then protonated to ketone **130** (Scheme 41).[50] The reaction rate displayed strong counter ion dependence, and the potassium alkoxide proved to be the optimal substrate, especially when crown ether such as 18-crown-6 was added, which resulted in additional 180-fold rate acceleration. This indicated that ion pair dissociation was important for maximal rate increase, allowing for much milder reaction conditions compared with the neutral oxy-Cope rearrangement.

128 **129** **130**

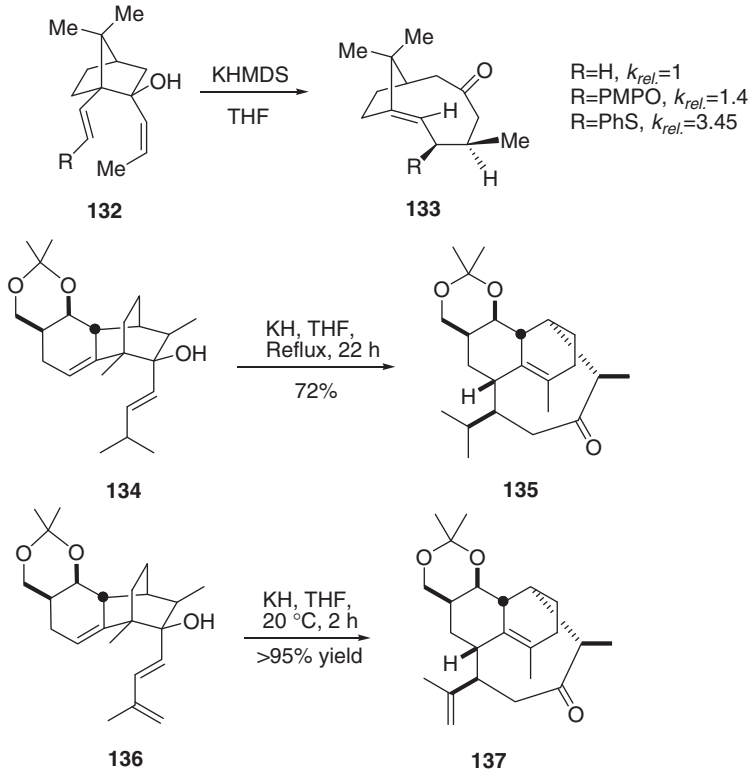


Scheme 41

Baumann and coworkers investigated Cope rearrangements of different 1,5-dienes **131** using DFT methods to explain the drastic changes in reaction rate.[51] The $n \rightarrow \sigma^*$-orbital interaction between the oxygen lone pair and the σ^*-orbital of the neighboring C3–C4 bond readily destabilizes the σ-bond which is being broken in the course of the rearrangement and hence decreases the activation enthalpy for the Cope rearrangement. It could be shown that the more negatively charged the substituent R in **131** is, the longer and thus weaker the C3–C4 bond becomes, which nicely parallels the observed rate accelerations (Scheme 42).

Additional rate accelerations of the AOC could be achieved by resonance effects. Installing oxygen or sulfur moieties at the terminal carbon atom of the bridgehead vinyl group in **132** accelerated the Cope rearrangement toward **133** by 1.4- and 3.45-fold, respectively (Scheme 43).[52] During the assembly of the diterpenoid vinigrol, an additional unsaturation significantly accelerated the sigmatropic process. Although **134** required heating under reflux in THF for over 22 h to give rise to **135**, the additional unsaturation in **136** greatly facilitated the process and led to a quantitative rearrangement to furnish **137** within just 2 h at room temperature.[53]

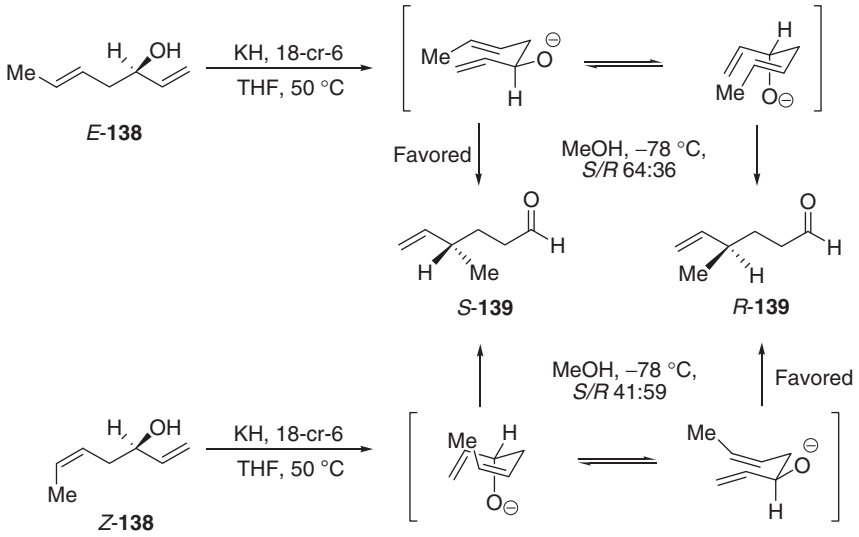
5.19.8.2 Stereoselectivity



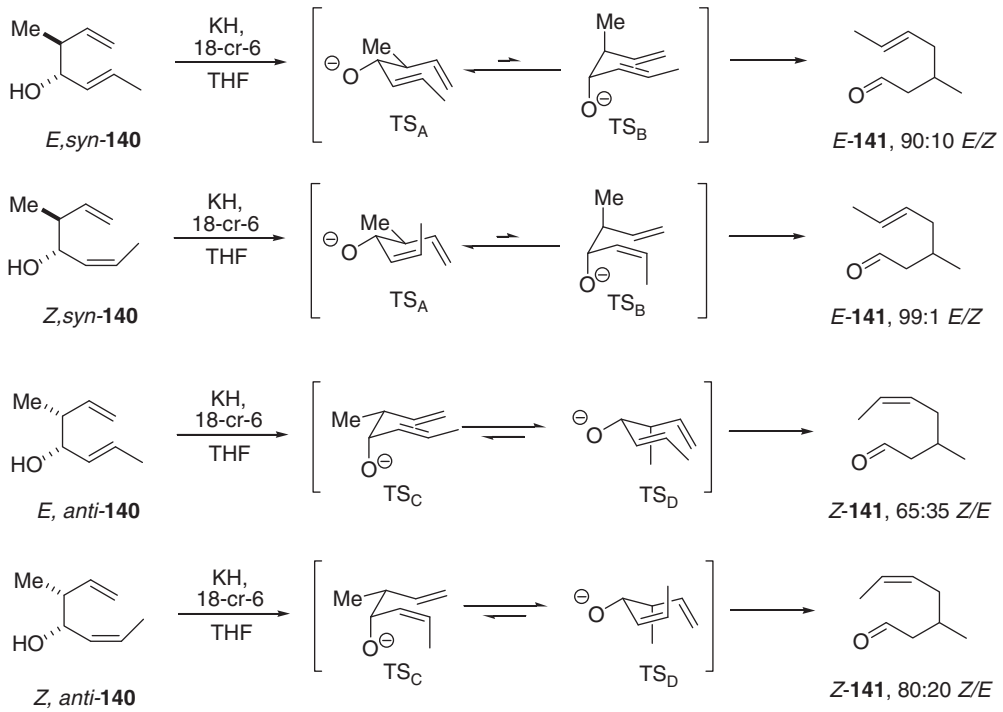
The control over the diastereoselectivity of the AOC of chiral acyclic substrates has attracted much attention recently. Because these acyclic systems are less rigid than their cyclic counterparts, one chair-like transition state conformation may flip easily into the other chair conformation, furnishing opposite enantiomers as products. In the Cope rearrangements of *E*- and *Z*-**138**, the

131

R	Bond distance (Å) C3 – C4	$\Delta G^{\ddagger}$ (kcal mol^{-1})	k (s^{-1})
H	1.548	36.3	1.63×10^{-14}
OH	1.552	33.8	1.05×10^{-12}
$O^{\ominus}$	1.604	6.3	1.64×10^{8}



Scheme 42

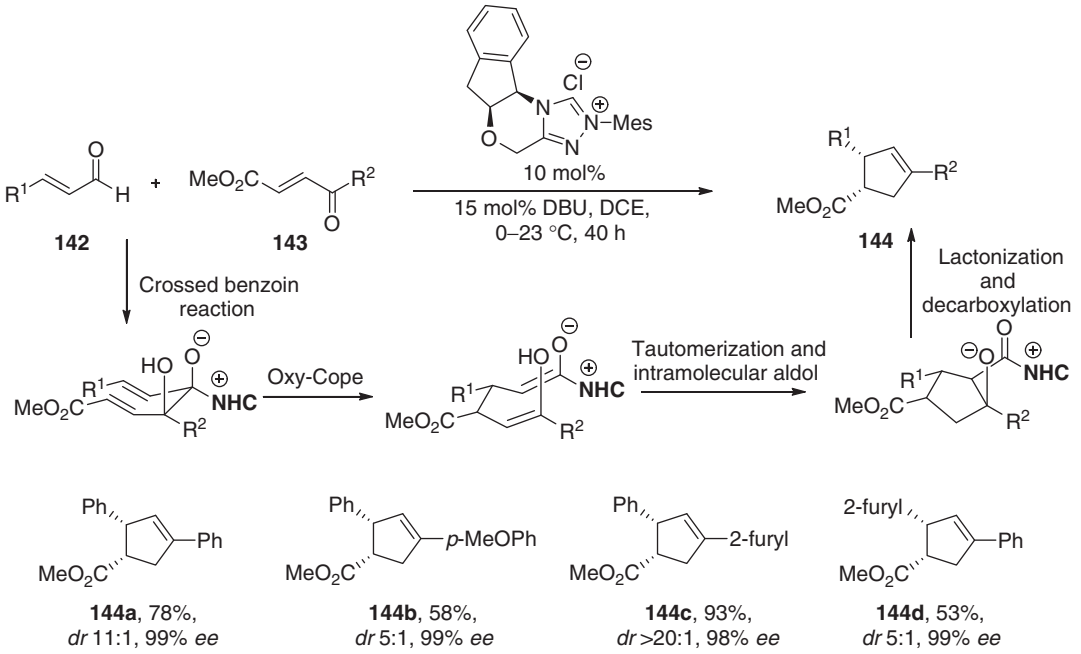


Scheme 43

efficiency of chirality transfer depends exclusively on the orientational preference of the alkoxide substituent (Scheme 44).[54] The reactions were quenched at low temperature by the addition of methanol to give rise to mixtures of *S*- and *R*-**139**, which were obtained with the indicated ratios. In both cases the oxyanion substituent favors the pseudoequatorial position in the transition state of the sigmatropic process. However, the selectivity proved to be quite low and may well be overridden by a change of the substitution pattern.

In the course of the total syntheses of the natural products, (+)-furanal and (–)-antirhine, Nakai and coworkers showed that improved diastereoselectivity can be achieved by placing an alkyl substituent on the carbon atom adjacent to the carbinol center (Scheme 45).[55] They very accurately studied the dependence of product configuration on the starting relative configuration between the two chiral centers as well as the double bond geometry. It turned out that the preference for the equatorial position of the oxy group prevailed in all cases studied, albeit to a different extent. Thus, the pair of diastereomeric 1,5-dienes, *E,syn*-**140** and *Z,syn*-**140,** both rearranged with high diastereoselectivity to *E*-**141** because the adjacent methyl group enforced the preference for transition state A (TS_A) with both substituents occupying pseudoequatorial positions. In the case of *Z,syn*-**140,** TS_B suffered from additional 1,3-diaxial interactions with the *Z*-configured methyl group, making TS_A the almost exclusive pathway for the Cope rearrangement (99:1 vs. 90:10 *E*/*Z*).

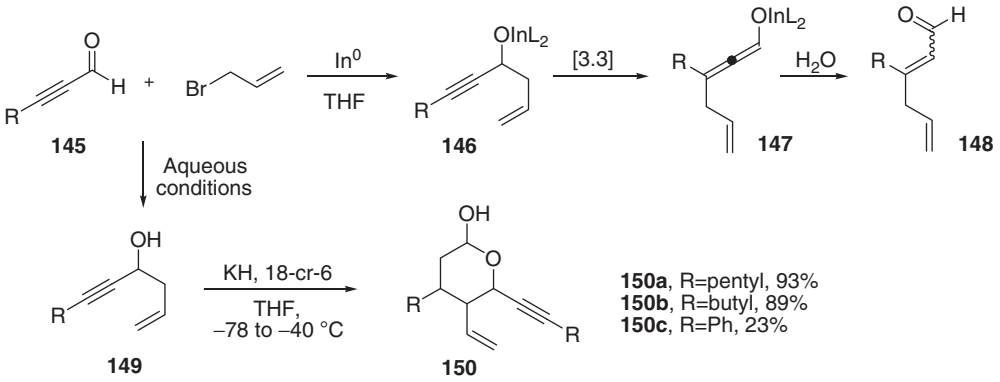
Scheme 44



Scheme 45

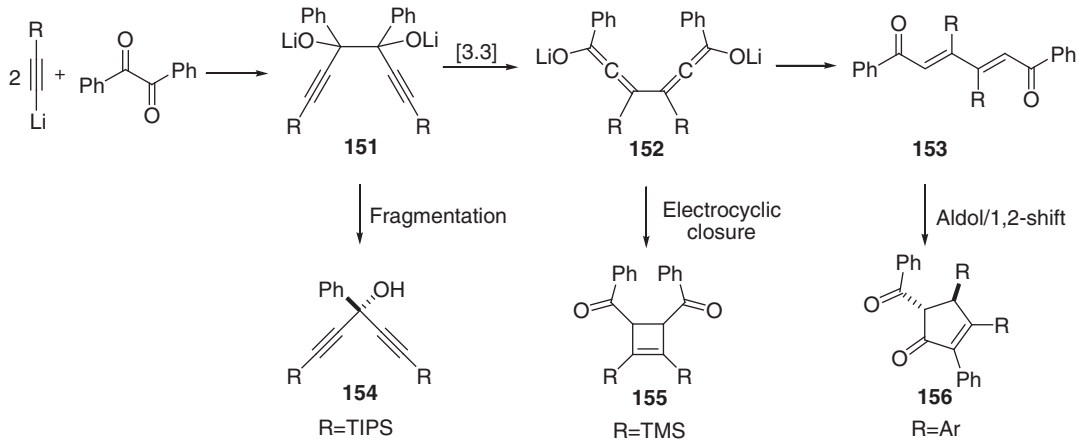
For 1,5-dienes *anti*-**140**, only one of the substituents was able to occupy the favorable pseudoequatorial position and, based on the *Z*-configuration in product *Z*-**141**; this was the oxy group originating from TS_D. In the case of *Z,anti*-**140**, the diastereoselectivity was again higher because the competing TS_C once again suffered from unfavorable 1,3-diaxial interactions with the *Z*-configured methyl group (80:20 *Z*/*E* vs. 65:35 *Z*/*E*). In subsequent studies, Lee et al. also investigated the orientational preference of the oxyanion group and the effect on the diastereoselectivity of the AOC.[56]

5.19.8.3 Application in Synthesis – Acyclic Examples



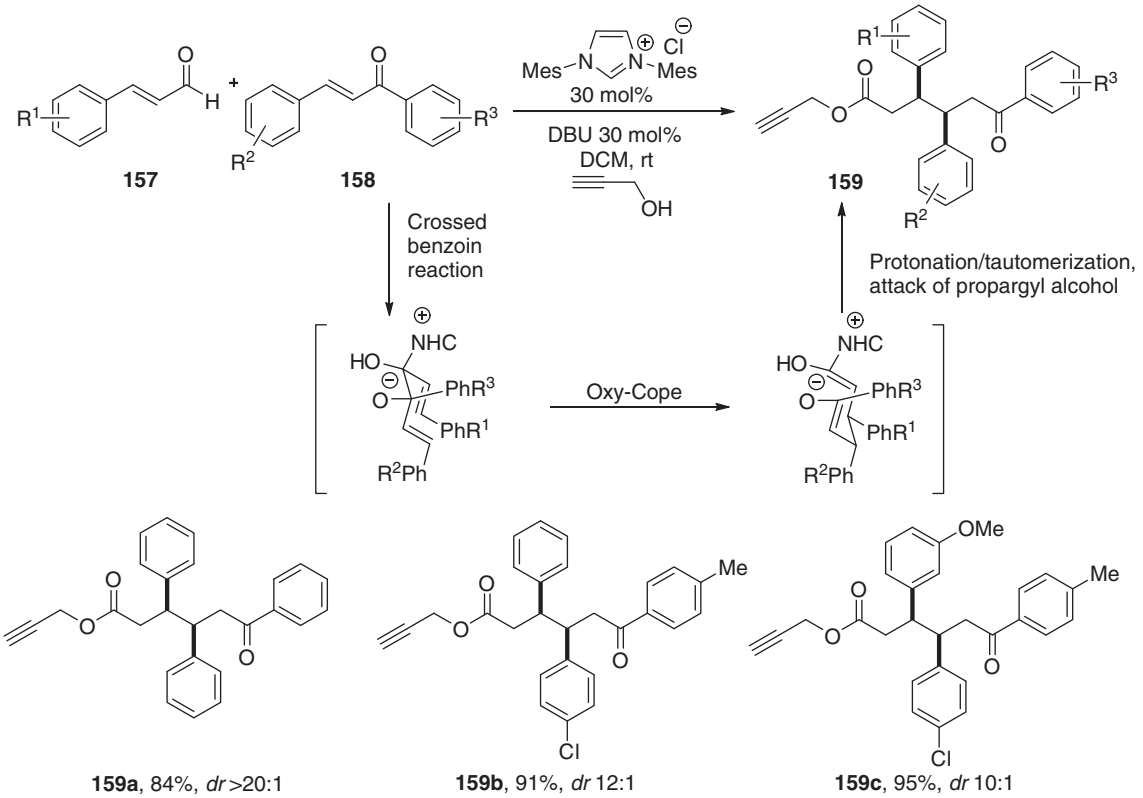
As in the neutral oxy-Cope rearrangement, examples involving acyclic substrates in the AOC are rather scarce. Bode et al. reported an interesting cascade reaction in which a highly enantioselective *N*-heterocyclic carbene (NHC)-catalyzed benzoin reaction between cinnamaldehydes **142** and 4-oxoenoates **143** preceded the oxy-Cope rearrangement, which was followed by an

intramolecular aldol/lactonization/decarboxylation sequence (Scheme 46).[57] This extremely elaborate cascade reaction gave rise to highly functionalized cyclopentenes **144** in excellent stereoselectivity and good to very good yields.



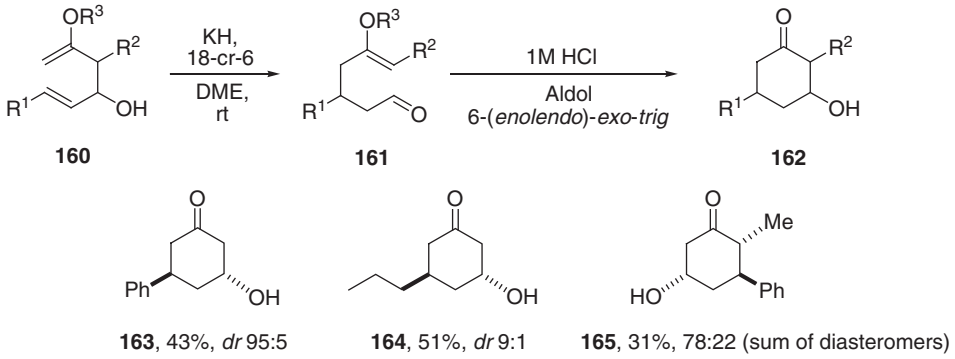
Scheme 46

When Mitzel and coworkers conducted the indium-promoted coupling of propargyl aldehydes **145** with allyl bromide under anhydrous conditions, they observed the formation of aldehydes **148** which were derived from an oxy-Cope rearrangement of **146** followed by hydrolysis of the resulting allenol intermediate **147** (Scheme 47).[58] They were able to selectively generate alcohol **149** when running the reaction in a protic medium. Subjecting **149** to the typical AOC conditions surprisingly resulted in the formation of lactol **150** in moderate to very good yields as a mixture of two diastereomers. The origin of this lactol formation was partial fragmentation of **149** back to the propargylic aldehyde **145,** which then reacted with the intermediate allenol to form the cyclic lactols **150**.



Scheme 47

Another participation of alkynes in the AOC was demonstrated by the group of Alabugin.[59] After addition of two equivalents of Li-alkynes to benzil, the dianionic intermediate **151** could be incorporated into different cascade transformations depending on the choice of the substituent R on the alkyne moiety (Scheme 48). If bulky groups like triisopropylsilyl were present, the intermediate dianion was incapable of undergoing the sigmatropic rearrangement resulting in fragmentation to give carbinol **154**. In the case of smaller silyl substituents, the dianionic oxy-Cope rearrangement (DAOC) proceeded, followed by 4π-electrocyclic ring closure to yield cyclobutene **155** as a mixture of 2 diastereomers. Subsequent to the Cope step, substrates with aromatic substituents underwent an aldol condensation closing the cycle in a favorable 5-(*enolexo*)-*exo-trig* fashion followed by a 1,2-phenyl migration to give the functionalized cyclopentenones **156**.

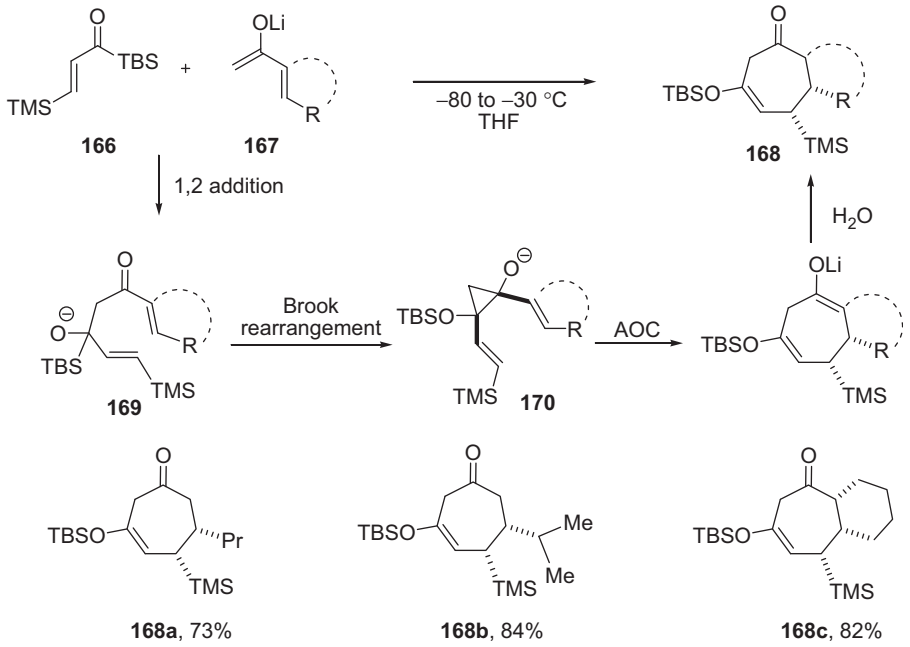


Scheme 48

Chen and coworkers developed an access to functionalized *syn*-ε-ketoesters **159** employing a crossed benzoin/oxy-Cope/esterification cascade (Scheme 49).[60] A number of differently substituted cinnamaldehydes **157** were reacted in an NHC-catalyzed crossed benzoin reaction with enones **158**. The benzoin intermediates underwent an oxy-Cope rearrangement followed by esterification with propargyl alcohol to give ε-ketoesters **159** in very good yields and diastereoselectivities. In few cases, depending on the substitution pattern, an *anti*-diastereoselective reaction was observed.

Scheme 49

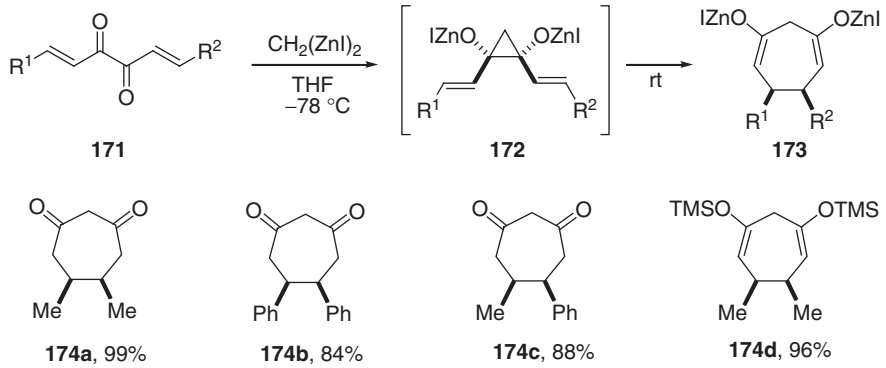
Hartley and coworkers developed an AOC of acyclic, racemic enol ethers **160** furnishing enol ether aldehydes **161** that underwent a subsequent cyclization in a 6-(*enolendo*)-*exo-trig* intramolecular aldol reaction on acidic workup to give rise to β-hydroxy cyclohexanones **163–165** with up to three stereocenters (Scheme 50).[61]



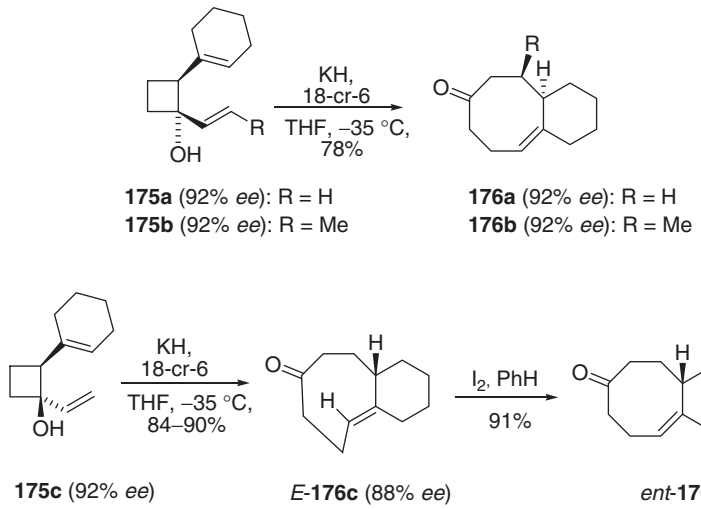
Scheme 50

5.19.8.4 Application in Synthesis – Cyclic Examples

5.19.8.4.1 Medium size rings



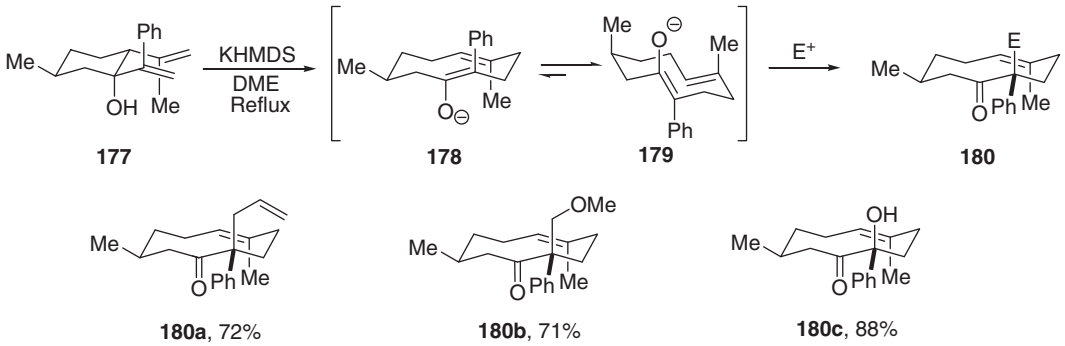
As discussed before (Section 5.19.3), the inherent strain of small rings can be exploited to provide a substantial driving force for the Cope rearrangement. Thus, the AOC has been employed frequently to synthesize medium size rings from highly strained three- and four-membered rings. Takeda and coworkers applied this strategy toward the synthesis of functionalized 3-cycloheptenones **168** in a very elegant cascade reaction (Scheme 51).[62] Reaction of lithium dienolates **167** with acyl silanes **166** furnished intermediate 1,2-addition products **169** that underwent a spontaneous Brook rearrangement to form *cis*-1,2-divinylcyclopropanediols **170**, followed by a rapid AOC to give rise to the desired *cis*-configured 3-cycloheptenones **168**.



Scheme 51

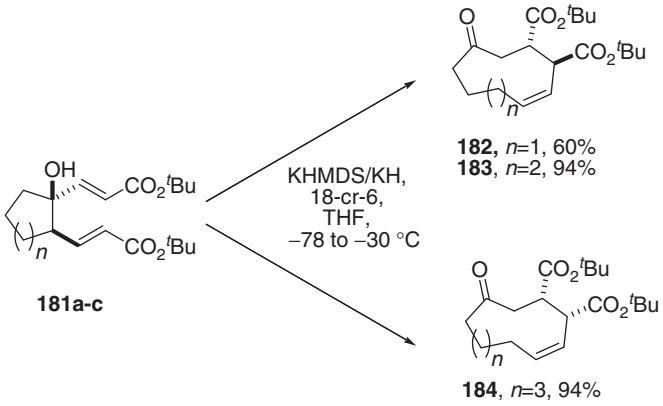
Matsubara and coworkers developed another synthetic access to seven-membered rings by the stereospecific rearrangement of zinc alkoxides of *cis*-1,2-divinylcyclopropanediols **172** generated from 1,2-diketones **171** by cyclopropanation with bis(iodozinc)methane (Scheme 52).[63] The zinc alkoxides underwent the AOC on warming to room temperature and were either hydrolyzed to furnish cycloheptane-1,3-diones **174a-c** or trapped by the addition of an electrophile, for example, trimethylsilyl chloride (TMSCl), to give silyl dienol ether **174d**.

This methodology was successfully extended to the synthesis of annulated eight-membered rings starting from 1,2-divinylcyclobutanols (Scheme 53).[64] Enantiomerically highly enriched *cis*-1,2-divinylcyclobutanols, **175a** and **175b,** underwent the AOC to furnish bicyclo[6.4.0]dodecenones, **176a** and **176b**, respectively, with complete chirality transfer. Unexpectedly, *trans*-1,2-divinylcyclobutanol **175c** underwent the [3.3]-sigmatropic rearrangement under identical conditions as well and the product *E*-**176c** was obtained with only slightly reduced enantiopurity supporting a concerted reaction mechanism. *E*-**176c** incorporating



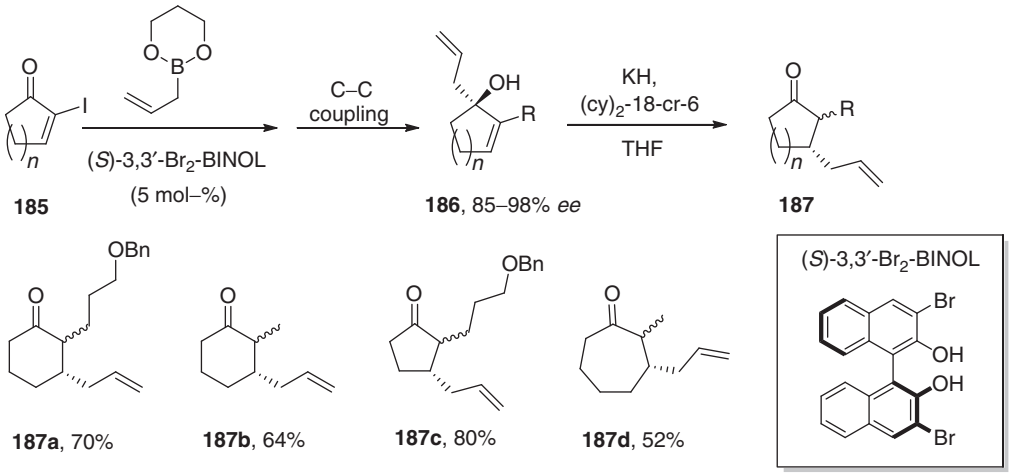
Scheme 52

Scheme 53



both planar and central chirality could easily be converted by isomerization with iodine into the corresponding *Z*-olefin, which constitutes the enantiomer of **176a**. A similar approach was demonstrated by Snapper et al., giving rise to annulated cyclic nine- to eleven-membered cycloalkenones.[65]

Barriault and coworkers subjected enantiomerically pure divinylcyclohexanols **177** to the AOC and trapped the intermediate enolates **178**/**179** with different electrophiles to give cyclodecenones **180a-c** bearing a quaternary stereocenter with complete transfer of chirality (Scheme 54).[66] Surprisingly all products had the opposite relative configuration than what was predicted, indicating that the initially formed enolate **178** underwent a rapid rotation to enolate conformation **179** after the sigmatropic process. The versatility of this strategy was demonstrated by the formal total synthesis of (–)-mesembrine.

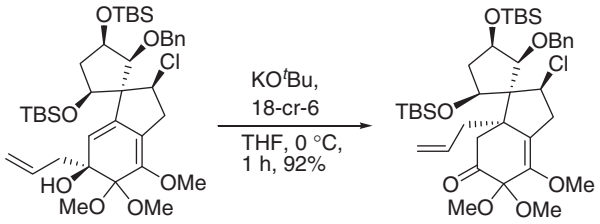


Scheme 54

Larger ring sizes were accessible from *trans*-1,2-divinylcyclopentanols, -hexanols, and -heptanols **181a-c** (Scheme 55).[67] After careful optimization of the reaction and quenching conditions, cyclononenone **182**, cyclodecenone **183**, and cycloundecenone **184** were obtained in good to excellent yields. Although the relative *trans*-configuration of **182** and **183** indicated the intermediacy of chair transition state conformations, it was concluded based on the unexpected relative *cis*-configuration of **184** that the AOC of divinylcycloheptanol **181c** had apparently proceeded through a boat-like transition state conformation.

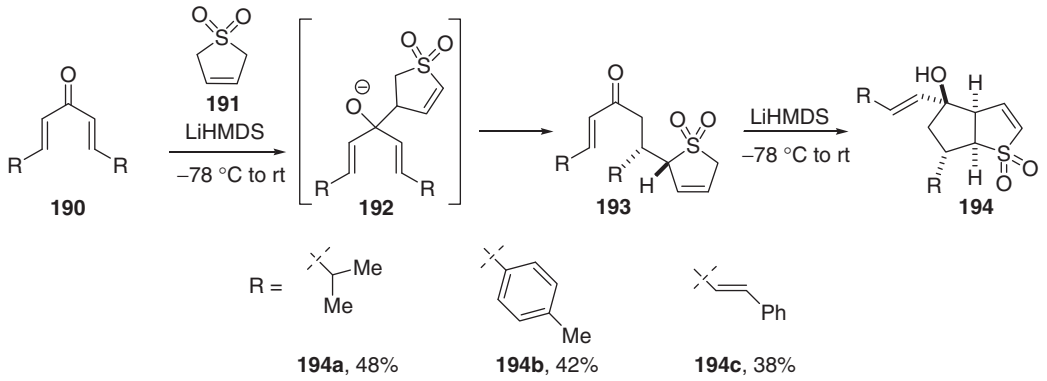
Scheme 55

A formal conjugate allylation of α-substituted cycloalkenones was established by the group of Taber through the AOC.[68] Various carbinols **186** were obtained through enantioselective 1,2-addition of allylboronate to enones **185** and a subsequent C–C coupling. The allyl group was then transposed in a highly suprafacial process furnishing 3-allylated cycloalkanones **187** in the course of the AOC with full chirality transfer (Scheme 56). In that way, cyclic ketones **187a-d** with five- to seven-membered rings were easily accessed.



Scheme 56

5.19.8.4.2 Polycyclic ring systems

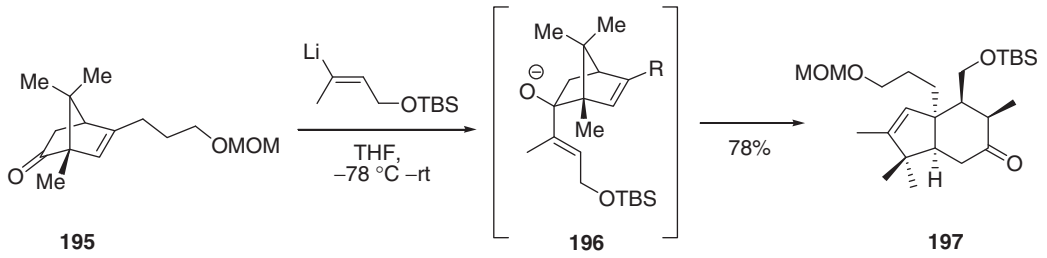


Aside from simple ring expansions, the AOC has been widely used to assemble more complex, annulated polycyclic ring systems. The sigmatropic process is often embedded in larger reaction cascades, each step of which leads to the formation of an additional ring system.

A remarkable example of functional group tolerance as well as excellent diastereoselectivity in an AOC was recently demonstrated by Castle and coworkers in the course of the total synthesis of (–)-acutumine.[69] They installed an all-carbon quaternary stereocenter by the AOC of the highly functionalized dienol **188** under very mild conditions, giving rise to ketone **189** in excellent yield and as a single diastereomer (equation 9). The conjugation of the additional enol ether with the homoallylic alcohol most likely accelerated this reaction.

188 **189** (9)

Wulff and coworkers used a cascade reaction to access orthogonally functionalized bicyclic sulfones **194** (Scheme 57).[70] Treatment of a solution of ketones **190** and sulfone **191** with lithium hexamethyldisilazide (LiHMDS) resulted in the formation of the 1,2-addition intermediates **192**, which underwent the AOC on warming the solution to room temperature. If the initial oxy-Cope product **193** was treated *in situ* with another equivalent of LiHMDS, a second aldol-type addition took place to give bicyclic sulfones **194a-c** with four contiguous stereogenic centers as single diastereomers.

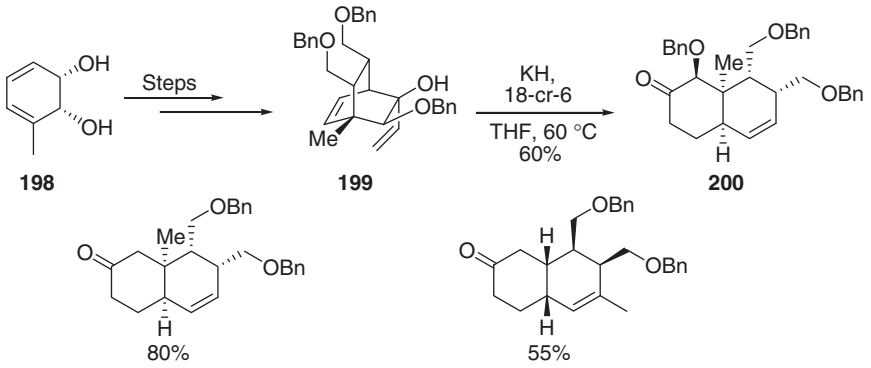


190 **192** **193** **194**

194a, 48% **194b**, 42% **194c**, 38%

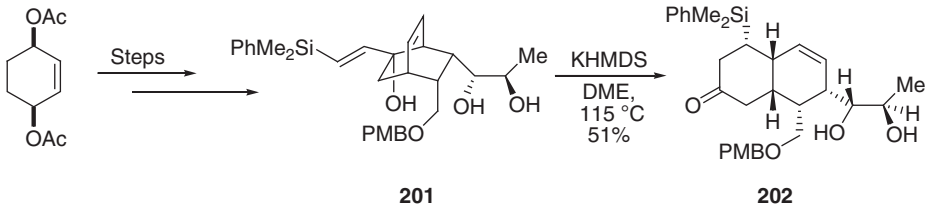
Scheme 57

The synthesis of the enantiomerically pure core structure of the insect antifeedant dumsin was realized by Paquette and coworkers, who employed an AOC as the key step (Scheme 58).[71] Diastereoselective addition of a vinyl lithium compound to ketone **195** led to intermediate **196**, which rearranged smoothly to the bicyclic ring system **197** in good yield.



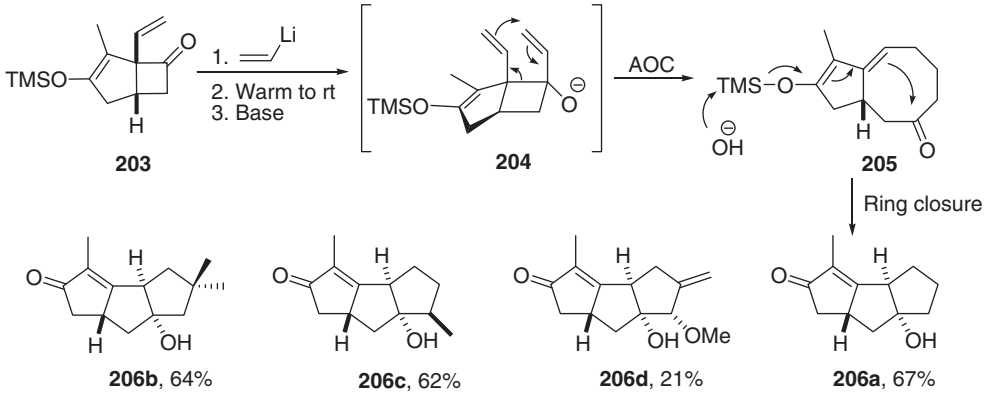
195 **196** **197**

Scheme 58



Banwell developed an elegant synthesis of enantiopure *cis*-decalin cores employing the AOC (Scheme 59).[72] Microbially derived *cis*-1,2-dihydrocatechol **198** was transformed into **199** via a straightforward, eight-step reaction sequence including a Diels–Alder reaction. Subjecting **199** to typical AOC conditions gave the *cis*-decalin **200** in 60% yield. Modification of the substrate structure gave access to similar decalins in equally good yields for the last step.

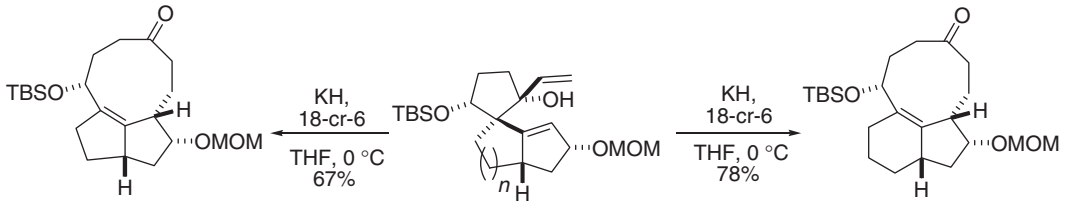
The *cis*-decalin unit of the antitumor macrolides superstolide A and B was generated using an AOC by Jin and coworkers (Scheme 60).[73] Applying a chemoenzymatic desymmetrization approach with *Candida rugosa* lipase, enantiopure **201** was obtained from a *meso*-diacetate. The rearrangement of **201** gave rise to **202** in only moderate yield due to the unprotected diol moiety present in the molecule. When the diol was protected as an acetonide, a base-promoted elimination set in under the rearrangement conditions.



In a series of reports, Moore and coworkers constructed tricyclic polyquinanes in a three-step reaction sequence (Scheme 61).[74] Stereocontrolled *exo*-addition of vinyl lithium to bicyclo[3.2.0]heptenone **203** furnished the alkoxide **204,** which rearranged on

Scheme 59

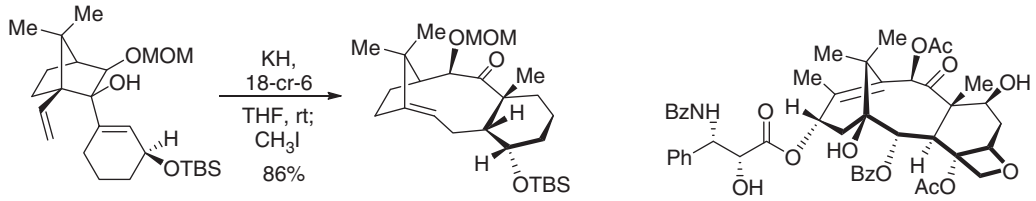
Scheme 60



Scheme 61

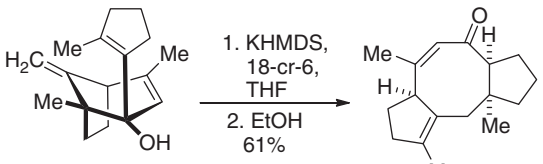
warming to room temperature to give rise to Cope product **205**. Treatment of **205** with base initiated a transannular vinylogous aldol reaction and formation of the tricyclic ring structure of polyquinane **206a** in 67% overall yield. By variation of the vinyl lithium species, differently substituted polyquinanes **206b-d** could be accessed as well in typically good overall yields.

An extremely rapid AOC was employed in the preparation of the carbocylic ring system of the aquariolide diterpene **208a**. Starting from spirocyclic dienol **207a**, the 5-5-9-ring system of the natural product was obtained in good yield at 0 °C (Scheme 62).[75] Also, the six-membered analogue **208b** could be accessed by this facile oxy-Cope rearrangement.



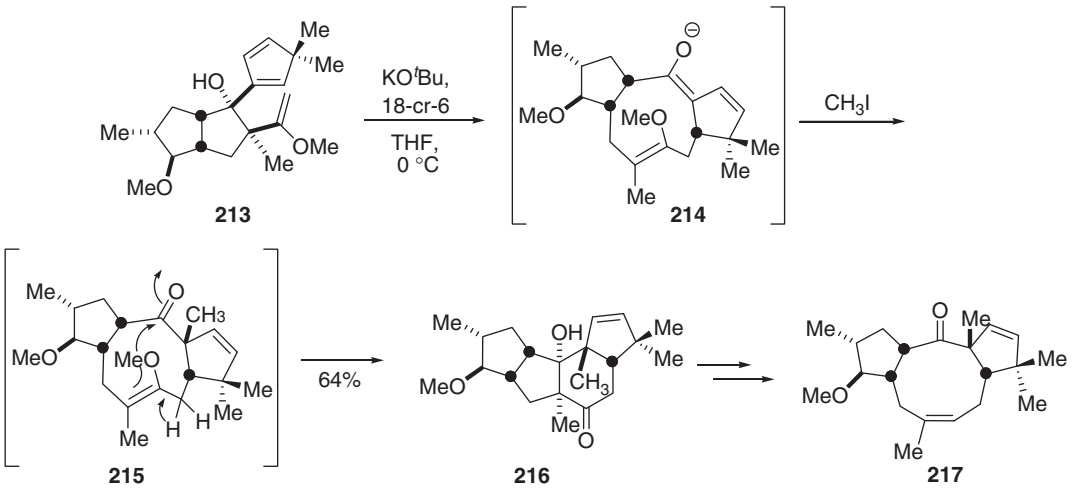
In a series of reports, Paquette and coworkers evaluated the capacity of the AOC for the assembly of potential taxol precursors from different enantiopure starting materials.[76] The tricyclic core structure **210** was obtained in very good yield by the AOC of **209** under very mild reaction conditions followed by the highly diastereoselective trapping of the generated enolate with methyl iodide (Scheme 63).

Likewise, the dicyclopenta[*a,d*]cyclooctene core of the ceroplastin sesterpene was accessed using the AOC (equation 10).[77] On deprotonation, **211** underwent an extremely rapid AOC in only 20 min at room temperature to give the core unit **212** in good yield.



208a, *n*=1 **207a/b** **208b**, *n*=2

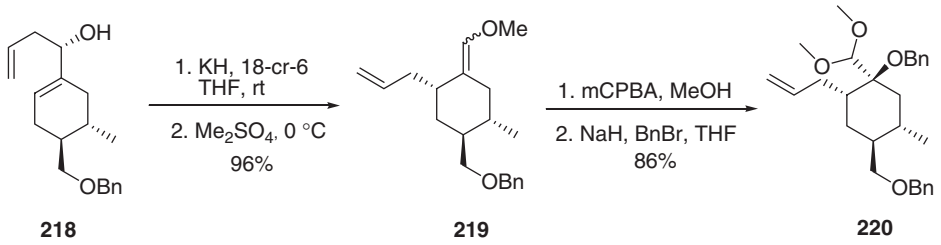
Scheme 62



209 **210**

Scheme 63

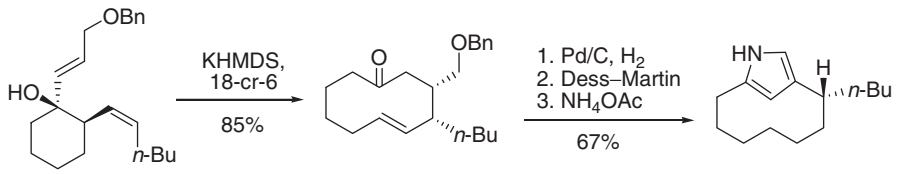
211 **212** (10)



A very impressive example of an AOC embedded in a multiple reaction sequence was demonstrated by the group of Paquette during the assembly of the 5-9-5-tricyclic framework of the diterpenoid natural products, jatrophatrione and citlalitrione (Scheme 64).[78] The rapid AOC of *cis*-1,2-divinylcyclopentanol **213** led to the intermediate enolate **214**, which was stereoselectively alkylated *in situ* with methyl iodide to furnish intermediate **215**. This compound underwent a spontaneous transannular ene cyclization resulting in the tetracyclic 5-5-6-5-scaffold **216** in a remarkable overall yield of 64%. **216** was eventually converted into the desired diterpenoid structure **217** in a four-step sequence.

213 **214** **215** **216** **217**

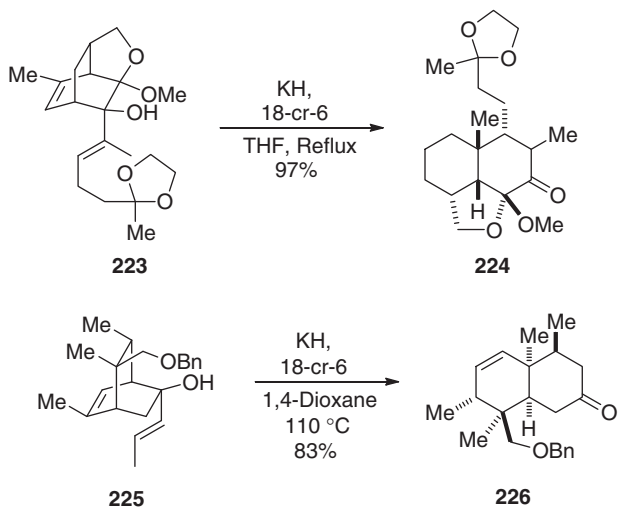
Scheme 64



During the total synthesis of the antitumor antibiotic, (–)-okilactomycin, Smith and coworkers rearranged **218** under typical AOC conditions and trapped the intermediate enolate with dimethyl sulfate to obtain **219**, which was further oxidized and benzylated to furnish acetal **220** in excellent overall yield (Scheme 65).[79] A direct oxidation of the intermediate enolate as well as the generated silyl enol ether failed or gave low yields.

218 **219** **220**

Scheme 65

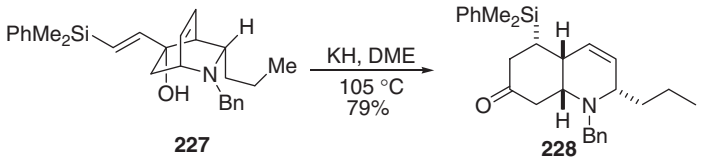


To obtain the crucial 10-membered ring of the prodigiosin alkaloid streptorubin B, Thomson and coworkers utilized an AOC of *trans*-1,2-divinylcyclohexanol **221** to obtain **222** in very good yield and with complete stereochemical transfer (Scheme 66).[80] In a subsequent three-step sequence, they installed the annulated pyrrole ring setting the stage for the endgame of the total synthesis.

221 **222**

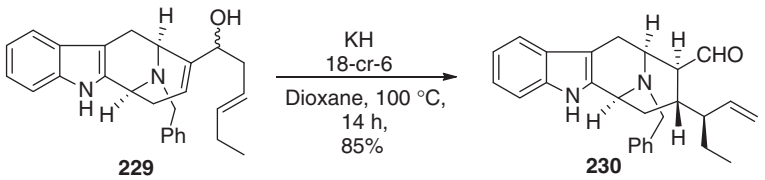
Scheme 66

As discussed in Section 5.19.8.4.1, the AOC is often used to generate the decalin core of complex natural products. This methodolody was exploited by Liao and coworkers with the quantitative rearrangement of **223** to give the functionalized decalin derivative **224** in excellent yield, which served as the key intermediate toward the total syntheses of the sesterpenic acids, bilosespenes A and B (Scheme 67).[81] They also applied this methodology to obtain the decalin core structure **226** of another diterpenic acid in very good yield starting from carbinol **225**.[82]



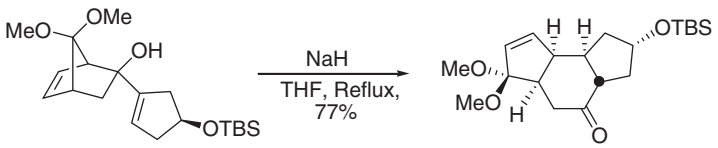
223 **224**

225 **226**



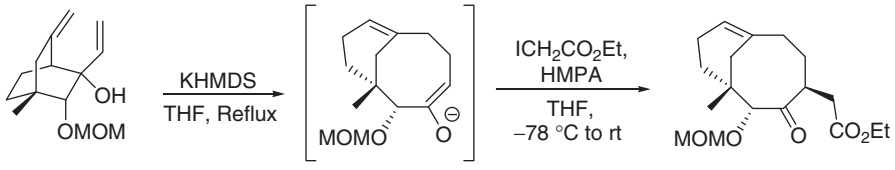
Scheme 67

Heteroanalogues of the decalin core can also be accessed by the AOC as was nicely shown by Polniaszek et al.[83] During the total synthesis of the alkaloids, 195A and 2-*epi*-195B, the azabicyclo[2.2.2]octenol **227** underwent an AOC on treatment with KH and heating in dimethoxyethane to give rise to the decahydroquinolone **228** in good yield (equation 11).



227 228 (11)

In a series of publications, Cook and coworkers demonstrated the usefulness of the AOC for the assembly of ajmaline-related indole alkaloids, which exert interesting biological activities. Refluxing of the potassium alkoxide of **229** in dioxane gave rise to aldehyde **230** in very good yield and complete stereocontrol, from which the total synthesis of (+)-ajmaline was completed in only seven additional steps (equation 12).[84]

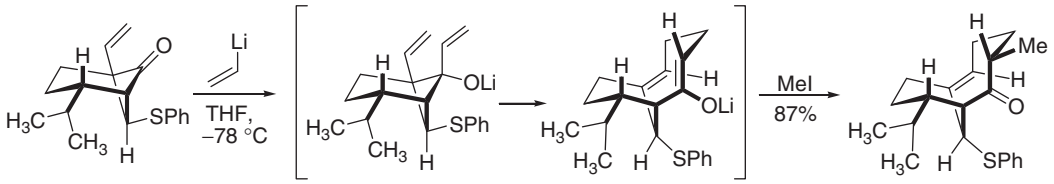


229 230 (12)

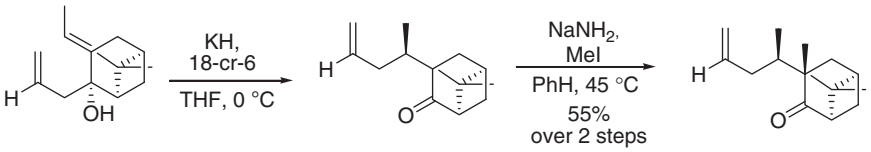
Over the past decades, the group of Paquette has made major contributions to the AOC and demonstrated its synthetic potential in numerous syntheses of natural products. The AOC of carbinol **231** served as a key step toward the spinosyn A core structure **232** (equation 13).[85] Interestingly, the use of KH at room temperature led to decomposition and byproduct formation, whereas the use of sodium hydride in refluxing THF allowed for smooth rearrangement. As a consequence of the substantial strain release that came with the dismantling of the norbornene ring, no crown ether needed to be added.

231 232 (13)

A key intermediate toward the total synthesis of the sesquiterpene lactones vulgarolide and deoxocrispolide was obtained by the AOC of **233** to give rise to the intermediate enolate **234** (Scheme 68).[86] Proceeding with remarkable facility, the rearrangement was completed in just 20 min and the generated enolate was trapped with ethyl iodoacetate at low temperature to furnish alkylated **235** with complete diastereoselectivity and with very good yield in two steps.



233 234 235, 78%

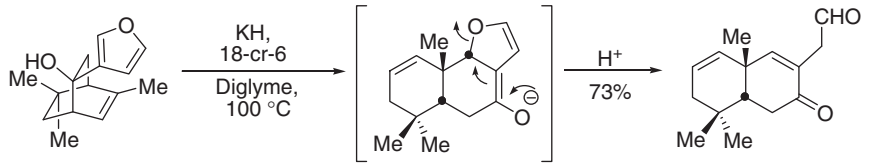


Scheme 68

An even more impressive alkylative trapping of an intermediate enolate was demonstrated by Paquette et al. during their total synthesis of (–)-salsolene oxide.[87] Clean *exo*-addition of vinyl lithium to ketone **236** gave rise to the intermediate alkoxide **237** which, due to its inherent ring strain, spontaneously underwent the oxy-Cope rearrangement to furnish enolate **238** (Scheme 69). The enolate anion was trapped by the addition of an excess methyl iodide to furnish **239** in excellent yield and diastereoselectivity.

In a total synthesis of (+)-nootkatone, Laine and coworkers employed the AOC of **240** to generate ketone **241** (Scheme 70).[88] Trapping of the intermediate enolate species proved to be problematic, forcing them to opt for a two-step approach in which the crude product of the rearrangement was isolated and deprotonated with sodium amide. Alkylation with methyl iodide gave the desired precursor **242** for (+)-nootkatone in good yield over these two steps.

Scheme 69



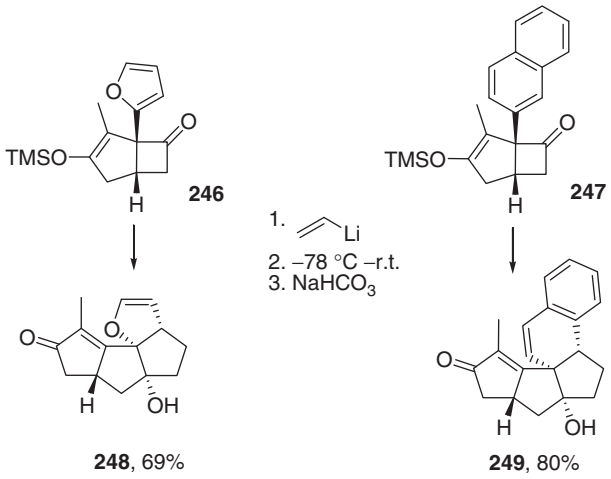
Scheme 70

5.19.8.5 Aromatic Oxy-Cope Rearrangement

For aromatic groups to participate in oxy-Cope rearrangements, the π-electron delocalization has to be disrupted, which makes the sigmatropic process less favorable. Nevertheless, a few examples have been developed in which aromatic systems undergo AOC.

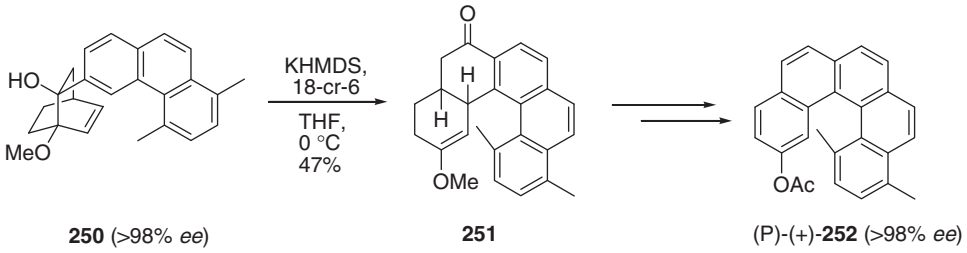
During the total synthesis of (+)-pallescensin A, the group of Paquette employed furyl carbinol **243** in which the furyl moiety was part of the 1,5-diene system (Scheme 71).[89] Elevated temperatures and the use of 18-crown-6 as complexing agent were necessary to promote the sigmatropic process at elevated temperature to furnish the intermediate enolate **244**, which underwent β-elimination of the alkoxide ion to give rise to aldehyde **245**.

Scheme 71



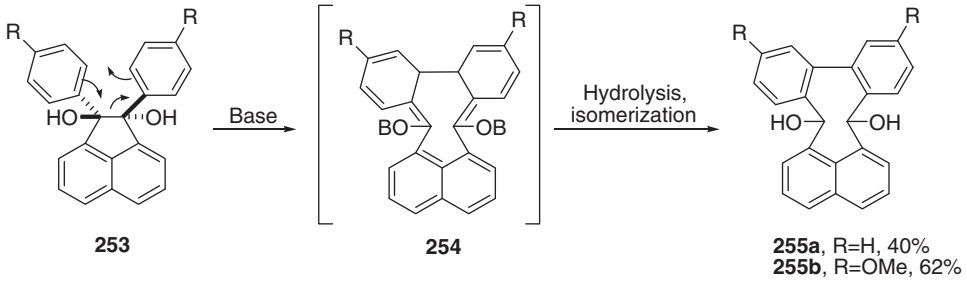
The participation of furyl and naphthyl groups in the AOC was also shown by Moore and coworkers (Scheme 72).[90] They obtained the linear-fused polyquinanes, **248** and **249**, by vinyl lithium addition to the cyclobutanones, **246** and **247**, respectively, and subsequent AOC and transannular ring closure on basic workup (see Scheme 62 for detailed mechanism).

Karikomi and coworkers employed an aromatic AOC to access chiral [5]helicene **252** (Scheme 73).[91] Starting from enantiopure carbinol **250**, the phenanthrene moiety participated in the rearrangement leading to ketone **251** which was aromatized in a four-step sequence to give helicene **252**. The enantiopurity of the product was found to be the same as in the starting material, which showed that the central chirality of **250** was completely transferred into the helical chirality of **252**.



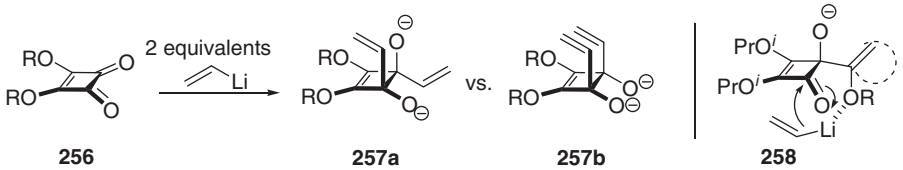
Although the preceding examples involved only one double bond being part of an aromatic system, Huq and coworkers demonstrated that substrates **253** were able to undergo AOC with both double bonds as parts of aromatic systems participating in the sigmatropic process (Scheme 74).[92] On hydrolysis, the intermediate enolate dianion **254** isomerized to give products **255** with a restored aromatic system.

5.19.8.6 DAOC



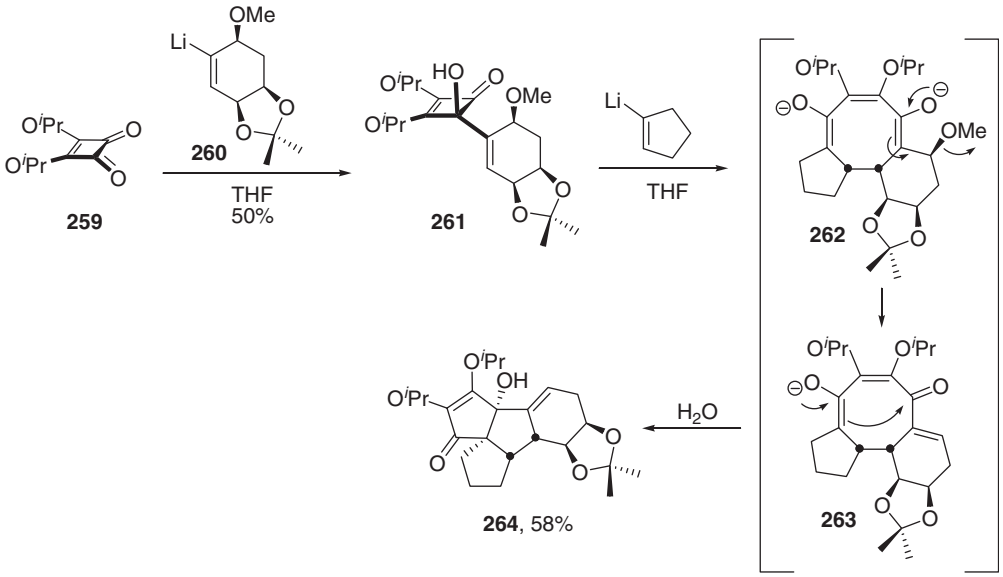
Although known since the early 1980s,[93] doubly charged systems have only recently been increasingly utilized in the dianionic variant of the oxy-Cope rearrangement. The group of Paquette conducted extensive studies on the DAOC of vinyl lithium adducts of squarate esters.[94] When added to squarate esters **256**, the two organometallic additions will furnish two stereoisomers, **257a** and **257b**, with the vinyl substituents in the *trans*- or *cis*-configuration, respectively (Scheme 75). Because only the *cis*-diastereomer is able to undergo the sigmatropic process, a certain level of stereocontrol of the second addition was achieved by incorporation of

Scheme 72



Scheme 73

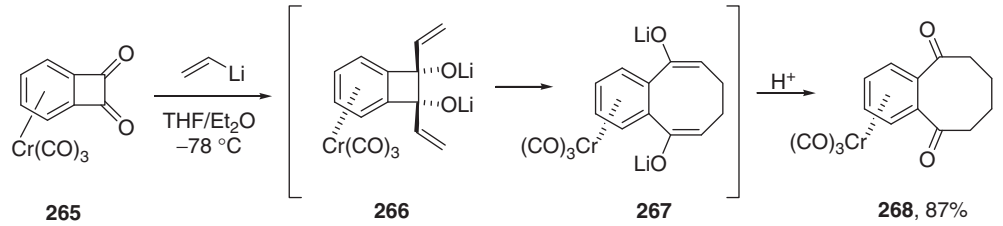
Scheme 74



an ether oxygen substituent in the first organometallic reagent, which served to direct the second vinyl lithium equivalent as shown in **258**.

Scheme 75

Addition of one equivalent of the optically pure organolithium reagent **260** to squarate ester **259** gave 50% of the monoadduct **261**, which could easily be separated from the diastereomeric adduct by chromatography (Scheme 76).[95]

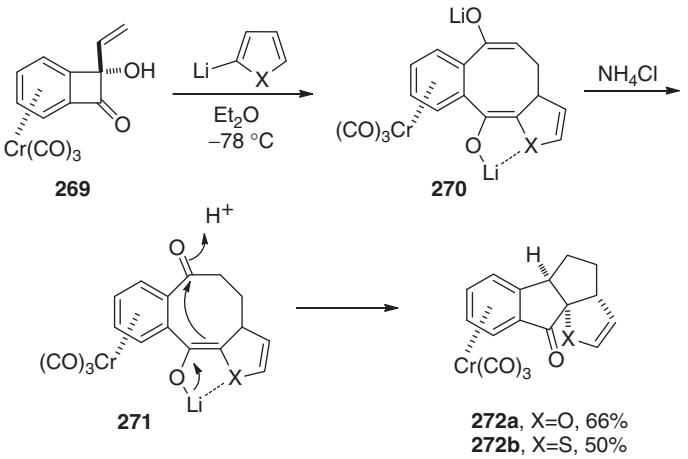


Treatment of **261** with an excess of cyclopentenyllithium preferentially gave the *cis*-adduct, which underwent DAOC to dienediolate **262** followed by *β*-elimination to give ketone **263**, which was then attacked in a transannular aldol reaction by the

Scheme 76

second enolate present to furnish the highly functionalized polyquinane **264** in good overall yield and complete transfer of chirality over the cascade sequence.

Butenschön and coworkers used the arenetricarbonylchromium(0) complex **265** to selectively obtain the *cis*-adduct **266** on addition of an excess of vinyl lithium (Scheme 77).[96] The bulky tricarbonylchromium moiety was effectively shielding one side of the molecule, allowing for nucleophilic attack of both vinyl groups only from the other face. The *in situ*-generated *cis*-configured dianion underwent spontaneous DAOC to give rise to dienediolate **267**, which on hydrolysis was converted into diketone **268** in very good overall yield.



Scheme 77

Interruption of the organolithium addition at the stage of the monoadduct **269** and subsequent treatment of the resulting product with a variety of organolithium reagents contributed to the diversity of this approach. In a special example, a lithiated furane or thiophene was added to **269** to obtain the intermediate dienediolate **270**, accounting for the first example of a DAOC in which an aromatic system was involved (Scheme 78).[97] The heteroatom present in the furan and thiophene ring stabilized the neighboring enolate such that controlled hydrolysis under mild conditions led to ketone **271**, which was then engaged in a transannular aldol reaction to give rise to the polycyclic scaffolds **272a/b** in good overall yields.

5.19.9 Conclusions

The Cope rearrangement of 1,5-dienes is among the most fundamental C–C bond-forming reactions currently available to synthetic chemists. It is unique in forming C–C σ-bonds between unfunctionalized carbon centers in a highly stereospecific and predictable manner. It creates stereogenic centers and stereogenic double bonds with high fidelity in chair-like transition states whenever they are geometrically accessible. A wealth of theoretical investigations have recently shed light on the mechanism of the Cope rearrangement and on the exact nature of the transition state in particular. Taking advantage of the inherent strain in small rings, the Cope rearrangement is among the most useful and versatile methods to access medium size rings starting from *cis*-1,2-divinyl-substituted cyclopropanes and cyclobutanes as the substrates. Coupled with asymmetric enolate-based reactions, conjugation-driven Cope rearrangements have been successfully employed in the context of acyclic stereocontrol. The oxy- and

Scheme 78

anionic oxy-Cope variants proceed under much milder conditions and have proven highly useful in the synthesis of polycyclic natural products. A large number of total syntheses of complex natural products have relied on the power of the AOC in particular.

5.20 Claisen Rearrangements

AM Martín-Castro and M Tortosa, Universidad Autónoma de Madrid, Madrid, Spain

© 2014 Elsevier Ltd. All rights reserved.

This chapter is a revision of the previous edition chapter by P. Wipf, Vol. 5, pp 827–873, © 1991, Elsevier Ltd.

5.20.1	**Introduction**	913
5.20.2	**Aliphatic Claisen Rearrangement**	913
5.20.2.1	Mechanistic Overview	913
5.20.2.2	Synthesis of Allyl Vinyl Ethers	914
5.20.2.3	Kinetic Aspects of the Aliphatic Claisen Rearrangement	916
5.20.2.3.1	Influence of substituents on the rearrangement rate	916
5.20.2.3.2	Influence of solvents and temperature on the rearrangement	917
5.20.2.3.3	Catalyzed aliphatic rearrangements	918
5.20.2.3.3.1	Metal catalysis	918
5.20.2.3.3.2	Organocatalysis	920
5.20.3	**Other [3,3]-Sigmatropic Rearrangements**	921
5.20.3.1	Aliphatic Claisen Rearrangement of Propargyl Vinyl Ethers	921
5.20.3.2	Aromatic Claisen Rearrangement	924
5.20.3.3	Carroll Rearrangement	929
5.20.3.4	Eschenmoser Rearrangement	930
5.20.3.5	Johnson Rearrangement	933
5.20.3.6	Ireland Rearrangement	936
5.20.3.7	Decarboxylative Claisen Rearrangement	941
5.20.3.8	Reformatsky Rearrangement	943
5.20.4	**Stereoselective Claisen Rearrangement**	945
5.20.4.1	General Aspects	945
5.20.4.2	Intra-annular Stereoselection	945
5.20.4.2.1	Transition state geometry	945
5.20.4.2.2	Enol ether geometry	949
5.20.4.2.3	Allylic double bond geometry	953
5.20.4.2.4	Configuration at C4	954
5.20.4.3	Extra-annular Stereoselection	961
5.20.4.4	Enantioselective Rearrangements and Asymmetric Catalysis	966
5.20.4.4.1	Chiral metal catalysts	966

Glossary

Chiral auxiliary Asymmetric fragment that is temporarily incorporated into an organic compound so that a subsequent synthetic step can be carried out asymmetrically. Out of the two possible enantiomers, only one will be selectively obtained after removal of the original auxiliary in a third step of the synthetic sequence.

Chiral ligand Enantiomerically pure organic compound which is used in combination with a metal atom producing a chiral catalyst for asymmetric synthesis. The ligand chirality is transferred to the reaction product, which as a result is obtained enantioselectively.

Enantioselectivity Degree to which one enantiomer of a chiral product is preferentially produced in a reaction, as a consequence of the presence of an additional source of chirality.

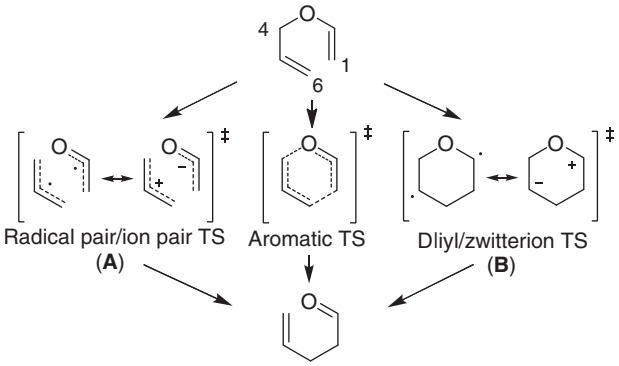
Organocatalyst Organic compound capable of increasing the rate of a chemical reaction either by temporary covalent binding or by noncovalent interactions with the substrate.

Pericyclic This term is applied to concerted reactions wherein the transition state has a cyclic geometry and multiple carbon–carbon bond-making and -breaking events take place.

Sigmatropic rearrangement Type of organic intramolecular pericyclic reactions wherein the carbon skeleton of the substrate is transformed in a structural isomer by way of a σ-bond migration from one terminus of a π-bonded system to its more distant terminus with simultaneous shift of the π system.

 doi:10.1016/B978-0-08-097742-3.00521-8

5.20.1 Introduction



In 1912, Rainer Ludwig Claisen discovered the intramolecular rearrangement of an allylic fragment from the O-position of β-naphthol to the vicinal C-position of the arene.[1] Soon, it was evident that the scope of the reaction was far beyond the use of aryl vinyl ethers. Additionally, the highly ordered transition state involved allowed predicting the stereochemical outcome of the process. These features, along with the good availability of the starting materials, established the rearrangement as a powerful tool for the synthesis of new complex structures. Consequently, many aspects related to mechanism, reaction conditions, asymmetric variants, and synthetic applications have been extensively reviewed.[2]

A century later, this chapter is aimed to cover the most relevant advances in the Claisen rearrangement since the publication of the first edition of *Comprehensive Organic Synthesis* (*COS*) in 1991.[2g] However, this overview is not intended to be exhaustive, so not all the relevant examples are included. The first part of the chapter deals with methods for the preparation of allyl vinyl ethers, as well as mechanistic and kinetic aspects of the Claisen rearrangement with special attention on the use of catalysts. In this section, only the use of achiral catalysts is covered as the catalyzed asymmetric rearrangement is discussed later in the chapter. Next, different [3,3]-sigmatropic rearrangements closely related to the title reaction are presented. The second part of this overview is focused on the stereoselective version of the rearrangement. Two approaches to control the stereoselectivity of the reaction have been considered depending on whether the elements of stereocontrol are embedded in the allyl vinyl ether moiety (intra-annular stereoselectivity) or are external to it (extra-annular stereoselectivity). A significant part of this section refers to recent diastereo- and enantioselective approaches in which the stereoselectivity of the reaction can be controlled by a remote stereocenter covalently bonded to the allyl vinyl ether moiety or by a chiral catalyst. Examples of the synthesis of natural or biologically active compounds are shown in each section. Due to the wealth of data, sections concerning the photo,[3] aza,[4] zwitterionic amino,[5] thia,[6] phospha,[7] and metallo[8] as well as retro-Claisen rearrangements[9] have been omitted. Tandem processes involving Claisen rearrangements are covered in a different chapter (*see* Chapter 5.21). Literature examples were mostly taken from reports published between 1991 and 2012, in order to provide information that is complementary to the first edition of *COS*.

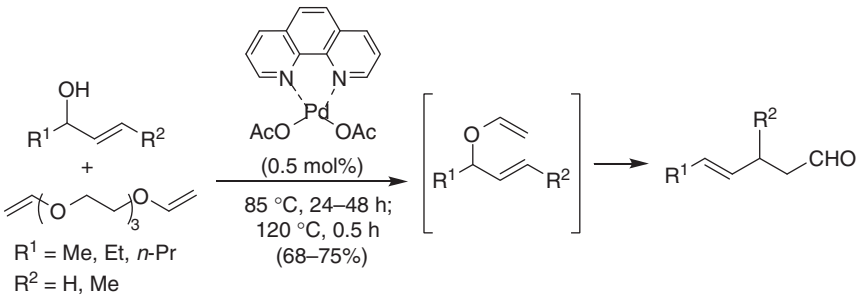
5.20.2 Aliphatic Claisen Rearrangement

5.20.2.1 Mechanistic Overview

The term 'aliphatic Claisen rearrangement,' which describes the thermal isomerization of an allyl vinyl ether into a γ,δ-unsaturated carbonyl compound, is applied to a $[\pi^2s + \sigma^2s + \pi^2s]$ reaction proceeding through a six-membered cyclic transition state,[1] classified as a [3,3]-sigmatropic rearrangement following the Woodward–Hoffmann rules[10] and frontier orbital theory.[11] The initially postulated aromatic transition state for the rearrangement, involving concerted and synchronous σ- and π-type 2p overlappings of both allylic fragments of the substrate,[12] has been thoroughly revised over the years. Studies of the secondary kinetic deuterium isotope effects on the σ-bond dissociation and the new σ-bond formation during the rearrangement revealed two nonaromatic alternate structures for the transition state (**Scheme 1**),[13] an oxoallyl–allyl radical pair, also represented by an ionic pair (**A**), and a 1,4-diyl or zwitterionic intermediate (**B**). An early dissociation of the C4–O bond produces pair **A**, whereas intermediate **B** results from an advanced C1–C6 bond formation. Kinetic studies demonstrated a large extent of C4–O bond dissociation in the transition state, thus favoring the radical-pair structure **A**,[14] in accordance with the similarly dissociative transition state postulated for the enzymatic [3,3]-sigmatropic rearrangement of chorismic acid to prephenic acid.[15] Numerous theoretical calculations predicting similar plausible structures for the transition state of the aliphatic Claisen rearrangement have been reported.[16,17]

Scheme 1

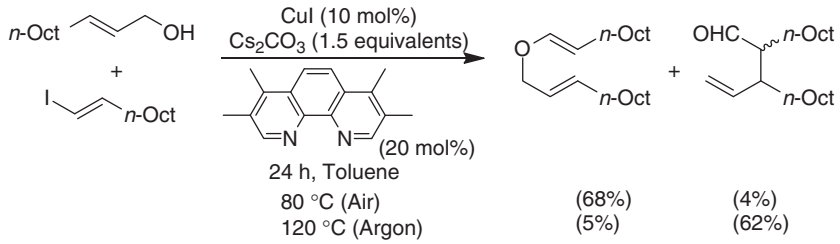
A three-step pathway for the rearrangement has been proposed from the observation of the molecular changes occurring during the reaction on vibrational excitation in the electronic ground state by a stimulated Raman process.[18] The initial formation of a bis-allyl-like intermediate as a result of the C4–O-bond weakening is followed by incipient formation of a C1–C6 bond giving



an aromatic-like intermediate species. In a third step, the rearrangement product is obtained after the simultaneous C4–O-bond breaking and C1–C6-bond formation.

Recently, the comparison of the experimental $\Delta G^{\neq}$ values for different aliphatic Claisen rearrangements with the benchmark calculated free energy barriers for the gas-phase reactions provided a calculated structure for the transition state,[19] which closely resembles the fairly dissociative structure postulated on the basis of kinetic isotope effects.[20]

Regarding the only two permitted conformations for the six-membered cyclic transition state of a *supra–supra* process (i.e., chairlike and boatlike geometries), both theoretical methods[16,21–23] and the experimentally observed asymmetry transfer from the π-bonds of the substrate to the new σ-bond of the product clearly suggest that the chairlike transition state is lower in energy than the analogous boatlike transition state.

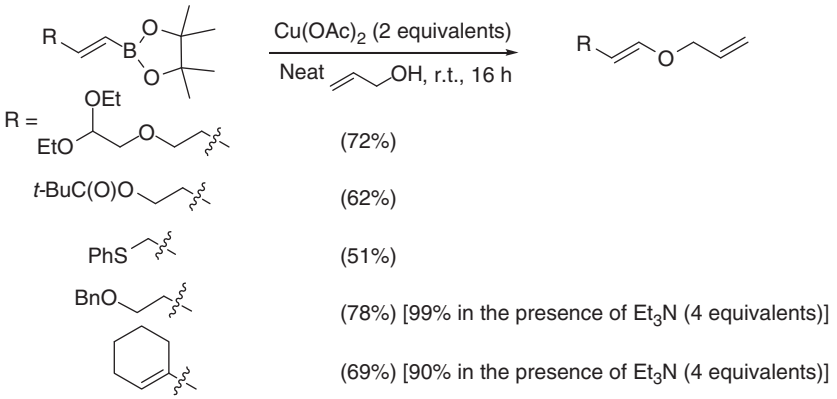


5.20.2.2 Synthesis of Allyl Vinyl Ethers

The initially reported methods for the preparation of allyl vinyl ethers consisted of either the acid- or base-promoted cleavage of allyl ketals,[24,25] or a mercury-catalyzed transfer of a vinyl group from vinyl ethers to allylic alcohols.[26–29] The usually low yields reported for the above protocols along with the high toxicity of mercury(II) salts prompted the development of improved approaches to the synthesis of allyl vinyl ethers. *O*-vinylation reaction of allylic alcohols with commercial triethyleneglycol divinyl ether was proved to be successful for the preparation of allyl vinyl ethers, which *in situ* rearranged into γ,δ-unsaturated aldehydes (Scheme 2).[30]

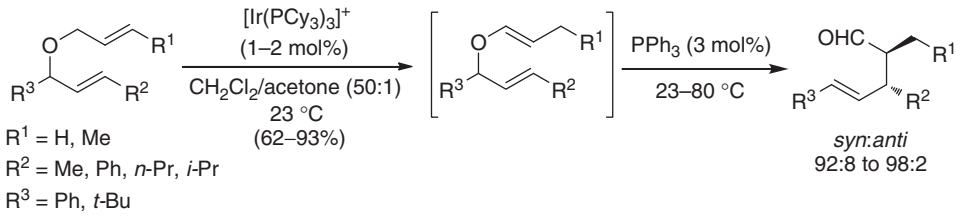
Scheme 2

O-allylation reactions have also been used for the preparation of allyl vinyl ethers.[31] Perhaps, one of the most attractive new protocols for the synthesis of allyl vinyl ethers involves metal-promoted C–O coupling reactions. The copper-catalyzed coupling reaction of a vinyl halide and an allylic alcohol under Ullmann-type conditions in the presence of tetramethyl-1,10-phenanthroline afforded a method for the synthesis of allyl vinyl ethers, which could be isolated or, if desired, directly transformed into the Claisen products on changing the reaction temperature (Scheme 3).[32]



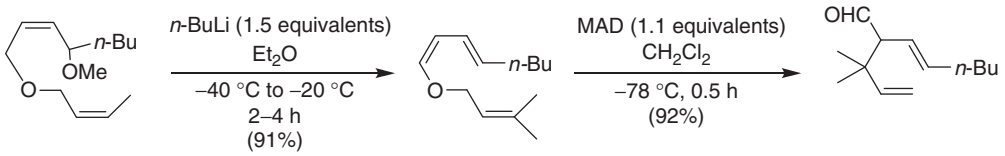
Scheme 3

The $Cu(OAc)_2$-promoted coupling reaction of pinacol vinyl boronates and allylic alcohols has been developed as a mild and functional-group-tolerant method for the synthesis of isolable allyl vinyl ethers. The addition of a tertiary amine to the reaction medium proved beneficial (Scheme 4).[33]

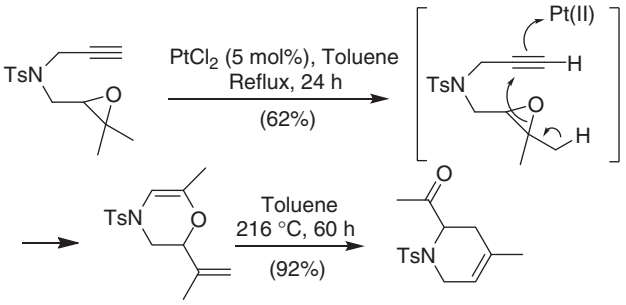


Although different Ni(0)-,[34] Ru(II)-[35] and Ir(I)-based[36–38] complexes have been described as catalysts for the isomerization of bis(allyl) ethers, the resulting allyl vinyl ethers are usually not easily isolable but rearrange *in situ* to the γ,δ-unsaturated aldehydes (Scheme 5).[36]

The 1,4-elimination reaction of 1-allyloxy-4-methoxy-(2*Z*)-alkenes with *n*-butyllithium is a general method for the stereoselective preparation of allylic (1*Z*,3*E*)-dienyl ethers, which can be transformed into the Claisen products on treatment with an organoaluminum reagent (Scheme 6).[39]

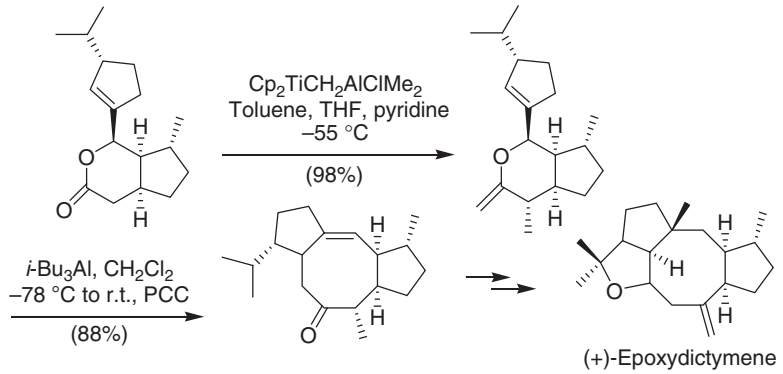


Cyclic allyl vinyl ethers (3,4-dihydro-2*H*-1,4-oxazines) have been prepared by $PtCl_2$-catalyzed isomerization of alkynyl epoxides, and were further converted to piperidine derivatives by Claisen rearrangement (Scheme 7).[40]

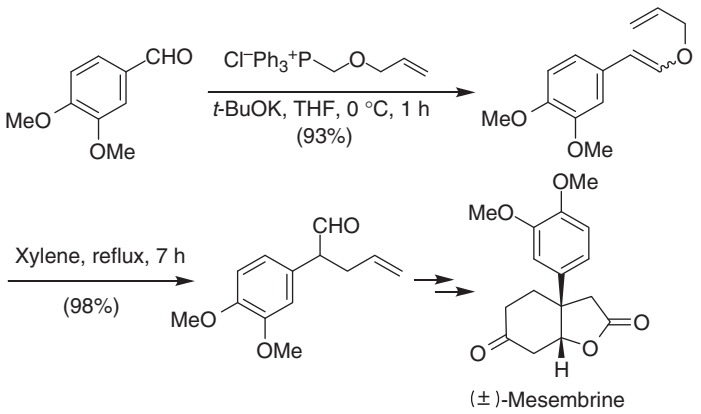


Scheme 4

Scheme 5



Scheme 6



Scheme 7

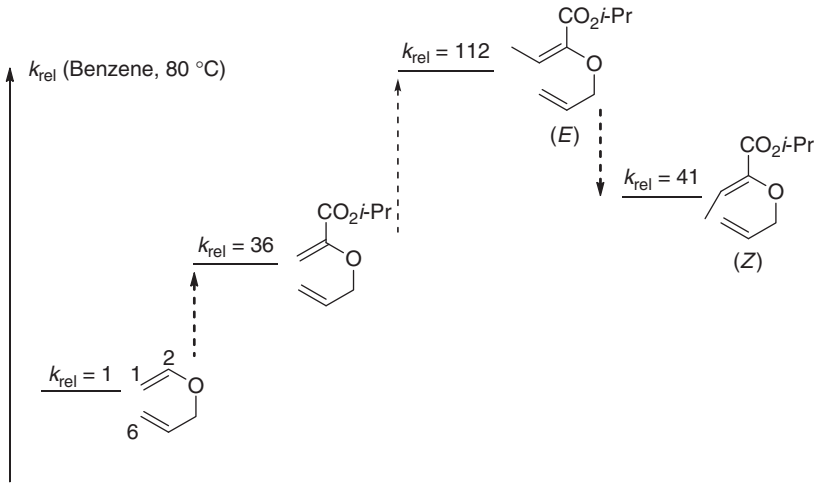
Olefination reactions have also been traditionally used for the construction of allyl vinyl ethers. In this sense, the use of the Tebbe reagent ($Cp_2Ti(\mu\text{-}CH_2)(\mu\text{-}Cl)AlMe_2$) has provided good yields from allyloxy carbonyl compounds.[41–43] This was the method of choice for the preparation of the substrate which underwent an aluminum-promoted Claisen rearrangement, described as the key step in the total synthesis of the diterpene (+)-epoxydictymene (Scheme 8).[44]

Wittig olefination of carbonyl derivatives with allyloxy triphenylphosphonium chloride afforded isolable allyl vinyl ethers.[45] This protocol provided the starting material for the thermal Claisen rearrangement utilized as a key step in the synthesis of the alkaloid (±)-mesembrine (Scheme 9).[46]

Scheme 8

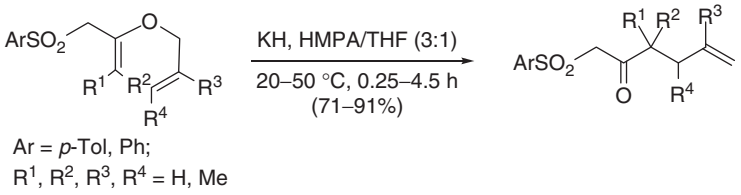
Scheme 9

5.20.2.3 Kinetic Aspects of the Aliphatic Claisen Rearrangement



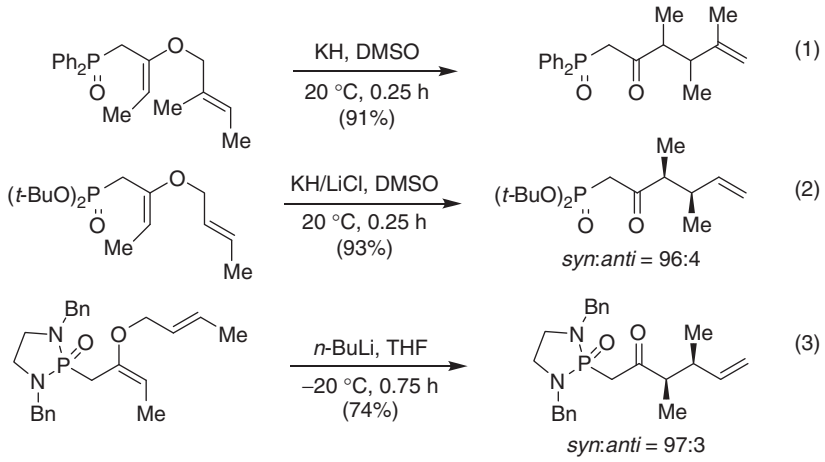
5.20.2.3.1 Influence of substituents on the rearrangement rate

The effect of disparate functional groups installed at different sites of the allyl vinyl ether on the rearrangement rate has been thoroughly examined. Depending on the predominant electron-withdrawing (or donating) character or the radical-stabilizing properties of the groups, as well as their position at the substrate skeleton, different structures for the transition state of the rearrangement, ranging from the radical pair **A** to the diyl structure **B** (Scheme 1), have been proposed. Electron-withdrawing cyano[47,48] and trifluoromethyl[49] groups, as well as electron-donor alkoxy[50] and trialkylsiloxy[51–54] substituents, have received particular attention in the literature. In general, a marked accelerating influence on the reaction rate has been reported for both electron-donor and electron-acceptor substituent positions at C2 and C4 of the allyl vinyl ether framework. These results have been confirmed by a number of theoretical calculations.[55]



The accelerating role played by an alkoxycarbonyl group at C2 in the kinetics of the Gosteli–Claisen rearrangement[56] has been evidenced by computational studies.[57] Thus, a 36-fold rate acceleration by such a group was reported. The presence of one or more electron-donor alkyl groups at C1, C6, or both amplified the effect on the rate, in particular for *E*-configured substrates (Scheme 10).

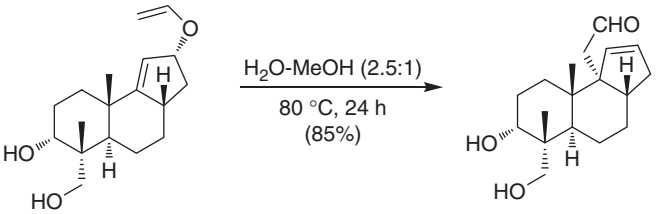
The theoretically predicted positive effect of electron-donor substituents at C2 on the rate of the aliphatic Claisen rearrangement[58] was experimentally verified with substrates having a sulfur[59] or phosphorus[60,61] stabilized carbanionic center bonded to C2 of allyl vinyl ethers. These studies gave rise to the so-called carbanionic Claisen rearrangement, which affords γ,δ-unsaturated ketones regioselectively under unusually mild conditions, which are attributed to the π-donor effect of a carbanion. Arylsulfonyl groups are the only sulfur-based anion-stabilizing groups capable of accelerating the rearrangement (Scheme 11). The use of potassium hydride as the base in neat hexamethylphosphoramide (HMPA) as the solvent gave the best results, since these conditions maximized the charge on the carbanionic atom.



Different phosphorus-based groups have also been reported as anion-stabilizing functions capable of accelerating the Claisen rearrangements. Thus, phosphine oxides (Scheme 12, equation 1),[60] phosphonates (Scheme 12, equation 2),[60] and

Scheme 10

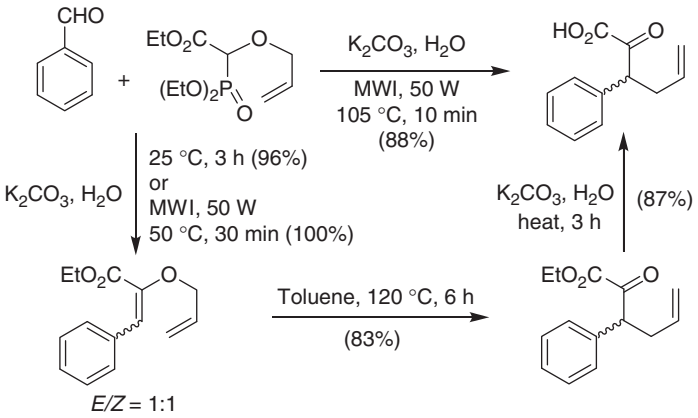
Scheme 11



Scheme 12

phosphonamides (Scheme 12, equation 3)[61] stabilize a carbanionic charge on a carbon atom bonded to the C2 position of the substrates, producing a large acceleration of the Claisen rearrangement (Scheme 12).

5.20.2.3.2 Influence of solvents and temperature on the rearrangement

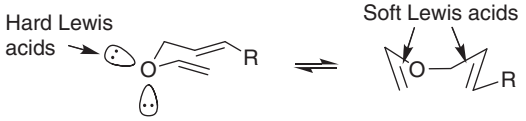


The role of solvents in the aliphatic Claisen rearrangement has been largely examined over the years. Experimental data[15,62–64] and theoretical calculations[65,66] have shown the positive effect of water on the rate of the reaction. This effect has been attributed to hydrophobic interactions and to the hydrogen-bond donating properties of water, as well as to the contribution of solvent polarization to the activation energy of the rearrangement.[67] Sometimes, the addition of small amounts of a cosolvent (typically methanol or dimethyl sulfoxide) facilitates the solubility of the substrate. The Claisen rearrangement reported as the key step in

the synthesis of aphidicolin proceeded with poor yield (20%) under gas-phase thermal conditions, whereas the Claisen product was obtained in an 85% isolated yield in water–methanol (Scheme 13).[68]

Scheme 13

Microwave irradiation (MWI) has also proved to be beneficial for the thermal rearrangement, the synthetic potential of which has been broadly demonstrated in the synthesis of natural and unnatural products.[69] The benefits of MWI are evident from multistep sequences wherein a Claisen rearrangement is one of the involved reactions (*see* Chapter 5.21). The tandem three-step, one-pot Horner–Wadsworth–Emmons olefination/Claisen rearrangement/hydrolysis sequence described in water under MWI for the synthesis of homoallylic α-ketoacids[70] was clearly more advantageous than the stepwise conventional sequence (Scheme 14).

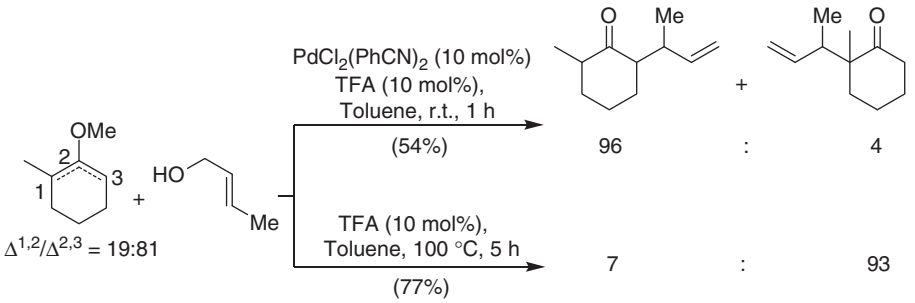


Scheme 14

5.20.2.3.3 Catalyzed aliphatic rearrangements

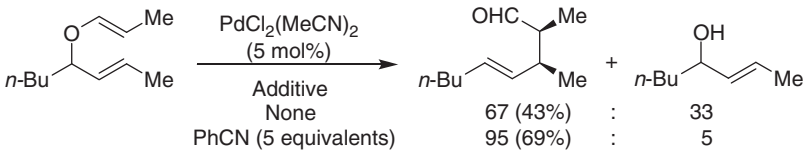
A marked enhancement of the rearrangement rate may be achieved in the presence of catalysts under mild experimental conditions. The use of both metal catalysts and organocatalysts has been reported to this end.

5.20.2.3.3.1 Metal catalysis



The Claisen rearrangement is efficiently catalyzed by Lewis acids through metal coordination to either one of the lone electron pairs at the oxygen atom or simultaneously to the allyl and vinyl double bonds (Scheme 15). Hard Lewis acids prefer the oxygen electron pair as the coordination site, and a chairlike transition state is predominant in the rearrangement. Contrarily, soft Lewis acids (typically, Hg(II)- and Pd(II)-based acids) usually coordinate to both π-bonds of the substrate, which behaves as a bidentate ligand adopting a boatlike geometry in the favored transition state of the rearrangement.

Scheme 15

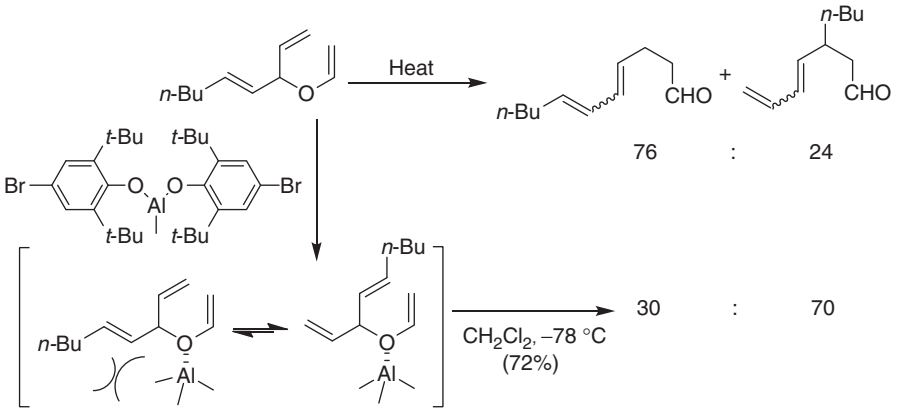


Since the initial report of $PdCl_2(CH_3CN)_2$-promoted aliphatic Claisen rearrangements,[71] many examples describing the use of catalysts based on Pd(II) have been published. The stereochemical outcome of all of them has been explained in terms of a

marked preference for the boatlike transition state.[72–75] Additionally, Pd(II)-catalyzed rearrangements were reported to provide different regioselectivities to those obtained by noncatalyzed thermal rearrangements. These different results were attributed to the different rates of the rearrangement of the less and the more substituted enol allylic ethers, which are interconvertible in the presence of the Pd-catalyst (Scheme 16).[76]

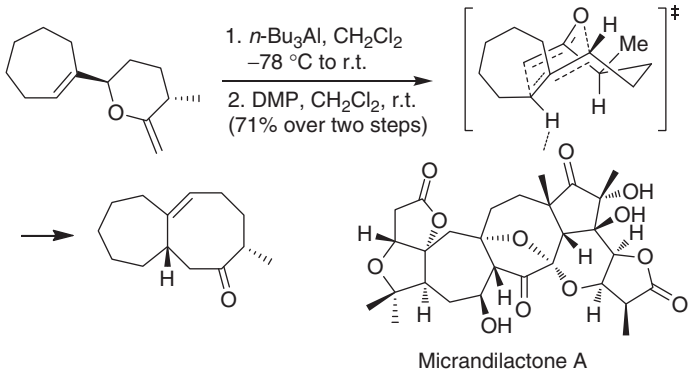
Scheme 16

The low yields reported for the Pd(II)-catalyzed Claisen rearrangement of α-unsubstituted allyl vinyl ethers, which are due to undesired hydrolysis as a side reaction,[77] have been improved in the presence of PhCN or *i*-PrCN as additives capable of limiting the formation of the allylic alcohol (Scheme 17).[78]



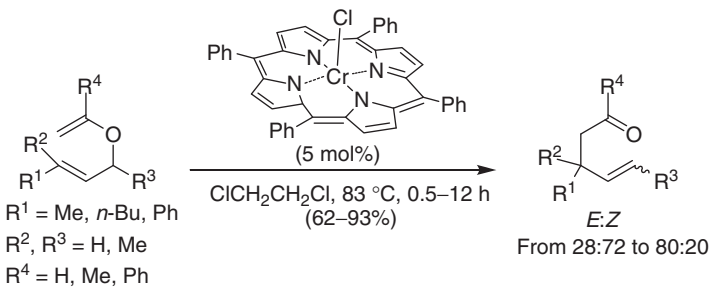
Scheme 17

The rearrangement of aliphatic allyl vinyl ethers proceeds under mild conditions in the presence of aluminum Lewis acid catalysts. The use of Et_2AlSPh or Et_2AlCl-PPh_3 produces the corresponding γ,δ-unsaturated aldehydes or ketones in moderate to good yields.[79]



The stereoselectivity of the Al-catalyzed rearrangements clearly demonstrates the marked preference of the organoaluminum reagents for selective coordination to one of the oxygen electron lone pairs, favoring a chairlike conformation for the transition state of the reaction, as will be discussed later in this chapter.

This coordination mode was also responsible for the observed inversion in the regioselectivity of the rearrangements of bisallyl vinyl ethers, which thermally reacted preferentially through the less substituted allylic double bond, but gave the opposite regioisomer under aluminum catalysis (Scheme 18).[80]



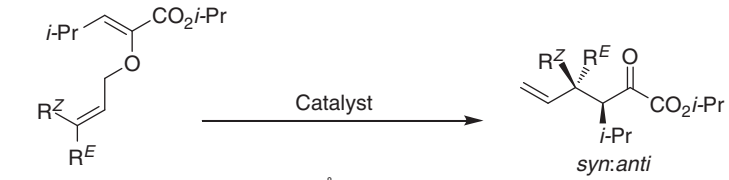
Scheme 18

The central 7–8 fused bicyclic core of the nortriterpenoid micrandilactone A was constructed by a mild *i*-Bu_3Al-catalyzed Claisen rearrangement via a chairlike transition state (Scheme 19).[81]

Scheme 19

The catalytic activity of Cu(II), Sn(IV), and Ti(IV) Lewis acids in the Claisen rearrangement has also been examined.[28] However, the synthetic applicability of these species is restricted because practically equimolecular mixtures of [1,3]- and [3,3]-rearrangement products were formed. Improved levels of regioselectivity in the Claisen rearrangement of allyl vinyl ethers were achieved in the presence of catalytic amounts of a metalloporphyrin, Cr(TPP)Cl. The complete regioselectivity of the reaction was attributed to the concerted nature of the rearrangement under weak Lewis acid catalysis, capable of depressing the formation of ionic intermediates (Scheme 20).[82]

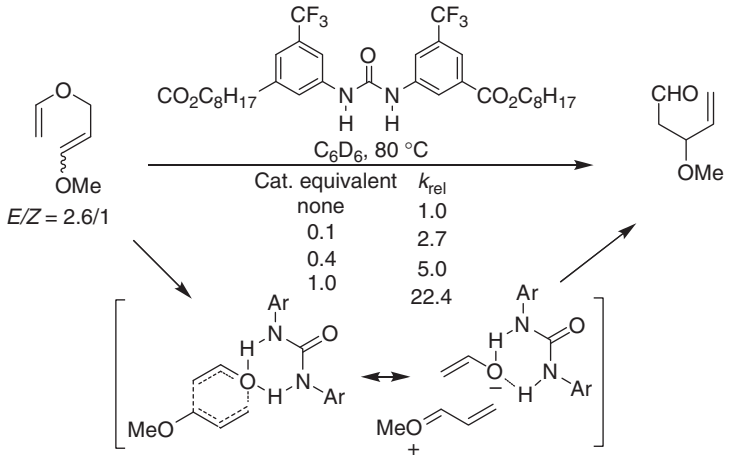
Scheme 20



Different Lewis acids such as $Cu(OTf)_2$,[83] $Yb(OTf)_3$,[83] $Bi(OTf)_3 \cdot 4H_2O$,[84] and $MgCl_2$[85] have been reported to catalyze the Claisen rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers, with disparate *anti*/*syn* selectivities (Scheme 21). Thus, (*Z*,*Z*)-configured substrates afforded high levels of *syn*-selectivity, whereas (*Z*,*E*)-configured allyl vinyl ethers reacted with practically no selectivity.

5.20.2.3.3.2 Organocatalysis

Hydrogen bonding stabilization of the transition state has been described as responsible for the reported organocatalytic acceleration of different Claisen rearrangements. Thus, a marked enhancement of the rate was described for the rearrangement of electron-donor-substituted allyl vinyl ethers (Scheme 22).[86,87]



1,3-Bis[3,5(trifluoromethyl)phenyl]thiourea failed to catalyze the rearrangements of 2-alkoxycarbonyl-substituted allyl vinyl ethers.[88] However, an *N*,*N*′-diphenylguanidinium salt induced substantial rate enhancement in the rearrangement of differently substituted allyl vinyl ethers, probably due to the stabilization of the transition state by hydrogen bonding (Scheme 23).[89]

A bisamidinium catalyst was also capable of accelerating the rearrangement of a 2-trifluoromethyl allyl vinyl ether (Scheme 24).[90] The transition state stabilization by the formation of a double hydrogen bond between the catalyst and the oxygen atom of the substrate was invoked as responsible for the observed rate enhancement.

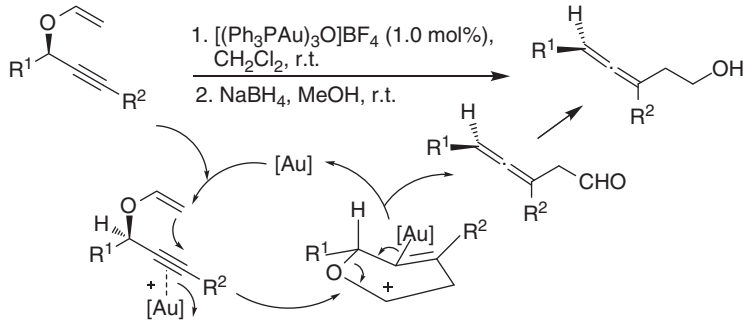
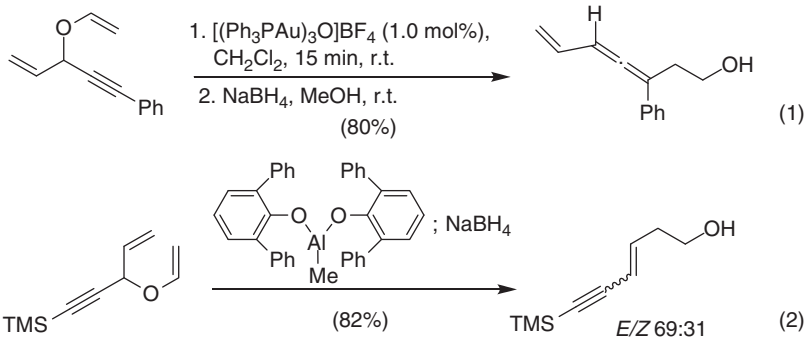
5.20.3 Other [3,3]-Sigmatropic Rearrangements



5.20.3.1 Aliphatic Claisen Rearrangement of Propargyl Vinyl Ethers

Propargyl vinyl ethers have also been reported to undergo [3,3]-sigmatropic rearrangements, usually under catalytic conditions. The synthetic utility of the resulting allene derivatives is frequently evidenced by their straightforward transformations into a

Scheme 24



variety of organic arrays. A series of propargyl vinyl ethers underwent smooth Claisen rearrangement in the presence of catalytic amounts of the gold-oxo complex $[(Ph_3PAu)_3O]BF_3$.[91] The addition of $NaBH_4$ to the reaction medium afforded homoallenic alcohols in high yields. When starting from enantiomerically enriched propargyl vinyl ethers, the central chirality of the carbinol was effectively transferred to the axial chirality in the allene product (**Scheme 25**). Surprisingly, under Ph_3PAuBF_4 catalysis, no chirality transfer was detected and the rearranged product was almost racemic. The catalytic system $Ph_3PAuOTf$, in turn, produced erosion in the yield because of competing [1,3]-rearrangement. The proposed mechanism involves a 6-*endo-dig* addition of the enol ether portion onto the gold(I)–alkyne complex and subsequent Grob-type fragmentation, affording the *β*-allenic aldehyde and the regeneration of the Au(I) catalyst.

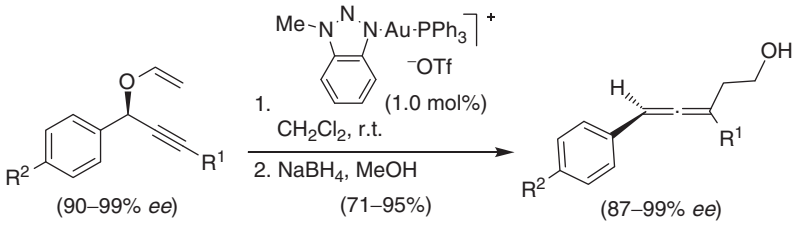
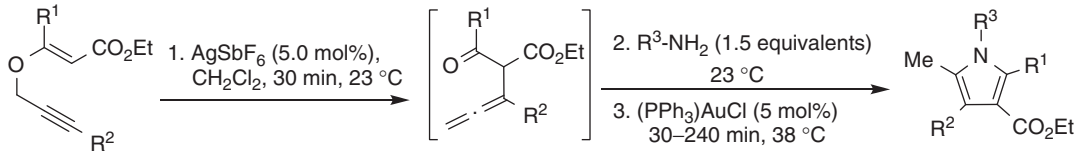


Scheme 25

Vinyl ethers capable of reacting either via allylic or propargylic Claisen rearrangement exhibit a high selectivity for the acetylenic pathway under Au(I)-catalyzed conditions (**Scheme 26**, equation 1). Contrarily, reactions catalyzed by hard Lewis acids are selective for the allylic rearrangement (**Scheme 26**, equation 2).[28]

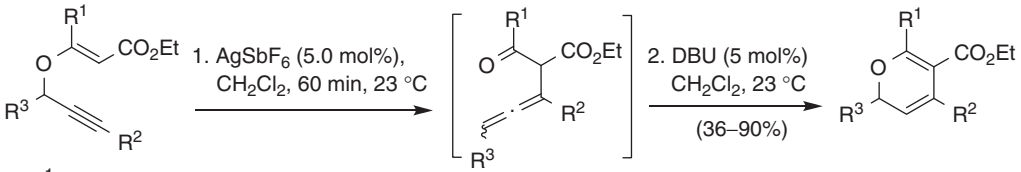
Scheme 26



More recently, 1,2,3-triazole–Au complexes have been reported as efficient catalysts capable of promoting propargyl vinyl rearrangements in high yields. These homogeneous catalysts chemoselectively activate the starting alkynes, thus avoiding their undesired isomerization to allenes and, therefore, providing excellent levels of chirality transfer in the rearrangement (Scheme 27).[92]

R^1 = H, *n*-Bu, TMS
R^2 = F, NO_2, CO_2Me, Me

Scheme 27



Ag(I) salts effectively catalyze the propargyl-Claisen rearrangement. $AgBF_4$ has been reported to promote the reaction at room temperature in benzene.[93] Under $AgSbF_6$ catalysis, a series of propargyl vinyl ethers rearranged to generate allenic ketones, which were further condensed with a primary amine to give, after Au(I)-catalyzed 5-*exo*-*dig* cyclization, highly substituted 5-methylpyrroles.[94] This Ag(I)-catalyzed propargyl-Claisen rearrangement proceeded rapidly at room temperature in CH_2Cl_2 in high yields with low catalyst loadings (Scheme 28).

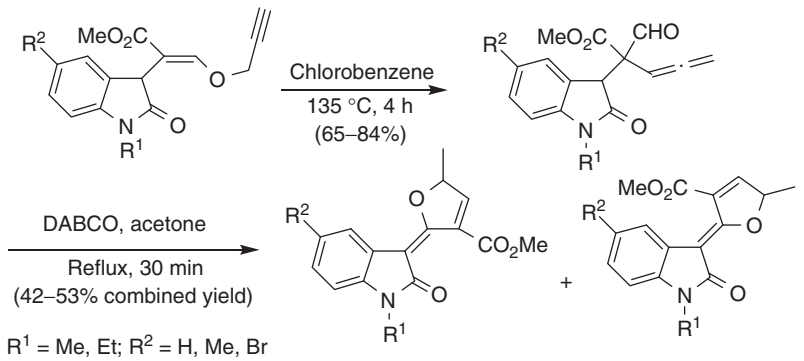
R^3 = Me, Et, *i*-Pr, CH_2Ph, Ph

Scheme 29

The cationic triphenylphosphine–gold(I) complex formed from $(PPh_3)AuCl$ and $AgBF_4$ was reported to catalyze the Claisen rearrangement of a series of propargyl vinyl ethers, which afforded, after heterocyclization of the intermediate allenyl carbonyl derivatives, tri- and tetrasubstituted furans in good yields (Scheme 30).[96]



The thermal propargyl-Claisen rearrangement has not been extensively reported in the literature. However, the thermal rearrangement of propargyl vinyl ether derivatives was described to give allene carbonyl intermediates, which were further used for the synthesis of highly functionalized allene-appended oxindoles (Scheme 31).[97]

MWI has also been reported to accelerate the propargyl-Claisen rearrangement, which was described as the key step in the total synthesis of the triterpenoid azadirachtin, allowing the formation of the sterically congested C8–C14 bond (Scheme 32).[98]

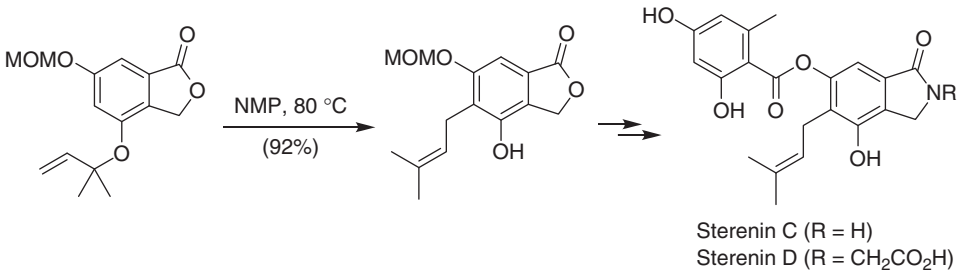
5.20.3.2 Aromatic Claisen Rearrangement

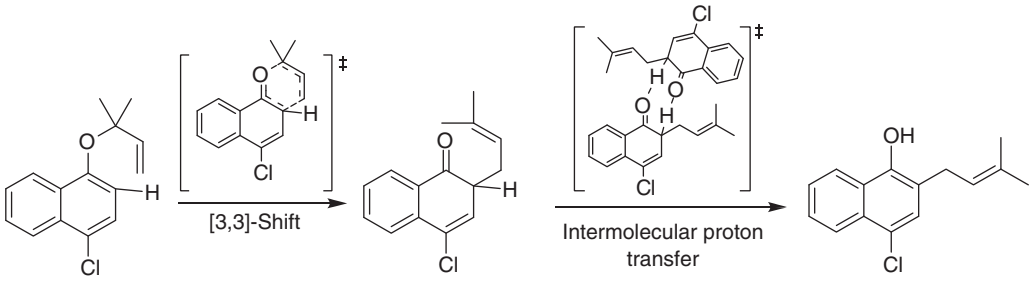
The so-called aromatic [3,3]-sigmatropic rearrangement of allyl aryl ethers developed simultaneously with the aliphatic version of the reaction.[99–101] The initial *ortho*-dienone resulting from the rearrangement immediately enolizes into the corresponding *ortho*-allyl phenol (*ortho* Claisen rearrangement, Scheme 33, equation 1). When the *ortho* position in the substrate is occupied by a substituent, the intervening *ortho*-allyl dienone evolves into the corresponding *para*-allyl phenol via a second [3,3]-rearrangement (*para* Claisen rearrangement, Scheme 33, equation 2).

Experimental results and theoretical calculations agree in predicting the regioselectivity of the rearrangement when both *ortho* positions are not equivalent. Thus, a *p*-acceptor keto group at the *meta* position directs the rearrangement to the sterically less favored *ortho*-substituted product (Scheme 34, equation 1). Contrarily, a bulky silyl enol ether group at the *meta* position gives preferentially the *para*-substituted product (Scheme 34, equation 2).[102]



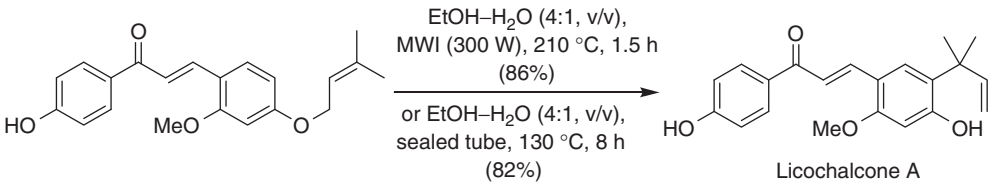
Scheme 33

Scheme 34



A thermally induced regioselective aromatic Claisen rearrangement has been described as a key step for the introduction of the prenyl group in the context of the synthesis of the glucocorticoid inhibitors sterenins C and D (Scheme 35).[103]

Scheme 35

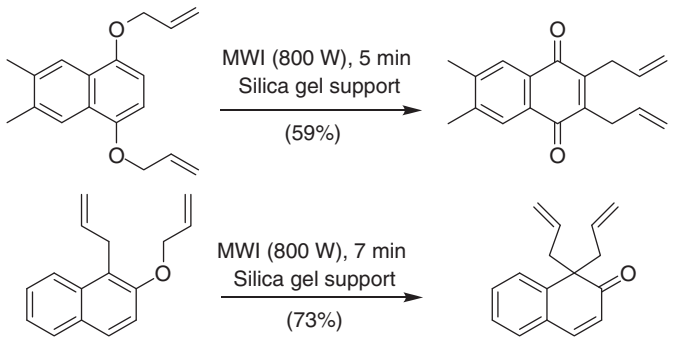


Recently, theoretical calculations on the aromatic Claisen rearrangement of 1-(4-chloronaphthyl) 1,1-dimethylallyl ether have demonstrated that, out of the two steps involved in the aromatic Claisen rearrangement, the initial [3,3]-intramolecular shift is the rate-limiting step for the water-catalyzed reaction;[104] in contrast, under neat conditions, the subsequent proton transfer takes place intermolecularly and is the rate-limiting step (Scheme 36).[105] The obtained calculated energy profile evidenced the rate accelerating role played by water as a catalyst of the aromatic Claisen rearrangement via hydrogen-bonding with the oxygen of the substrate.[104]

Accordingly, a rate enhancement of the reaction in an aqueous medium has been reported for many different allyl aryl ethers. The rearrangement of this class of compounds in organic solvents or under solvent-free conditions was much slower.[106] Thus, a water-accelerated aromatic Claisen rearrangement was reported as one of the key steps of the synthesis of the biologically active

Scheme 36

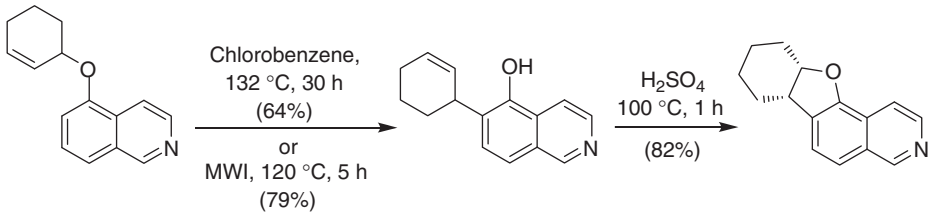
compound gambogin.[107] Similarly, an aromatic Claisen rearrangement of a prenyl ether in an ethanol–water cosolvent system has been recently reported as the crucial final step for a concise preparation of the biologically active derivative licochalcone A (Scheme 37).[108]



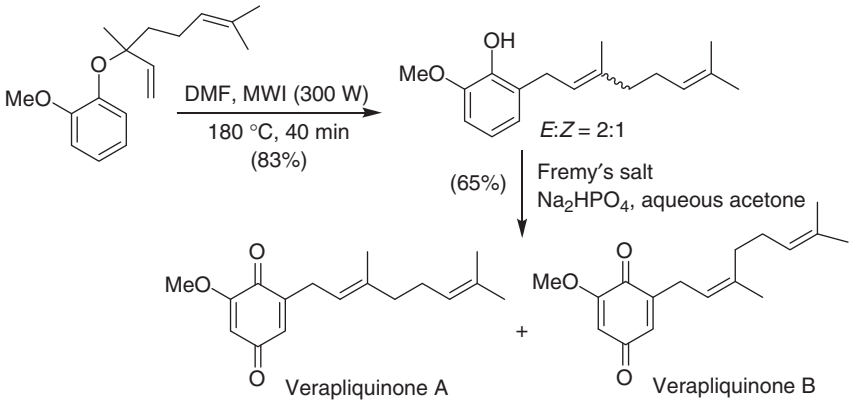
Scheme 37

The use of a microreaction system with high pressure/high temperature water has been recently developed as an efficient method to rearrange allyl methylphenyl ethers into the corresponding *o*-allyl phenols with high yields and selectivities.[109] A hydrogen bond between the solvent and the substrate was invoked to account for the excellent results of the reactions.

High temperatures are typically required for the noncatalyzed aromatic Claisen rearrangements. The use of a continuous flow reactor was described as a convenient method for scaling-up the rearrangement of 1-[4-(allyloxy)phenyl]ethanone in high yields and short reaction times, potentially avoiding the safety and chemical hazards involved in large-scale batch reactors.[110]



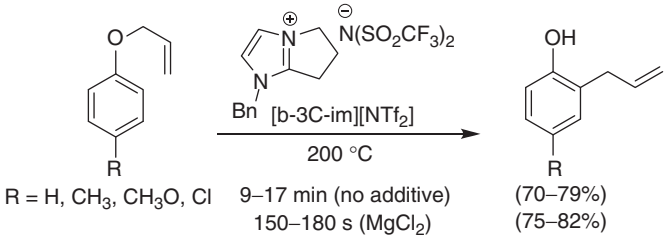
The use of MWI has been profusely reported to accelerate the aromatic Claisen rearrangement, as compared with the conventional thermal process.[111–113] Particularly interesting are the results of the microwave-assisted aromatic Claisen rearrangements of 1,4-bis-hydroxybenzene derivatives, which provide bis-allyl ketones on a silica gel support under environmentally benign solvent-free conditions (Scheme 38).[114]



Scheme 38

Microwave-assisted aromatic Claisen rearrangements of allyloxyisoquinolines have been reported as a useful procedure for the construction of a key intermediate in the synthesis of furo[3,2-*f*]isoquinolines derivatives, which are valuable phosphodiesterase IV inhibitors. As compared with the conventional thermal rearrangement, the microwave-accelerated process worked at lower temperatures and needed shorter reaction times (Scheme 39).[115]

MWI proved similarly useful in accelerating the aromatic Claisen rearrangement reported as a key step in the context of the synthesis of the marine benzoquinones verapliquinones A and B (Scheme 40).[116]

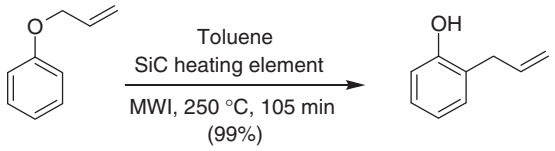


Scheme 39

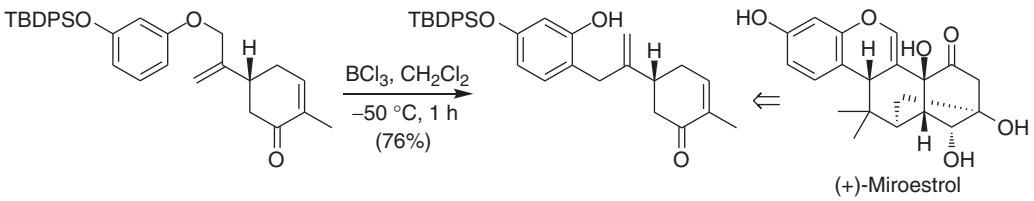
Scheme 40

The combined use of MWI and the bicyclic imidazolium ionic liquid [b-3C-im][NTf_2] as solvent has been successfully applied to an aromatic Claisen rearrangement, producing good yields in very short ($\leq$ 3 min) reaction times. The presence of a Lewis acid (i.e., $MgCl_2$) as an additive shortened the required reaction times even further and slightly improved the yields (Scheme 41).[117]

Aromatic Claisen rearrangements under MWI in toluene doped with the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim][PF_6]) as the reaction medium have also been reported.[118]



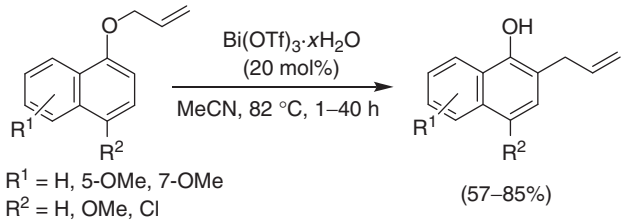
Scheme 41



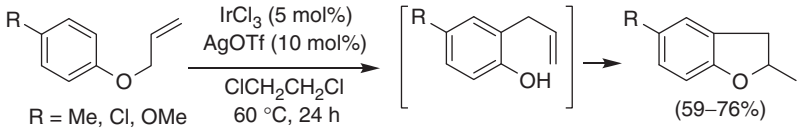
However, the use of microwave energy to accelerate aromatic Claisen rearrangements has been traditionally restricted to microwave-absorbing solvents (i.e., ethanol, methanol, dimethyl sulfoxide, and, to a small extent, water). The problem of low microwave absorption of nonpolar solvents was circumvented by utilizing a cylinder of sintered silicon carbide as passive heating element. This strongly microwave-absorbing material transfers the generated thermal energy to the aromatic rearrangement media, affording the Claisen products in high yields (Scheme 42).[119]

The benefits of microwave heating for the aromatic Claisen rearrangement at small scale have been recently reported as easy to scale-up to a manufacturing capability equivalent to pilot-plant scale by way of a commercial continuous flow microwave reactor.[120,121] For effective scale-up of microwave-assisted Claisen rearrangements, a continuous flow system avoids the problems inherent to the limited penetration depth of microwaves in most solvents, which is particularly noticeable when working at large-scale.

Significant rate enhancement of the aromatic Claisen rearrangement in the presence of boron trichloride has been extensively reported.[2,122] However, the use of BCl_3 usually generates undesired side products, which restricts the synthetic applicability of this catalyst. Nevertheless, the presence of specific substituents on the aromatic ring of the starting allyl aryl ether (typically a silyloxy function) mediates the BCl_3-catalyzed rearrangement such that high levels of regioselectivity are procured.[123] This has been particularly useful for the regioselective synthesis of resorcinol carvonyl ethers, described as formal key intermediates in the synthesis of miroestrols (Scheme 43).[124]

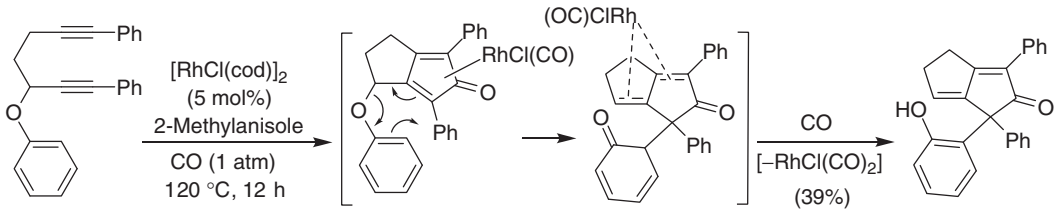


Scheme 42



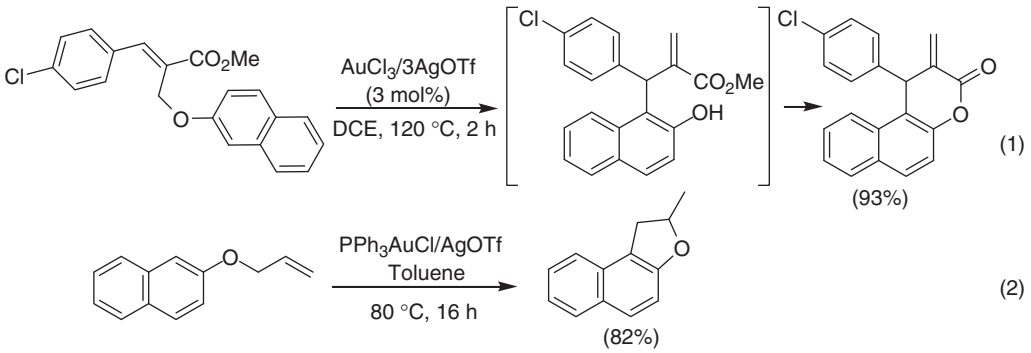
Scheme 43

Bismuth triflate has also been reported as a catalyst for the Claisen rearrangement of allyl naphthyl ethers.[125] The synthetic versatility of the regioselectively obtained *ortho*-allyl naphthols (Scheme 44), along with the low toxicity and good stability of the catalyst, makes these $Bi(OTf)_3$ catalytic conditions an attractive protocol for the synthesis of biologically active compounds.



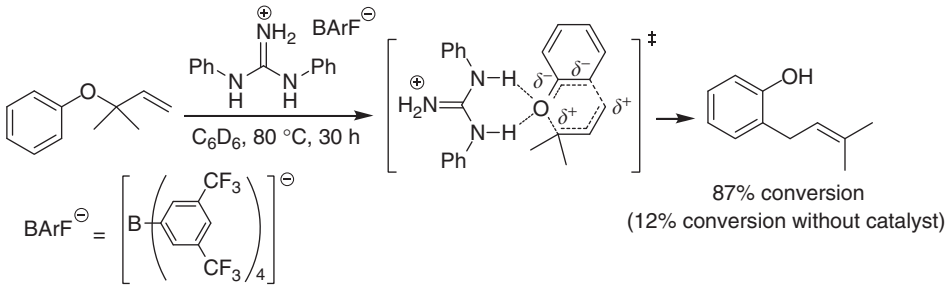
Scheme 44

An effective one-pot combination of an aromatic Claisen rearrangement and a subsequent hydroaryloxylation of the rearranged phenols takes place in good yields in the presence of a catalytic amount of iridium(III) chloride and silver triflate as additive (Scheme 45).[126] Although the reported mild conditions are useful for synthesizing differently substituted dihydrobenzofurans, the reaction proved sensitive to the degree of substitution of the starting olefinic fragment.



Scheme 45

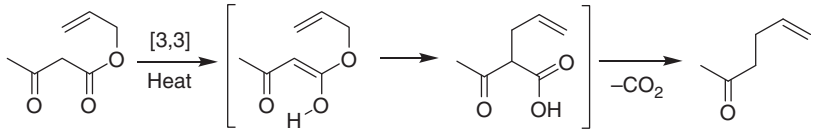
The aromatic Claisen rearrangement has also been reported under mild conditions from an aryloxy-substituted RhCl(CO) (cyclopentadienone) complex, prepared *in situ* by a Rh-catalyzed [2 + 2 + 1] carbonylation of suitably substituted diynes (Scheme 46).[127] Despite the high interest of the intervening Rh complex, the reported yields for the rearranged products are only moderate.



Scheme 46

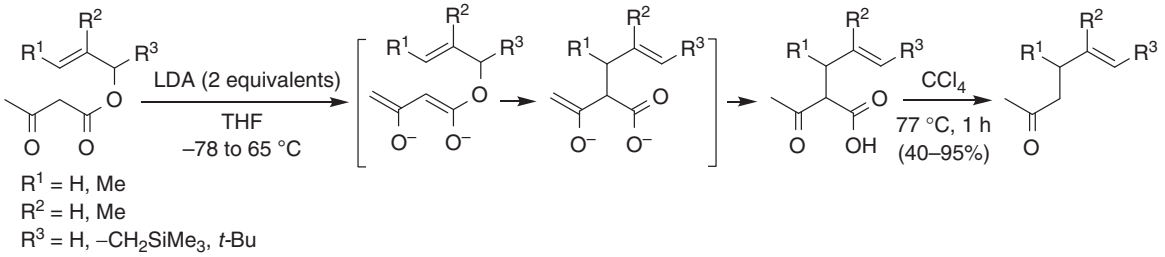
Combined gold/silver catalytic systems have been successfully applied for achieving Claisen rearrangements of allyl aryl ethers under mild conditions. Both $AuCl_3$/AgOTf and PPh_3AuCl/AgOTf systems have been reported as efficient catalysts for the rearrangement of different aromatic substrates. Subsequent *in situ* cyclizations of the rearranged products have afforded ready access to either 3,4-dihydrocoumarins (Scheme 47, equation 1)[128] or dihydrobenzofurans (Scheme 47, equation 2).[129] The formation of isomeric rearranged products under specific experimental conditions (typically lower temperatures) has been attributed to competitive [1,3] versus [3,3] sigmatropic rearrangements.[128] If desired, the formation of the dihydrobenzofurans could be inhibited in the presence of Proton-sponge®, and the rearranged *o*-allyl phenols could be isolated in good yields.[130]

Scheme 47



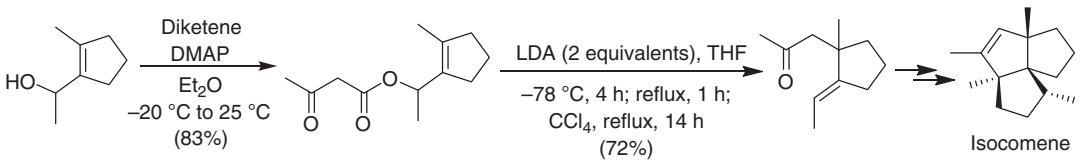
Guanidinium hydrogen bond donors, used in substoichiometric quantities, have been reported to induce rate enhancement in the rearrangement of allyl aryl ethers (Scheme 48).[89] However, to date, the organocatalytic version of the aromatic Claisen rearrangement has been poorly exploited.

Scheme 48



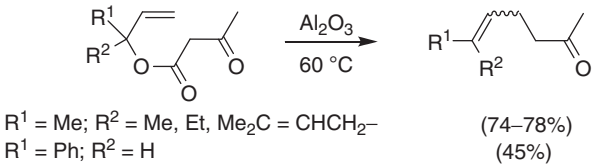
5.20.3.3 Carroll Rearrangement

The Carroll rearrangement was described as a complementary variant of the aliphatic Claisen rearrangement, consisting of the thermal transformation of allylic *β*-keto esters into *β*-keto acids, via a [3,3]-sigmatropic rearrangement, and subsequent decarboxylation to produce *γ*,δ-unsaturated ketones (Scheme 49).[131–133]



Scheme 49

The initially reported high temperatures required for the reaction could be avoided in the presence of a base (e.g., Al(*i*-PrO)$_3$,[134,135] NaOAc,[136] NaH,[137] *s*-collidine[138]). *γ*,δ-Unsaturated ketones have been obtained in good yields from the corresponding allylic acetoacetates, on treatment with lithium diisopropylamide (LDA) (2 equivalents) at −78 °C, via rearrangement of the intervening dianions and subsequent decarboxylation on heating in CCl_4 (Scheme 50).[139] α-Substituents on the allylic fragment of the substrate proved beneficial to the rearrangement.

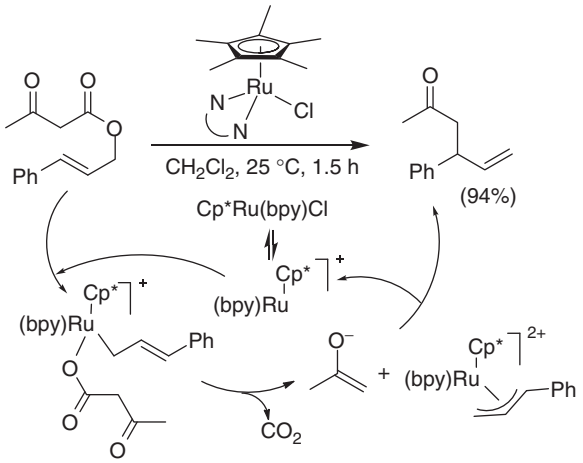


Scheme 50

These optimized conditions for the rearrangement of allylic β-keto esters have been reported as the key steps in the preparation of a variety of biologically active compounds. An example is outlined in Scheme 51. The reported improved procedure for the preparation of allylic β-keto esters, consisting of the reaction of an allylic alcohol with diketene in the presence of a catalytic amount of 4-(dimethylamino)pyridine (DMAP), afforded the desired acetoacetate, which, on treatment with LDA (2 equivalents) and further heating, produced the γ,δ-unsaturated ketone serving as a key intermediate in the formal total synthesis of the sesquiterpene isocomene (Scheme 51).[140]

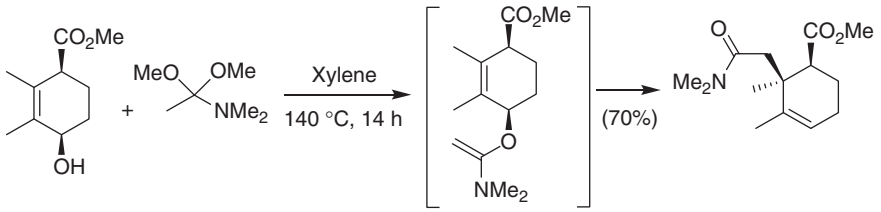
Scheme 51

An enhancement of the rate of the Carroll rearrangement was reported by performing the reaction with the substrates adsorbed on Al_2O_3 in the absence of any solvent.[141] These conditions have proved particularly useful for acetoacetates derived from tertiary allylic alcohols (Scheme 52).



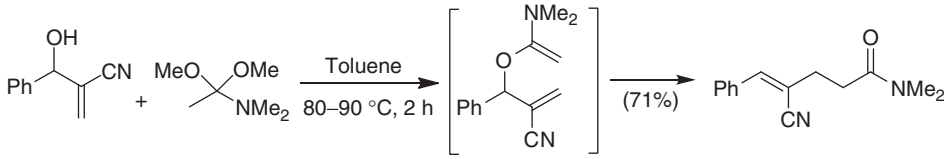
Scheme 52

Different metallic derivatives have been reported as efficient catalysts for the Carroll rearrangements. In the presence of catalytic amounts of $Ti(OEt)_4$[142] or $Pd(PPh_3)_4$,[143] Carroll-type rearrangements of differently substituted allylic β-keto esters proceed smoothly to produce the corresponding γ,δ-unsaturated ketones.



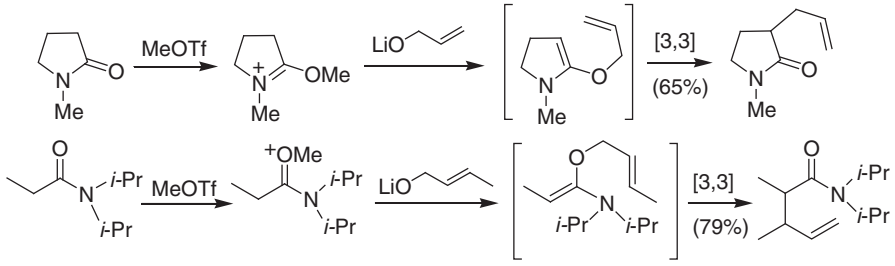
Bipyridyl(pentamethylcyclopentadienyl)ruthenium chloride has also been used as a selective catalyst for the transformation of allylic β-keto esters into γ,δ-unsaturated ketones (Scheme 53).[144] Although the reaction is described as a formal decarboxylative Carroll rearrangement, the proposed mechanism involves ruthenium π-allyl intermediates, which are selectively attacked at the more substituted allyl terminus.

5.20.3.4 Eschenmoser Rearrangement



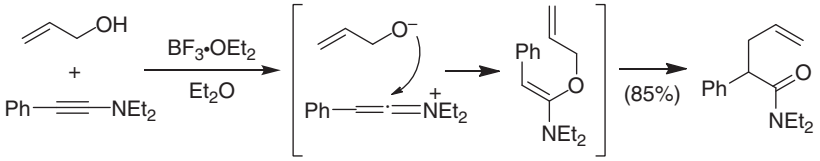
The Eschenmoser rearrangement was originally reported in 1964 as a valuable method for the synthesis of γ,δ-unsaturated amides.[145] The process consists of the *in situ* formation of an unstable ketene *N,O*-acetal (by reaction of an allylic alcohol with an amide acetal, typically *N,N*-dimethylacetamide dimethyl acetal, followed by alcohol elimination) and its subsequent [3,3]-sigmatropic rearrangement to afford a γ,δ-unsaturated amide. The electron-donating amino substituent on the carbon fragment involved in the rearrangement accelerates the process in comparison with the classical Claisen variant. Consequently, mild experimental conditions are required, which makes the rearrangement tolerant with a wide range of functional groups (Scheme 54).[146] Similarly, Baylis–Hillman adducts have proved to be convenient substrates for the Eschenmoser rearrangement (Scheme 55).[147]

Scheme 53



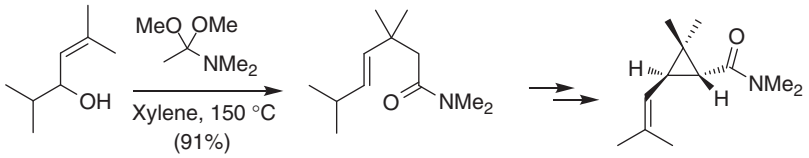
Scheme 54

Scheme 55



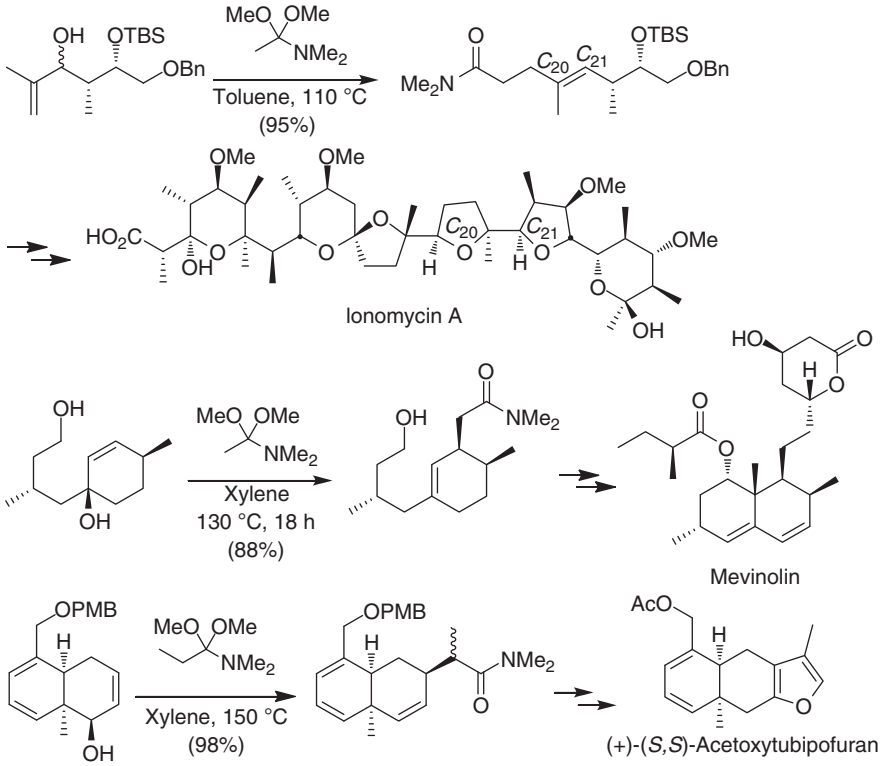
However, the method of choice for the preparation of more elaborated ketene *N,O*-acetals derived from sterically hindered or poorly nucleophilic acyclic and cyclic amides consisted of the alkylation of the starting amides with ethyloxonium tetrafluoroborate[148] or methyl triflate,[149–151] and subsequent heating of the intervening amidinium salts in the presence of allylic sodium or lithium alkoxides. The *in situ* generated ketene *N,O*-acetals immediately rearrange to the γ,δ-unsaturated amides (Scheme 56).

Scheme 56



The preparation of ketene *N,O*-acetals has also been reported by reaction of an allylic alcohol and 1-(diethylamino)propyne (ynamine). High temperatures or a catalytic amount of $BF_3 \cdot OEt_2$ are usually required for the initial formation of the ketene

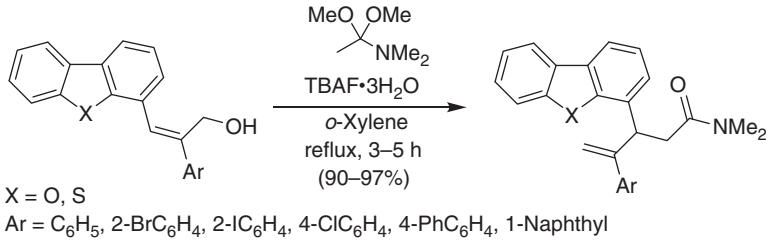
N,O-acetal and its subsequent *in situ* rearrangement. This variant of the Eschenmoser rearrangement is known as the ynamine–Claisen rearrangement or Ficini rearrangement (Scheme 57).[152,153]



Scheme 57

The Eschenmoser rearrangement has been described as the key step of the synthesis of a pyrethroid amide derivative (Scheme 58).[154]

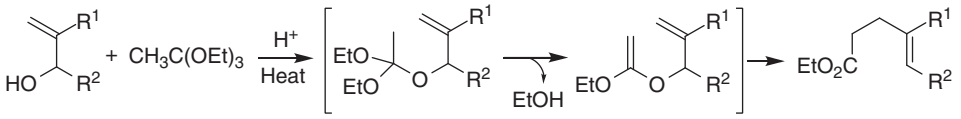
Scheme 58



Eschenmoser rearrangements of both acyclic and cyclic allylic alcohols have been reported as convenient routes for the preparation of key intermediates in the syntheses of a variety of biologically active compounds.[155–159] Some selected examples are represented in Scheme 59.[155,156]

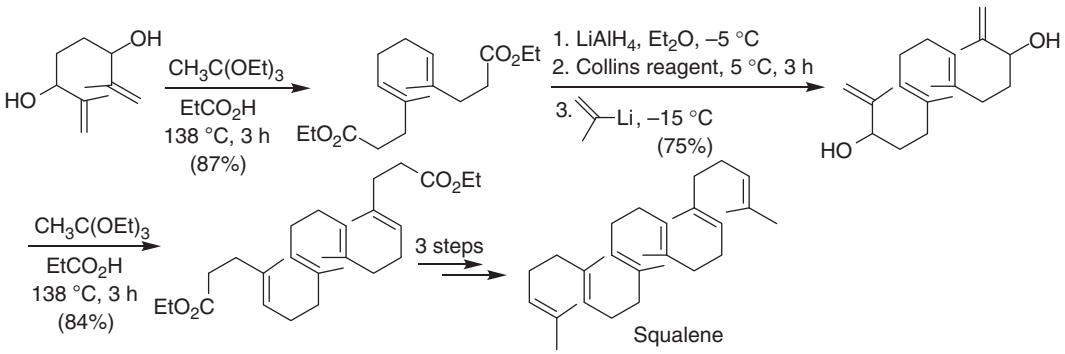
Scheme 59

The drastic experimental conditions usually required in the Eschenmoser rearrangement may restrict its synthetic applicability. The use of tetra-*n*-butylammonium fluoride trihydrate has been reported as highly useful phase-transfer catalyst, allowing the



Eschenmoser rearrangement of sterically congested allylic alcohols to take place in high yields in the presence of *N*,*N*-dimethylacetamide dimethyl acetal in refluxing toluene or xylene (Scheme 60).[160]

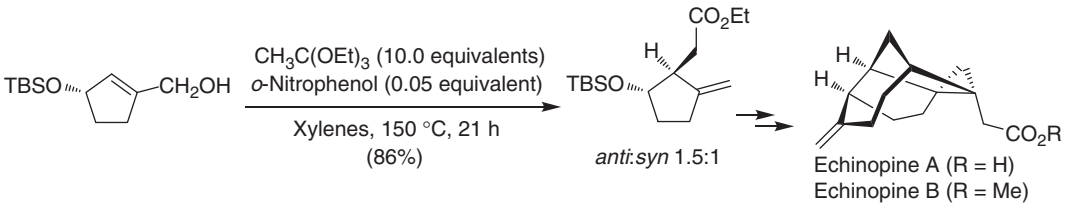
Scheme 60



5.20.3.5 Johnson Rearrangement

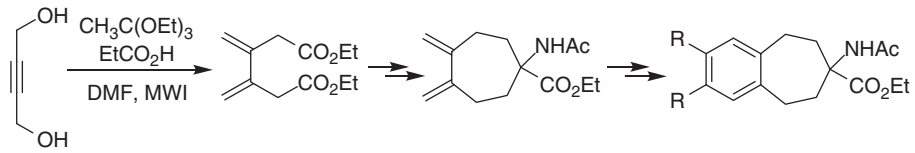
The Johnson rearrangement was first reported in 1970 as the acid-catalyzed condensation of an allylic alcohol with an excess of orthoester. The initially formed mixed orthoester evolves into a mixed ketene acetal, which *in situ* rearranges into a γ,δ-unsaturated carboxylic ester (Scheme 61).[161]

Scheme 61



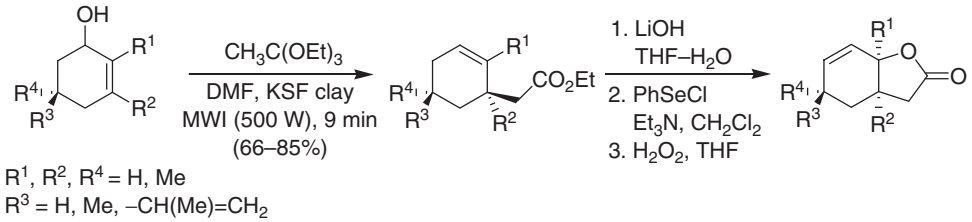
Two general procedures have been described for the preparation of the mixed orthoesters, which are precursors of the *O*-allyl ketene acetals, the latter being the actual substrates of the rearrangement. One of them consists in the acid-catalyzed transesterification of trimethyl orthoacetate with a properly substituted allylic alcohol. Although the initially formed mixed orthoesters can be isolated under $MgCl_2$ catalysis,[162] trace amounts of a weak acid (typically propionic acid) permitted the reaction of allylic alcohols with an excess of orthoacetate to go to completion and give the rearranged *trans*-γ,δ-unsaturated esters, which are used as intermediates in the synthesis of many natural products. Thus, the initially reported synthesis of squalene makes use of two orthoester rearrangements (Scheme 62).[161]

Scheme 62



The second method of choice for the preparation of the intervening mixed orthoesters is the addition of an allylic alcohol to a ketene acetal. The use of $PdCl_2$(COD) as the catalyst,[163] *t*-BuOH as the solvent,[164] or, more recently, uncatalyzed solvent-free conditions[165] have been reported to this end.

A rate enhancement of the orthoester rearrangement in the presence of a catalytic amount of *o*-nitrophenol has been reported in the context of the syntheses of biologically active alkaloid (+)-galanthamine[166] and the sesquiterpenes echinopines A and B (Scheme 63).[167]



Scheme 63

Although the Johnson rearrangement usually requires high temperatures, the microwave-assisted processes have also been reported. The combined use of a catalytic amount of propionic acid and MWI allowed a double Johnson rearrangement to produce diethyl 3,4-bismethyleneadipate, which was utilized as intermediate for the synthesis of benzocycloheptane-derived amino acids (Scheme 64).[168]

Scheme 64

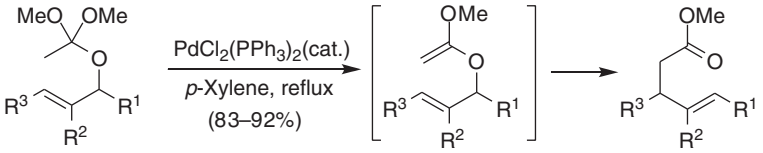
The combination of montmorillonite KSF clay as a solid acid catalyst and MWI has also been reported to produce clean Johnson rearrangement products from cycloalkenols, which were subsequently transformed into *cis* bicyclic unsaturated lactones (Scheme 65).[169]

Scheme 65

Heterogeneous catalysis based on silica-supported sodium hydrogen sulfate ($NaHSO_4$-SiO_2)[170] or iodine adsorbed on silica (I_2-SiO_2)[171] also accelerates the Johnson rearrangement of differently substituted Baylis–Hillman adducts.

Some metallic compounds have proved to be efficient catalysts for the Johnson rearrangement. Thus, $PdCl_2(PPh_3)_2$[163] and triisobutylaluminum[172] cleanly promote both the *in situ* alcohol elimination from the starting mixed orthoester, and the immediate rearrangement. These catalytic conditions have been reported for the preparation of γ,δ-unsaturated esters [Pd catalysis (Scheme 66, equation 1)] or γ,δ-unsaturated alcohols [Al catalysis (Scheme 66, equation 2)] in high yields under mild conditions.

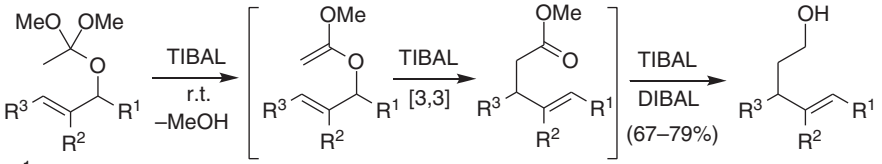
The acidic conditions reported for the Johnson rearrangement are usually compatible with the presence of diverse heteroatomic substituents on the allyl vinyl framework. Alkoxy,[173] halo,[174] sulfenyl,[174] and phenylseleno[175] substituents on the orthoester component have proved compatible with the experimental conditions of the rearrangement. An α-sulfinyl orthoester was used to prepare dienoate esters by way of a Johnson rearrangement and subsequent pyrolytic sulfoxide 1,2-elimination in the course of a synthesis of precursors of 1α,25-dihydroxyvitamin D_3 (Scheme 67).[176]



Heteroatomic substituents on the allylic alcohol have also been reported. The Johnson rearrangement of a *trans*-dichlorinated allylic alcohol with methyl orthoacetate was developed as the key step of the synthesis of the antitumor agent halomon (Scheme 68).[177]

The Johnson rearrangement of boron-substituted allylic alcohols produced 1,3-disubstituted allylboronic esters in high yields (Scheme 69).[178]

The functionality of the products resulting of the Johnson rearrangements allows their transformation into synthetically useful building blocks. In this sense, the synthesis of the core quaternary carbon center present in tetradirectional dendrimeric frameworks has been prepared by a Johnson rearrangement (Scheme 70).[179]



The Johnson rearrangement of γ-trifluoromethyl γ-alkyl allylic alcohols has been developed as an efficient strategy for the construction of CF_3-substituted quaternary carbon atoms (Scheme 71).[180]

The use of unsaturated cyanohydrins as the allylic component of the Johnson rearrangement has emerged as a useful protocol for the preparation of δ-ethoxycarbonyl α,β-unsaturated nitriles in good yields, although large excess amounts of both acid and triethyl orthoacetate are required (Scheme 72).[181]

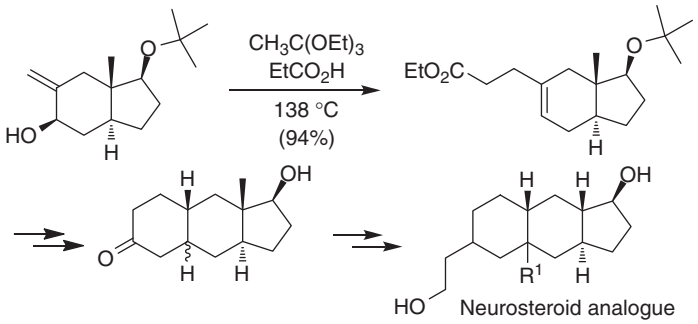
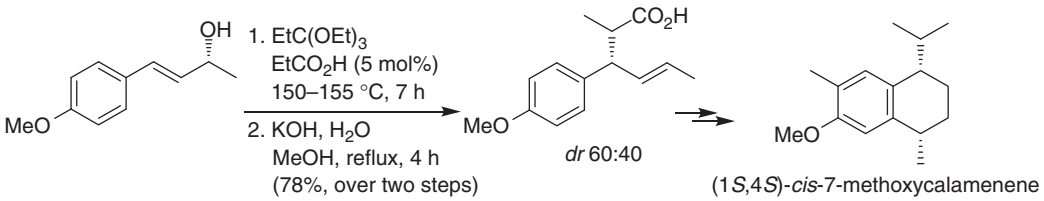
Scheme 70



Scheme 71

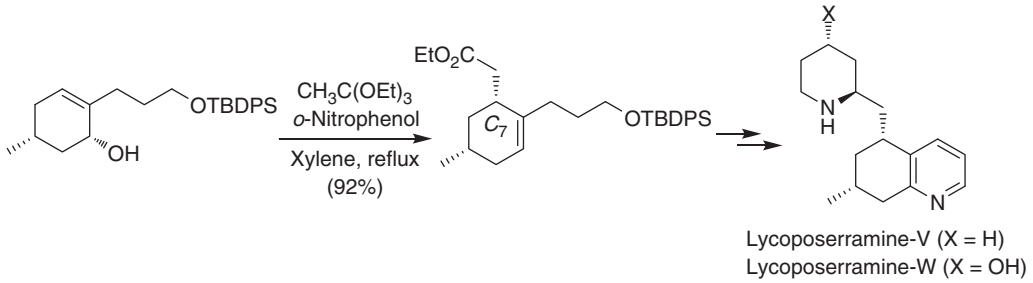


Scheme 72

A Johnson rearrangement has also provided a ready access to an intermediate used for the preparation of 1,6-difunctionalized dodecahydrobenz[*f*]indenes, precursors of linear tricyclic neurosteroid analogs (Scheme 73).[182]

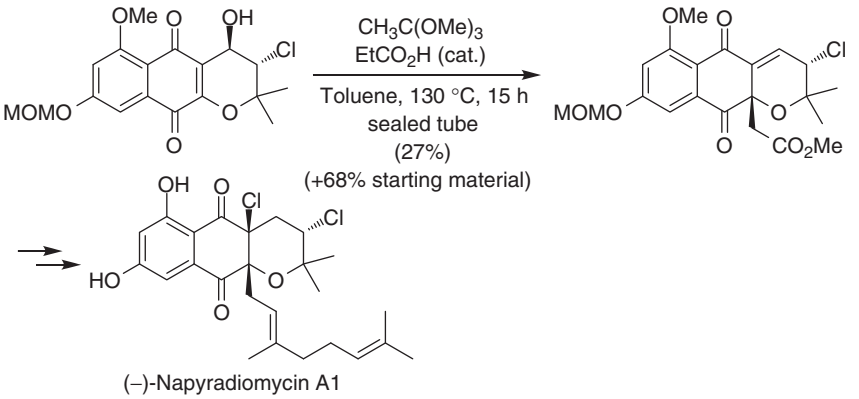
Scheme 73

In the context of the synthesis of natural products, the Johnson rearrangement has served as a valuable tool for the efficient incorporation of specific structural fragments into the target molecules. Thus, the isopropyl unit at the benzylic position of the terpenoid-like (1*S*,4*S*)-*cis*-7-methoxycalamenene was constructed via a Johnson rearrangement (Scheme 74).[183]



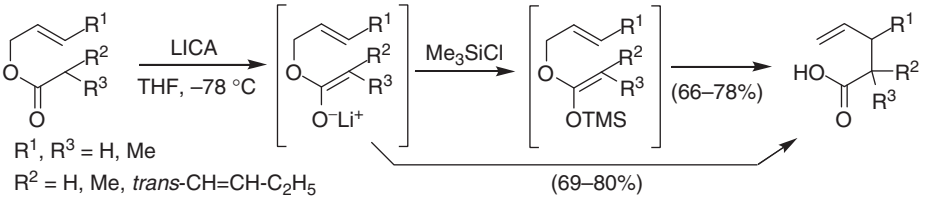
Scheme 74

The carbon residue at C7 in the key intermediate of the synthesis of the phegmarine-type alkaloids lycoposerramine V and W was introduced by a thermal orthoester rearrangement (Scheme 75).[184]



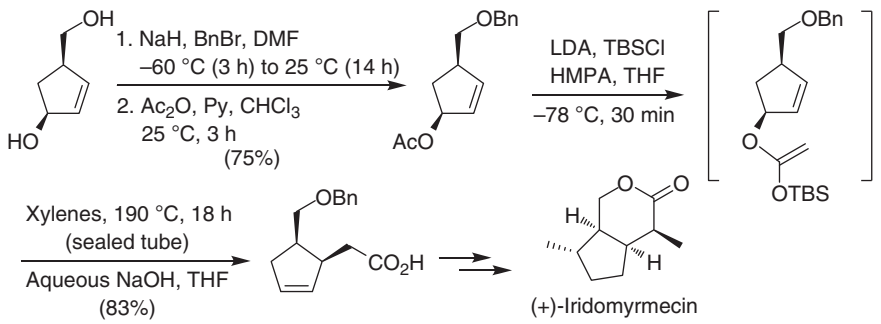
Similarly, an acid-catalyzed orthoester rearrangement has been reported as the key step in the synthesis of the halogenated biologically active compound (–)-napyradiomycin A1 (Scheme 76).[185]

5.20.3.6 Ireland Rearrangement

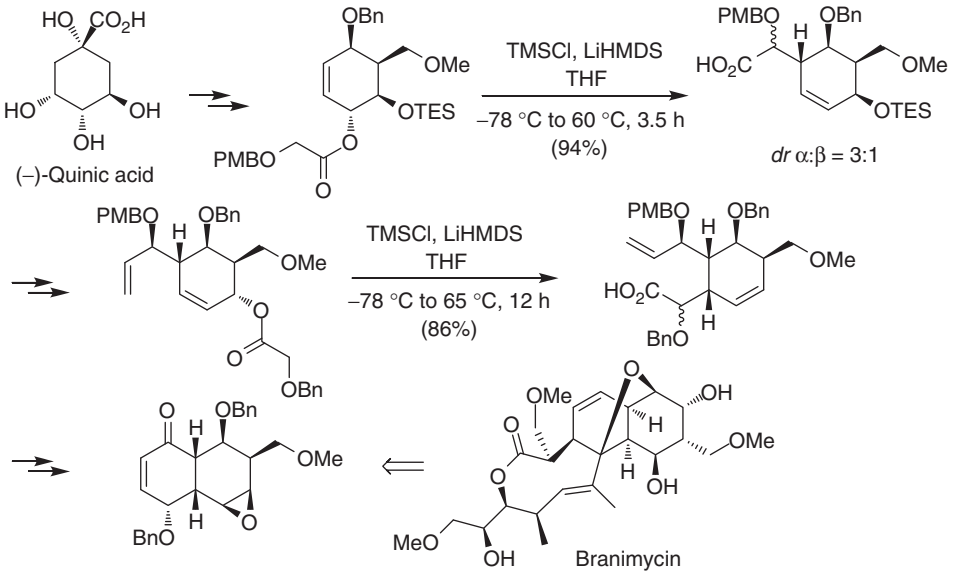


The Ireland rearrangement was originally described in 1972 as the concerted intramolecular reorganization of an enolate anion derived from an allyl ester into a γ,δ-unsaturated carboxylic acid. When this intermediate enolate is quenched with trimethylsilyl chloride, the resulting *O*-allyl-*O*-silyl ketene acetal rearranges readily, usually at low temperatures under basic or neutral conditions (Scheme 77).[186]

Scheme 75

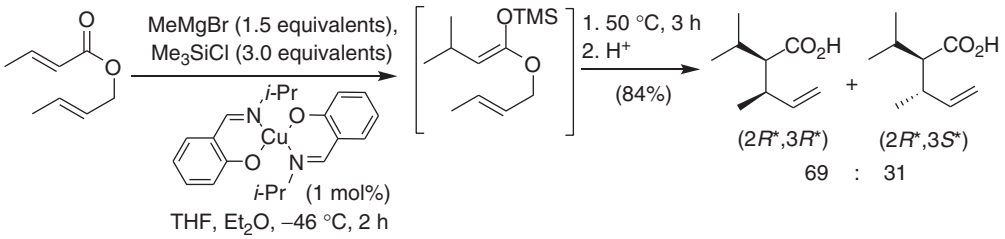


Scheme 76



Scheme 77

Although several syntheses of the precursor *O*-allyl-*O*-silyl ketene acetals have been reported, two procedures are particularly worth mentioning. Deprotonation of allylic esters and subsequent enolate-trapping with Me_3SiCl or *t*-$BuMe_2SiCl$ generates a silyl ketene acetal which rearranges *in situ*. On hydrolysis of the intervening silyl ester, a γ,δ-unsaturated carboxylic acid is formed. This protocol has been applied to the synthesis of many biologically active compounds. The *O*-allyl-*O*-silyl ketene acetal used as the substrate of the Ireland rearrangement reported in the synthesis of the insecticidal iridoid (+)-iridomyrmecin was prepared by way of this method (Scheme 78).[187]

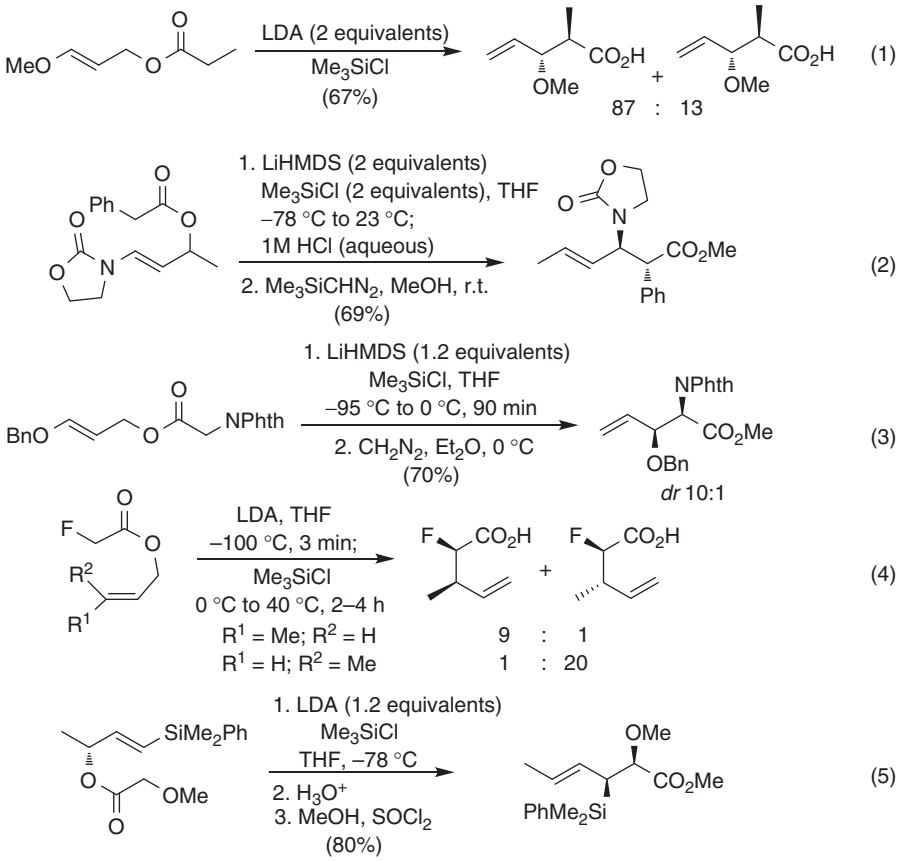


Scheme 78

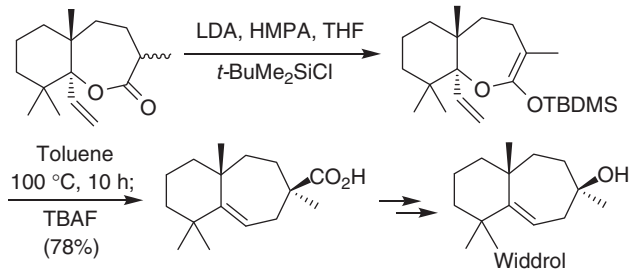
Two successive Ireland rearrangements, performed under the above conditions, have been utilized for installing the monosubstituted double bonds required for the construction of the *cis*-fused decalin core present in the antibiotic branimycin (**Scheme 79**).[188]

Scheme 79

Conjugate addition to allylic α,β-unsaturated esters followed by *O*-silylation of the intervening enolates has also been described as an efficient procedure for the preparation of *O*-allyl-*O*-silyl ketene acetals, which *in situ* undergo rearrangement to give γ,δ-unsaturated acids. In this sense, conjugate additions of organocopper reagents,[189,190] lithium ester enolates,[191] trialkylphosphines,[192] 1,4-diazabicyclo[2.2.2]octane (DABCO),[193] or alkyl radicals[194–196] to allylic α,β-unsaturated esters and rearrangement of the intervening allyl silyl ketene acetals have been reported. A copper(II)-catalyzed conjugate addition of Grignard reagents to allylic crotonates and the subsequent *in situ* rearrangement of the resulting intermediates to produce 2-allyl 3-alkyl carboxylic acids is represented in **Scheme 80**.[189]

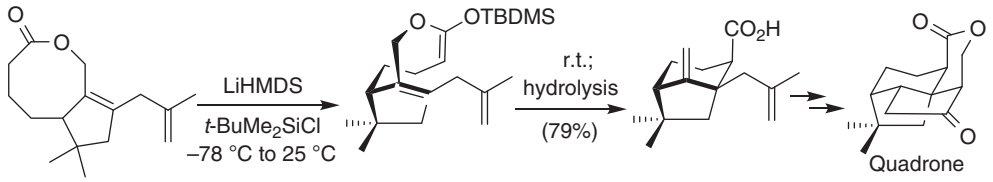


Scheme 80



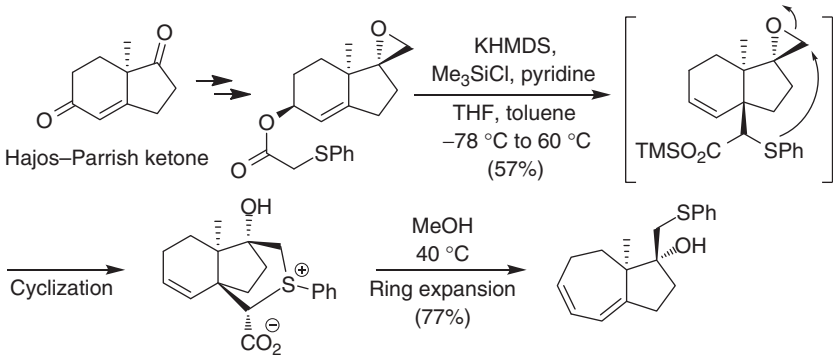
The usually mild conditions reported for the Ireland rearrangement render it compatible with a wide range of functional groups in the substrate. The presence of heteroatom substituents either at the ester or at the allylic fragment generates differently substituted unsaturated acids. Thus, esters of alkoxy allylic alcohols give *anti*-β-alkoxy acids (**Scheme 81**, equation 1).[197,198] Similarly, an enamide moiety in the alcohol portion of the rearrangement substrate provides *anti*-β-amino acids (**Scheme 81**, equation 2).[199] In turn, heteroatomic functions at the ester fragment give α-heteroatom-substituted γ,δ-unsaturated carboxylic acids (**Scheme 81**, equations 3 and 4).[200,201] The Ireland rearrangement of glycolates, bearing an alkoxy substituent at the ester fragment, derived of silyloxy allylic alcohols affords diastereoisomerically enriched α-alkoxy-β-silylhexenoates, which have proved to be efficient chiral carbon nucleophiles (**Scheme 81**, equation 5).[202]

The Ireland rearrangement of vinyl lactones has been described as an elegant route to functionalized cycloalkanes under smooth conditions.[203] This protocol has been utilized as the key step in a stereospecific total synthesis of the sesquiterpene widdrol (**Scheme 82**).[204]



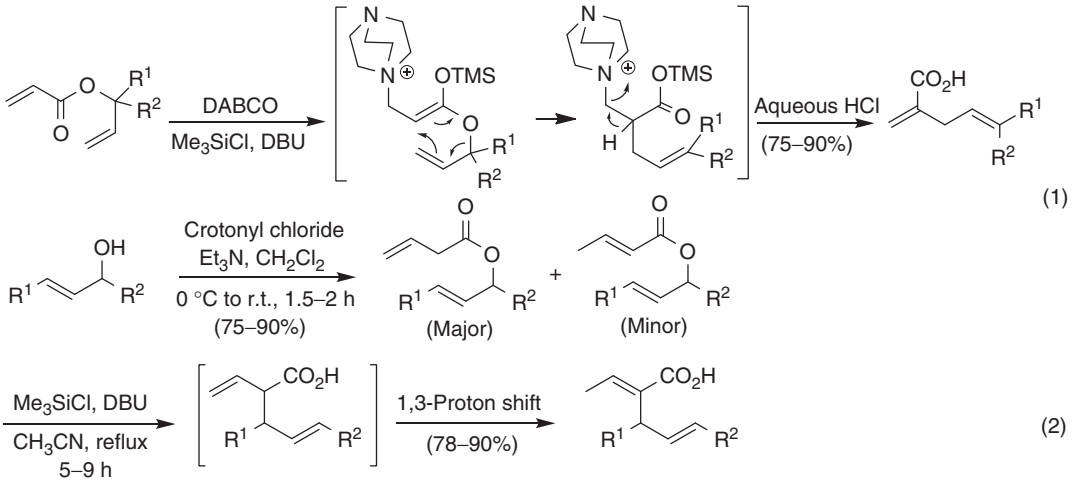
Similarly, the bridged cycloalkane intermediate in the synthesis of (±)-quadrone was prepared by the lactone version of the Ireland rearrangement (**Scheme 83**).[205]

Scheme 81



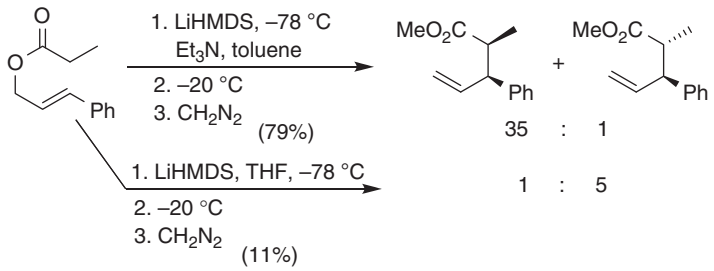
Scheme 82

Scheme 83



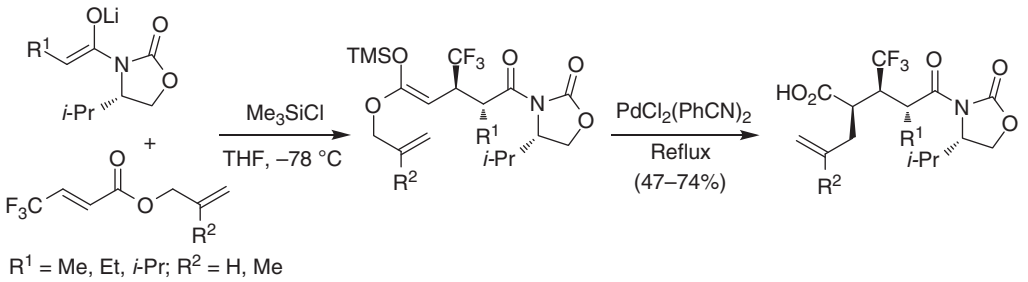
The bicyclo[5.3.0]decane ring system possessing an angular methyl group is a skeleton common to naturally occurring pseudoguaianes, and has been readily synthesized by way of an Ireland rearrangement of a thiophenyl acetate – prepared from the Hajos–Parrish ketone – and a subsequent ring expansion reaction of the rearranged intermediate (Scheme 84).[206]

The DABCO-catalyzed Ireland rearrangement of allylic acrylates in the presence of an excess amount of Me_3SiCl and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) has been reported to produce α-methylene-γ,δ-unsaturated carboxylic acids



Scheme 84

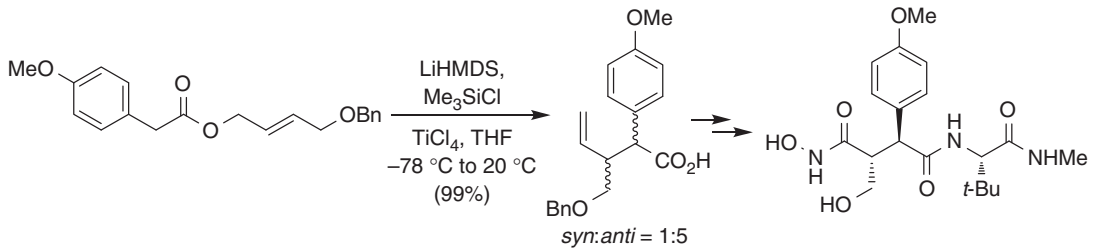
(Scheme 85, equation 1).[207] This methodology has been efficiently expanded to a range of allylic but-3-enoates. The combined use of DBU and Me_3SiCl promotes the formation of the silyl ketene acetal and its rearrangement/isomerization reactions to afford a variety of 2-ethylidene-γ,δ-unsaturated carboxylic acids (Scheme 85, equation 2).[208]



Scheme 85

Lithium hexamethyldisilazide (LiHMDS) in triethylamine/toluene produces Et_3N-solvated allylic enolates, which exhibits a marked acceleration of their Ireland rearrangements (~20 times faster) when compared with the analogous rearrangements in neat tetrahydrofuran (THF). The stereoselectivity of these processes was also reported to be reversed (Scheme 86).[209] Enolization of the ester in Et_3N/toluene affords the *Z* enolate predominantly. Subsequent Claisen rearrangement at −20 °C proceeds with excellent diastereoselectivity. When the enolization takes place in neat THF the rearrangement took place only in 11% yield with lower diastereoselectivity. The low yield could be due to a poor enolization or a poor rearrangement from the *E* enolate.[210]

Scheme 86



Different metallic additives have proved efficient in accelerating the Ireland rearrangement. For example, catalytic amounts of $PdCl_2(PhCN)_2$ are beneficial for the rearrangement of silyl ketene acetals (Scheme 87).[211]

R^1 = Me, Et, *i*-Pr; R^2 = H, Me

Scheme 87

The combined use of LiHMDS/Me_3SiCl with catalytic amounts of $TiCl_4$ accelerates the Ireland rearrangement as compared with the uncatalyzed process.[212] These improved Ireland rearrangement conditions have been applied as a key step for the synthesis of succinate-based hydroxamate inhibitors of tumor necrosis factor-converting enzyme and matrix metalloproteases (Scheme 88).[213]

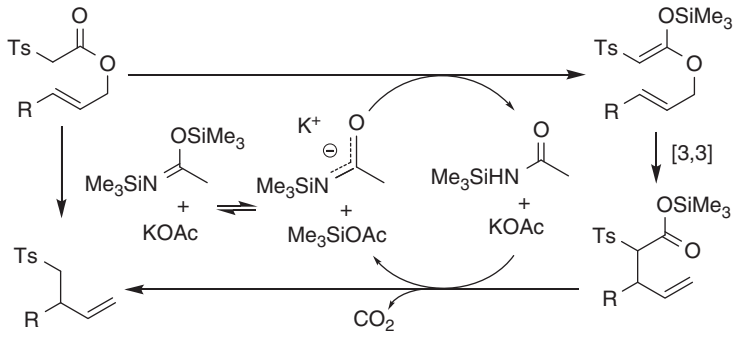
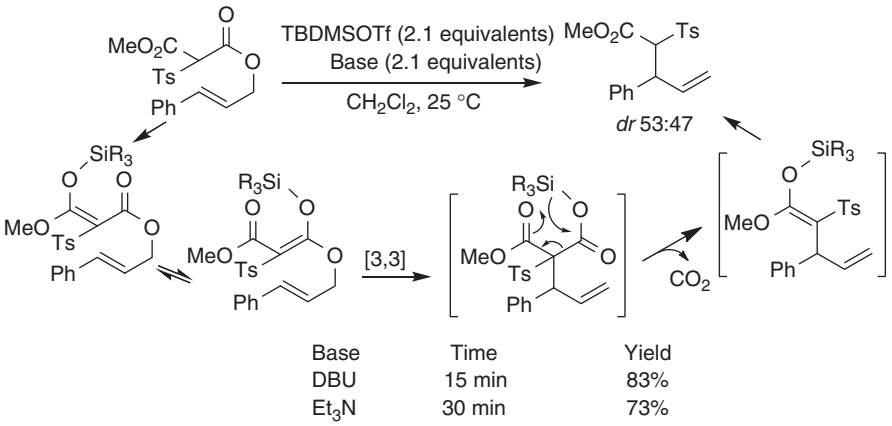
Scheme 88

5.20.3.7 Decarboxylative Claisen Rearrangement



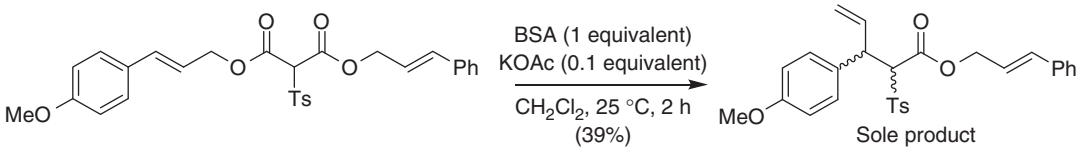
A novel variant of the Ireland–Claisen rearrangement, in which an electron-withdrawing α-substituent is present at the ketene acetal skeleton, has been developed. The one-pot rearrangement-decarboxylation sequence takes place smoothly in a highly regio- and stereoselective manner, regardless of the substitution pattern at the allylic portion of the substrate. Sulfonyl groups have proved to adapt successfully to this decarboxylative Claisen rearrangement to yield homoallylic sulfones in high yields.[214,215] Treatment of allylic tosylacetates with substoichiometric amounts of *N*,*O*-bis(trimethylsilyl)acetamide (BSA) and potassium acetate afforded α-tosyl silyl ketene acetals, which *in situ* underwent thermal rearrangement followed by acetate-induced desilylation-decarboxylation to provide γ,δ-unsaturated sulfones in one step. Similar results were achieved by brief exposure to MWI (Scheme 89).

Scheme 89



A catalytic cycle involving acetate as a silyl transfer reagent was proposed (Scheme 90).

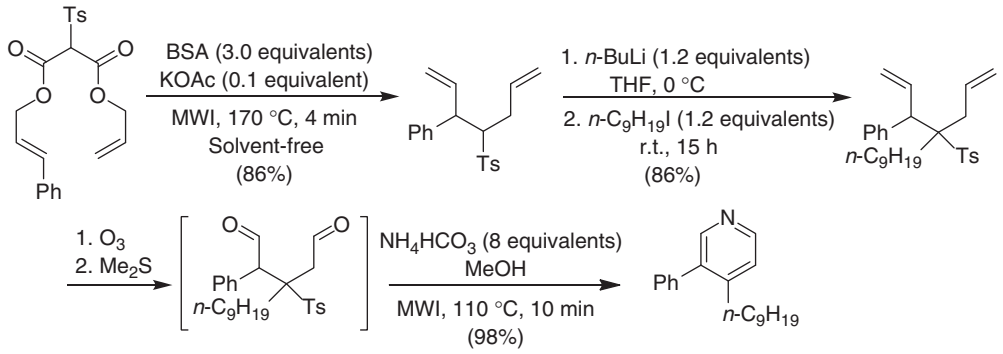
Decarboxylative Claisen rearrangement conditions have also been successfully applied to allyl methyl esters of tosylmalonic acid to provide an effective regiospecific access to the products of the formal allylation of methyl tosylacetate. Both reagent systems, BSA/KOAc and DBU/TBDMSOTf, proved useful for these substrates, which afforded, under mild conditions, the allylated methyl tosylacetates by a sequence not requiring acetate in the decarboxylation step. A mechanism involving silatropic



Scheme 90

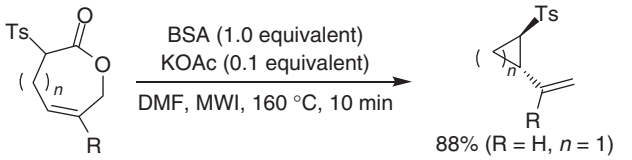
rearrangement of the intervening silyl esters would account for the results obtained in the presence of silyl triflates and DBU (Scheme 91).[216]

Scheme 91



A first-order rate constant was determined for the decarboxylative Claisen rearrangement of these allyl methyl 2-tosylmalonate esters and a rate enhancement was observed for those substrates possessing an electron-rich aryl group bonded to the allylic double bond. These data are indicative of a positive charge development at the benzylic position during the rearrangement and, therefore, are consistent with a dipolar transition state for the reaction.[217] In complete agreement with these kinetic studies, substituted bis(allyl) 2-sulfonylmalonates underwent a highly regioselective rearrangement-decarboxylation sequence when treated with BSA/KOAc. Thus, allylic side-chains bearing remote vinylic electron-rich substituents rearranged preferentially (Scheme 92).[218]

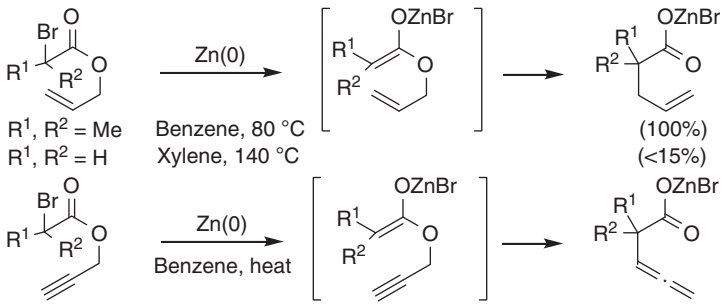
Scheme 92



When bis(allyl) 2-tosylmalonates were treated with the BSA/KOAc reagent combination under MWI, a double decarboxylative Claisen rearrangement sequence took place and provided substituted 1,6-heptadienes, which were subsequently transformed into polysubstituted pyridines (Scheme 93).[219]

When substrates possessing heteroaromatic rings were exposed to the decarboxylative Claisen rearrangement conditions, the corresponding dearomatized products were formed. Particularly interesting are the alkylidene-substituted indolines prepared by microwave-assisted decarboxylative rearrangement reactions of substituted acetate derivatives of 3-(hydroxyalkyl)indoles.[220] These dearomatized products were conveniently transformed into polyfunctionalized compounds due to the synthetic versatility of the exocyclic methylene group.

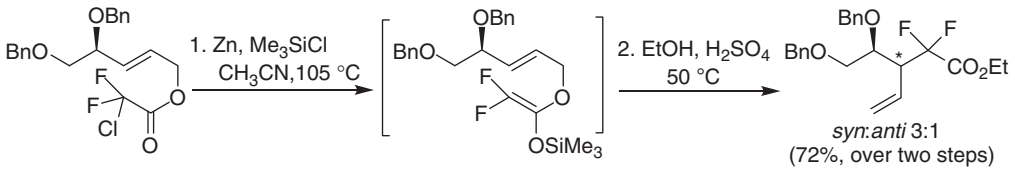
Scheme 93



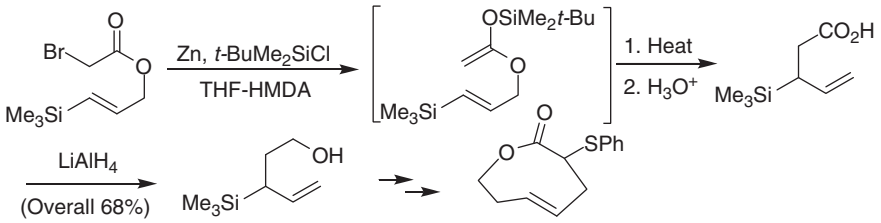
Transannular, decarboxylative Claisen rearrangement reactions of seven- and eight-membered unsaturated lactones bearing an α-arylsulfonyl substituent have been reported for the diastereoselective synthesis of *trans*-sulfur-substituted vinylcyclopropanes[221] and vinylcyclobutanes[222] in high yields (Scheme 94).

Scheme 94

5.20.3.8 Reformatsky Rearrangement



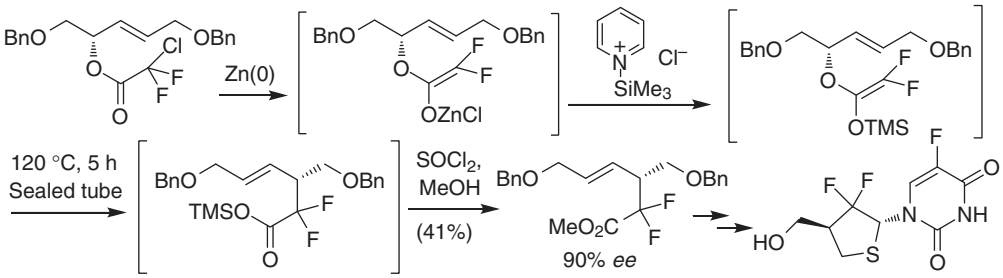
The [3,3]-sigmatropic rearrangement of zinc allylic ester enolates, which provides an access to zinc carboxylates of γ,δ-unsaturated carboxylic acids, is known as the Reformatsky rearrangement.[223] This rearrangement, compatible both with allylic and propargylic substrates, requires the *in situ* formation of the zinc enolates by zinc-mediated dehalogenation of *O*-allyl (or *O*-propargyl) α-bromo esters (Scheme 95). Under the initially reported conditions (heating at moderately high temperatures in a hydrocarbon solvent in the presence of an excess of zinc dust), the allylic α-bromo esters reacted smoothly under nonacidic and nonbasic conditions. The undesired condensation of the zinc enolate giving 1,3-dicarbonyl compounds is minimized with alkyl-substituted enolates, which give the highest yields of rearrangement products.



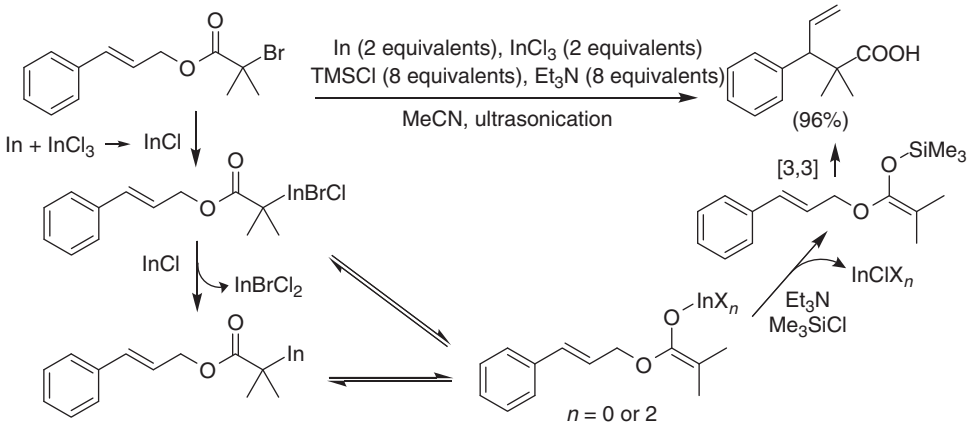
Scheme 95

The presence of Me_3SiCl is frequently required for the zinc-promoted Reformatsky rearrangement to take place,[224] and, as a consequence, a silyl ketene acetal is proposed as the reaction intermediate. The reaction has been used for the synthesis of *gem*-difluoro-substituted γ,δ-unsaturated acids, which has been reported as a key step in the preparation of fluorine-containing carbocyclic nucleosides (Scheme 96).[225,226] The chirality of the substrate is transferred during the rearrangement.[226]

This modified Refortmatsky rearrangement has been satisfactorily used for the preparation of a key intermediate in the synthesis of medium-sized lactones (Scheme 97).[227]



Scheme 96



Scheme 97

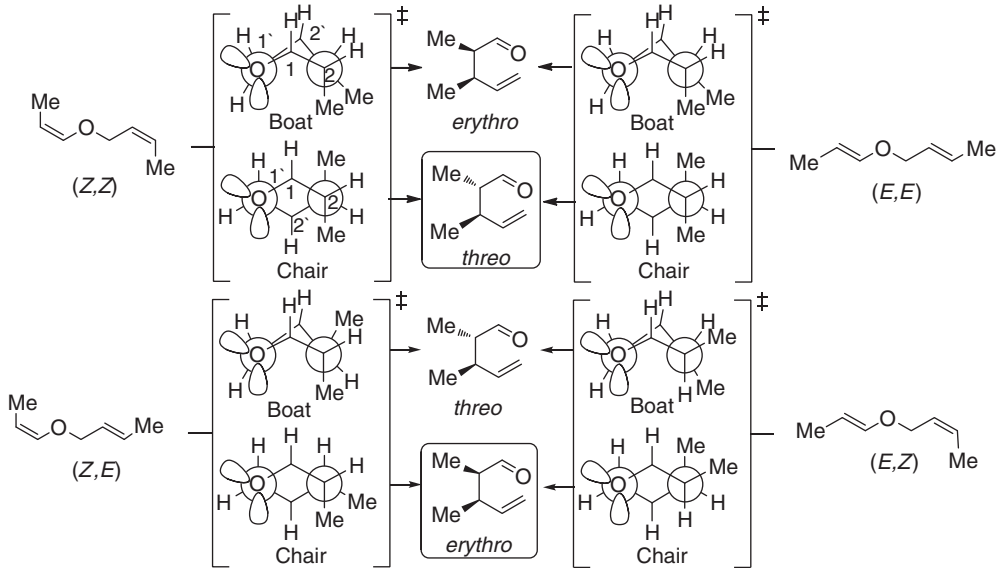
In the context of the asymmetric synthesis of *gem*-difluorinated nucleoside analogs, the addition of pyridine to the reaction mixtures of the Reformatsky rearrangement has proved useful for improving both the yield and the stereoselectivity of the reaction.[228] The additive activates the silyl chloride, thus facilitating the conversion of the initially formed zinc enolate into the *O*-silyl ketene acetal, which undergoes the rearrangement (Scheme 98).

Scheme 98

Recently, a modified indium-mediated Reformatsky rearrangement was reported.[229] It consists of the reaction of substituted allyl (or propargyl) α-bromoacetates with indium and indium(III) chloride in the presence of Me_3SiCl and Et_3N under ultrasonication. The scope of the method has proved general for a large variety of substrates, including those which are base sensitive. The proposed mechanism implies the formation of indium ester enolates, which are converted into the silyl ketene acetal, the rearrangement of which generates the corresponding carboxylic acid (Scheme 99).

Scheme 99

5.20.4 Stereoselective Claisen Rearrangement



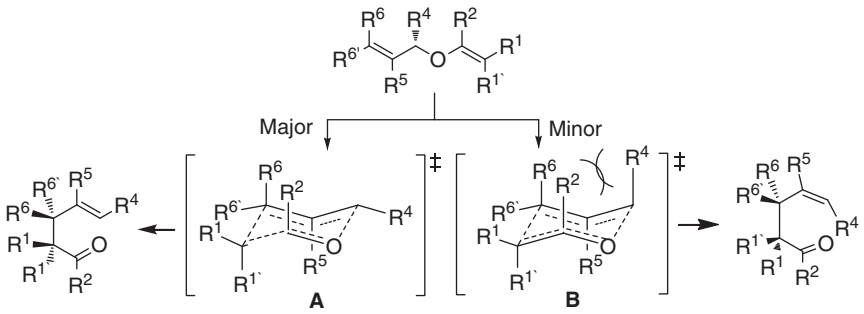
5.20.4.1 General Aspects

The highly ordered cyclic transition state involved in the Claisen rearrangement, along with the steric restrictions imposed by the orbital symmetry rules, effect a reliable transfer of stereochemistry from starting materials to products. There are two approaches to control the stereoselectivity of the reaction that we will refer to as 'intra-annular stereoselection' and 'extra-annular stereoselection,' depending on whether the elements of stereocontrol are embedded in the allyl vinyl ether moiety or are external to it. In the intra-annular stereoselection, there are three possible elements of stereocontrol that will determine the stereochemistry of the products: the geometry of the vinyl ether bond, the geometry of the allyl double bond, and the configuration at C4. In the extra-annular stereoselection, the diastero- and enantioselectivity of the reaction can be controlled either by a remote stereocenter covalently linked to the allyl vinyl ether moiety or by a chiral catalyst.

5.20.4.2 Intra-annular Stereoselection

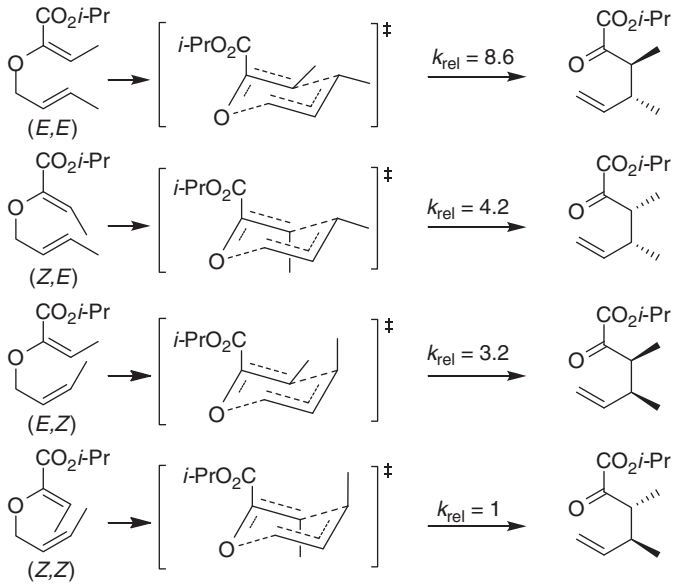
5.20.4.2.1 Transition state geometry

The generally accepted geometry for the transition state of the Claisen rearrangement in acyclic systems is a chair conformation, controlled by the steric[230] and electronic[53] features of the system. The gas-phase rearrangement of acyclic (*Z*,*Z*)-, (*E*,*E*)-, (*Z*,*E*)-, and (*E*,*Z*)-allyl vinyl ethers into the corresponding *erythro* and *threo* products proceeds preferentially through chairlike transition states in order to minimize steric interactions, as shown in the Newman projections represented in **Scheme 100**.[2j] The chairlike transition state determines that the geometry of the vinylic and the allylic double bonds in the starting material controls the relative stereochemistry of the two new stereogenic centers created through the sigmatropic process.



Scheme 100

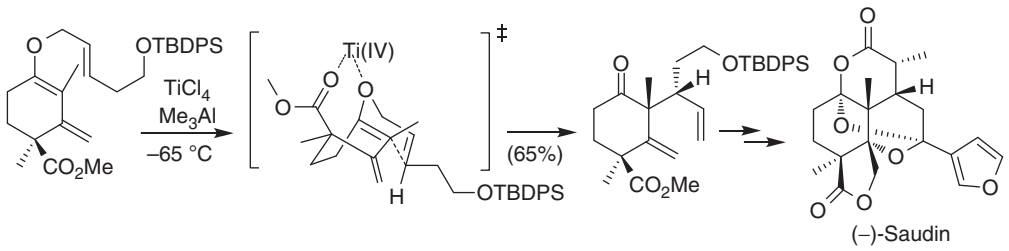
In the presence of a substituent at C4 ($R^4 \neq H$), there are two possible chairlike transition states that place the C4 substituent in a pseudoequatorial (**A**) or pseudoaxial (**B**) position (**Scheme 101**). The preference for transition state **A**, in which R^4 occupies a pseudoequatorial position, determines the prevalence of *E* alkenes as major products in the rearrangement of acyclic systems.



Kinetic studies on the uncatalyzed [3,3]-rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers, first reported by Gosteli in 1972,[56] have evidenced that these substrates, regardless of the geometry of both vinylic and allylic olefins, have a clear preference for reacting through a chairlike transition state. The reaction rates, however, are closely dependent on the substituents and the geometry of the double bonds in the substrate (**Scheme 102**).[57]

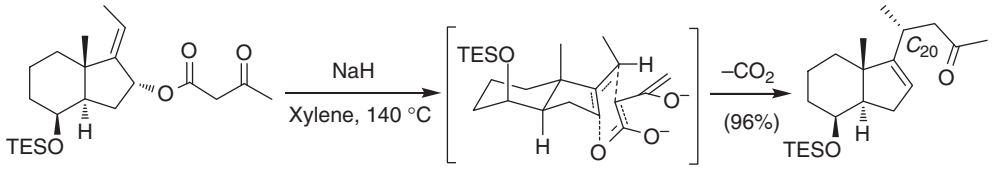
Recent computational studies have proved that the thermal aromatic Claisen rearrangement also proceeds through a chairlike transition state. The observed *E*/*Z*-product selectivity, ranging between 90:10 and 98:2, was attributed to the progression of the rearrangement through differently favored chairlike conformers.[231]

Claisen and Claisen-related [3,3]-sigmatropic rearrangements evolving through the most stable chairlike transition state have been applied to the synthesis of a number of natural products.[232,233] In the presence of hard Lewis acid catalysts (typically aluminum or titanium), selective coordination to one of the two electron lone pairs at the oxygen atom of the substrates favors a chairlike conformation for the transition state.[234] The asymmetric synthesis of (−)-saudin uses a Lewis acid ($TiCl_4/Me_3Al$)-mediated Claisen



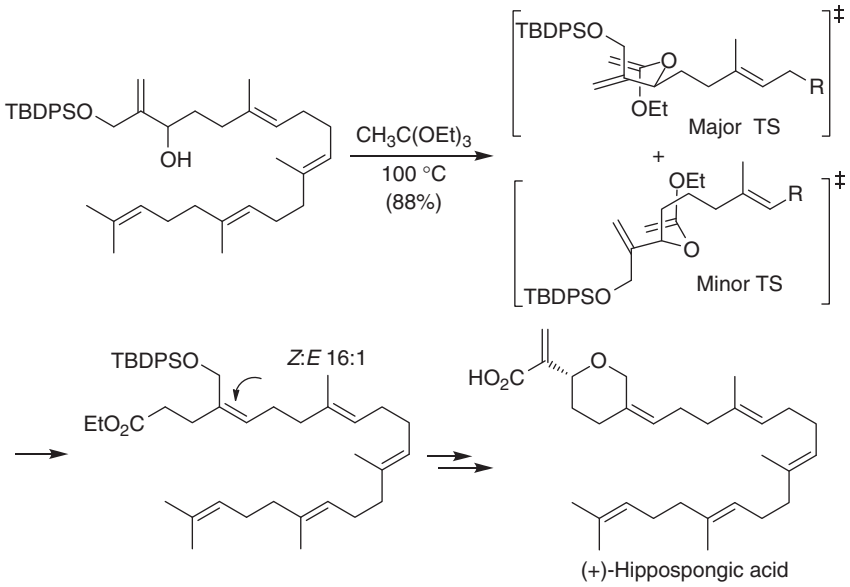
Scheme 101

Scheme 102



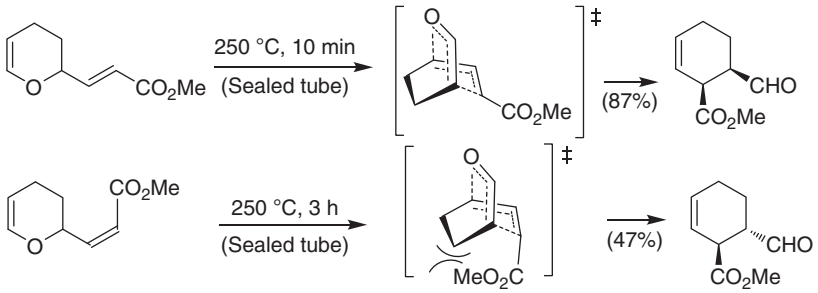
rearrangement of an allyl vinyl ether to introduce the correct configuration at the two quaternary carbon atoms (C13 and C16). The facial selectivity derives from a bidentate coordination by Ti(IV) of both the oxygen atoms of the vinyl ether and the ester, enforcing the boatlike conformation in which the rearrangement takes place via the chairlike transition state on the less hindered $\alpha-$face (Scheme 103).[235]

Scheme 103



The six-membered chairlike cyclic transition state of the Carroll rearrangement, reported for the stereocontrolled synthesis of functionalized vitamin D_3 side-chain units with the natural C20 (*S*) configuration, is responsible for the excellent chirality transfer from the starting allylic β-keto ester to the rearranged ketone (Scheme 104).[236]

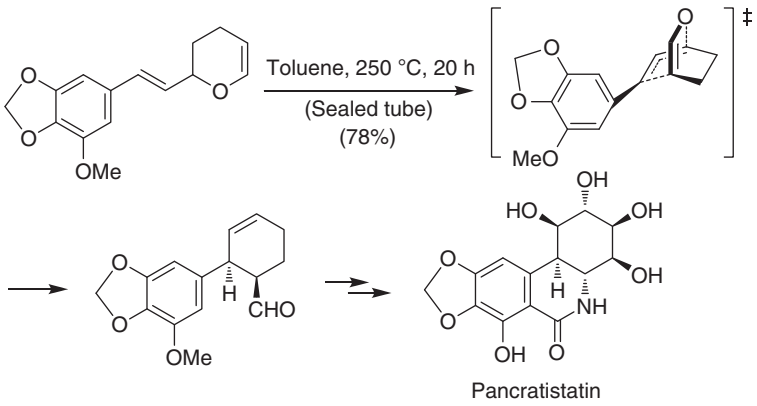
In the total synthesis of the gastrulation inhibitor (+)-hippospongic acid A, the Johnson rearrangement of an allylic alcohol bearing a TBDPS-protected hydroxymethyl group at C2 afforded the corresponding γ,δ-unsaturated ester as a 16:1 *Z*:*E* olefin



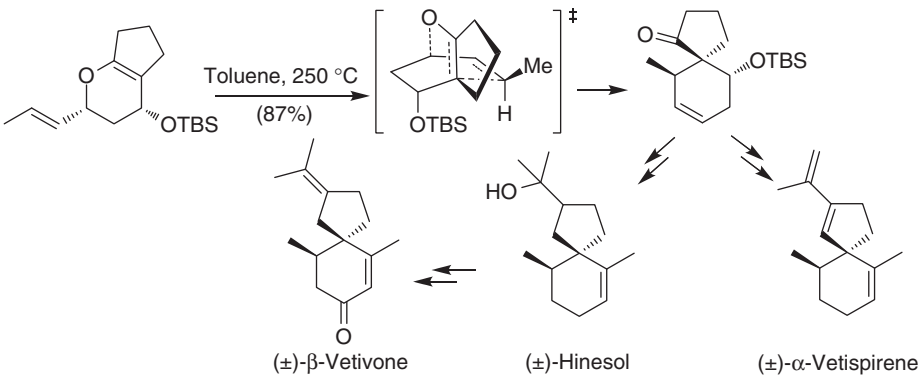
Scheme 104

mixture. The most favorable chairlike transition state bearing the long carbon chain in an equatorial orientation gave the desired major olefin, whereas the minor isomer derived from the alternate chair conformer where the steric interactions with the bulky TBDPS ether are minimized (Scheme 105).[237]

Scheme 105



Although it is well accepted that the Claisen rearrangement proceeds through a chairlike transition state for acyclic systems, the rearrangement takes place through a boatlike transition state for pyranoid- and furanoid-glycals bearing an endocyclic vinylic double bond. Thus, the Claisen rearrangement of 3,4-dihydro-2*H*-pyranylethylenes proceeds preferentially through a boatlike transition state to afford differently substituted cyclohexenes. This boat conformation explains the stereochemistry as well as the relative reactivity depending on the geometry of the allylic double bonds of the substrates (Scheme 106).[238]

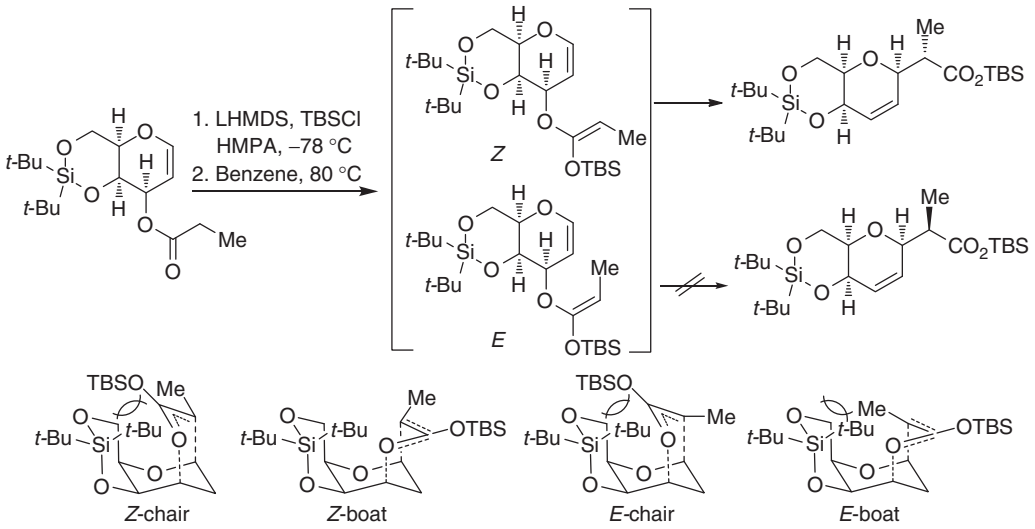


Scheme 106

A similar protocol has been described as a highly diastereoselective key step in the synthesis of the antitumor alkaloid pancratistatin (Scheme 107).[239]

A highly stereoselective thermal Claisen rearrangement of bicyclic dihydropyran derivatives through a boatlike transition state provided multifunctionalized spiro[4.5]decanes.[240] This methodology was used for the construction of the key intermediate in the synthesis of the vetivane sesquiterpenes (±)-α-vetispirene, (±)-hinesol, and (±)-β-vetivone (Scheme 108).[241]

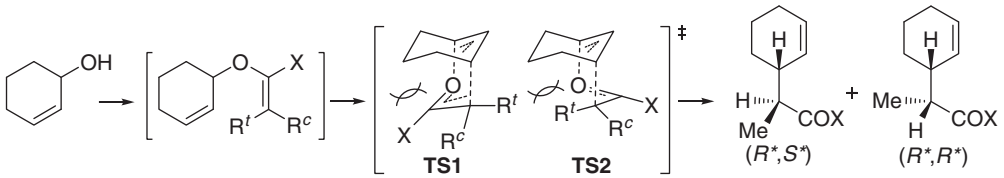
Scheme 107



Scheme 108

When the stereoselectivity is not good enough, modifications in the starting material can sterically modulate the activation energy for the rearrangement to improve the overall diastereoselectivity. This strategy has been used recently in the total synthesis of the marine natural products halicondrins.[242] The first attempts to perform an Ireland–Claisen rearrangement on a glycal derivative (lacking a silyl ether bridge) to synthesize the C27–C38 fragment of halicondrin B, resulted in an 8:1 mixture of diastereoisomers. It was reasoned that the introduction of a silyl ether bridge in the glycal structure could affect the activation energy for the Claisen rearrangement, improving the overall stereoselectivity of the process. Using the conditions reported by Ireland, the starting glycal was converted to *O*-silyl ketene acetals (*Z*/*E* 7.3:1 ratio) which, on heating, afforded a single diastereoisomeric carboxylate (Scheme 109). The (*Z*)-ketene acetal reacts through a boatlike transition state (*Z*-boat) to avoid the steric destabilization present in the chairlike transition state (*Z*-chair). However, for the (*E*)-ketene acetal both transition states appear to have a severe steric destabilization. Thus, the rearrangement takes place preferentially for the (*Z*)-*O*-silyl ketene acetal through a boatlike transition state, resulting in an improvement of the overall diastereoselectivity.

In simple cyclohexenols, the geometry of the transition state depends on the geometry of the vinyl ether (Table 1).[243] For *Z*-silyl ketene acetals (R^c = Me), the rearrangement takes place preferentially through a boatlike transition state, whereas for *E*-silyl ketene acetals (R^t = Me) the transition state prefers a chairlike geometry. Transition states **TS1** and **TS2** explain the different pathways for *Z*- and *E*-silyl ketene acetals. When R^c = Me and R^t = H, the chairlike transition state **TS1** is destabilized as compared to the boatlike conformer **TS2** due to the steric interaction between the substituent X and the cyclohexene ring. However, when R^t = Me and R^c = H, the interaction between R^t and the carbocycle destabilizes the transition state **TS2** relative to **TS1**.



From cyclic enol ethers, it is possible to control the geometry of the transition state by proper choice of the catalyst (Scheme 110).[72] In the presence of 2,6-dimethylphenol, the *E-anti* diastereoselectivity is explained by a chairlike transition state. However, using a Pd(II) catalyst the rearrangement takes place through a boatlike transition state, where the diene acts as a bidentate ligand to give the major *E-syn* product.

The transannular Ireland–Claisen rearrangement of medium or large ring lactones proceeds through a boatlike transition state usually due to restrictions imposed by the macrocycle. A recent example depicted in Scheme 111 shows the transannular rearrangement of a ζ-lactone through a boatlike transition state to afford a *cis*-vinylcyclobutane as a single diastereomer.[222] This reaction has served as the key step in the formal synthesis of (±)-grandisol.

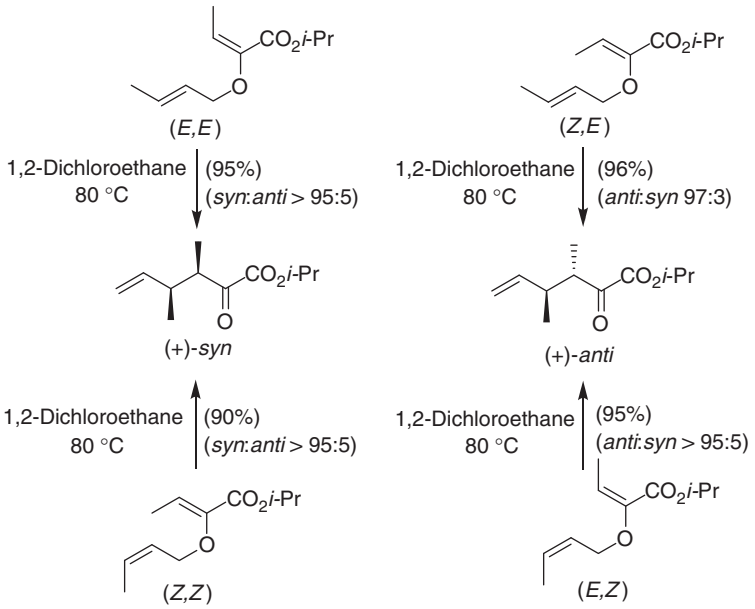
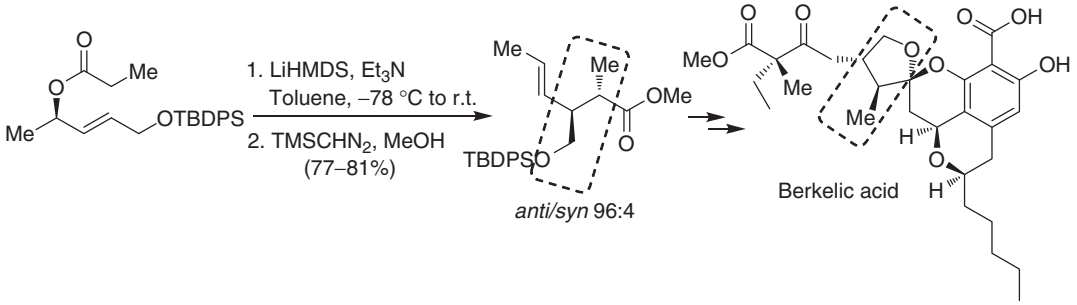
Scheme 110



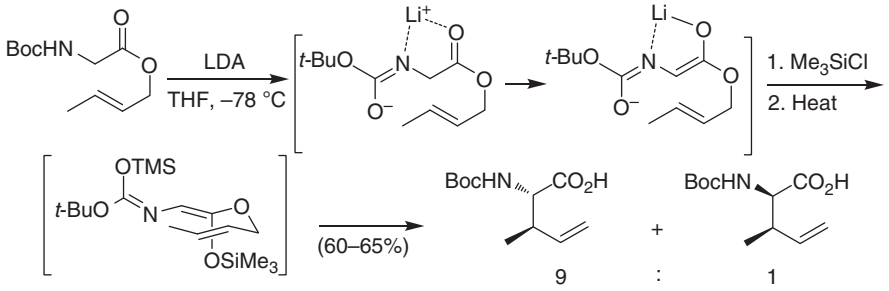
5.20.4.2.2 Enol ether geometry

As mentioned above, due to the highly ordered transition state of the Claisen rearrangement, the enol ether and the allylic double bond geometries determine the relative configuration of the new stereocenters created in the process. Therefore, different strategies to control the enol ether geometry have been developed. Considering the marked preference of aliphatic allyl vinyl ethers for evolving through a chairlike transition state, the relative stereochemistry of the two vicinal stereocenters of the rearranged product



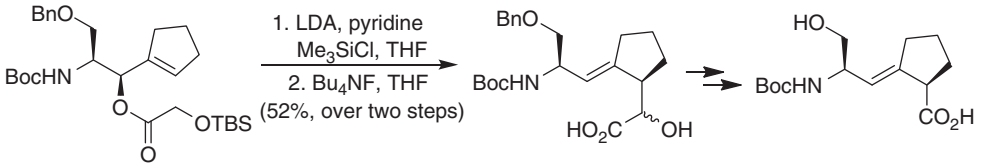
Scheme 111

will depend on the geometry of the enol ether on assuming a fixed geometry at the allylic olefin. 2-Alkoxycarbonyl-substituted allyl vinyl ethers have proved especially attractive substrates for examining the influence of the enol ether geometry on the stereochemical outcome of the rearrangement.[57,75] For *E*-configured allylic substrates, those with an (*E*)-enol ether double bond rearrange to the *syn* product, whereas a (*Z*)-enol ether double bond gives the *anti* product. Contrarily, *Z*-configured allylic substrates evolve to the *syn* or *anti* product when starting from (*Z*)- or (*E*)-enol ethers, respectively (Scheme 112).



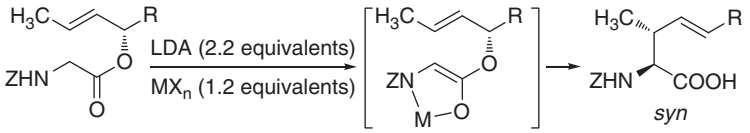
Scheme 112

One of the factors that contributes to the versatility of the Ireland–Claisen rearrangement is the possibility to easily control the *E*/*Z* stereochemistry of the enol ether. Using LDA as base, in THF or THF/HMPA as solvent systems, it is possible to selectively obtain the *E* or *Z* silyl ketene acetal intermediates, respectively.[244] Consequently, a highly reliable and predictable transfer of stereochemistry from the starting material to the product can be realized. Although in most cases synthetically useful *E*/*Z* stereoselectivities are obtained, it is still necessary to find more efficient methods. As previously mentioned, an unprecedented *E*/*Z* selectivity has been observed in the enolization of acyclic esters using a combination of lithium hexamethyldisilazide in Et_3N/toluene (see Scheme 86).[209] The efficiency of the process makes it one of the most significant modern developments in Claisen chemistry. These conditions have been recently applied to the total synthesis of berkelic acid (Scheme 113).[245]



Scheme 113

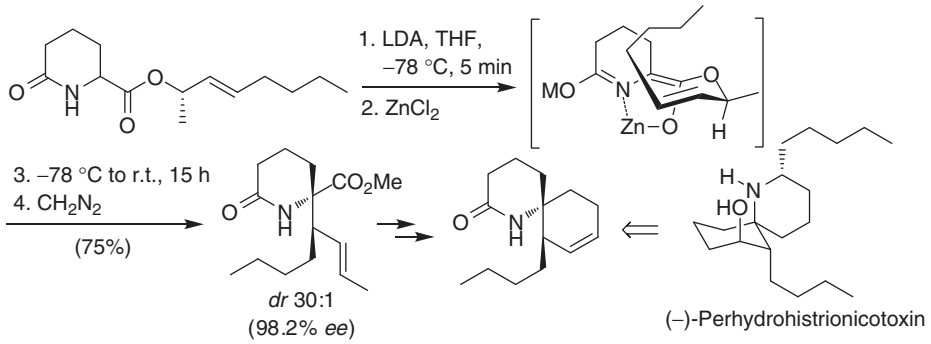
The presence of heteroatom substituents at the α-position of the ester fragment effectively controls the stereochemistry of the allyl silyl ketene acetal. An *N*-acylamino substituent at the α-position of the carboxylic acid moiety can determine the enolate stereochemistry and hence the stereochemical course of the process. The initial coordination of the Li^+ between the carbonyl oxygen atom and the anionic nitrogen substituent generates the *E* enolate, which rearranges through a chairlike transition state to afford the *threo* product (Scheme 114).[246] This methodology has been applied to the synthesis of highly substituted α-amino acids in good yields and high stereoselectivities.[200,247]



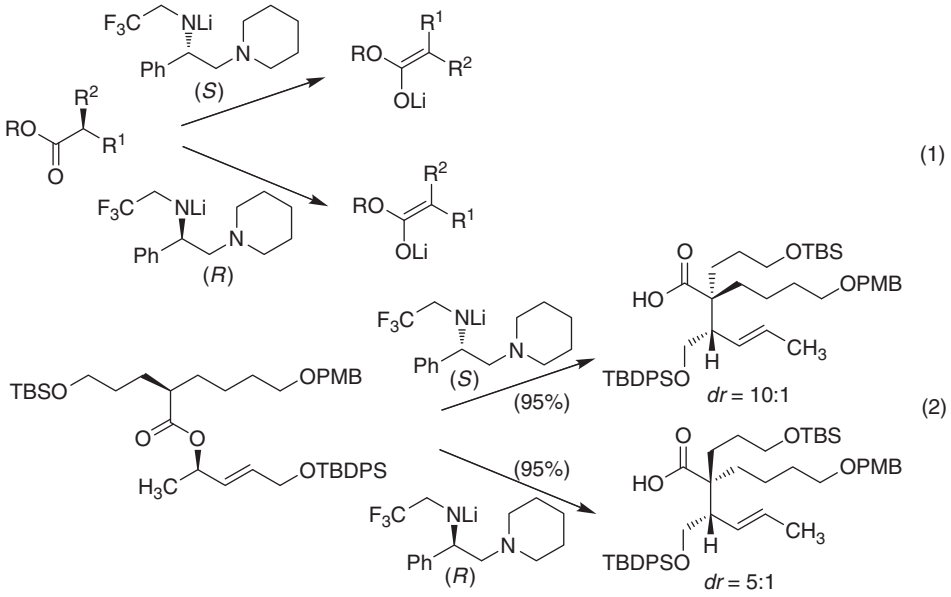
Scheme 114

Oxygen substituents at the α-position of *O*-allylic esters also proved effective in the chelation control of the Ireland rearrangements; this methodology was utilized in the context of different synthetic sequences.[248,249] During the synthesis of the amide isostere of the dipeptide Ser-*trans*-Pro, the (*E*)-alkene was formed with high levels of diastereoselectivity through the use of a chelation-controlled Ireland rearrangement of a protected allylic glycolate (Scheme 115).[250]

Scheme 115



Esters derived from α-amino acids allow a good control over the enolate formation through chelation with a metal salt through the so-called chelate version of the Claisen rearrangement, which is a variation of the previously discussed ester enolate rearrangement. Deprotonation of *N*-protected amino acid allylic esters with LDA and subsequent addition of a metal salt (typically $ZnCl_2$) affords an intermediate chelated zinc enolate, which rearranges on warming to room temperature to produce the unsaturated amino acids (Scheme 116). The higher stability of the chelated zinc-enolates, as compared to the corresponding lithium enolates, makes these intermediates considerably more advantageous as substrates for the rearrangement. As the enolate geometry is determined by chelation and a chairlike transition state is preferred, compounds with a *syn* relative configuration are formed diastereoselectively in the rearrangement of (*E*)-allylic esters.[251]



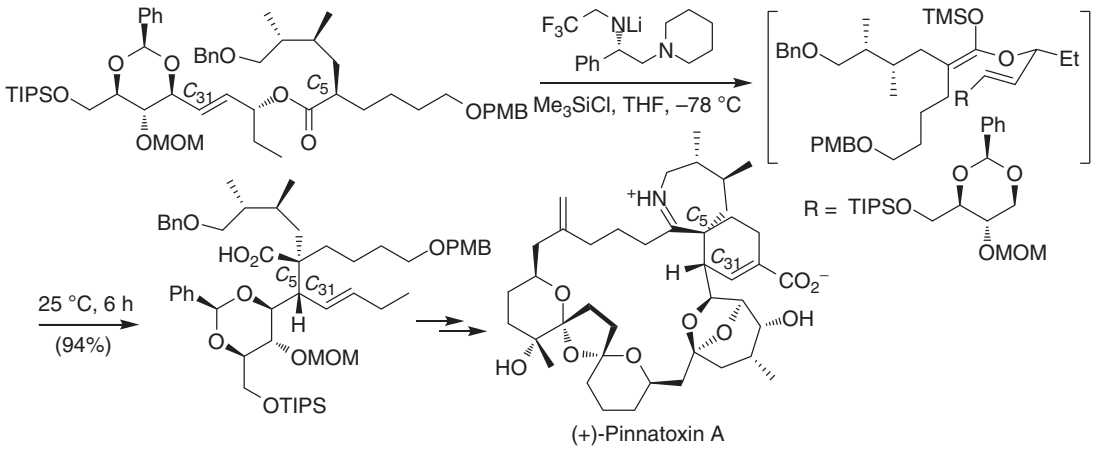
Scheme 116

The utility of this strategy has been nicely exemplified in a formal synthesis of the non-natural alkaloid (–)-perhydrohistrionicotoxin, in which a cyclic amino acid chelate Claisen rearrangement was used as the key step.[252] Again, the zinc chelation dictated the enolate geometry of the intermediate, the rearrangement of which, via a chairlike transition state, proceeded with a high level of π-facial selectivity (Scheme 117).

One of the deficiencies of the Ireland–Claisen rearrangement is the low diastereoselectivity observed for α-branched esters due to lack of geometry control in the enol ether formation. Recently, an unprecedented stereoselective enolization of α-branched esters using chiral lithium amide bases has been reported (Scheme 118, equation 1).[253] By choosing the right enantiomer of the base, both enolates can be selectively prepared from the corresponding allylic ester (Scheme 118, equation 2).

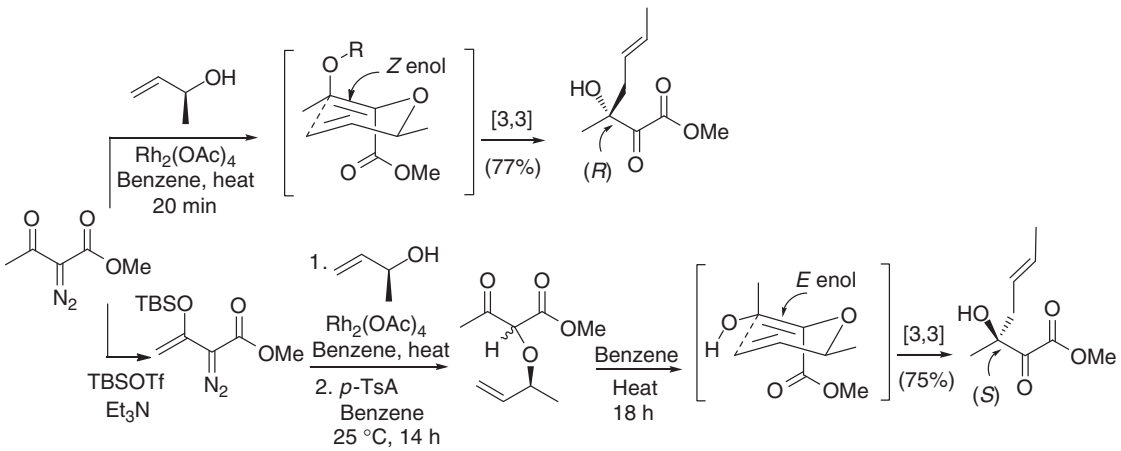
Scheme 117

Scheme 118



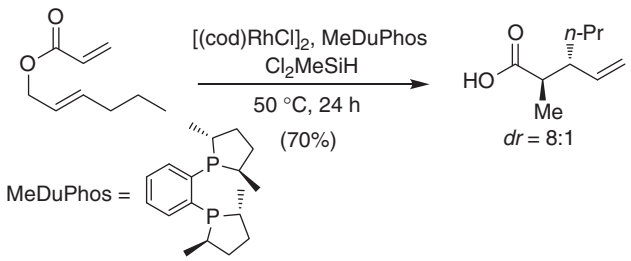
The two vicinal stereogenic centers – quaternary C5 and tertiary C31 – present in the marine toxin (+)-pinnatoxin A were constructed by way of a highly stereoselective Ireland rearrangement of an α-branched ester.[254,255] The stereoselective enolization of the ester precursor using a Koga-type chiral lithium amide produced high levels of diastereoselectivity in the rearrangement (Scheme 119).

The use of rhodium carbenoids constitutes another way of controlling the geometry of trisubstituted enol ethers (Scheme 120). Treatment of differently substituted α-diazo ketones with an allylic alcohol in the presence of a rhodium catalyst proceeds through O-H insertion via a rhodium-stabilized ylide, and allows the selective formation of the *Z*-enol ether, which rearranges to afford the tertiary (*R*)-alcohol.[256] Alternatively, a dicarbonyl allyloxy derivative, prepared in three steps from the α-diazo ketone, gives selectively the *E*-enol ether, which evolves to the (*S*)-alcohol through a sigmatropic rearrangement.



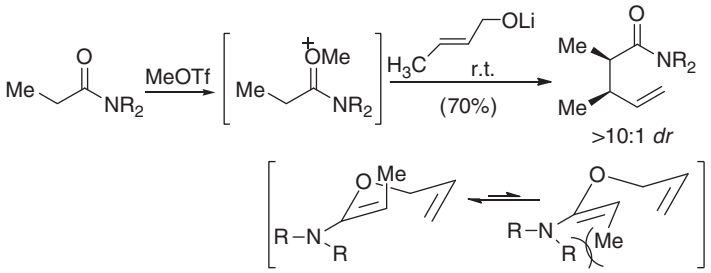
(*E*)-Silyl ketene acetals can also be generated by treatment of allyl acrylates with a rhodium catalyst in the presence of a phosphine ligand and a silane (Scheme 121).[257] These (*E*)-silyl ketene acetals undergo an Ireland–Claisen rearrangement with good diastereoselectivity. Again, the geometry of the silyl ketene acetal is the crucial control element.

Sometimes, the vinyl double bond geometry is controlled by steric interactions. This is the case for *N*,*O*-ketene acetals, synthesized by reaction of propionamide salts and lithium alkoxides (Scheme 122).[149] The *Z*-enolate is more stable than the *E*-enolate due to destabilizing interactions between the nitrogen substituents and the enamine substituent at the β position. The *Z*-enolate reacts faster to give the Eschenmoser rearrangement product.

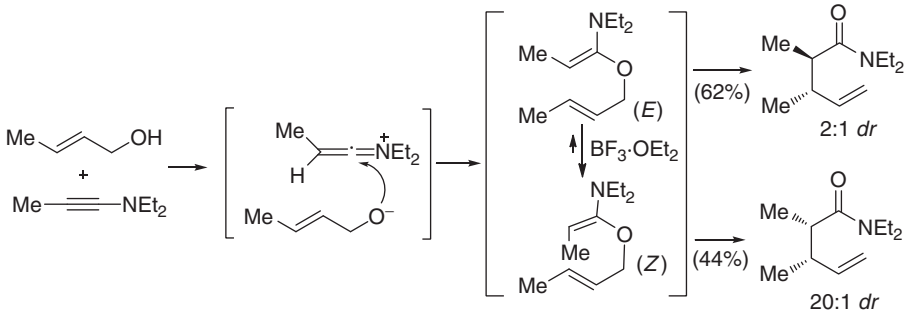


Allylic *N*,*O*-acetals can also be synthesized by addition of allylic alcohols to ynamines through a keteniminium intermediate (Ficini–Claisen rearrangement). At elevated temperatures, the *E*-ketene acetal is preferentially formed and rearranges to give the corresponding γ,δ-unsaturated amide with moderate diastereoselectivity (Scheme 123). In the presence of a Lewis acid, the thermodynamically favored *Z*-ketene acetal is generated, which on rearrangement affords the diastereomeric amide.[258] This method is somewhat limited by the instability of ynamines and their somewhat difficult preparation.

Scheme 119

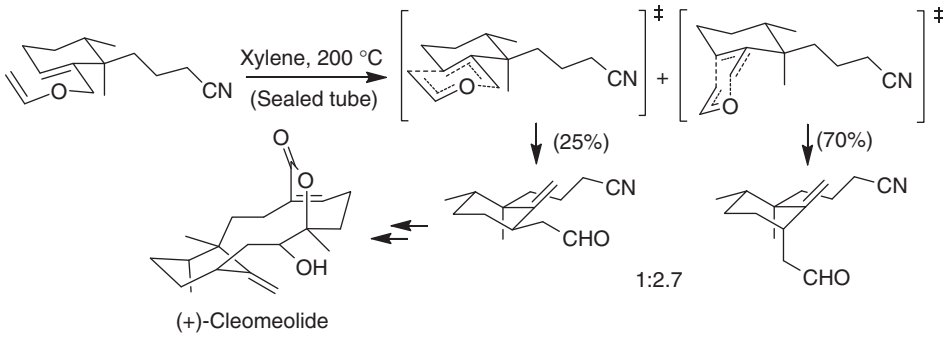


Scheme 120



Scheme 121

5.20.4.2.3 Allylic double bond geometry

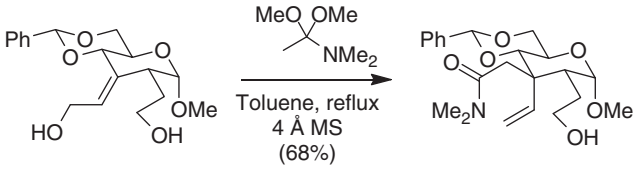


The choice of the allylic double bond geometry in the starting materials is crucial to obtain the desired relative configuration in the rearranged products. This is especially important in the total synthesis of naturally occurring or biologically active products, as a result of the high intra-annular diastereoselectivity of the reaction. In the total synthesis of the macrocyclic diterpene lactone (+)-cleomeolide, a thermal aliphatic Claisen rearrangement allowed the construction of the methylenecyclohexane fragment. The endocyclic nature of the trisubstituted allylic double bond of the precursor ether was responsible for the diastereomeric ratio of the rearrangement products; the minor one was further transformed into the natural product. The axial or equatorial arrangement of the newly formed C–C bond was dependent on the evolution of the rearrangement through either of the two possible chairlike transition states (Scheme 124).[259]

Scheme 122

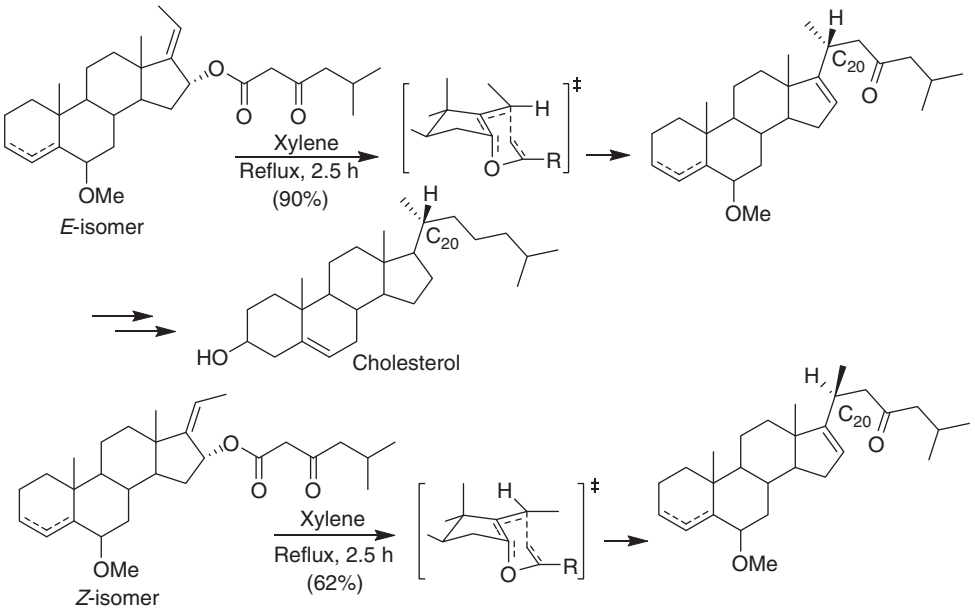
Scheme 123

Scheme 124



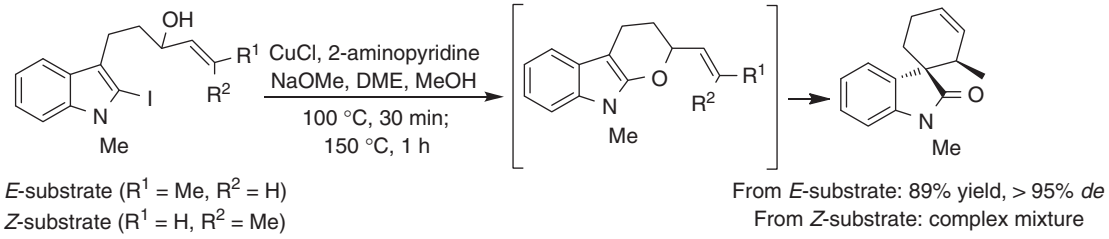
The stereochemical outcome of the Eschenmoser rearrangement utilized for the synthesis of carbocycles from carbohydrate derivatives proved to be dependent on the olefin geometry at the exocyclic allylic fragment of the chosen diol (Scheme 125).[260]

In this context, the Carroll version of the Claisen rearrangement had been used to install the C20 stereogenic center of sterol side chains. Only the *E*-isomer of the starting allyl *β*-keto ester affords the natural configuration (20*R*) at C20 present at cholesterol, whereas the *Z*-isomer gives the opposite configuration (20*S*). The differences detected in the yields for both rearrangements (90% from *E*-allylic ester and 62% from *Z*-isomer) derive from the axial arrangement of the methyl group in the transition state for the *Z*-isomer relative to its equatorial positioning in the transition state for the *E*-isomer (Scheme 126).[137]



Sometimes, a change in the allylic double bond geometry can shut down the Claisen rearrangement. A recent example can be found in the one-pot synthesis of spirocyclic oxindoles through intramolecular Ullmann coupling and Claisen rearrangement (Scheme 127).[261] Although the starting *E*-configured indole substrate undergoes the one-pot sequence with excellent yield and diastereoselectivity, the *Z*-isomer only affords a complex mixture. This result can be rationalized considering destabilizing steric interactions between the *cis*-olefin and the hydrogen atoms of the dihydropyran ring in a boatlike transition state.

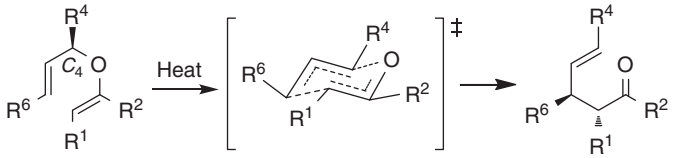
5.20.4.2.4 Configuration at C4



In allyl vinyl ethers with a substituent next to the ether oxygen and, therefore, with an asymmetric center at C4, the highly ordered cyclic transition state of the Claisen rearrangement determines a chirality transfer from C4 to the newly formed stereocenter at C6 and, accordingly, also at C1 (Scheme 128).[262] In acyclic systems, the substituent bonded to the stereogenic C4 atom prefers to

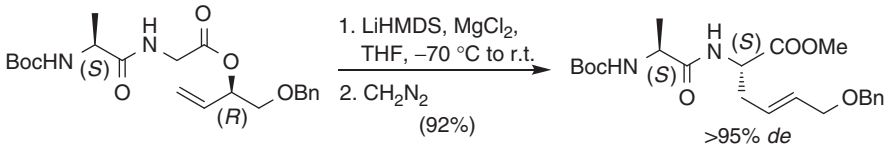
Scheme 125

Scheme 126



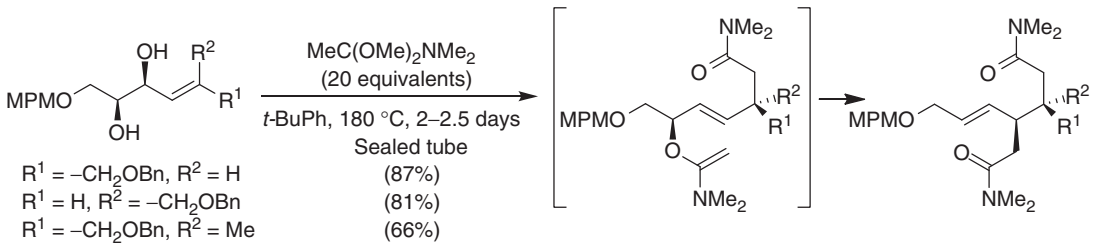
Scheme 127

occupy a pseudo-equatorial position in the chairlike transition state. This preference controls the geometry of the new double bond in the Claisen products (see Section 5.20.4.2.1). Numerous examples describing the applicability of this efficient chirality transfer during the Claisen rearrangement have been reported.[263] The 1,3-chirality transfer evidences the suprafacial nature of the thermal intramolecular rearrangement.[264]



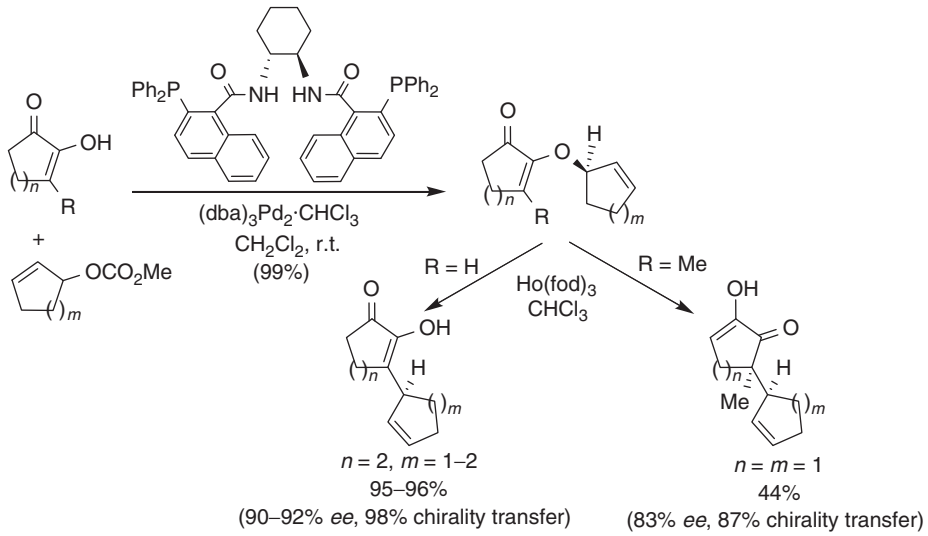
This chirality transfer has been applied to the synthesis of diastereomerically pure peptides (Scheme 129).[265] The geometry of the vinylic double bond is controlled by formation of a chelated magnesium enolate. The chirality of the allylic stereocenter is transferred to the product allowing for the generation of (*R*)- or (*S*)-amino acids. The stereocenter in the vicinal amino acid does not have any influence on the rearrangement.

The chirality of enantiomerically pure *E*-allylic *syn*-diols derived from tartaric acid has been effectively transferred through sequential sigmatropic rearrangements under Eschenmoser's conditions (*see* Chapter 5.21). When the sequence commenced with a trisubstituted olefin, two contiguous stereocenters, including a quaternary carbon atom, were constructed in the process (Scheme 130).[266]

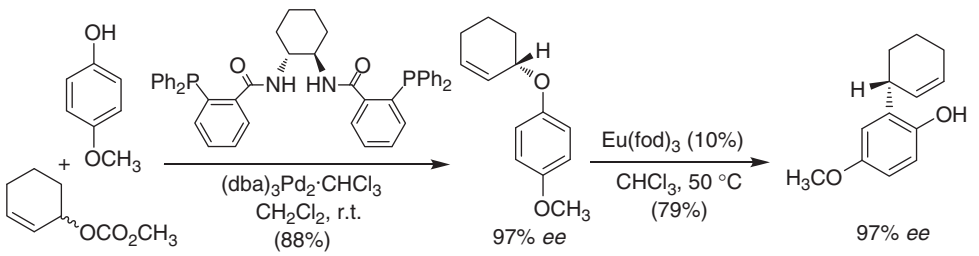


An excellent chirality transfer has been also observed in the holmium-catalyzed Claisen rearrangement of chiral allyl vinyl ethers derived from cyclic 1,2-diketones, especially with sterically less hindered substrates (Scheme 131).[267] The allyl vinyl ethers

Scheme 128



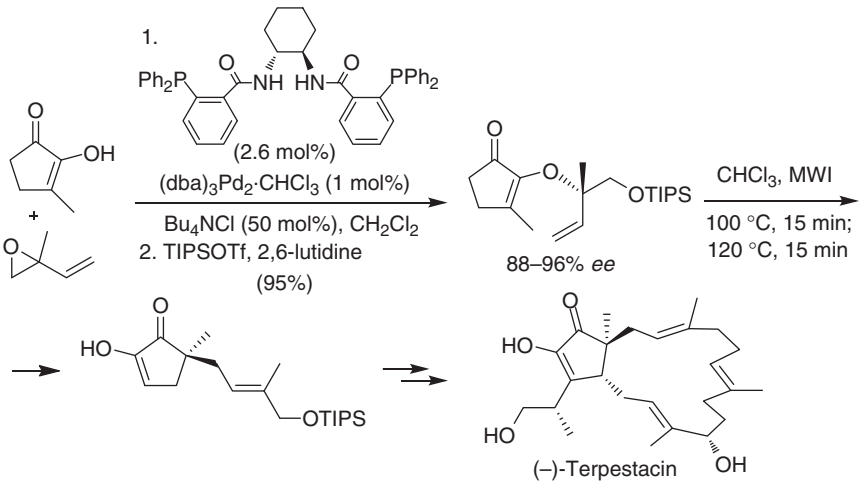
Scheme 129



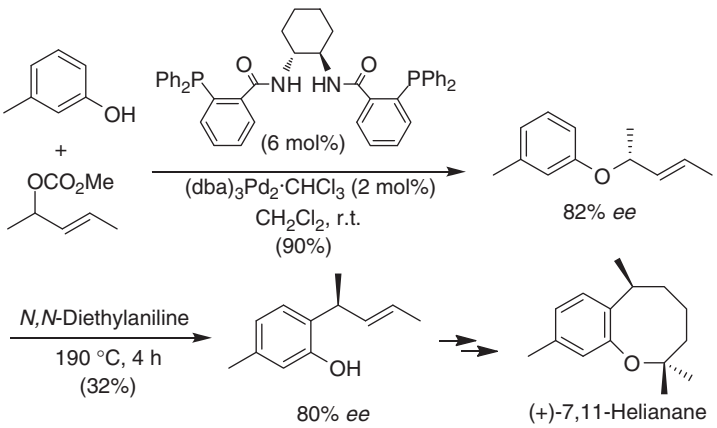
Scheme 130

were prepared by enantioselective palladium-catalyzed allylic *O*-alkylation of the corresponding 3-substituted cyclic 1,2-diketones in the presence of a C_2-symmetric chiral ligand.

A similar concept was applied to the aromatic Claisen rearrangement. The requested chiral allyl vinyl ethers were prepared by enantioselective *O*-alkylation of hydroquinone monomethyl ether, following a methodology similar to that described in Scheme 131.[268] The rearrangement proceeded with excellent chirality transfer in the presence of a catalytic amount of $Eu(fod)_3$ as the Lewis acid catalyst (Scheme 132).

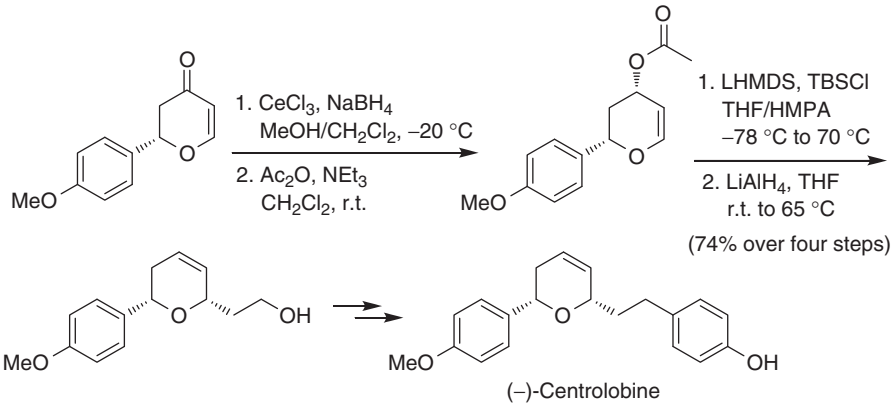


Scheme 131



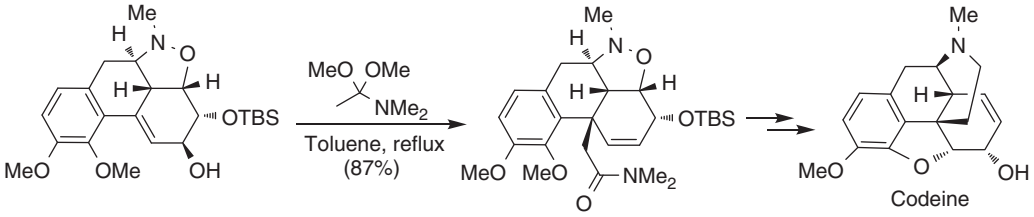
Scheme 132

An asymmetric version of this strategy has been reported as a key step in the synthesis of naturally occurring (–)-terpestacin.[269] The highly enantioselective Pd-catalyzed asymmetric allylic alkylation between commercially available 3-methyl-1,2-cyclopentanedione and isoprene monoepoxide, followed by *in situ* silylation of the adduct, provided the allyl vinyl ether, the chirality of which was efficiently transferred by a Claisen rearrangement under microwave conditions to the *C*-alkylation product (Scheme 133).



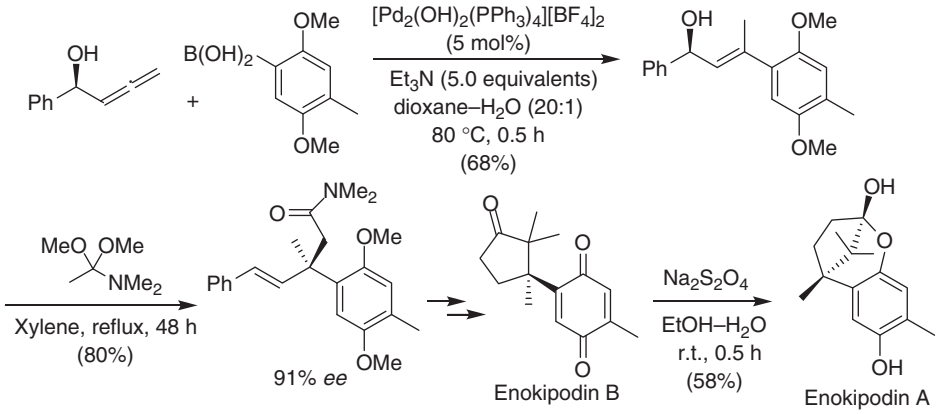
Scheme 133

A sequence of palladium-catalyzed asymmetric allylic alkylation reaction, followed by thermal aromatic Claisen rearrangement, which took place with excellent transfer of stereochemical information, has been recently applied to the synthesis of the marine sesquiterpene (+)-7,11-helianane (Scheme 134).[270]



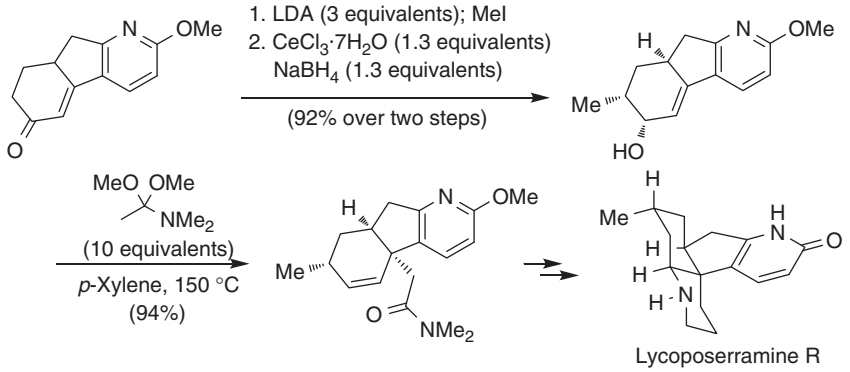
Scheme 134

The combination of a selective Luche reduction of the carbonyl function and a highly stereoselective Ireland rearrangement has been developed as an efficient route to chiral *cis*-6-substituted 2-(2-hydroxyethyl)5,6-dihydro-2*H*-pyrans.[271] This methodology has been satisfactorily utilized in the total synthesis of the antibiotic (–)-centrolobine (**Scheme 135**).



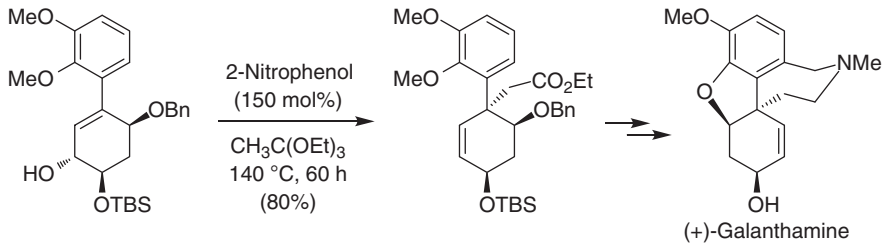
Scheme 135

The chirality of C4 in the allyl vinyl ether can also be transferred intramolecularly to create quaternary stereocenters.[272] These processes are self-immolative sequences, combining an enantioselective transformation, which creates a chiral center, and a subsequent enantiospecific sigmatropic rearrangement, whereby the initial chirality is destroyed and transferred to a newly created quaternary carbon atom. This strategy has been widely applied in the synthesis of complex naturally occurring or biologically active compounds possessing at least one stereogenic quaternary carbon atom.[273–276] In this context, one of the quaternary stereocenters of codeine has been recently installed by an Eschenmoser rearrangement (**Scheme 136**).[277]



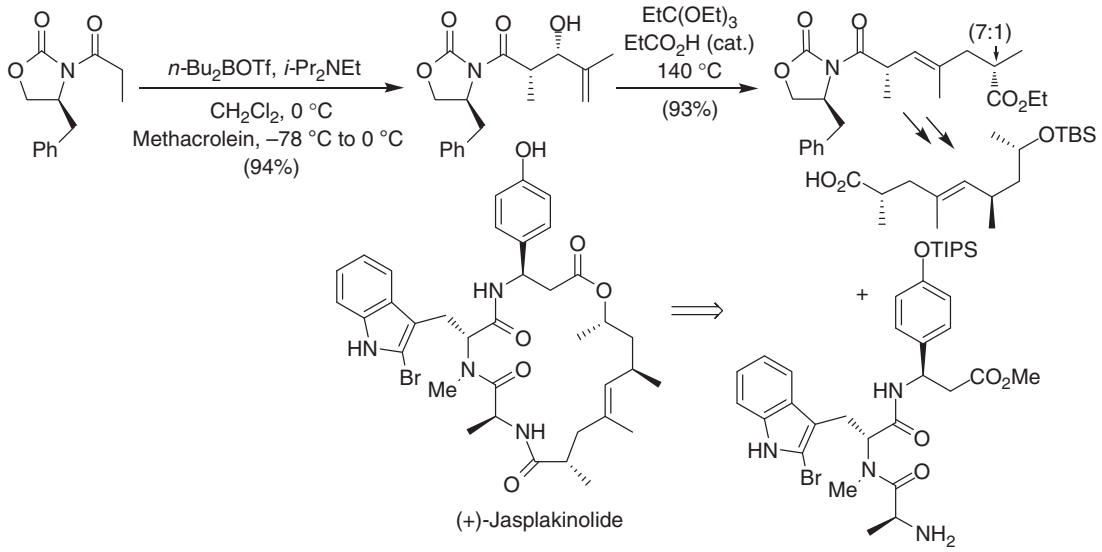
Scheme 136

Similarly, the asymmetric quaternary carbon atom of the sesquiterpenoids enokipodins A and B was constructed via an enantiospecific Eschenmoser rearrangement (**Scheme 137**).[278] The optically active starting allyl vinyl ether was prepared by the palladium-catalyzed addition of an arylboronic acid to an optically active allenic alcohol, the chirality of which had been previously generated by an enantioselective carbonyl reduction with the (*R*)-CBS (Corey–Bakshi–Shibata) reagent and BH_3.



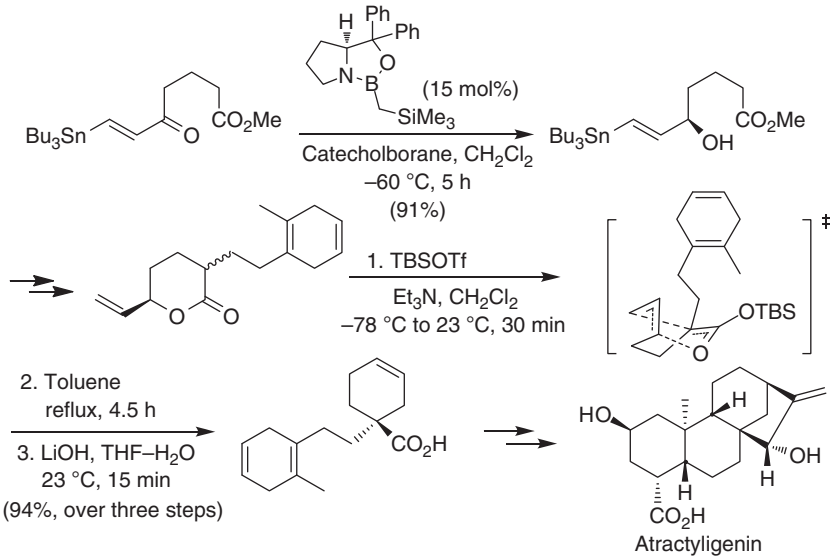
Scheme 137

A stereoselective Eschenmoser rearrangement was developed to create the all-carbon quaternary center contained within the alkaloid lycoposerramine R (Scheme 138).[279] The starting allylic alcohol was diastereoselectively prepared by way of α-methylation of a suitably substituted enone and subsequent Luche reduction.



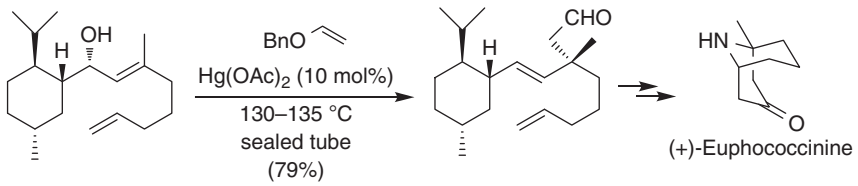
Scheme 138

The chirality of a cyclohexenol derived from D-glucose was efficiently transferred in the course of a Johnson rearrangement to stereoselectively generate the quaternary carbon center present in (+)-galanthamine (Scheme 139).[166]



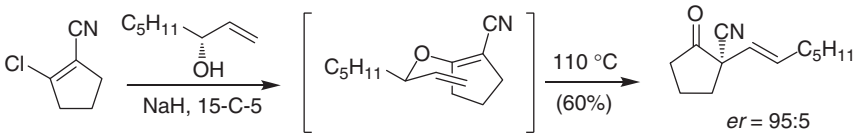
Scheme 139

The chairlike transition state for the Johnson rearrangement of an allylic alcohol, which, in turn, had been prepared by an auxiliary-assisted aldol addition, was responsible for the efficient 1,4-chirality transfer observed in a convergent synthesis of the cyclic depsipeptide (+)-jasplakinolide (Scheme 140).[280] The highly stereoselective rearrangement afforded the stereogenic α-methyl carbonyl functionality and the *E*-olefin geometry present in the polyketide fragment of the natural product.



Scheme 140

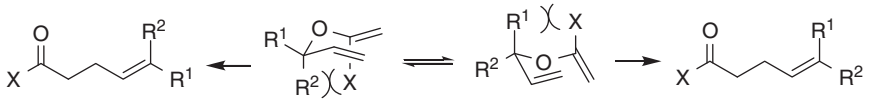
In the synthesis of atractyligenin, an Ireland rearrangement of a lactonic silyl enolate was described as the key step, evolving through a favored boatlike transition state. In this way the chirality of a secondary alcohol generated by an oxazaborolidine-catalyzed (CBS) reduction of an enone was efficiently transferred to the quaternary carbon stereocenter present in the key intermediate (Scheme 141).[281]



Scheme 141

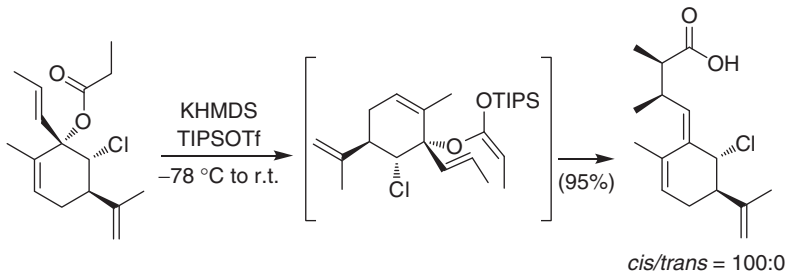
The construction of quaternary stereocenters has also been addressed via thermal aliphatic Claisen rearrangements with excellent chirality transfer from the starting allyl vinyl ethers.[282] In the context of the synthesis of the naturally occurring alkaloid (+)-euphococcinine, the quaternary carbon stereocenter present in the key intermediate was created by a thermal aliphatic Claisen rearrangement. The requested allylic alcohol was obtained by stereoselective addition of a vinylaluminum reagent to *p*-menthyl-3-carboxaldehyde and its chirality was efficiently transferred during the rearrangement (Scheme 142).[283]

Scheme 142



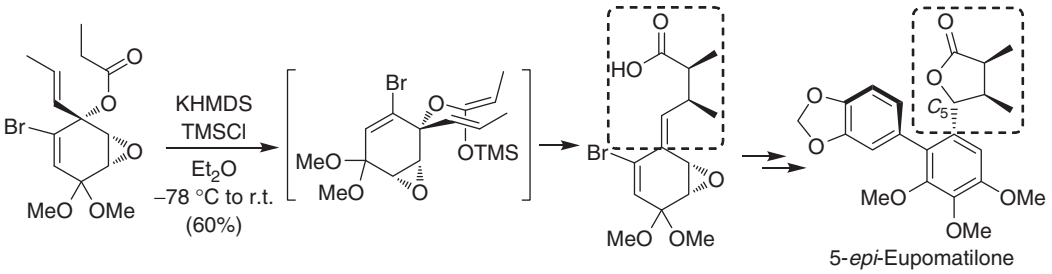
The Claisen rearrangement of cyano-substituted endocyclic enol ethers, synthesized by a conjugate addition–elimination reaction of allylic alkoxides to 2-chlorocycloalkenecarbonitriles, allows for the stereoselective formation of cyclic oxonitriles with a quaternary stereocenter (Scheme 143).[284] The enantiomeric ratios were typically greater than 9:1.

Scheme 143



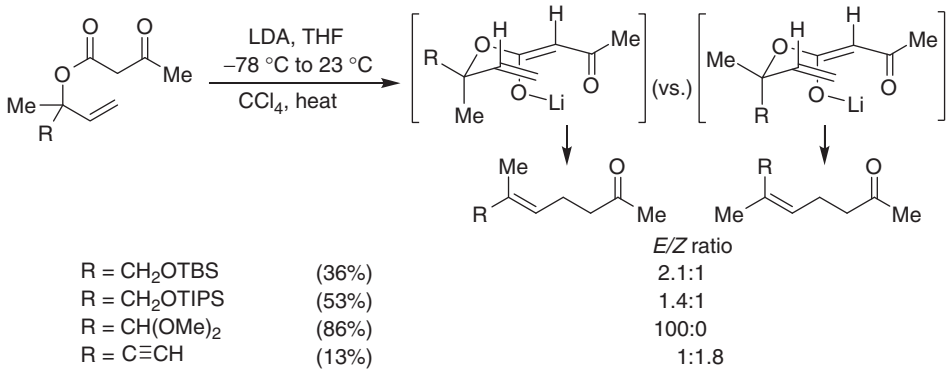
In tertiary allyl vinyl ethers, the outcome of the Claisen rearrangement become less obvious since both chairlike transition states suffer from 1,3-diaxial interactions (Scheme 144).

In this context, the Ireland rearrangement of tertiary bis-allylic esters derived from cyclohexenones has been reported to afford tri- and tetrasubstituted alkylidenes with unprecedented levels of stereoselectivity.[285] Scheme 145 shows an example in which a silyl ketene acetal rearranges through a transition state with the C6 carbon of the cyclohexenone occupying a pseudo-equatorial



Scheme 144

position. Interestingly, the higher-energy exocyclic alkene is formed. Once again, the chirality of the allylic stereocenter is transferred to the two new stereocenters in the product and to the new geometry of the double bond.

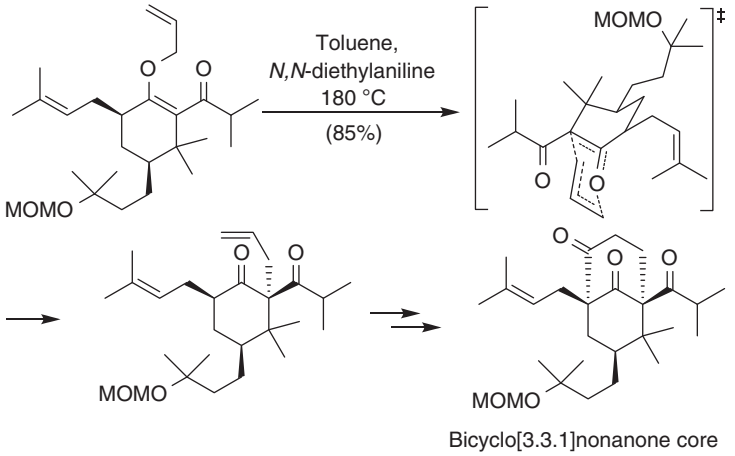


Scheme 145

This strategy has been applied to the total synthesis of a member of the eupomatilone family (Scheme 146).[285a] In this case the exocyclic alkene with the opposite stereochemistry was obtained.

Scheme 146

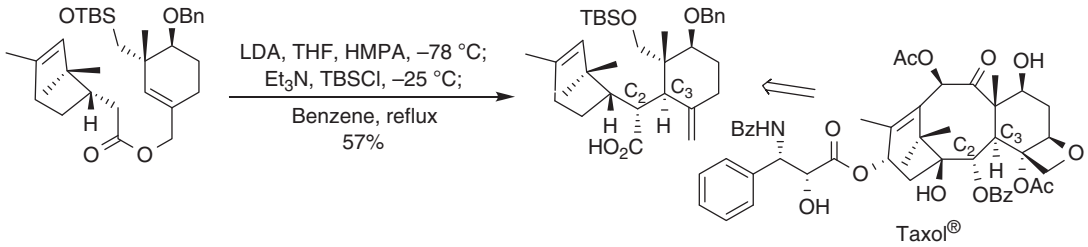
The Carroll rearrangement of β-keto esters derived from tertiary allylic alcohols has also been reported. The reaction takes place through the most stable chairlike transition state, which is closely dependent on the steric differences between the substituents at the allylic C4 position and, therefore, dictates the olefin geometry of the obtained γ,δ-unsaturated methyl ketones (Scheme 147).[286]



Scheme 147

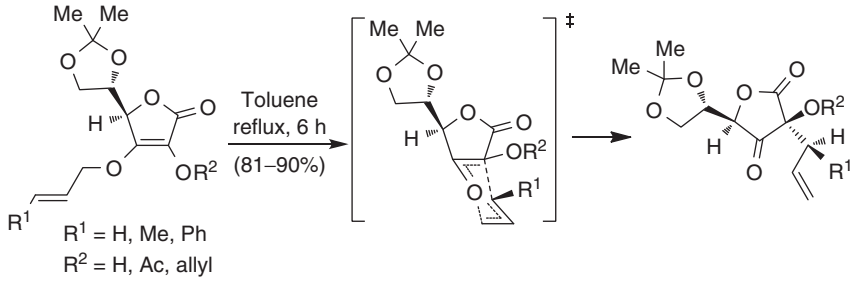
5.20.4.3 Extra-annular Stereoselection

The presence of additional stereocenters not directly participating in the six-membered cyclic transition state of the rearrangement may control the extra-annular diastereoselectivity and, accordingly, determine the stereochemical pathway of the process.



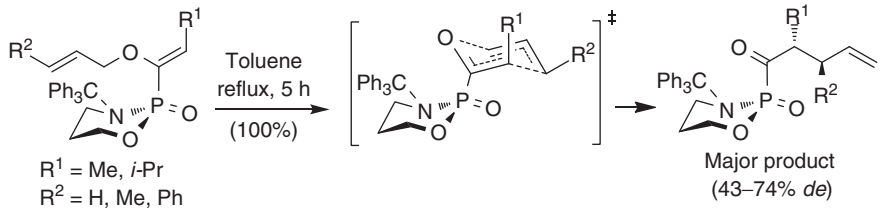
A diastereoselective thermal Claisen rearrangement was devised as the key step of the synthesis of the highly congested bicyclo[3.3.1]nonanone core of natural acylphloroglucinols. The stereochemistry of the asymmetric centers present at the allyl vinyl ether used as the substrate dictated the axial C–C bond formation in the rearrangement and, hence, controlled the configuration of the newly formed quaternary stereocenter (Scheme 148).[287]

Scheme 148



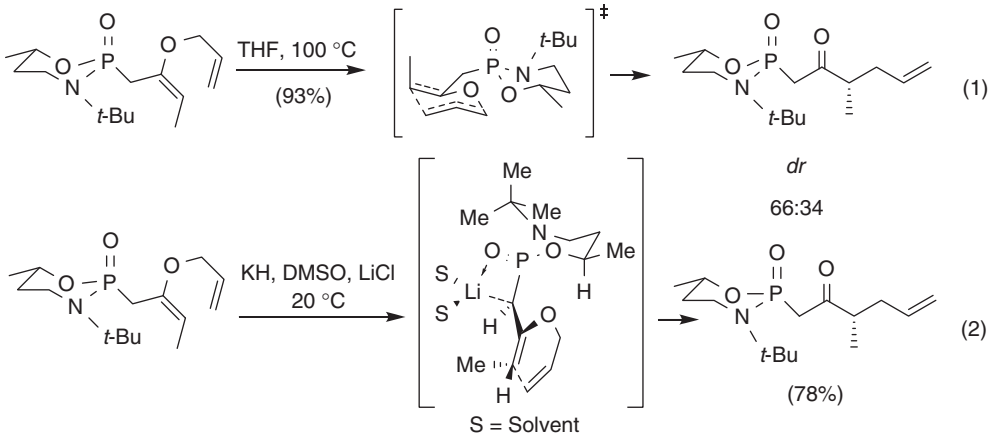
Heteroatomic stereogenic centers adjacent to both the vinylic and the allylic olefins of the starting materials of the Ireland[288,289] and Johnson[290] rearrangements have caused good *exo*-pericyclic stereocontrol in the reactions. Similarly, structural restrictions existing in chiral substrates have proved useful as asymmetric inducers of the diastereoselectivity of the rearrangements.[291]

The chirality of additional asymmetric centers present in the substrate of the key Ireland rearrangement step used for the generation of the C2–C3 bond in taxanes exerted a positive influence on the stereocontrol of the reaction (Scheme 149).[292]



Scheme 149

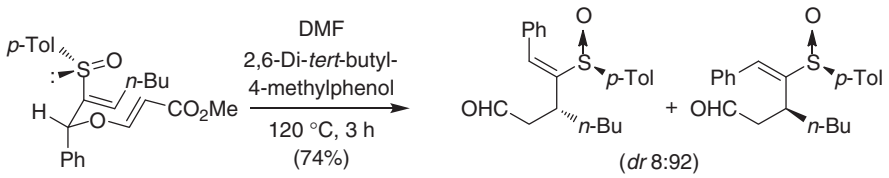
The influence of chiral auxiliaries on the stereochemical outcome of [3,3]-sigmatropic rearrangements has been investigated. In the synthesis of C2-functionalized gulono-γ-lactone derivatives from L-ascorbic acid, a highly diastereoselective thermal Claisen rearrangement was used to install an allyl fragment in the lactone core of the products. The steric constraints imposed by the bulky chiral 1,2-*O*-isopropylidene-1,2-ethanodiol moiety on the vinyl portion on the top face of the substrate determined the preference of the rearrangement to occur almost exclusively from the bottom face through the favored chairlike transition state (Scheme 150).[293]



Scheme 150

A chiral 1,3,2-oxazaphosphorinane directly bonded to the vinyl olefin of the rearrangement substrates provided modest to good diastereoselectivities resulting from the evolution through the favored chairlike transition state minimizing the electronic repulsion from the ring oxygen electron lone pair (Scheme 151).[294]

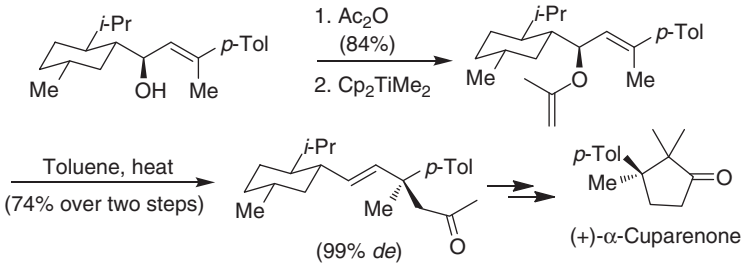
Scheme 151



A moderate degree of asymmetric induction was achieved by using a chiral, nonracemic 1,3,2-oxazaphosphorinane bonded by a methylene unit to the vinyl olefin of the ether framework. The favored rearrangement proceeded by bond formation on the *Re* face, thus avoiding steric interactions with the most hindered face of the chiral auxiliary (Scheme 152, equation 1).[295] The diastereoselectivity of the rearrangement of these substrates was substantially improved under basic conditions, whereby the 1,3,2-oxazaphosphorinane moiety acted as the anion-stabilizing group. In the presence of Li^+ as the counterion, the chirality was effectively transferred in the course of the carbanionic Claisen rearrangement, presumably as a result of the course of the rearrangement through an sp^2-hybridized anion, which is strongly complexed to lithium (Scheme 152, equation 2).[296]

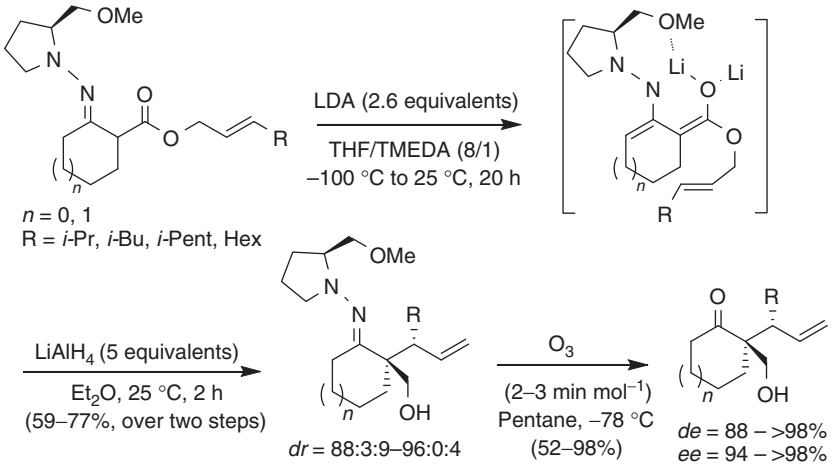
Scheme 152

The C_2-symmetric *N*,*N*′-dibenzyl-1,3,2-diazaphospholidine was also investigated as a chiral auxiliary of the reaction, both under neutral and basic conditions.[61,296] Although these rearrangements exhibited a good internal induction (intra-annular diastereoselectivity), the degree of extra-annular diastereoselectivity exerted by the chiral auxiliary was rather moderate.



Chiral auxiliaries located on the allylic portion of the starting vinyl allyl ethers have also been reported in the aliphatic Claisen rearrangement.[297] A chiral sulfinyl functionality positioned at the allylic fragment of an allyl vinyl ether proved capable of controlling the diastereoselectivity of the thermal Claisen rearrangement due to its ability to differentiate between the diastereotopic faces of the neighboring double bonds.[298] The presence of an additional stereocenter at C4 defined the matched or mismatched contribution of both stereogenic elements in the reaction, which was also modulated by the geometry of the allylic double bond (Scheme 153).[299] Interestingly, allyl vinyl ethers with a (*Z*)-vinyl sulfoxide rearranged through a chairlike transition

Scheme 153

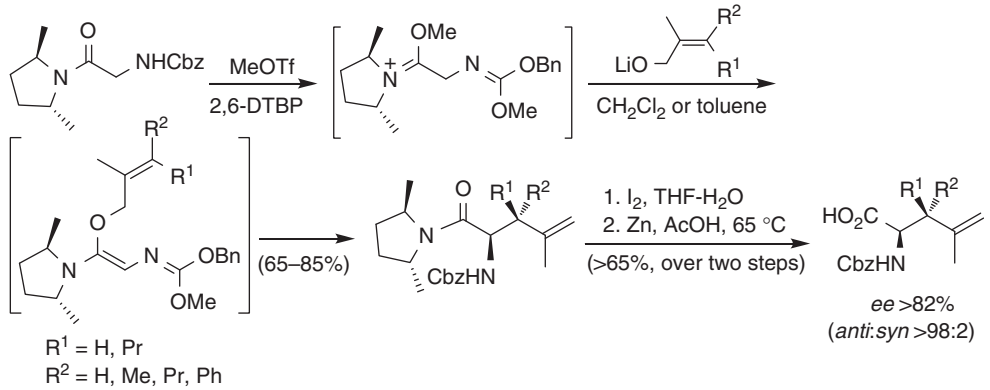


state which places the allylic substituent in a pseudoaxial position to avoid interactions with the sulfoxide moiety. The stereochemical outcome of these rearrangements was explained from an (s)-*cis* C═C/S═O conformation around the C–S bond for the chairlike transition state.

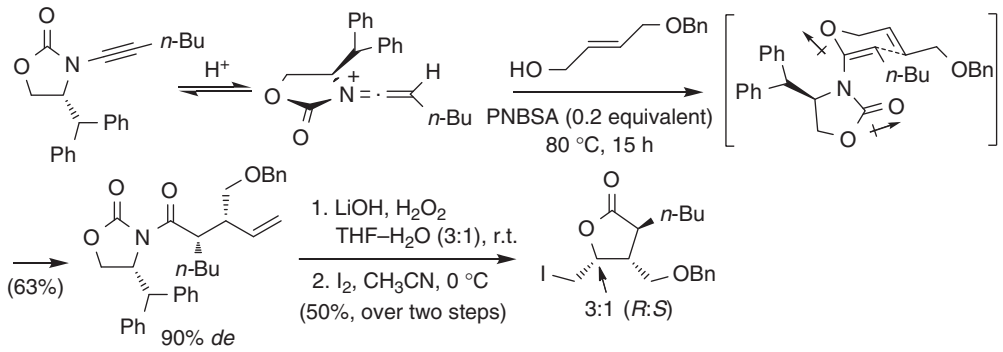
A completely stereoselective Claisen rearrangement was reported during the synthesis of the sesquiterpene (+)-cuparenone. The cooperative action of a chiral auxiliary directly bonded to the allyl fragment of the allyl vinyl ether along with the fixed configuration at C4 dictates a highly diastereoselective course of the reaction (Scheme 154).[300]

Scheme 154

Functionalized ketones bearing adjacent quaternary and tertiary stereocenters have been synthesized with high diastereo- and enantioselectivities by way of a Carroll rearrangement utilizing a chiral auxiliary. The rearrangement of dianions derived from SAMP-type β-hydrazonoesters, followed by reduction with $LiAlH_4$, and regeneration of the carbonyl function has been reported as a route to γ,δ-unsaturated β′-hydroxyketones with two stereogenic centers at the α and β positions. The intermolecular chelation of the lithium by the methoxymethyl (MOM) group of the chiral β-hydrazonoester differentiates both diastereotopic faces for the allylic approach in the chairlike transition state of the rearrangement (Scheme 155).[301]

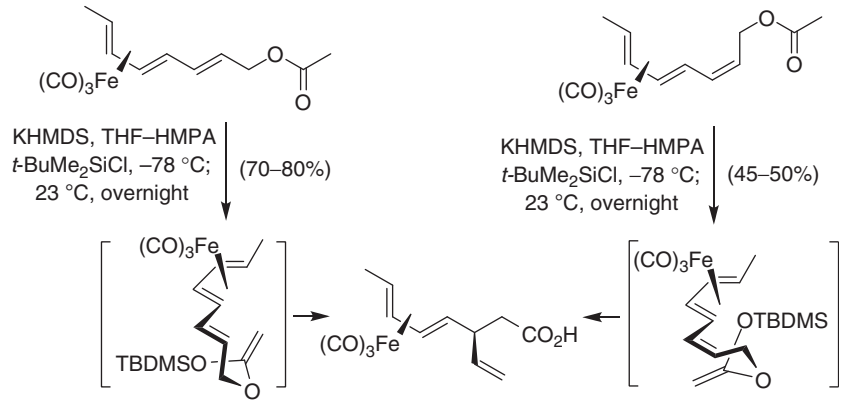


Scheme 155



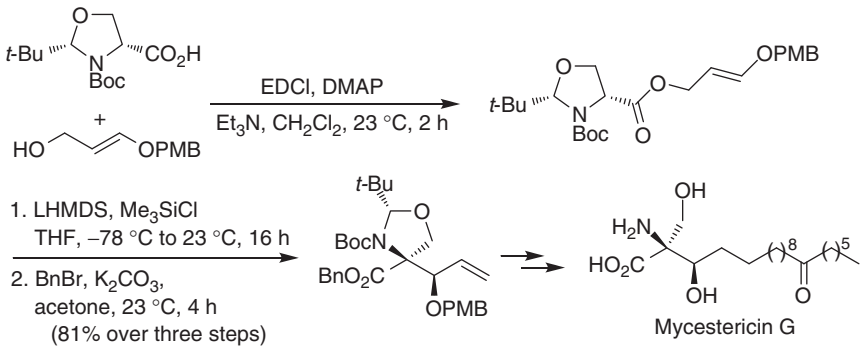
The presence of chiral auxiliaries on the nitrogen portion of *N,O*-ketene acetals has also provided high levels of diastereoselectivity in the Eschenmoser rearrangement.[150,302,303] The C_2-symmetric chiral auxiliary (2*R*,5*R*)-dimethylpyrrolidine has provided high levels of diastereoselectivity in an Eschenmoser rearrangement, which has been reported as a valuable tool for the synthesis of optically active *anti*-β-substituted γ,δ-unsaturated α-amino acids (Scheme 156).[304,305]

High levels of diastereoselectivity have been achieved utilizing a chiral oxazolidinone group as a chiral auxiliary in the Ficini–Claisen rearrangement of a range of ynamides.[306] The (*E*)-ketene aminal resulting from the addition of an allylic alcohol to the less hindered diastereotopic face of the initially formed iminium salt rearranged through a chairlike transition state in the conformation that minimized the dipole interaction between the urethane C═O bond and the vinyl C–O bond. In this conformation, the chiral auxiliary determined the preferred approach of the allylic olefin to the less hindered side of the vinyl double bond, leading to the major *syn* isomers from *trans*-substituted allylic alcohols (Scheme 157). This strategy has provided ready access to synthetically useful diastereomerically enriched lactones.

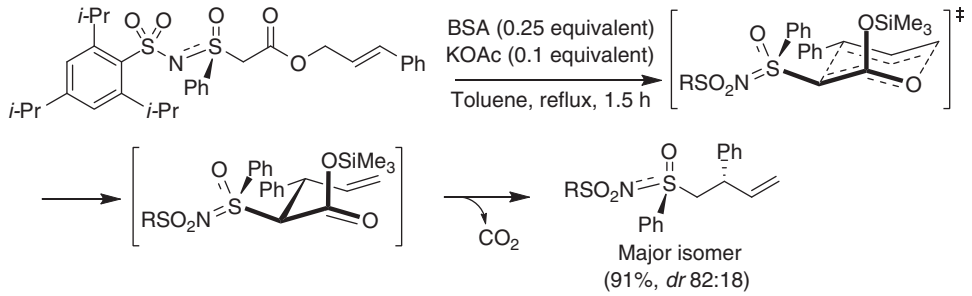


The use of chiral auxiliaries in diastereoselective Ireland rearrangements has also been investigated.[307–309] A chiral η^4-diene iron(tricarbonyl) complex provided high levels of stereocontrol in the Ireland rearrangement of trienylic esters. The excellent diastereofacial selectivity led to the formation of the new C–C bond *anti* to the $Fe(CO)_3$ group (Scheme 158).[310] The reaction proved to be completely diastereoconvergent, regardless of the *E*/*Z* geometry of the allylic olefin in the substrate.

Scheme 156



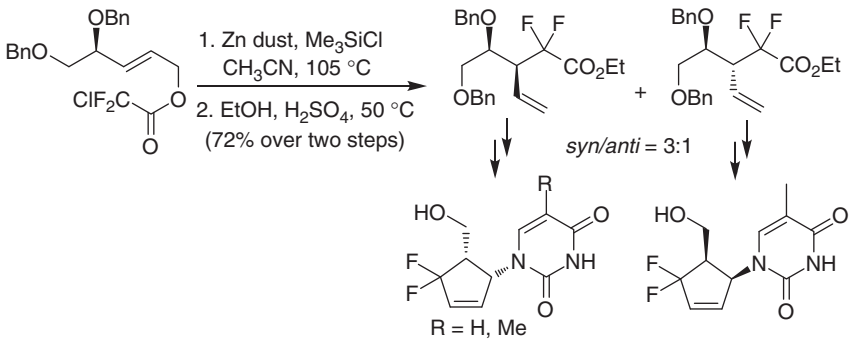
Scheme 157



Scheme 158

Excellent levels of remote stereocontrol have been recently reported in the Ireland rearrangement of a chiral oxazolidine enol ether, which has been described as the key step of the synthesis of the natural immunosuppressant agent mycestericin G (Scheme 159).[311]

The asymmetric version of the decarboxylative Claisen rearrangement has been studied on substrates bearing an *N*-arylsulfonylsulfoximine group as a chiral sulfone surrogate.[312] The reaction proceeds with good yields and diastereoselectivities. This stereochemical outcome has been rationalized by a pseudochair transition-state model for the rearrangement of the intermediate (*Z*)-sulfoximine-substituted silyl ketene acetals. By assuming an antiperiplanar conformation of the $ArSO_2N$ group to the ketene acetal C–C double bond, the favored approach of the allylic fragment – *syn* with respect to the sulfoximine oxygen atom and *anti* to the phenyl group – will account for the configuration of the major isomer obtained in the reaction (Scheme 160).

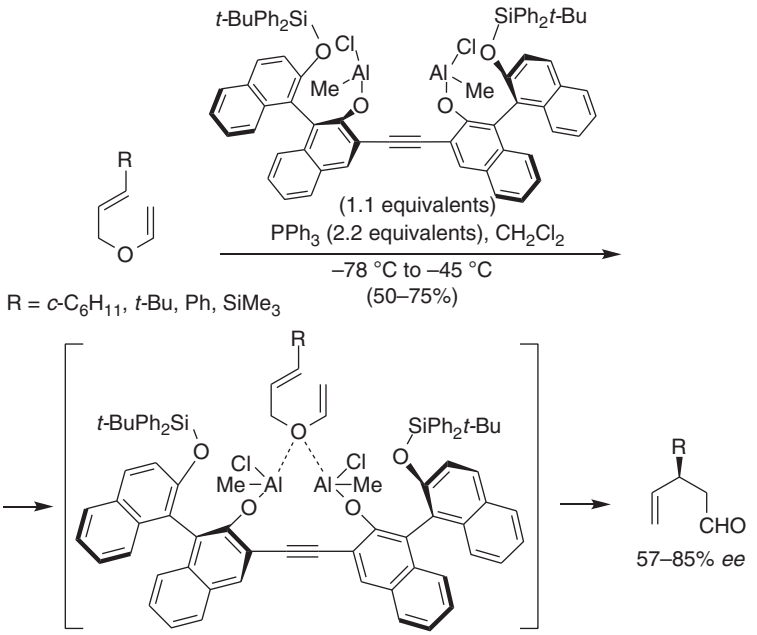


Scheme 159

Scheme 160

The presence of an additional asymmetric center on the allylic fragment also proved effective in the stereocontrol of a silicon-induced Reformatsky rearrangement which gave the key building block for the synthesis of difluoromethylenated nucleosides (Scheme 161).[313]

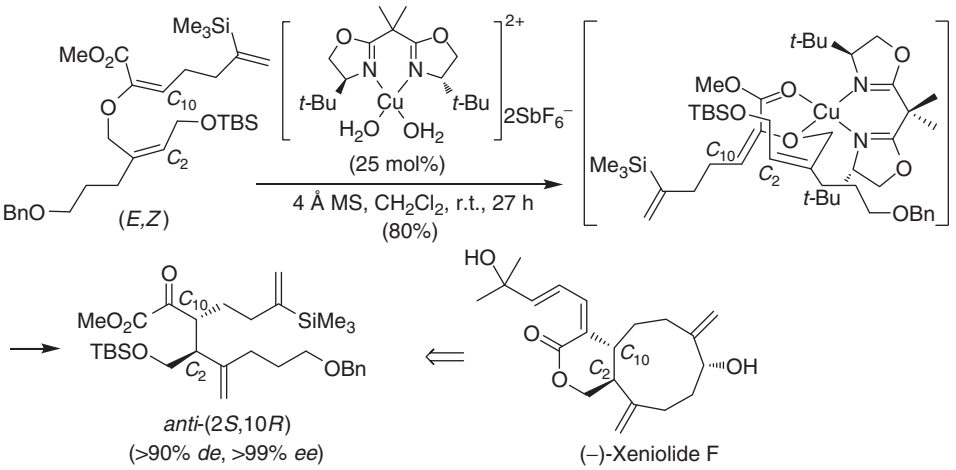
Scheme 161



5.20.4.4 Enantioselective Rearrangements and Asymmetric Catalysis

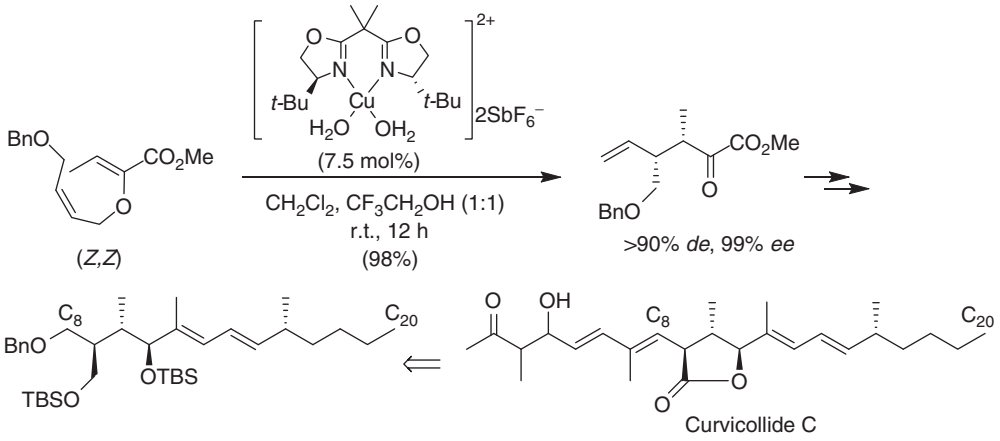
The presence of chiral enantiopure catalysts, cocatalysts, or solvents in the reaction media of the Claisen rearrangement may generate an asymmetric environment in the transition state, which, in turn, will be responsible for the degree of stereoselectivity achieved in the reaction.

5.20.4.4.1 Chiral metal catalysts



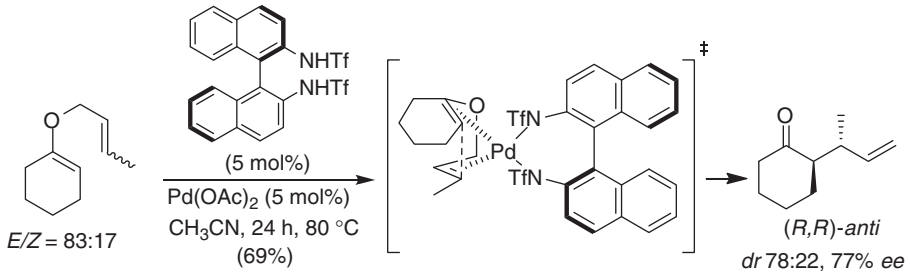
High levels of enantioselectivity in the Claisen rearrangement have been achieved over the past two decades by utilizing Lewis-acid catalysts bearing chiral ligands, which are capable of differentiating the two possible chairlike conformations for the transition state. Bulky chiral organoaluminum reagents have been reported to simultaneously accelerate the rearrangement of differently

substituted allyl vinyl ethers and discriminate the two possible chairlike conformations for the transition state, therefore affording one of the enantiomers preferentially.[314–316] A double coordination of chiral bis(organoaluminum) Lewis acids with the oxygen atom in the allyl vinyl ethers has also been reported to lead to asymmetric induction in the Claisen rearrangement (Scheme 162).[317]



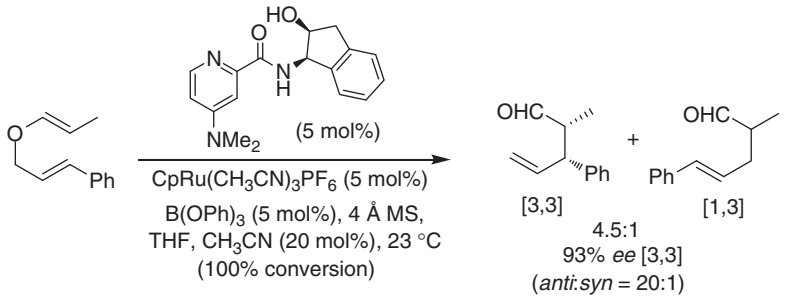
Scheme 162

Chiral bis(oxazoline) copper(II) complexes have been reported as powerful catalysts for the enantioselective aliphatic Claisen rearrangements of a range of 2-alkoxycarbonyl-substituted allyl vinyl ethers.[318] Both [Cu(*tert*-Bu-box)](OTf)$_2$ and [Cu(*tert*-Bu-box)](H$_2$O)$_2$(SbF$_6$)$_2$ catalysts provided excellent enantio- and diastereoselectivities in the rearrangement of the distorted square planar substrate/catalyst complex, proceeding through a chairlike transition state with the allylic ether portion approaching the vinyl ether fragment from the face opposite to the bulky *tert*-butyl substituent on the bisoxazoline ligand. These copper-catalyzed asymmetric Claisen rearrangements have been reported as the key step for the synthesis of some naturally occurring compounds.[319] In the context of the synthesis of the marine xenicane diterpene (–)-xeniolide F, the rearrangement of a highly functionalized (*E,Z*)-α-alkoxycarbonyl-substituted allyl vinyl ether in the presence of substoichiometric amounts of chiral [Cu{(*S,S*)-*tert*-Bu-box}](H$_2$O)$_2$(SbF$_6$)$_2$ proceeded with excellent *anti* diastereoselectivity, affording the desired enantiomerically pure key synthetic intermediate (Scheme 163).[319a]



Scheme 163

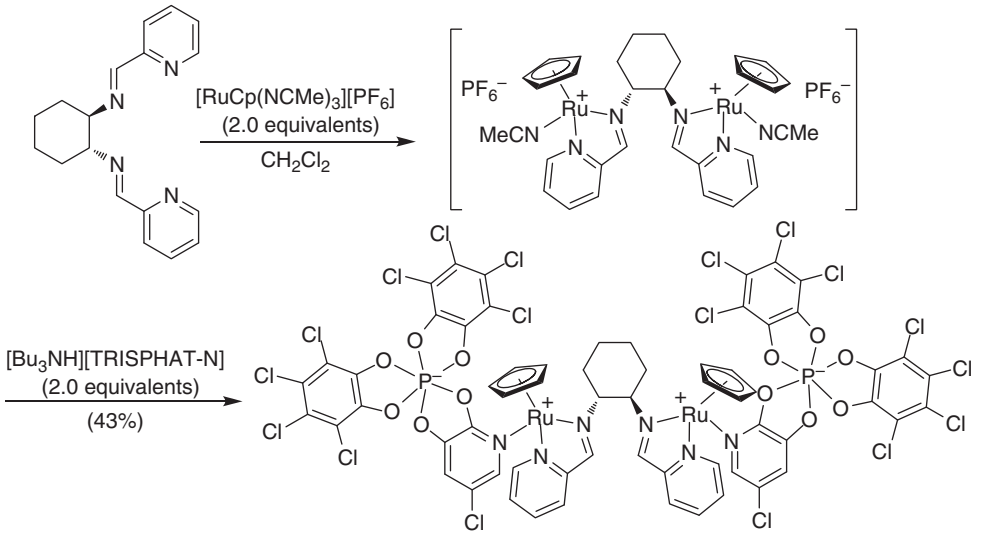
This strategy has also been described as a valuable tool for the enantio- and diastereoselective C-C bond construction in the key step of the synthesis of the C8–C20 fragment of antifungal polyketide curvicollide C (Scheme 164).[319]



Scheme 164

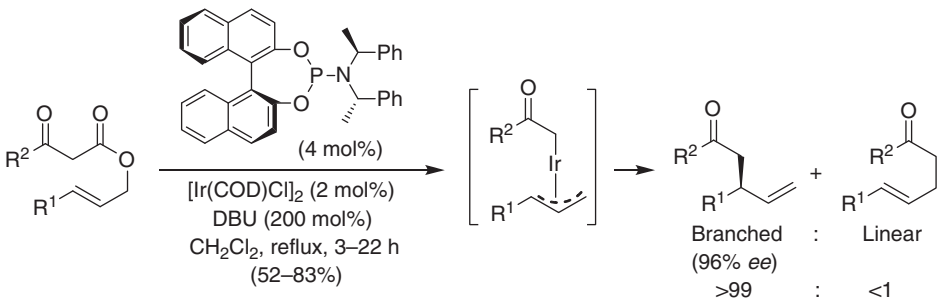
Chiral palladium complexes have also been used as catalysts for the enantioselective Claisen rearrangement. The Claisen rearrangement of cyclic (*E*)-allyl vinyl ethers proceeded in moderate yields with good *anti*/*syn* selectivities and enantioselectivities in the presence of catalytic amounts of the [(*R*)-diamino-binaphthyl trifluoromethanesulfonylamide]-palladium complex [(*R*)-DABNTf], as a result of the preferred rearrangement of the major (*E*)-allyl vinyl ether via a chiral bidentate boatlike transition state [the minor (*Z*)-substrate proved unreactive under the catalytic conditions] (Scheme 165).[320]

Scheme 165



A cooperative catalytic system consisting of a chiral ruthenium(II) complex (readily obtained by reacting $[CpRu(CH_3CN)_3]PF_6$ with a chiral ligand) and the Lewis acid cocatalyst $B(OPh)_3$ provided high enantio- and diastereoselectivities in the Claisen rearrangements of 1,6-disubstituted allyl vinyl ethers, although the efficiency of the reaction was limited to C6-aryl-substituted substrates (Scheme 166).[321] The minor competing [1,3]-rearrangement regioisomer was detected under all the assayed conditions, which may be indicative of a mechanism initiated by C–O bond cleavage.

Scheme 166

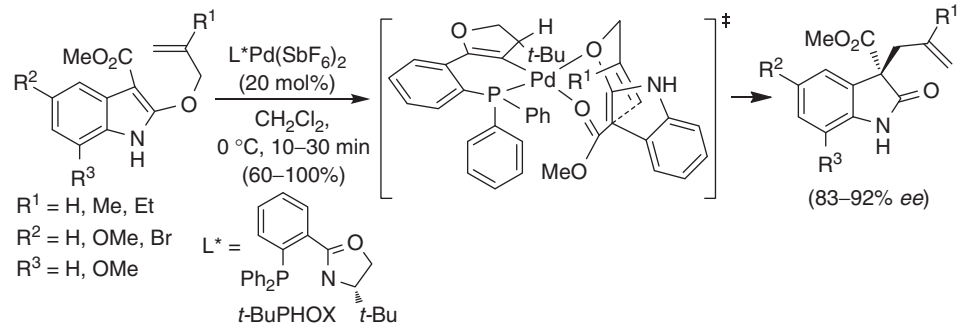


In the past years, a number of highly asymmetric Carroll rearrangements have been reported in the presence of chiral metal complexes as efficient catalysts capable of inducing high levels of stereoselectivity. The chiral palladium catalyst generated *in situ* from $Pd_2(dba)_3 \cdot CHCl_3$ and the optically active Trost bisphosphine ligand produced a high degree of asymmetric induction in the Carroll rearrangement of allyl α-acetamido-β-ketocarboxylates, giving optically active γ,δ-unsaturated α-amino ketones.[322] However, it has been the use of chiral ruthenium catalysts, which has been most widely investigated for achieving enantioselective versions of the Carroll rearrangement. The combined use of CpRu half-sandwich complexes – $[CpRu(NCCH_3)_3][PF_6]$ or $[CpRu(\eta^6\text{-naphthalene})][PF_6]$ – and enantiopure pyridine imine ligands provided high levels of regio- and enantioselectivities.[323]

A dinuclear zwitterionic complex, where the catalytically active chiral metallic species is stabilized by a hexacoordinated phosphorus anion (TRISPHAT-N), has proved highly efficient as a catalyst in the asymmetric Carroll rearrangement of a variety of allyl β-keto esters providing high levels of enantioselectivity (85% *ee*) (Scheme 167).[324]

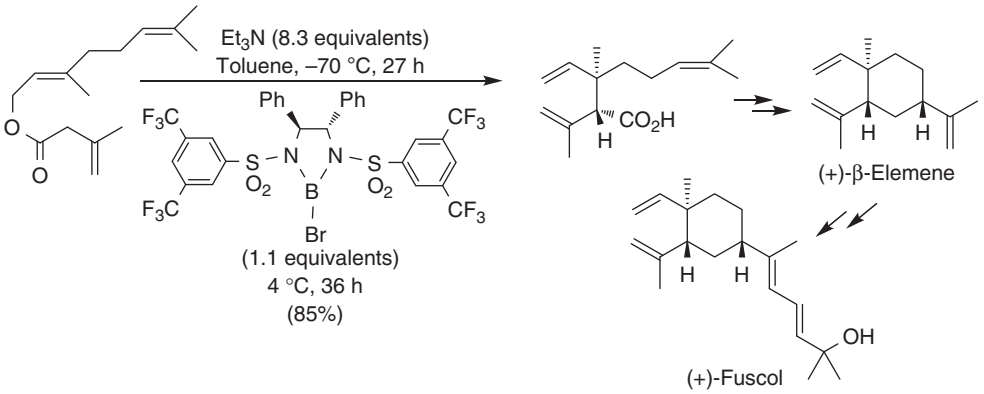
Scheme 167

The catalytic system comprising $[Ir(COD)Cl]_2$ and a phosphoramidite ligand has also provided high regio- and enantioselectivities in the transformation of γ-substituted allyl β-ketocarboxylates into branched γ,δ-unsaturated ketones. Although the reaction is a formal Carroll rearrangement, the proposed mechanism involves C–O bond scission and further enolate–allyl recombination (Scheme 168).[325]



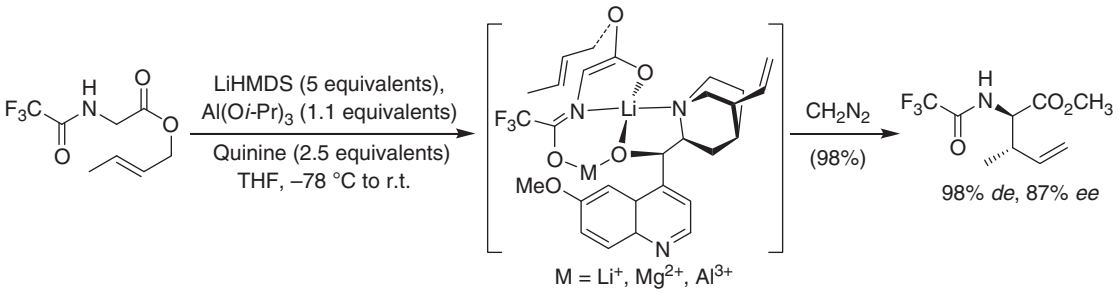
R^1 = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 3-$MeOC_6H_4$, 4-$CF_3C_6H_4$, 4-FC_6H_4, 2-furyl, Me, *n*-C_5H_{11}
R^2 = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 2-Naphthyl

Scheme 168



A catalytic enantioselective Eschenmoser rearrangement of aromatic substrates in the presence of the chiral *t*-BuPHOX palladium complex afforded a range of enantiomerically enriched allyl oxindoles bearing a quaternary stereocenter.[326] A two-point coordination of the substrate to the Lewis acidic palladium complex provided a rigid chiral environment to the favored chairlike transition state (Scheme 169).

This catalytic enantioselective methodology utilizing alkynyl substrates has been recently applied to the asymmetric synthesis of allenyl oxindoles bearing a quaternary stereocenter.[327]

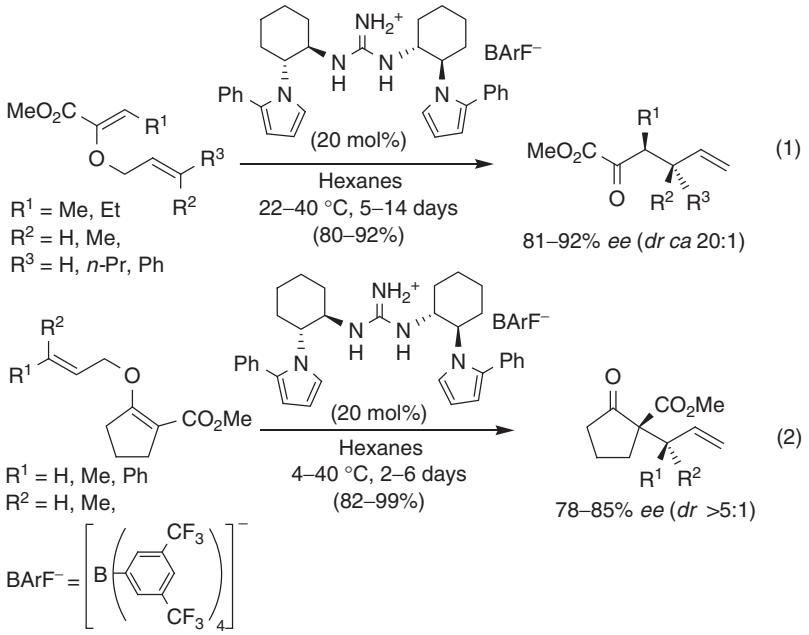


Scheme 169

A chiral boron Lewis acid has allowed for a highly enantioselective Ireland rearrangement of an achiral allylic ester. This reaction has been described as the key step in the asymmetric synthesis of the anti-inflammatory agent precursor (+)-fuscol, via the intermediate terpenoid (+)-β-elemene (Scheme 170).[328]

Scheme 170

The incorporation of chiral ligands [(–)-phenylglycinol, (–)-valinol, (–)-pseudoephedrine, (–)-ephedrine, cinchona alkaloids] to the coordination sphere of the chelating metal [$ZnCl_2$, $EtAlCl_2$, BCl_3, $CaCl_2$, $MgCl_2$, $Mg(OEt)_2$] in the bidentate enolate complex, which acts as the substrate for the chelate Claisen rearrangement, has also been developed as a useful strategy for asymmetric induction.[329] In this sense, the combined use of cinchona alkaloids (quinine or quinidine) and $Al(OiPr)_3$ afforded diastereo- and enantiomerically enriched amino acids in high yields.[330] This methodology has provided ready access to sterically congested amino acids with a β-quaternary center in a highly diastereo- and enantioselective manner.[331] When allylic amino esters bearing an *N*-protecting trifluoroacetyl group were treated with LiHMDS as the base, $Al(OiPr)_3$ [or $Mg(OEt)_2$] as the chelating salt, and quinine (or quinidine) as the chiral ligand, a rigid chiral bimetallic complex was formed by coordination of the bidentate ligand quinine to the lithium enolate and further stabilization of this complex by incorporation of a second metal ion (Li^+, Al^{3+}, or Mg^{2+}). This rigid chiral environment in the transition state accounts for the high enantioselectivity of the rearrangement (Scheme 171).[330]



Scheme 171

5.20.4.4.2 Chiral organocatalysts

Very few examples of the use of chiral organocatalysts in asymmetric Claisen rearrangements have been reported to date.

C_2-Symmetric guanidinium ions derived from *trans*-1-pyrrolo-2-aminocyclohexane are effective chiral organocatalysts for the enantioselective rearrangement of 2-alkoxycarbonyl-substituted alicyclic allyl vinyl ethers derived from α-ketoesters (Scheme 172, equation 1).[89] These catalytic conditions have provided ready access to molecules containing tertiary and quaternary stereocenters with high enantio- and diastereoselectivities. However, no enantioselectivity was induced in the rearrangement of nonsubstituted allyl vinyl ethers. Similarly, the rearrangement of cyclic *O*-allyl β-ketoesters in the presence of the above chiral guanidinium catalyst also provided the rearranged products with high levels of enantioselectivity (Scheme 172, equation 2).[332]

Scheme 172

Experimental observations and computational models have predicted a double hydrogen-bonding interaction of the guanidinium catalyst with the allyl vinyl ether substrate with both the ether oxygen atom and the ester group. This hydrogen-bond interaction stabilizes the developing negative charge in the transition state. An additional secondary interaction between the π-system of the catalyst's phenyl substituent and the allylic fragment of the substrate will contribute to stabilize the favored six-membered chairlike transition state and will hence determine the excellent stereocontrol of the rearrangement (Figure 1).[333]

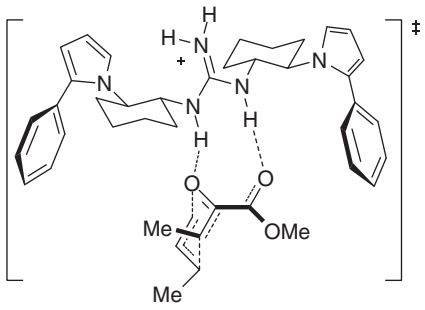


Figure 1 Favored transition state for the organocatalyzed rearrangement. Reproduced from Uyeda, C.; Jacobsen, E. N. *J. Am. Chem. Soc.* **2011**, *133*, 5062.

5.20.5 Conclusions and Outlook

Twenty years after the publication of the first *Comprehensive Organic Synthesis* chapter on the Claisen rearrangement, this reaction remains an excellent tool for the synthesis of complex molecules. Crucial to its continued importance are the advances made in

the synthesis of the starting materials required for the rearrangement. Metal-catalyzed coupling reactions and metal-promoted double bond isomerizations now allow easier access to allyl vinyl ethers. Additionally, new conditions have been found for the synthesis of silyl ketene acetals with unprecedented *E*/*Z* selectivities. However, the most significant advances have undoubtedly been made in the field of asymmetric catalysis, although some limitations do still exist. In particular, most of the examples described to date require the presence of a group able to coordinate to a metal or an organocatalyst. This is probably the aspect of the Claisen rearrangement that offers the most room for new discoveries in the coming years.

Glossary

***A* value** Utilized in conformational analysis, it is the difference in free energy (ΔG) between conformations having an axial substitution (high energy) and an equatorial substitution the lower energy conformation (low energy) for the same functional group.

Domino reaction A domino process involves two or more reactions occurring in succession without the addition of new reagents or modification of the conditions, whereby the intermediates are not isolated.

Interdependent rearrangement An interdependent rearrangement involves a reciprocal relationship between the intermediates formed during the reaction.

Sigmatropic rearrangement A sigmatropic rearrangement is a pericyclic reaction wherein an allylic σ-bond migrates along a π-system to form a new σ-bond.

5.21.1 Introduction

Architecturally complex natural products have been a source of inspiration for synthetic organic chemists for over 100 years. Although many methods to generate new C–C, C–O, C–N, etc., bonds have been established, the rapid assembly of complex organic structures remains a significant challenge. Sigmatropic rearrangements are important tools in this regard and, when combined in consecutive operations, the resulting processes are powerful synthetic transformations.

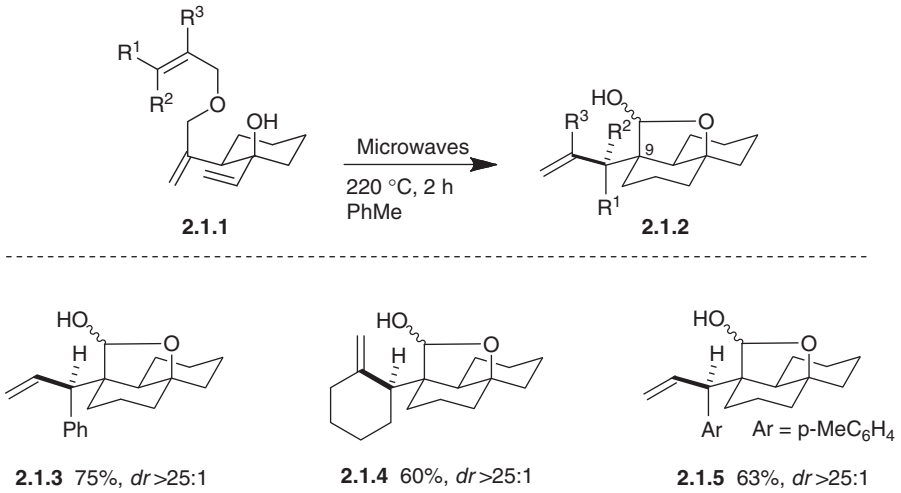
A sigmatropic rearrangement is a pericyclic reaction wherein an allylic σ-bond migrates along a π-system to form a new σ-bond. These concerted reactions proceed through well-ordered transition states, hence the stereochemical outcome of a sigmatropic rearrangement is usually predicted with ease. This predictable stereoselectivity, coupled with the fact that at least one π-bond relocates during each event, means that the sequencing of sigmatropic reactions into consecutive rearrangements is an attractive synthetic strategy. The conspicuous advantages of such sequences relate to their ability to rapidly elaborate complex frameworks bearing many new stereogenic centers. Evidently, sequences of sigmatropic rearrangements lead to more efficient syntheses and can be considered as a component of more sustainable synthetic chemistry practices.[1]

Consecutive sigmatropic rearrangements involve two or more discrete events that follow one another in a synthetic sequence. These two events can either be dependent on, or independent of, one another. For example, a so-called 'aromatic *para*-Claisen rearrangement' involves two [3,3]-sigmatropic rearrangements, an initial Claisen rearrangement followed by a Cope rearrangement. The Claisen rearrangement necessarily must occur first, so that the required functionality is set up for the Cope rearrangement. This is not the case, however, for the two sigmatropic shifts involved in the double 'aromatic *ortho*-Claisen rearrangement' of the diallyl ether of catechol to form 2,5-diallyl catechol.

A further distinction is possible within the subclass of processes involving two or more interdependent sigmatropic rearrangements. In one scenario, the two processes occur in a true 'domino' sense, whereby the intermediate(s) cannot be isolated and only the starting material and final product of the consecutive sigmatropic rearrangement sequence can be detected. On the other end of the spectrum, each discrete step of the consecutive sigmatropic rearrangement sequence can be conducted separately and isolation of the intermediate(s) is possible. These factors are determined by the relative rates of the contributing rearrangements, of course. Although there are practical implications stemming from these issues; as far as the present chapter is concerned, the

 doi:10.1016/B978-0-08-097742-3.00522-X

authors have elected to include examples from all conceivable permutations. They note that there is still controversy over the use of terms such as cascade, domino, consecutive, sequential, one pot, etc., and have attempted to use terminology consistently throughout this chapter and they hope that there will be no confusion over their intended meaning.



Finally, this chapter focuses on transformations published since the first edition of Comprehensive Organic Synthesis (i.e., since 1991). The authors have subclassified the content of this chapter according to the type of sigmatropic rearrangements involved. As might be expected, sequences involving [3,3]-sigmatropic shifts are in the majority.

5.21.2 [3,3]-[3,3] Rearrangement

5.21.2.1 Interdependent Sequences

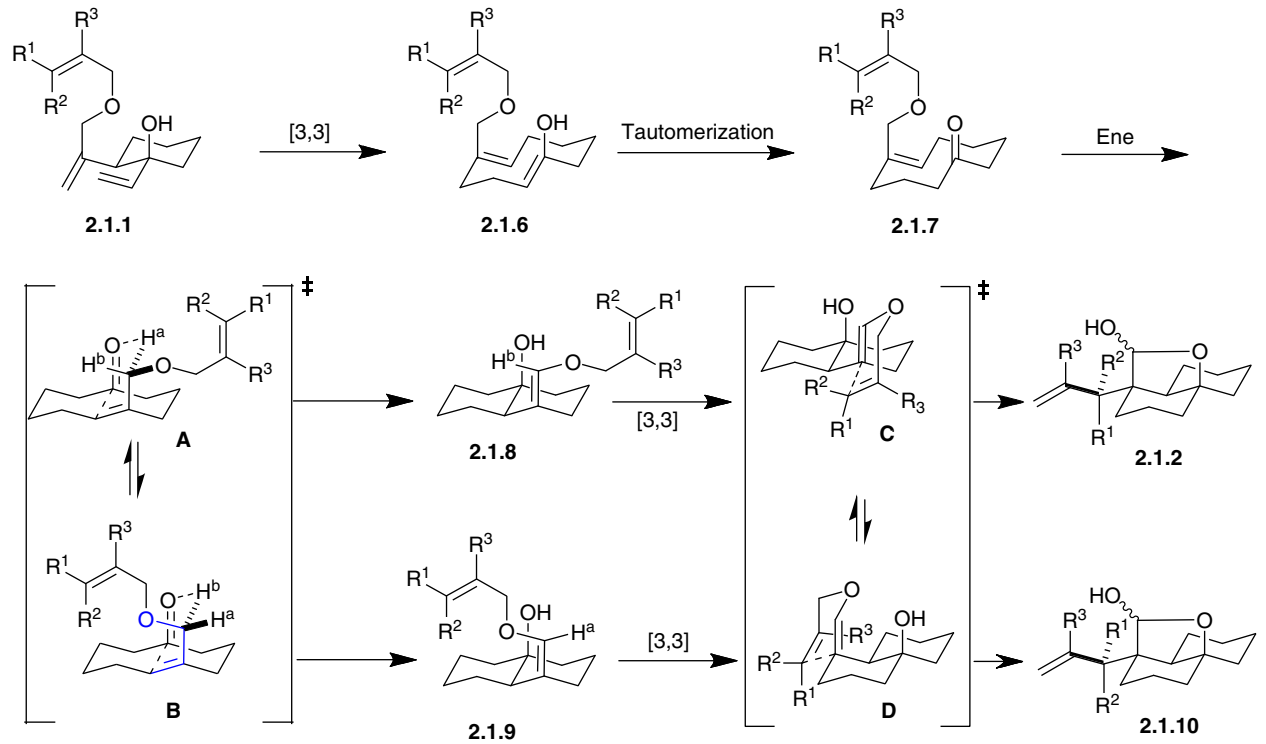
5.21.2.1.1 Cope–ene–Claisen

The stereocontrolled synthesis of quaternary carbon centers is a challenge often encountered in diterpene synthesis. Although there exists a broad range of methods capable of generating new carbon–carbon bonds, the formation of quaternary centers is among the most restrictive in organic chemistry.[2] Barriault and Denissova described a domino oxy-Cope–ene–Claisen reaction of allyl ether **2.2.1** to generate decalin frameworks **2.1.2** possessing at least three contiguous stereocenters (Scheme 1).[3] Depending on the pattern of substitution on the terminal allyl ether (i.e., R^1 and R^2) in precursor **2.1.1**, a tertiary or quaternary stereocenter was incorporated adjacent to C9. The broad scope and high diastereoselectivity of this approach are exemplified by the generation of decalins **2.1.3**–**2.1.5**.

2.1.1 **2.1.2**

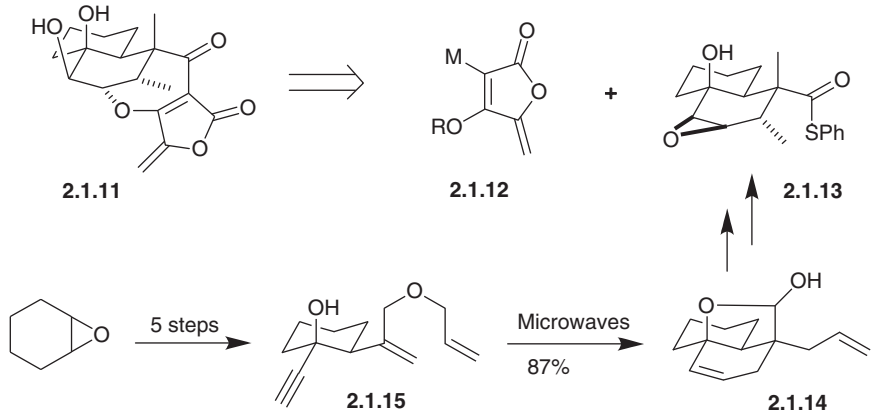
2.1.3 75%, *dr* >25:1 **2.1.4** 60%, *dr* >25:1 **2.1.5** 63%, *dr* >25:1

Scheme 1



The mechanism and the high diastereoselectivity of the reaction can be rationalized as follows (Scheme 2). Microwave heating of 1,2-divinylcyclohexanol allyl ether **2.1.1** is proposed to give enol **2.1.6**, which after a rapid tautomerization would furnish ketone **2.1.7**. There are two possible transition states (**A** or **B**) for the subsequent transannular ene reaction of ketone **2.1.7**. A close examination of transition state **B**, however, reveals the presence of severe 1,3-allylic strain between the allyl ether group and the macrocyclic ring (in blue). As a result, enol ether **2.1.9** is disfavored relative to geometrical isomer **2.1.8**. Finally, a Claisen rearrangement of **2.1.8** via transition state **C** furnishes a hydroxyaldehyde, which then cyclizes to form lactol **2.1.2** as the major isomer. The minor isomer lactol **2.1.10** is formed via transition state **D**.

This domino oxy-Cope–ene–Claisen sequence has been employed to prepare an advanced intermediate en route to the natural antibiotic tetradecamycin (**2.1.11**) (Scheme 3).[4] Thus, Barriault and Warrington reported the conversion of propargyl alcohol **2.1.15** to decalin **2.1.14** in 87% yield. The latter was transformed into the advanced intermediate **2.1.13** through a short sequence.

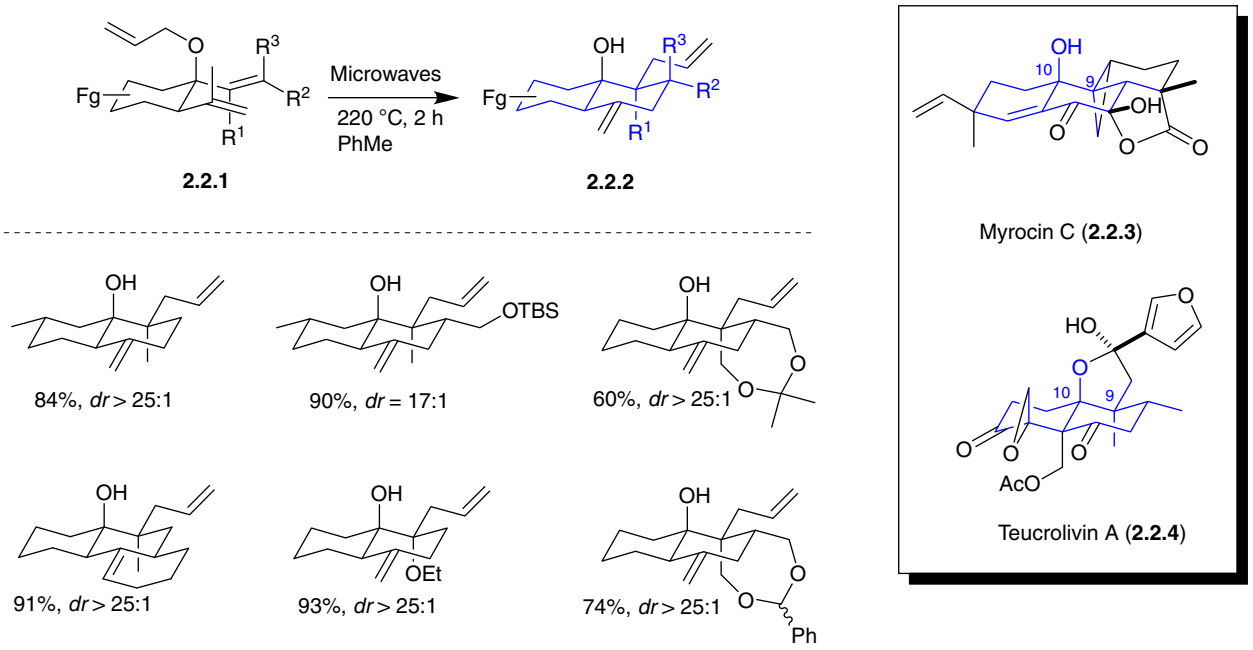


5.21.2.1.2 Cope–Claisen–ene

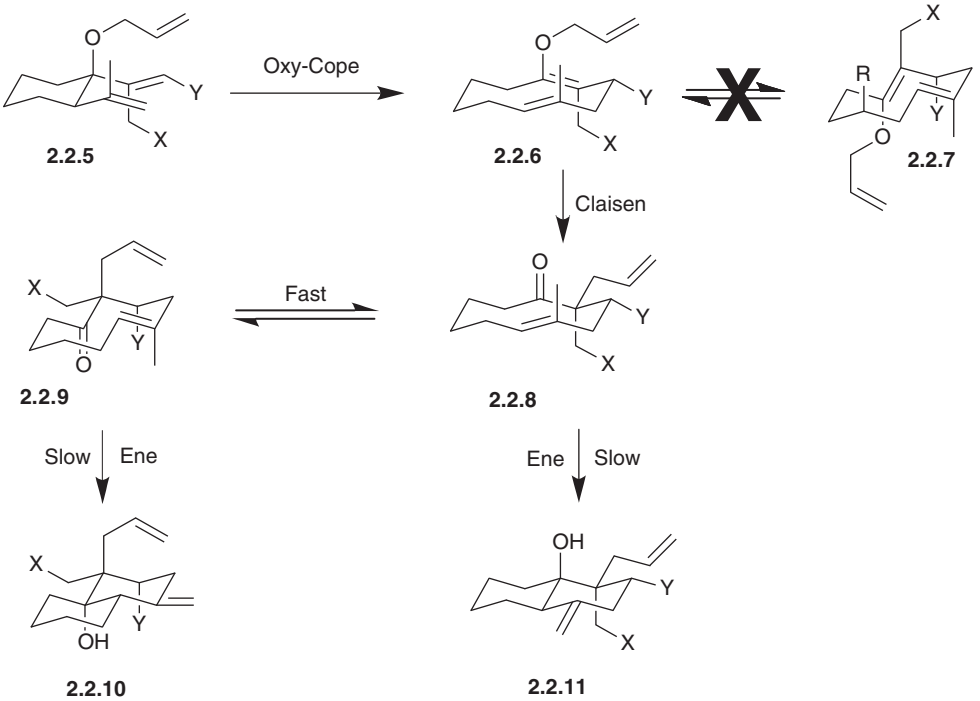
The stereocontrolled formation of two or more contiguous quaternary stereocenters is a significant challenge, particularly in cyclic systems. Barriault and Sauer developed a domino oxy-Cope–Claisen–ene sequence of allyl ethers **2.2.1** to produce decalins **2.2.2** possessing quaternary stereocenters at C9 and C10 in high yield and diastereoselectivity. This type of scaffold is embedded in several natural diterpenes including myrocin C (**2.2.3**) and teucrolivin A (**2.2.4**) (Scheme 4).[5]

On microwave irradiation, it is proposed that allyl ether **2.2.5** is converted to enol ether **2.2.6** via an oxy-Cope reaction (Scheme 5). The latter is positioned to undergo a Claisen rearrangement providing ketone **2.2.8**. This can be directly converted into **2.2.11** or undergo a rapid conformational interchange to produce **2.2.9**, which leads to the formation of **2.2.10**. It is

Scheme 2



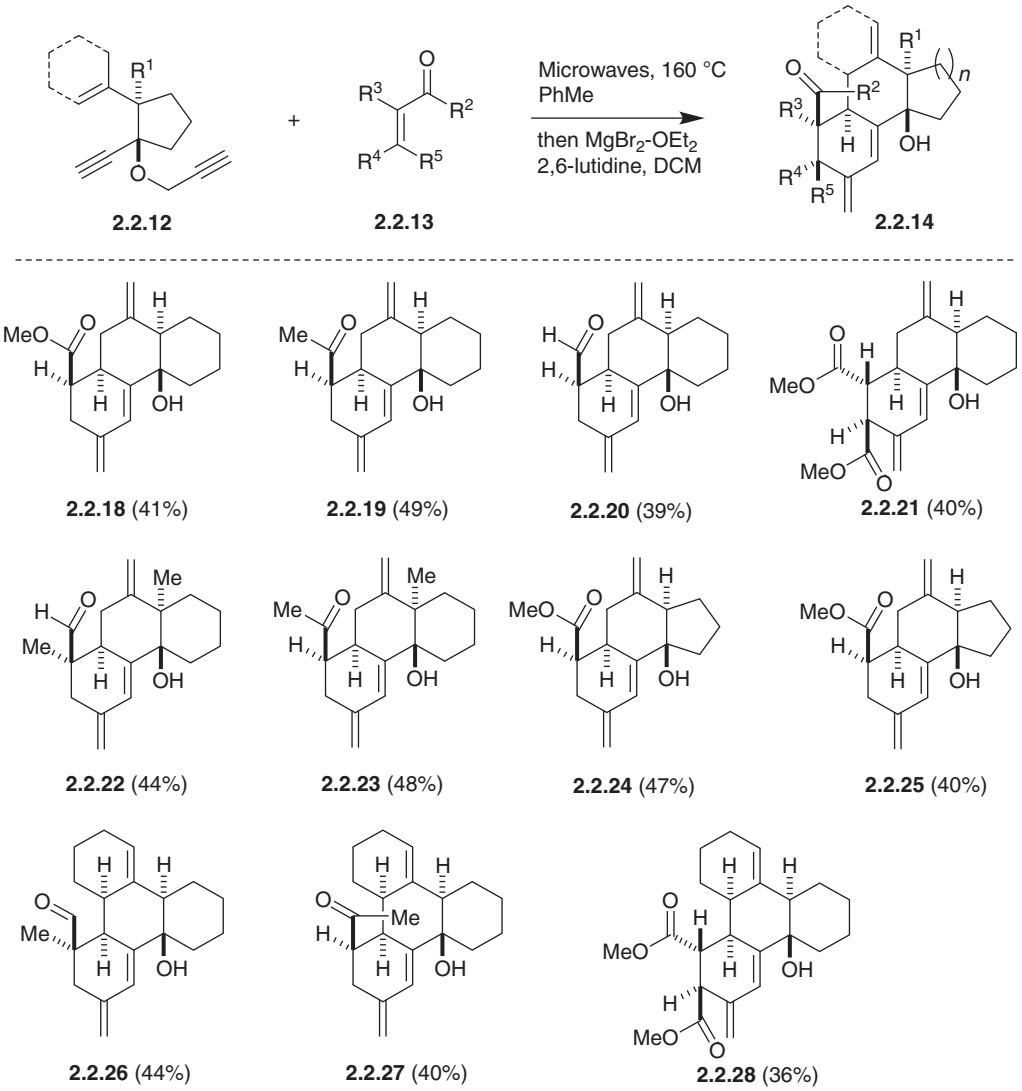
Scheme 3



important to note that the conformational preference of macrocycles **2.2.6**, **2.2.8** and **2.2.9** dictates the stereochemical outcome of the final product.[6]

Experimental evidence and DFT calculations demonstrated that the ring inversion of **2.2.6**–**2.2.7** does not occur at 220 °C. It would appear that the 'through-the-annulus' rotation of either substituent of the tetrasubstituted alkene has a prohibitively high-energy barrier,[7] with the Claisen rearrangement of **2.2.6**–**2.2.8** being a much faster process. Conversely, the ring inversion of ketone **2.2.8**–**2.2.9** is a faster process than the ene reaction. As a result, the diastereoselectivity can be rationalized using the Curtin–Hammett principle.[8]

In 2008, Barriault and coworkers reported a stereoselective synthesis of complex carbocycles **2.2.14** from five- and six-membered ring propargyl ethers **2.2.12** and dienophiles **2.2.13** via four successive pericyclic reactions (Scheme 6).[9] This transformation combined a domino oxy-Cope–Claisen reaction and a subsequent hydroxyl-directed Diels–Alder reaction. In all cases, only one diastereoisomer was observed ($dr > 25{:}1$) in yields ranging from 36% to 49%. The attractive feature of the proposed process resides in the ability to generate, in one pot, four new C–C bonds and as many as four new contiguous stereogenic centers (**2.2.28**) leading to complex carbocyclic frameworks (**2.2.18**–**2.2.28**).



Scheme 4

Scheme 5

Microwave irradiation of **2.2.12** triggered the oxy-Cope reaction to produce allene **2.2.15** (Scheme 7). This highly strained macrocycle rearranges to generate enone **2.2.16** which undergoes a transannular ene reaction to deliver allene **2.2.17**. The latter was subsequently treated with a magnesium-based Lewis acid and a dienophile (**2.2.13**). The resulting hydroxyl-directed Diels–Alder reaction gives a single cycloadduct **2.2.14** in overall yields ranging from 36% to 48%. Transition state **TS-A** was proposed to account for the observed diastereoselectivity.

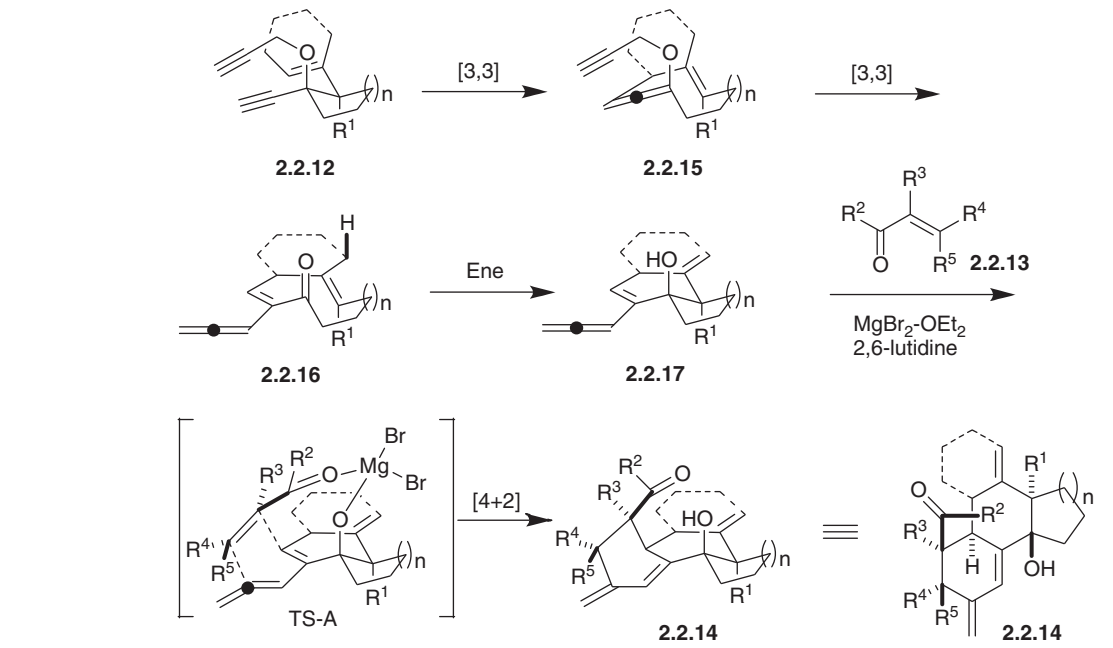
2.2.12 **2.2.13** **2.2.14**

2.2.18 (41%) **2.2.19** (49%) **2.2.20** (39%) **2.2.21** (40%)

2.2.22 (44%) **2.2.23** (48%) **2.2.24** (47%) **2.2.25** (40%)

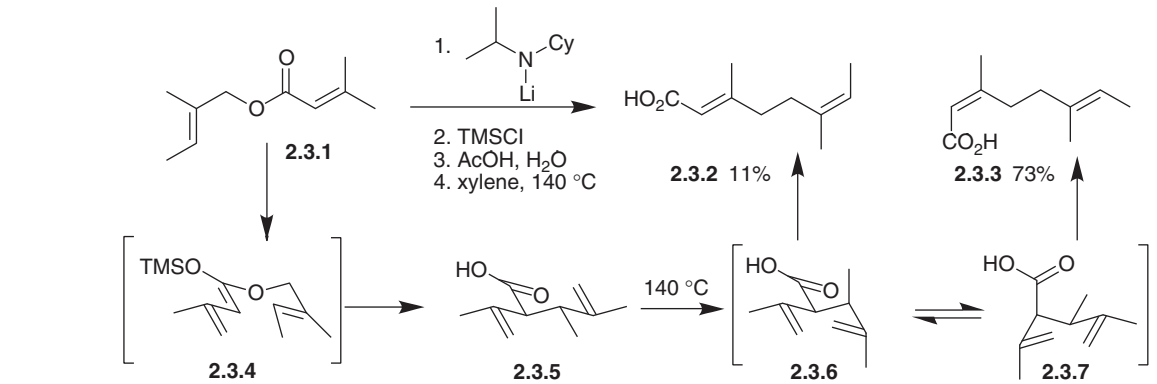
2.2.26 (44%) **2.2.27** (40%) **2.2.28** (36%)

Scheme 6



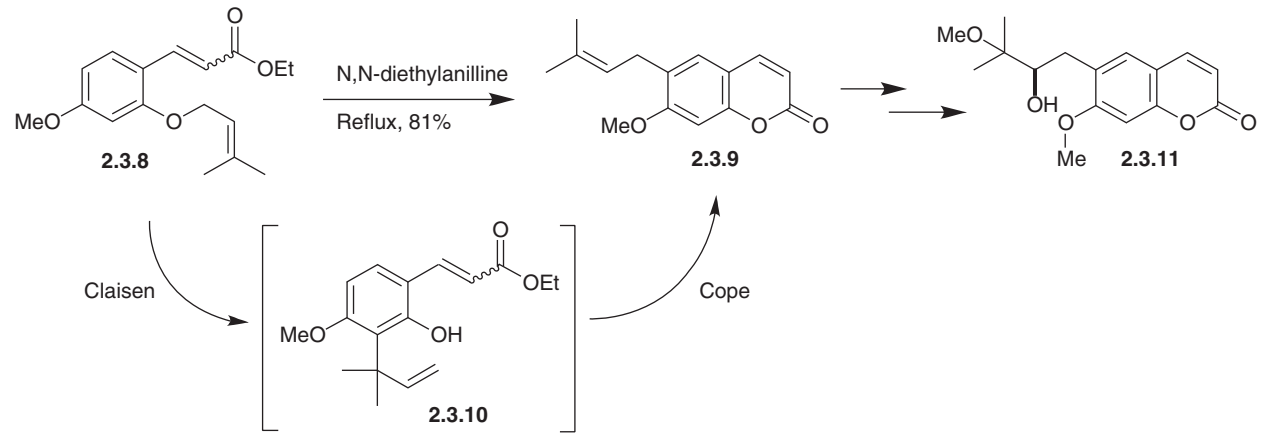
5.21.2.1.3 Claisen–Cope

Kraft et al. synthesized constitutional isomers of nerol by consecutive Ireland–Claisen and Cope rearrangements.[10] Thus, treatment of ester **2.3.1** with lithium cyclohexylisopropylamide (LICA) and trimethylsilyl chloride (TMSCl) in THF at −78 °C produced the silyl enol acetal **2.3.4** stereoselectively. This *Z*-configured alkene participated in an Ireland–Claisen rearrangement via a chair-like transition state to produce, after an aqueous work-up, carboxylic acid **2.3.5** as the sole isomer. On heating to 140 °C for 3 days, 1,5-diene **2.3.5** was converted into a 1:7 ratio of **2.3.2** and **2.3.3** in 84% yield. Acid **2.3.5** can undergo the Cope rearrangement via two chair-like transition states **2.3.6** and **2.3.7**. Because the *A* value of a methyl group is slightly larger than that of a carboxylic acid group, conformation **2.3.7** should be favored over **2.3.6**, thereby producing **2.3.3** as the major isomer (Scheme 8).



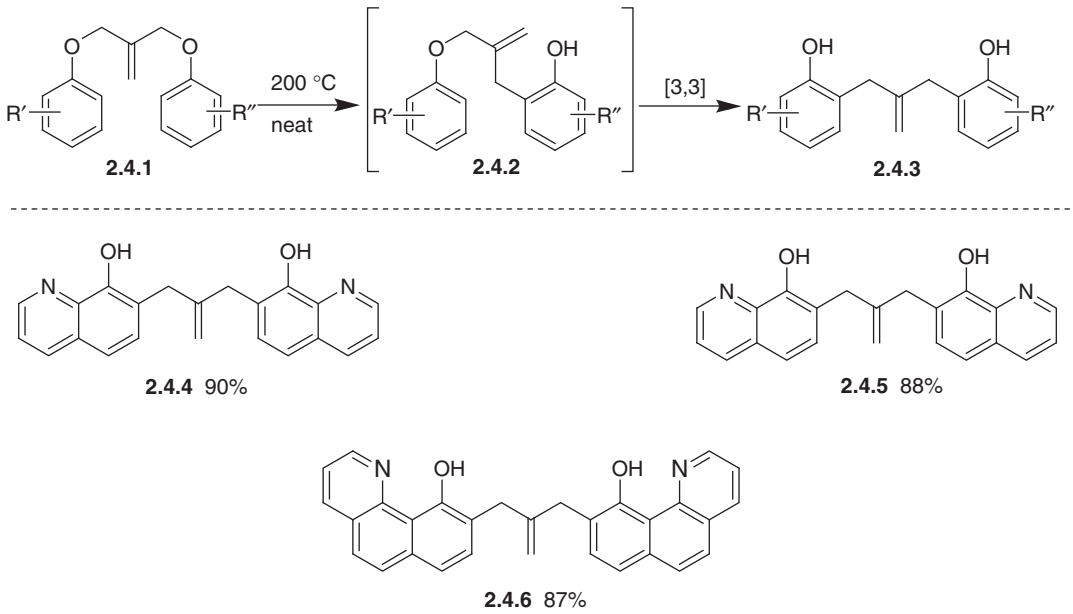
Natural coumarins such as (+)-trachypleuranin A (**2.3.11**) isolated from *Harboria trachypleura* were synthesized using an aromatic *para*-Claisen rearrangement (Scheme 9). Thus, domino Claisen–Cope rearrangements of phenyl prenyl ether **2.3.8** and intramolecular transesterification occurred in refluxing diethylaniline to give advanced intermediate **2.3.9** in 81% yield.[11] Natural products such as **2.3.11** have been shown to potentiate the action of anthraquinones as multidrug resistance efflux pump inhibitors.

5.21.2.1.4 Claisen–Claisen

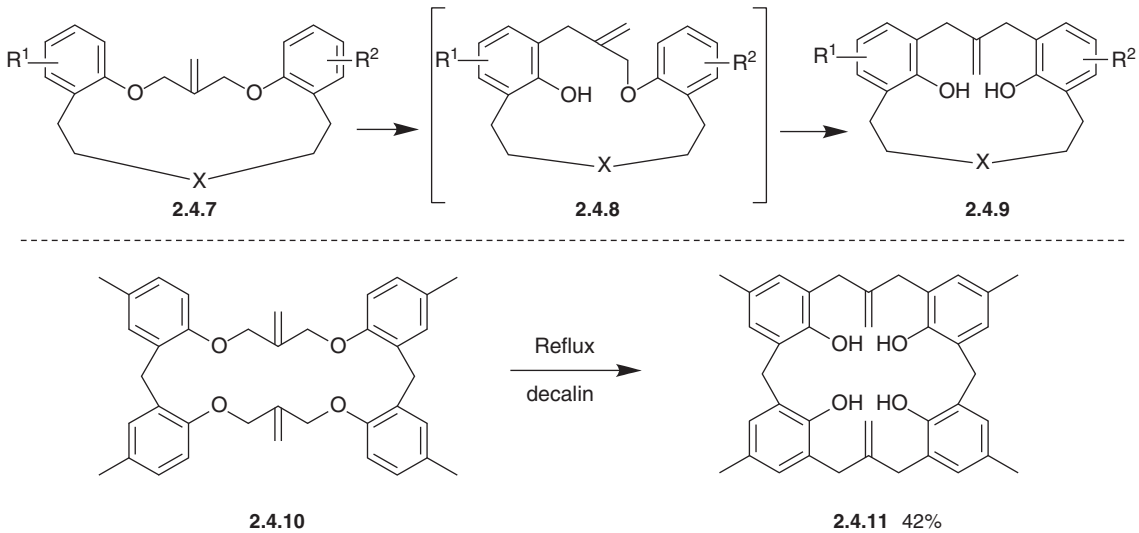


The examples described so far involve sequences of different sigmatropic rearrangements to construct new carbon–carbon bonds. In this section, the authors focus on the sequences involving only Claisen rearrangements. Seminal work from Hiratani reported the use of domino aryl Claisen rearrangements for the synthesis of ligands, sensors, and supramolecular building blocks (Scheme 10).[12] Thus, under thermal conditions, readily prepared di-ethers **2.4.1** are converted to monoether/monophenols **2.4.2**,

Scheme 7

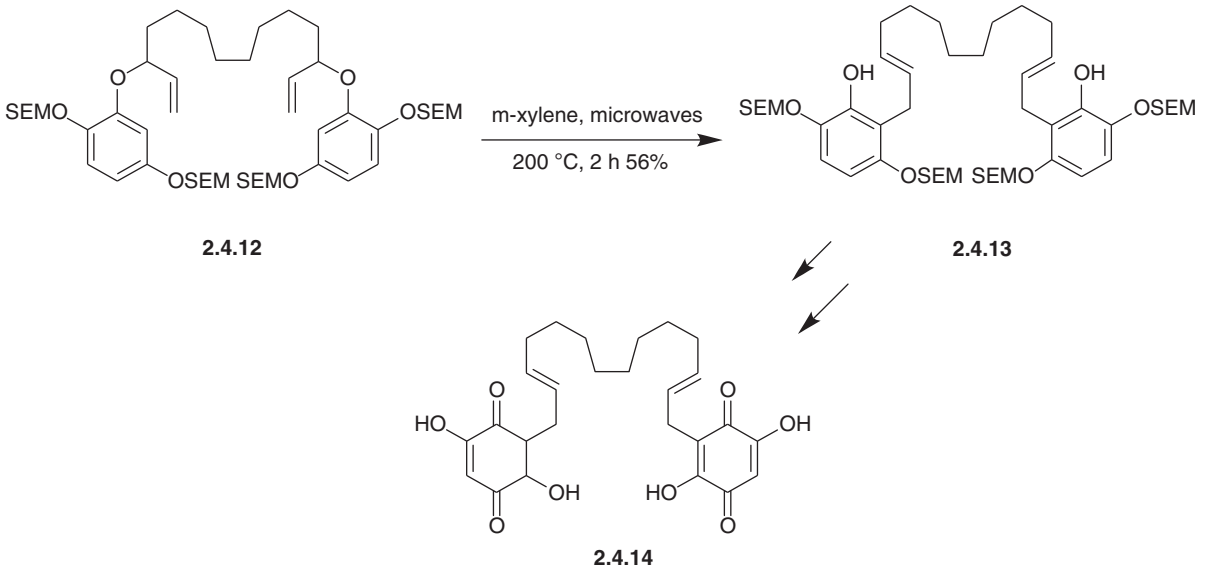


Scheme 8



Scheme 9

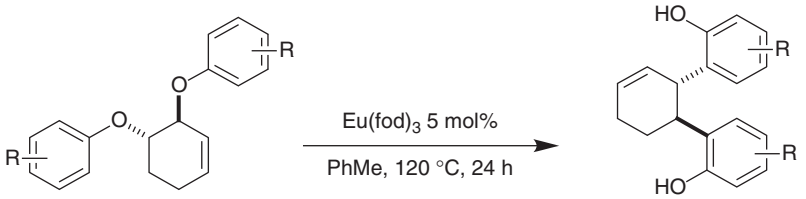
which further rearrange to di-phenols **2.4.3**. Quinolone-containing ligands **2.4.4**–**2.4.6** were prepared in high yield using this approach.



Scheme 10

Incorporation of a tether connection between the *ortho*-positions of the two aromatic rings allowed the sequence to be carried out within a macrocyclic context (i.e., **2.4.7**→**2.4.8**→**2.4.9**). In an extension of this work, macrocycle **2.4.10**, containing two diaryl methane units, was converted to calixarene **2.4.11** in 42% yield via a sequence of four consecutive Claisen rearrangements (Scheme 11).[13] This is a unique approach to compounds that are useful in host–guest chemistry.

Scheme 11



In a related example, Moody utilized a double Claisen rearrangement of a substrate containing two separate aromatic allyl ethers **2.4.12**, connected through a octamethylene chain (Scheme 12).[14] The product di-phenol **2.4.13** was converted to the proposed structure of lanciaquinone **2.4.14**. In some respects, this synthesis is reminiscent of Johnson's classic two-directional synthesis of squalene from 1970, which involves orthoester Johnson–Claisen rearrangements at the two ends of a growing acyclic chain.[15]

2.4.12 **2.4.13** **2.4.14**

Scheme 12

Batey has introduced a different twist on the twofold aromatic *ortho*-Claisen rearrangement theme. Thus, the rearrangement of the allyl aryl ether group of diaryloxy-cyclohexenes **2.4.15** (Scheme 13) sets up a new allyl aryl ether, which allows the second Claisen rearrangement.[16] The conversion of **2.4.15** to **2.4.16** proceeds with the replacement of two C–O bonds with two C–C bonds and is accompanied by smooth transfer of stereochemistry.

up to 93%
and 99% *ee*

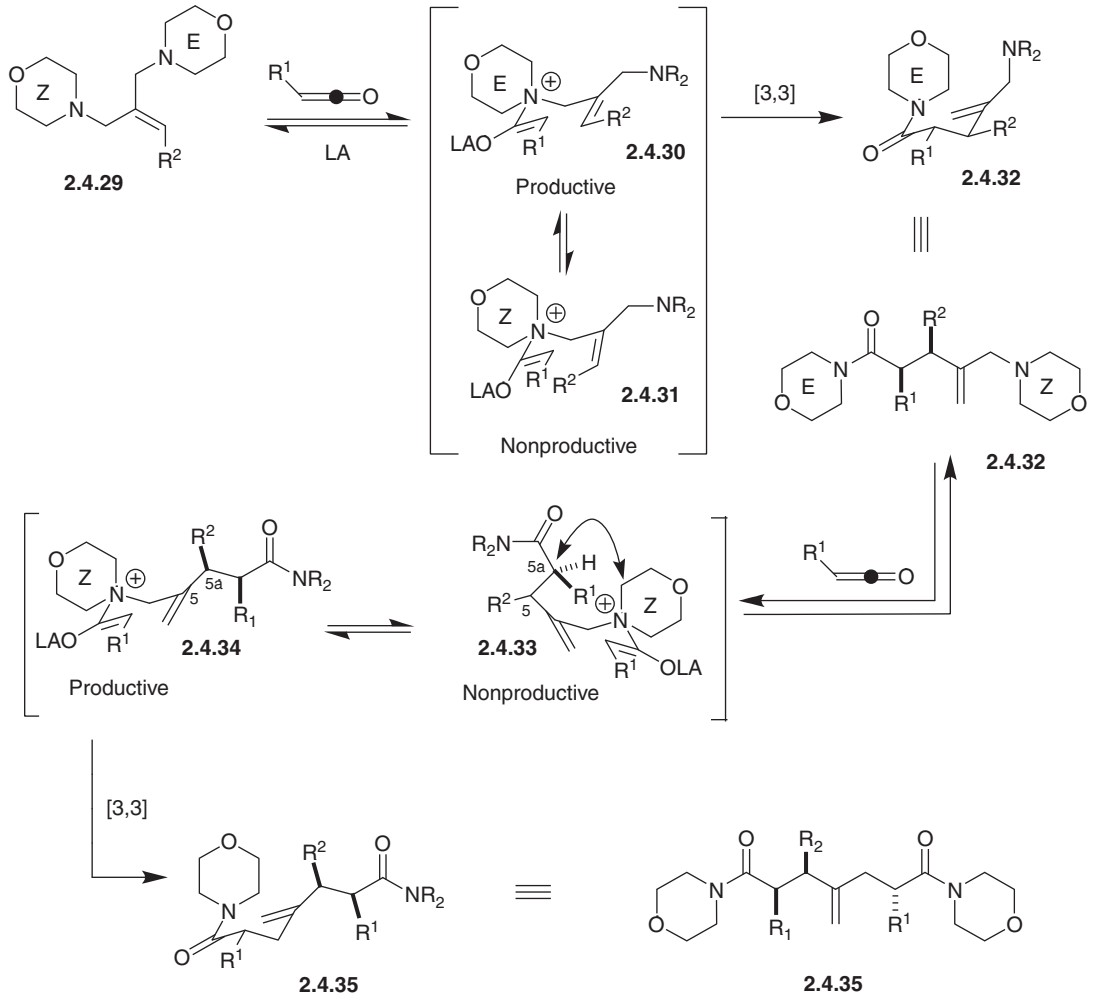
Scheme 13

Polypropionate units are frequently encountered in bio-active natural products and the asymmetric aldol reaction has been the dominant method to prepare such motifs for many years. That the Claisen rearrangement represents an attractive alternative method for polypropionate unit synthesis is demonstrated in the next example. Drawing inspiration from the work of Bellus and Malherbe,[17] MacMillan and Dong reported a highly stereoselective synthesis of complex acyclic 2,3,6-trisubstituted-1,7-dioxoheptanes **2.4.19** via a tandem Bellus–Claisen rearrangement of diamine **2.4.17** and acyl chloride **2.4.18** (Scheme 14).[18] This double [3,3]-shift proves to be tolerant to substantial structural variations (i.e., R^1 and R^2) in the two precursors. Substituted-1,7-dioxoheptanes **2.4.20–2.4.28** that incorporate alkyl, halo, cyano, alkoxy, and amino substituents were prepared in high yield and high diastereoselectivity (71–99% yield, 92:8 to 98:2 *syn–anti*). The advantage of this method resides in its capacity to build functional group- and stereocenter-rich acyclic chains that are not readily available using conventional chemical processes.

The process (Scheme 15) commences with elimination of the elements of HCl from the acyl chloride to form the ketene, which suffers nucleophilic addition by one of the two amine groups of substrate **2.4.29.** One can rationalize that destabilizing steric interactions will disfavor transition state **2.4.31** relative to **2.4.30**, thereby resulting in [3,3] rearrangement product **2.4.32**. Given that the nucleophilic addition of the amine **2.4.29** to the ketene is reversible,[19] the slower reacting *Z*-isomer **2.4.31** presumably reverts back to precursors and all starting material is thereby channeled through to amide **2.4.32**. A second ketene addition then generates an ammonium enolate that can adopt two chair-like transition states for [3,3] sigmatropic rearrangement, namely, **2.4.33** and **2.4.34**. The minimization of 1,2-allylic strain (C5–C5a) in **2.4.33** imposes destabilizing interactions between the axial methylene group (morpholine ring) and the amide chain, whereas the same torsional restriction in **2.4.34** orients the side chain away from the ring. As a result, the Bellus–Claisen rearrangement proceeds via transition state **2.4.34** to give diamide **2.4.35** as the major diastereoisomer.

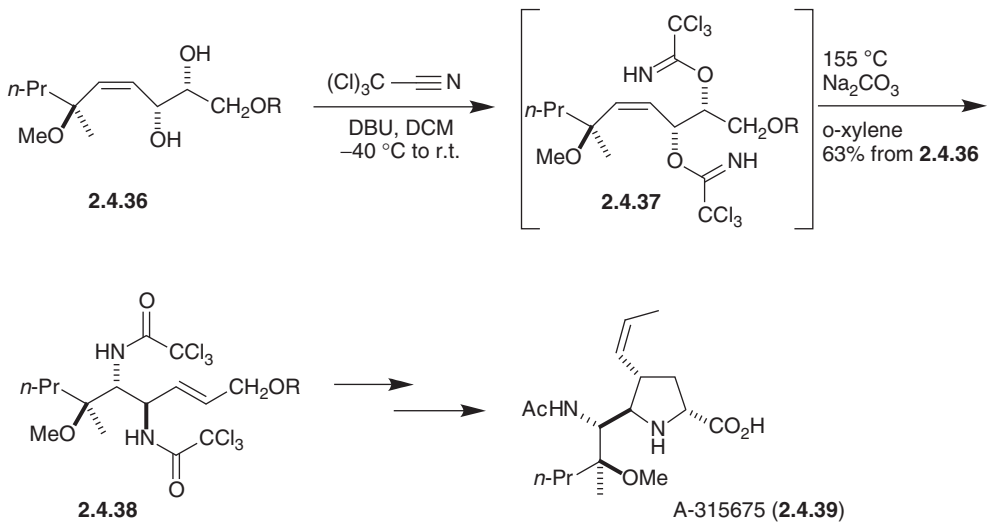
Scheme 14

Over the past few years, Chida's group has developed elegant applications of sequential [3,3]-sigmatropic rearrangements of allylic diols in total synthesis. The targets prepared include A-315675 (**2.4.39**), the synthesis of which involved a double Overman rearrangement as a key step (Scheme 16).[20] Thus, treatment of diol **2.4.36** with trichloroacetonitrile and 1,5-diazabicyclo [5.4.0]undec-5-ene (DBU) produced imidate **2.4.37**, which on heating under basic conditions delivered amide **2.4.38** in 63% yield over two steps. A short sequence from this double sigmatropic rearrangement product led to the natural product.



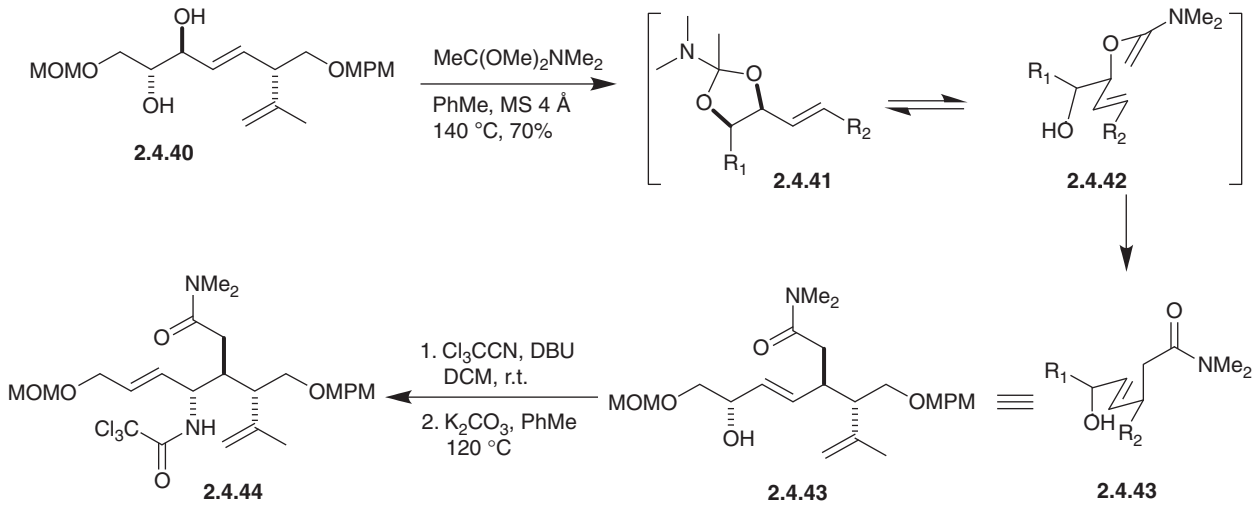
The Chida group applied a variation on this theme to the synthesis of kainic acid.[21] In this case, the initial Claisen rearrangement of **2.4.40** proceeded through cyclic orthoamide **2.4.41** and *N,O*-ketene acetal **2.4.42** intermediates to form allylic alcohol **2.4.43.** A subsequent Overman rearrangement, in a separate synthetic transformation, gave amide **2.4.44** (Scheme 17) en route to the natural product.

The Chida group also reported a formal total synthesis of (–)-morphine (**2.4.49**) employing a double orthoester Johnson–Claisen rearrangement as a key step (Scheme 18).[22] Thus, *trans*-diol **2.4.45** was treated with trimethylorthoacetate in the presence of a catalytic amount of 2-nitrophenol at 140 °C to give the corresponding substituted cyclohexene **2.4.48** in 36% yield. The reaction proceeds via intermediates **2.4.46** and **2.4.47**, with complete transfer of stereochemistry from substrate to product. The double *ortho*-Claisen rearrangement reported later by Batey (Scheme 13) bears a close similarity to this approach.[16]

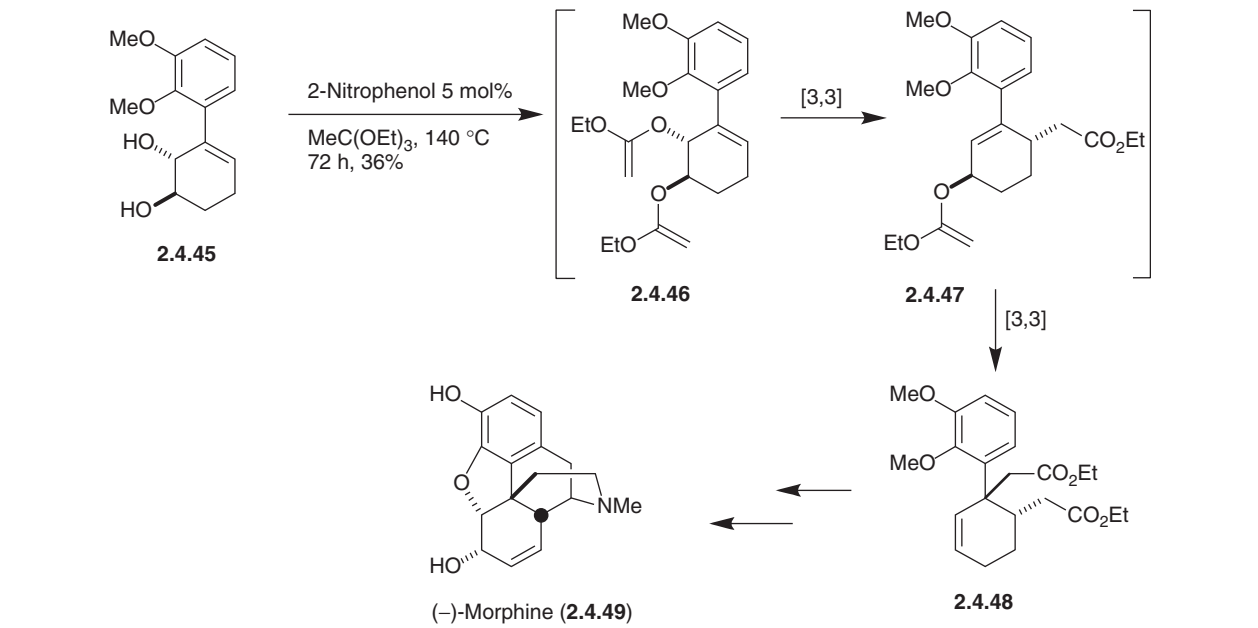


5.21.2.1.5 Claisen–Claisen cycloaddition

4-Oxatricyclo[4.3.1.0]decan-2-ones are fascinating ring systems found in several natural products isolated from the genus *Garcinia* of the *Guttiferae* family of plants.[23] Among them, forbesione (**2.5.2**) was isolated from the plant *Garcinia forbesii* (Scheme 19).[24] Quillinan and Scheinmann proposed a biogenesis of these scaffolds from 6-allylxanthones, by way of a double Claisen rearrangement followed by a Diels–Alder reaction.[25] In 2001, Nicolaou et al. reported the successful synthetic realization of this domino sequence and its application in the biomimetic synthesis of 1-*O*-methylforbesione (**2.5.3**).[26] In the event, the *O*-methylated natural product **2.5.3** was obtained as the major isomer in 63% yield on heating allylxanthone **2.5.1** at 120 °C in DMF for 20 min.



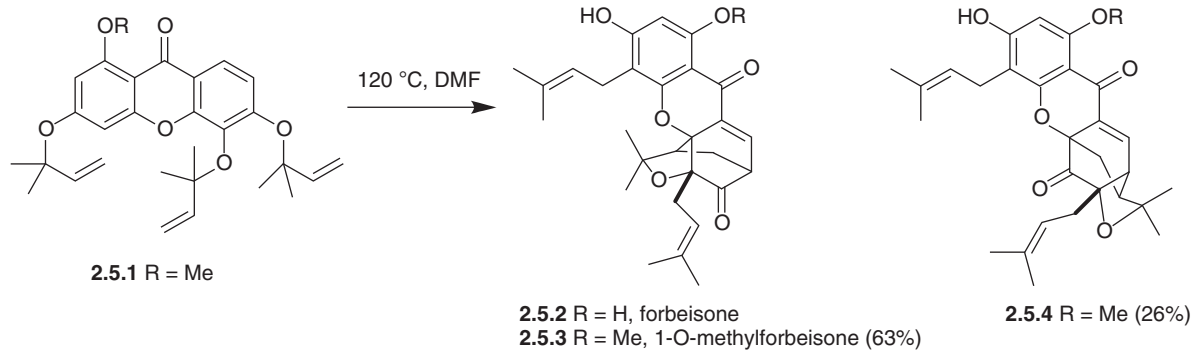
The cascade pericyclic reaction sequence is triggered by a [3,3]-sigmatropic rearrangement involving the α,α-dimethylallyl substituent at C-6 (Scheme 20). The less substituted alkene substituent attached to the resulting cyclohexadienone **2.5.5** undergoes an intramolecular Diels–Alder cycloaddition to afford the cycloadduct **2.5.6.** A regioselective *ortho*-Claisen rearrangement of the other allyl aryl ether group delivers the desired product **2.5.3** in 63% yield. A competitive Claisen rearrangement involving the C-5 allyl group gave intermediate **2.5.7**, which after an analogous Diels–Alder reaction and [3,3]-sigmatropic shift



Scheme 15

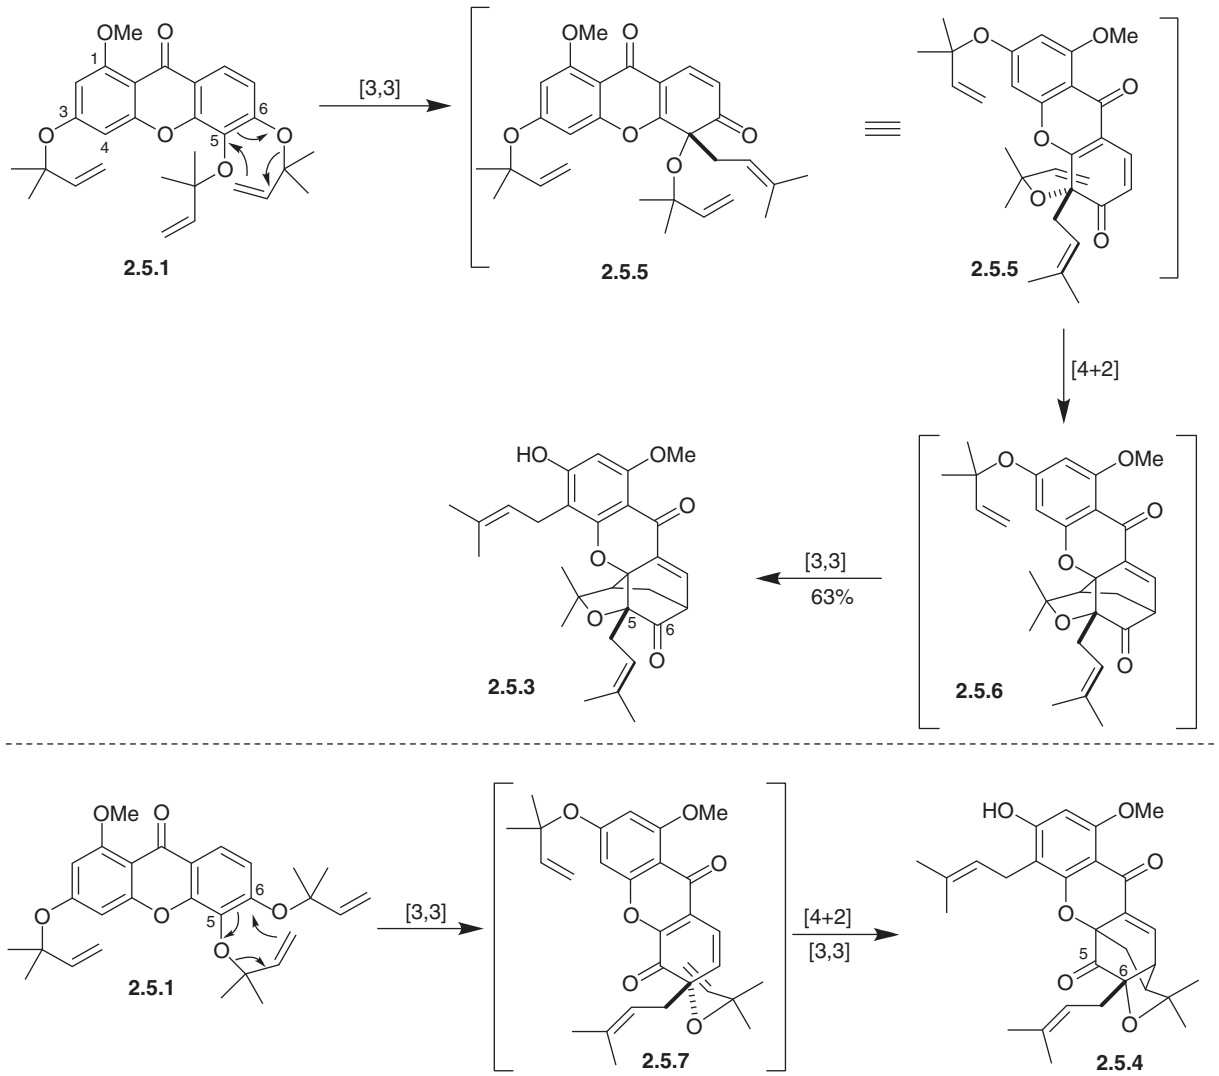
Scheme 16

Scheme 17



Scheme 18

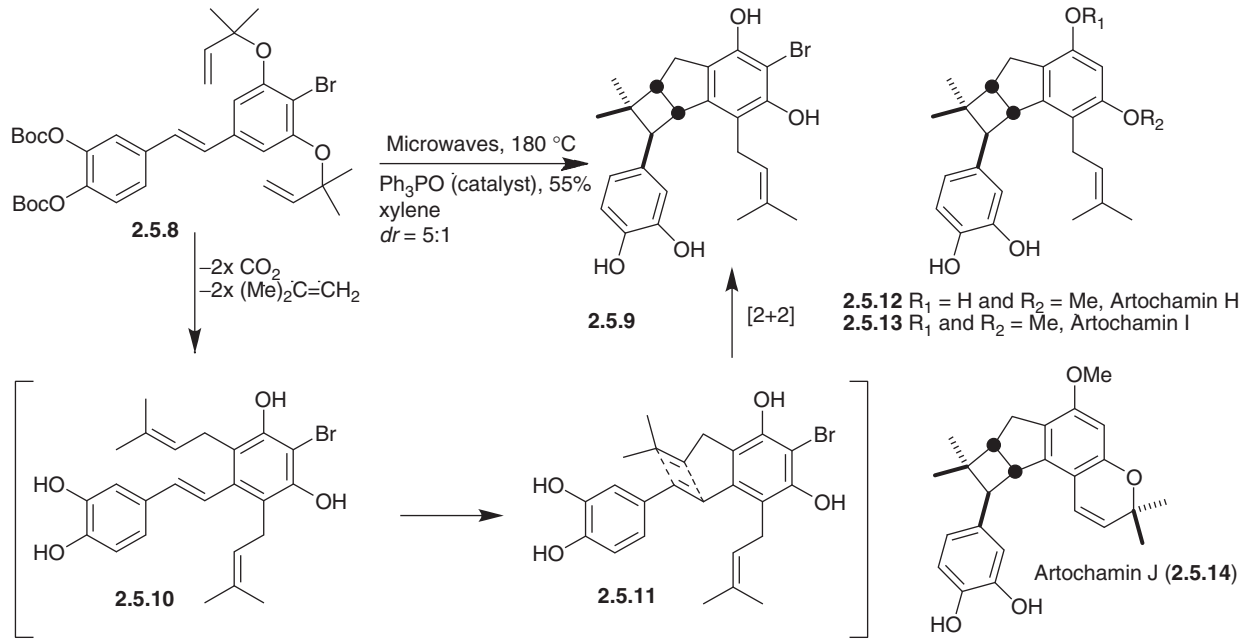
led to the minor isomer **2.5.4** (26% yield). The order of events in this overall transformation with respect to the two Claisen rearrangements has not been reported, hence the sequences shown in Scheme 20 are simply used for convenience.



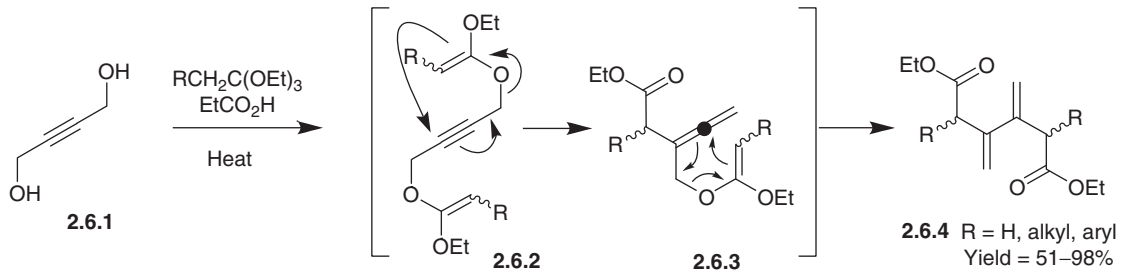
It has been postulated that the biosynthesis of the bicyclo[3.2.0]heptane framework of the artochamins involves a double Claisen rearrangement followed by a [2 + 2]-cycloaddition.[27] Nicolaou et al. evaluated this proposed pathway in a bioinspired total synthesis of artochamins H (**2.5.12**), I (**2.5.13**), and J (**2.5.14**) (Scheme 21).[28] Thus, stilbene **2.5.8** was heated at 180 °C in xylene with a catalytic amount of Ph_3PO to give tetracycle **2.5.9** in 55% yield as 5:1 diastereomeric mixture. An initial double *ortho*-aromatic Claisen rearrangement and *in situ* double *tert*-butyloxycarbonyl (Boc)-deprotection led to catechol **2.5.10**. The latter underwent an intramolecular formal [2 + 2]-cycloaddition, as formulated in structure **2.5.11**, to provide the desired product **2.5.9**, which was converted in four steps into Artochamins H-J. Mechanistic studies suggested that formation of the cyclobutane ring proceeds via a stepwise ionic pathway. Irrespective of the true biosynthesis and the mechanism of the ring forming process, this approach is an efficient method to construct the carbon framework of the artochamins.

5.21.2.1.6 Double [3,3]-sigmatropic rearrangements on alkynes

In this double orthoester Johnson–Claisen rearrangement developed by Ishino, an alkyne diol such as **2.6.1** participates in a [3,3]-sigmatropic shift to form an allene **2.6.3**, which in turn undergoes a second [3,3]-sigmatropic shift resulting in a conjugated



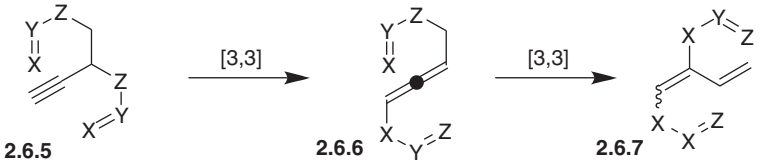
Scheme 19



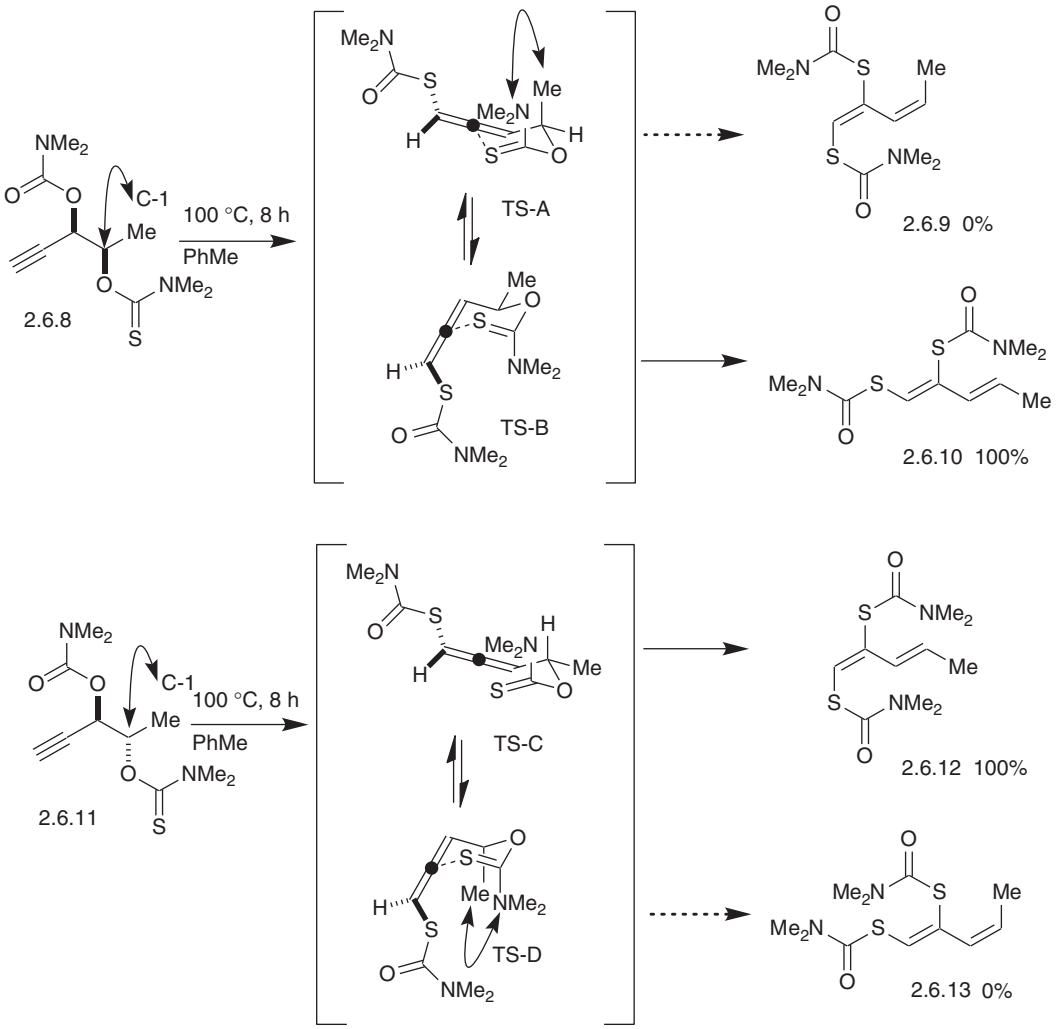
Scheme 20

1,3-butadiene **2.6.4** (Scheme 22).[29] The reaction proves tolerant to various substituents on the trialkyl orthoalkanoate to give allylic substituted products.

In a conceptually related study, Banert et al. reported the synthesis 1,2-difunctionalized 1,3-butadienes through a sequence of [3,3]-shifts of terminal alkynes **2.6.5** (Scheme 23, equation 1).[30] Although trichloroacetamide- (XYZ=NHCOCCl$_3$),



Scheme 21



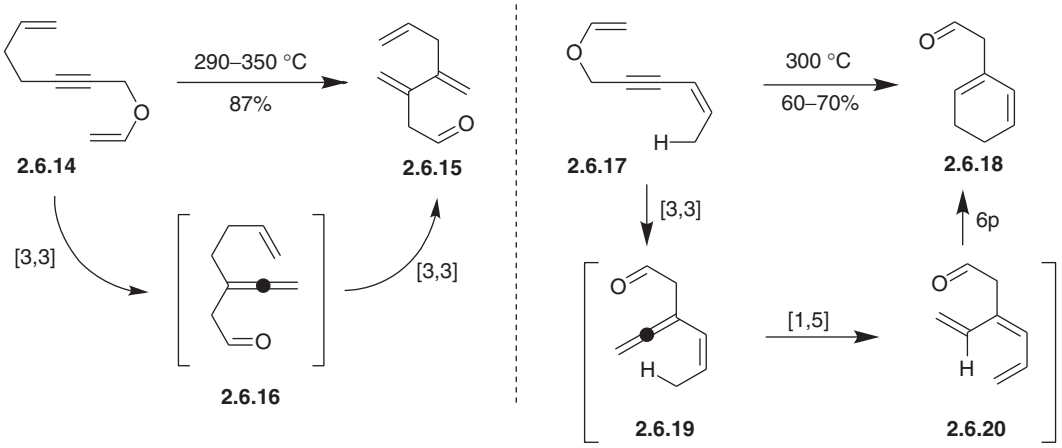
Scheme 22

thioester- (XYZ=SCOPh), thiocarbamate- (XYZ=SCONMe$_2$), thiocarbonate- (XYZ=SCO$_2$Ar), and dithiocarbonate- (XYZ=S-C(O)SMe) substituted alkynes **2.6.5** were converted to 1,3-dienes **2.6.7** in good yields, these compounds were obtained as a (separable) mixture of *E* and *Z* isomers. In a subsequent study, the reaction was found to be highly stereoselective with substrates carrying a stereocenter at C-1.[31] Thus, separate heating of the thiocarbamates diastereomers **2.6.8** (*syn*) and **2.6.11** (*anti*) gave the *E,Z*-dienes **2.6.10** and *E,E*-dienes **2.6.12,** respectively, each as a single geometrical isomer in quantitative yields. A close examination of the chair-like transition states **TS A-D** reveals the presence of severe 1,3-diaxial interactions between the axially oriented methyl and thiocarbamate groups in **TS-A** and **TS-D**. The stereoisomeric products derived from these transition states, namely, **2.6.9** and **2.6.13**, are not observed. The isolated products **2.6.10** and **2.6.12** result from transition states **TS-B** and **TS-C**, respectively, which lack these destabilizing interactions.

(1)

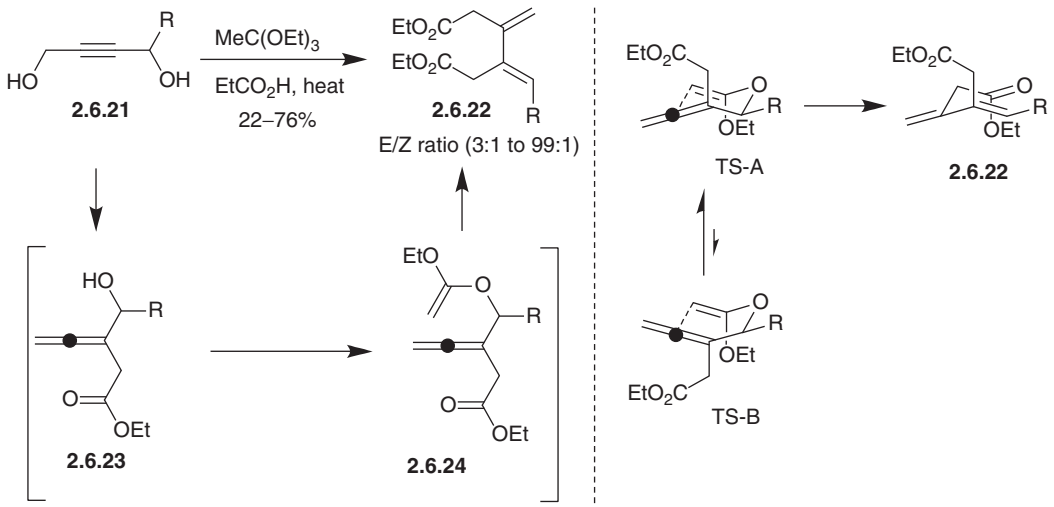
In the Banert examples, the order of events is known, because the propargylic substituent must rearrange first. With other substrates, the mechanism is less certain. Hopf demonstrated that pyrolysis of alkyne **2.6.14** at temperatures ranging from 290 to 350 °C gave aldehyde **2.6.15** in 87% yield (Scheme 24).[32] One can imagine a mechanism involving an initial Claisen or Cope rearrangement. Because only the product from an initial Claisen rearrangement, **2.6.16**, was observed in the reaction mixture, it is

Scheme 23



this pathway that operates. The allene **2.6.16** is converted to aldehyde **2.6.15** via a Cope rearrangement. In a related example, the pyrolysis of enol ether **2.6.17** gave aldehyde **2.6.18** in 60–70% yields. The domino process commences with a Claisen rearrangement to produce allene **2.6.19**. The latter undergoes the expected [1,5]-sigmatropic shift to produce aldehyde **2.6.20**, which on 6π electrocyclization gives **2.6.18**. It was found that cyclization of **2.6.17** at higher temperatures produced toluene via decarbonylation and aromatization.

Hopf also attempted the double Claisen rearrangement of the divinyl ether of butyne-1,4-diol but these efforts were met with limited success.[32] This type of consecutive sigmatropic rearrangement has been successfully achieved by Ishino, however, using a double orthoester Johnson–Claisen rearrangement (Scheme 22).[28a,b] More recent studies by Hong et al. reported the stereoselective synthesis of (*E*)-1,2,3-trisubstituted dienes **2.6.22** (R=alkyl, aryl) from substituted propargyl diols **2.6.21** via a double Johnson–Claisen rearrangement.[33] It was proposed that the ketene acetal of the primary alcohol is formed first, which after [3,3]-sigmatropic rearrangement furnishes allene **2.6.23**. The latter is transformed to a secondary ketene acetal **2.6.24**, which undergoes a second Claisen rearrangement to produce 1,3-diene **2.6.22**. The high selectivity of the process is presumably the result of the chair-like transition state **TS-A** being favored over boat-like transition state **TS-B** in the second Claisen rearrangement. The R– and $-CH_2CO_2Et$ substituents are *cis*-oriented in **TS-A**, thus giving rise to *E*-diene **2.6.22** (Scheme 25).

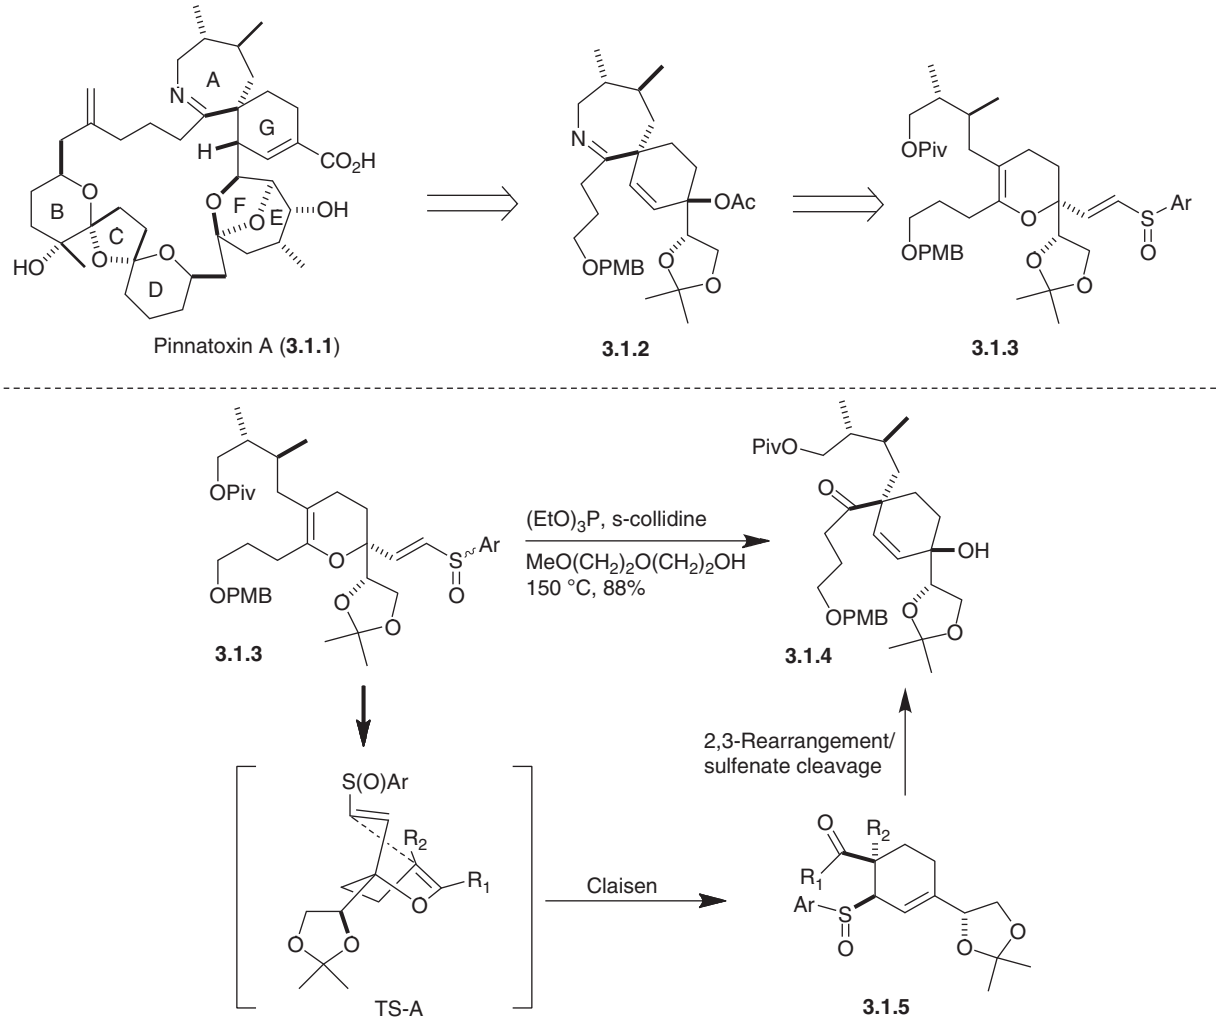


5.21.3 [3,3]-[i,j] Rearrangement

5.21.3.1 Claisen-[2,3]-Shift

Zakarian and Pelc devised a clever synthesis of the A/G spirocyclic fragment **3.1.2** of pinnatoxin A (**3.1.1**) via a domino Claisen/Mislow–Evans rearrangement (Scheme 26).[34] The sulfoxide **3.1.3** (as a mixture of diastereomers at the sulfur center) was heated at

Scheme 24



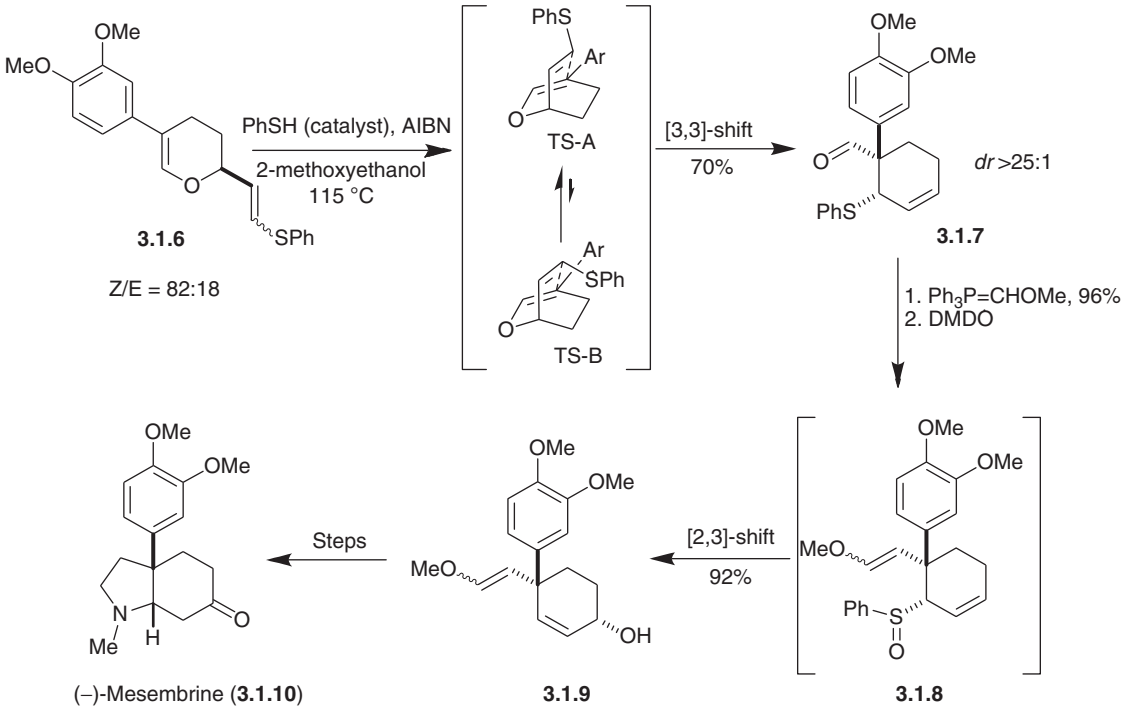
Scheme 25

150 °C in the presence of Ph_3PO and 2,6-collidine to give **3.1.4** in 88% yield as a single isomer. The domino reaction is triggered by a [3,3]-sigmatropic shift proceeding via transition state **TS-A** to furnish allylic sulfoxide **3.1.5**. A subsequent [2,3]-sigmatropic shift (Mislow–Evans reaction) forms an allyl sulfenate, which is cleaved to allyl alcohol **3.1.4** by triethyl phosphite. The latter was converted over several steps into the target subunit **3.1.2**.

The same group applied a related strategy to the synthesis of mesembrine (**3.1.10**), an alkaloid found in *Sceletium* plants (Scheme 27).[35] The direct domino [3,3]/[2,3] sigmatropic rearrangement was not applicable in this case, so a stepwise approach was pursued involving a Claisen rearrangement of alkenyl sulfide **3.1.6** followed by oxidation to the sulfoxide and a Mislow–Evans reaction to give the desired alcohol **3.1.9**. Interestingly, despite the presence of alkenyl sulfide **3.1.6** as an *E*/*Z* mixture, the stereochemical outcome of the Claisen rearrangement is consistent with only the *E*-isomer reacting. This led the authors propose an *E*/*Z* equilibration under the reaction conditions. Presumably, severe 1,3-allylic interactions in the *Z*-isomer **TS-B** make this transition state disfavored relative to that of the *E*-isomer, **TS-A.**

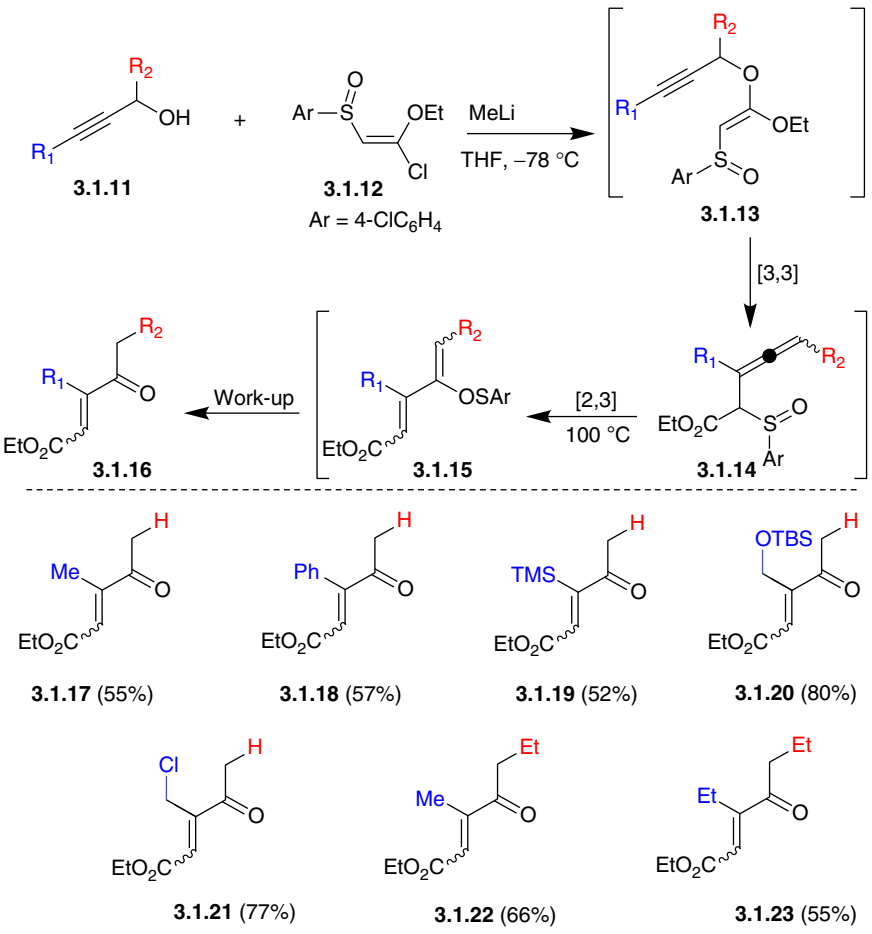
Posner et al. developed a new synthetic method to 4-oxo-2-alkenoate esters **3.1.16** from propargyl alcohols **3.1.11** and sulfoxide reagent **3.1.12** (Scheme 28).[36] This one pot transformation presumably proceeds via a [3,3]-sigmatropic rearrangement of Michael addition product **3.1.13**, followed by a [2,3]-shift of the allenyl sulfoxide **3.1.14** to give dienyl sulfenate **3.1.15**. Hydrolysis gives functionalized 4-oxo-2-alkenoates **3.1.17**–**3.1.23** in yields ranging from 52% to 80% as a mixture of *E*/*Z* isomers. This approach represents an efficient and convenient route to functionalized trisubstituted dienophiles, because it proceeds in one step from readily available propargylic alcohols and the bench stable reagent **3.1.12**.

Majumdar et al. observed a novel domino sigmatropic reaction during the thermolysis of propargylic sulfoxide **3.1.26** (Scheme 29).[37] Oxidation of sulfide **3.1.24** followed by refluxing in CCl_4 produced the rearranged structure **3.1.25** in 62–71% yields. This novel cascade reaction proceeds first by a [2,3]-sigmatropic rearrangement of the sulfoxide to produce sulfenate



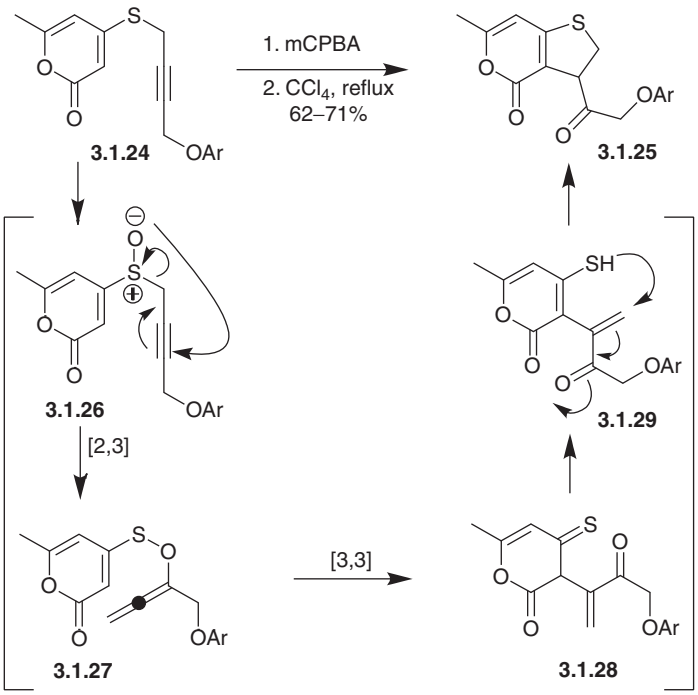
Scheme 26

intermediate **3.1.27**. This transient intermediate undergoes a [3,3]-sigmatropic rearrangement to give enone **3.1.28**. Tautomerization of the thione functionality affords thio-enol **3.1.29**, which undergoes an intramolecular Michael addition to give the observed product **3.1.25**.

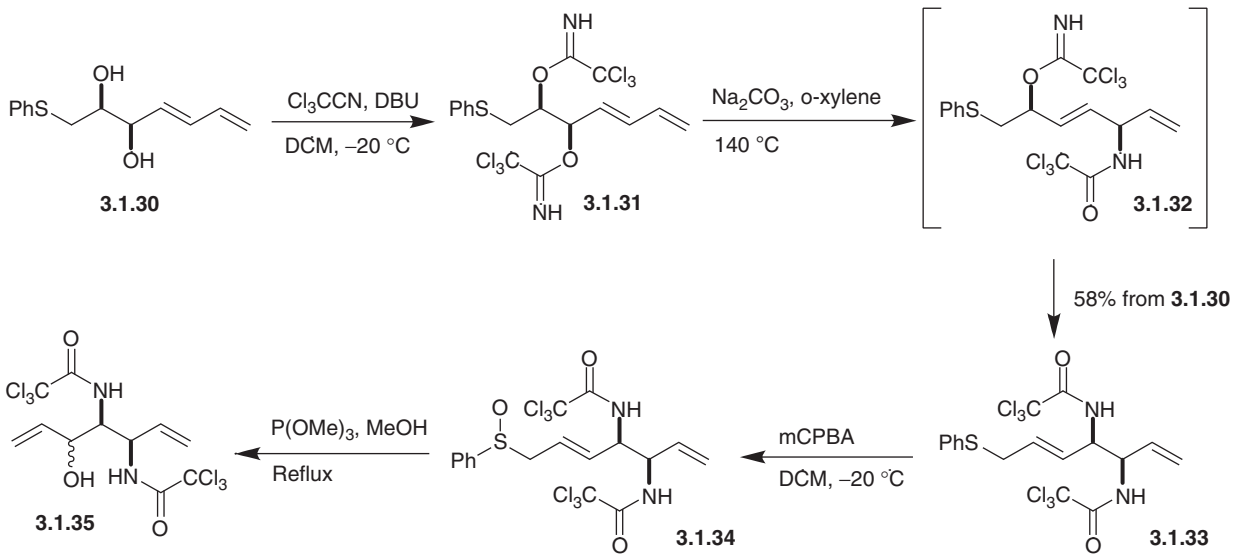


In an extended version of their earlier studies (see Schemes 16–18), Chida and coworkers reported the synthesis of agelastatin A using a sequence of two [3,3]-sigmatropic rearrangements followed by a [2,3]-shift (Scheme 30).[38] Thus, treatment of diol **3.1.30** with trichloroacetonitrile gave di-imidate **3.1.31**, which under basic conditions rearranged to give diamide **3.1.33** in 58% yield. Subsequent oxidation of the allylic sulfide **3.1.33** afforded allylic sulfoxide **3.1.34**, which underwent a [2,3]-shift yielding alcohol **3.1.35** on phosphite-mediated heterolysis of the intermediate sulfenate.

5.21.3.2 [1,5]-[3,3](-[3,3]) Shift

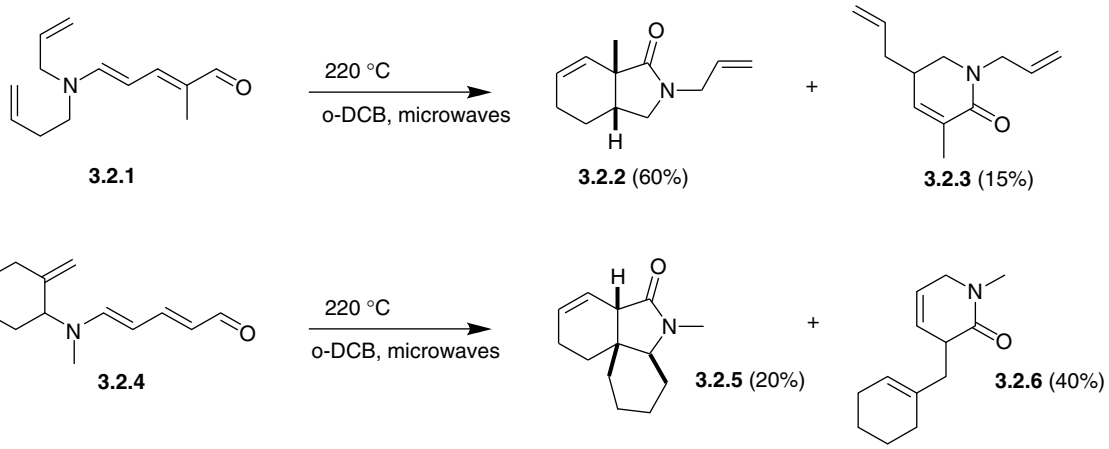


Vanderwal and coworkers have reported the synthesis of unsaturated amides via a thermal pericyclic rearrangement of Zincke aldehydes.[39] In the course of their studies, they found that Zincke aldehydes **3.2.1** and **3.2.4** were transformed into intramolecular Diels–Alder adducts **3.2.2**/**3.2.5** and dihydropyridones **3.2.3**/**3.2.6** (Scheme 31).[40] Further investigations featuring computational studies provided mechanistic insights into the cascade reaction.[41] It was found that Zincke aldehyde **3.2.7** undergoes [1,5]-hydrogen shift to produce a reactive ketene intermediate **3.2.8**, which cyclizes through nucleophilic addition to form the zwitterionic species **3.2.9**. The latter constitutes a common intermediate by which both bicyclic amide **3.2.12** and dihydropyridone **3.2.15** are generated, as shown in Scheme 31 via path a and path b, respectively. In the former, a 6π-electrocyclic ring opening sets up an intramolecular Diels–Alder reaction. In the latter, either a single (**3.2.3**) or a double (**3.2.6**) Cope rearrangement occurs.

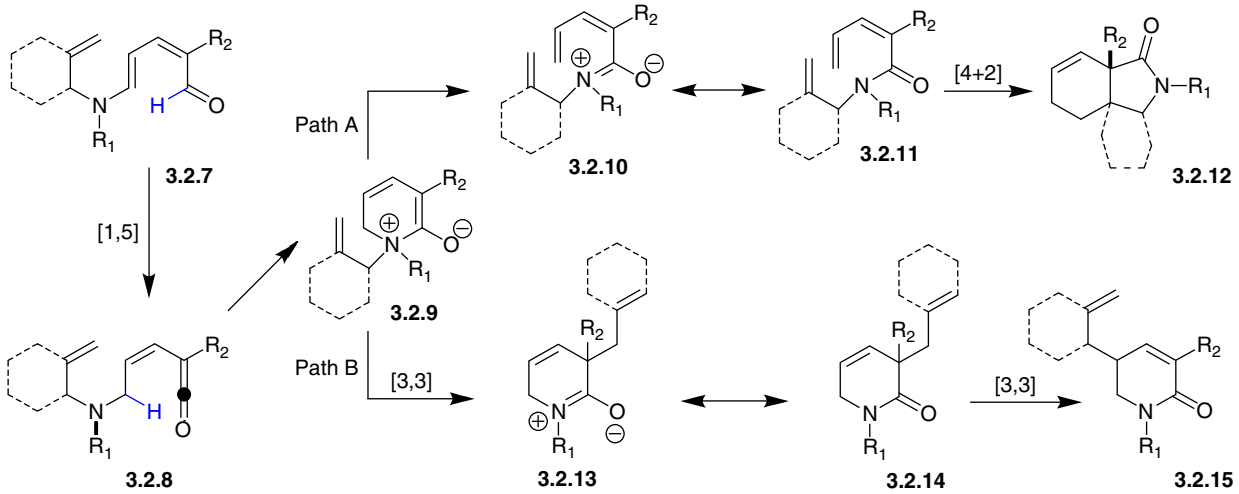


Scheme 27

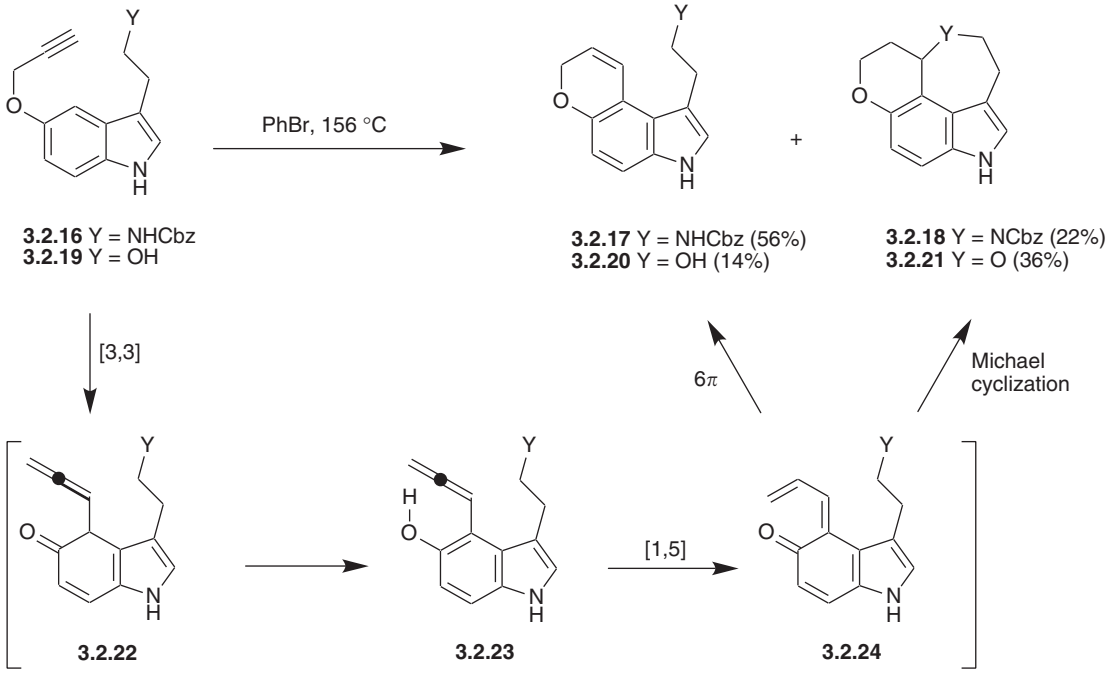
Scheme 28



Scheme 29

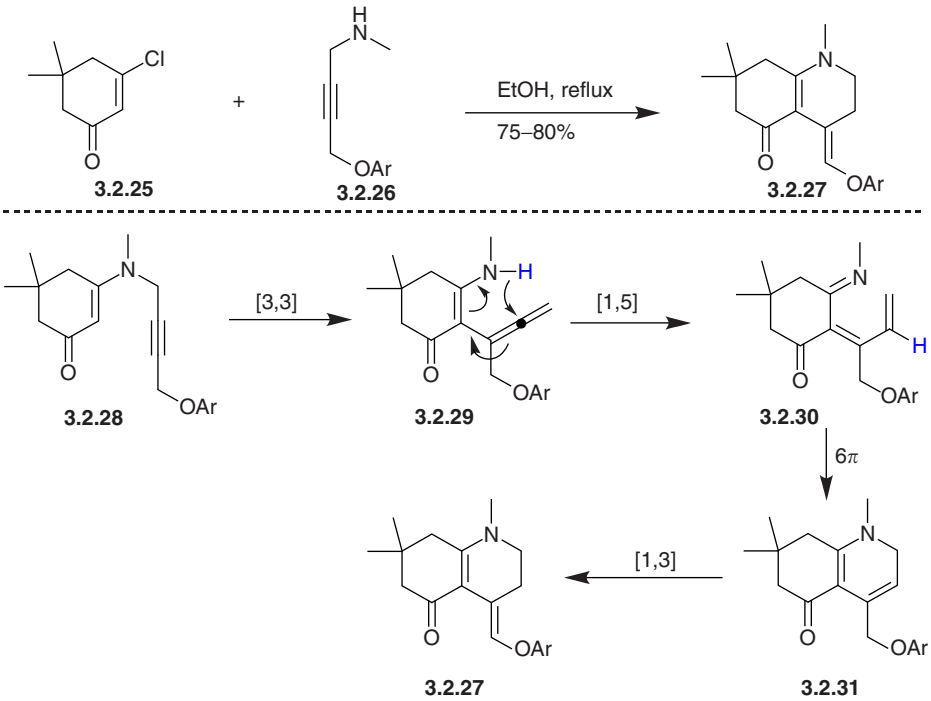


Scheme 30



Evidently, the substitution pattern of the allylic chain has a direct influence on the outcome of the reaction. The observed product ratios were consistent with computational findings.

Macor and coworkers reported the thermal conversion of 5-propargyloxyindoles to tricyclic indoles via a [3,3]-[1,5]-sigmatropic shift sequence, *en route* to serotonin analogs (Scheme 32).[42] Propargyloxyindole **3.2.16** was heated in bromobenzene at 156 °C to give tricycle **3.2.17** in 56% yield, along with tetracyclic indole **3.2.18** in 22% yield. The mechanism for the formation of tricycles **3.2.17** involves Claisen rearrangement of propargyl aryl ether **3.2.16** to give allenyl cyclohexadienone **3.2.22**, which after tautomerization would produce allenyl phenol **3.2.23**. The latter is poised to undergo a [1,5]-hydrogen shift to generate quinone methide **3.2.24**, which can be converted to **3.2.17** via a 6π electrocyclization. The formation of tetracycle **3.2.18** could arise from intermediate **3.2.24** through an intramolecular 1,4-addition of the nucleophilic group on the side chain (i.e., Y) followed by



Scheme 31

Scheme 32

cyclization (i.e., of the phenol to the terminal alkene). The isolation and resubmission of **3.2.17** in the same reaction conditions did not produce **3.2.18**. Products **3.2.17** and **3.2.18** could be derived from common intermediate **3.2.24**. It was hypothesized that the increase of the nucleophilicity of the side chain should favor the formation of the tetracyclic product. Replacement of the NHCbz group by a primary alcohol (**3.2.19**) led to a higher yield of the tetracycle **3.2.21** (36%) relative to the tricycle **3.2.20** (14%), providing some support for this possibility.

An aza-Claisen rearrangement-[1,5]-hydrogen shift sequence has also been used in the annelation of piperidine rings (Scheme 33).[43] Thus, heating a mixture of 3-chloro enone **3.2.25** and propargyl amines **3.2.26** produced hydroquinolones **3.2.27** in 75–80% yield. In all cases, the rearrangement took place through the amine intermediate **3.2.28**. The formation of the products can be explained by an initial [3,3]-sigmatropic rearrangement of the propargyl alkenylamine **3.2.28** to generate an intermediate enamine-allene **3.2.29**. A [1,5]-hydrogen shift followed by 6π-electrocyclization gives the endocyclic intermediate **3.2.31**, which leads to the final product by [1,3]-hydrogen shift.

Scheme 33

5.21.4 Conclusion

The results reviewed in this chapter highlight the synthetic power of sequences involving sigmatropic rearrangements. Studies directed toward the development of new synthetic methods, total synthesis, medicinal chemistry, and host–guest chemistry have all benefitted from the introduction of such sequences. It is perhaps not surprising that [3,3]-shifts dominate the landscape of consecutive sigmatropic rearrangements. Although sequences comprising exclusively sigmatropic rearrangements are powerful, their true potential becomes even more apparent when they are coupled with other bond-forming reactions, such as cycloadditions. It is surely in this guise that these processes will continue to flourish for many years to come.

5.22.1 Vinylcyclopropanes

5.22.1.1 Introduction

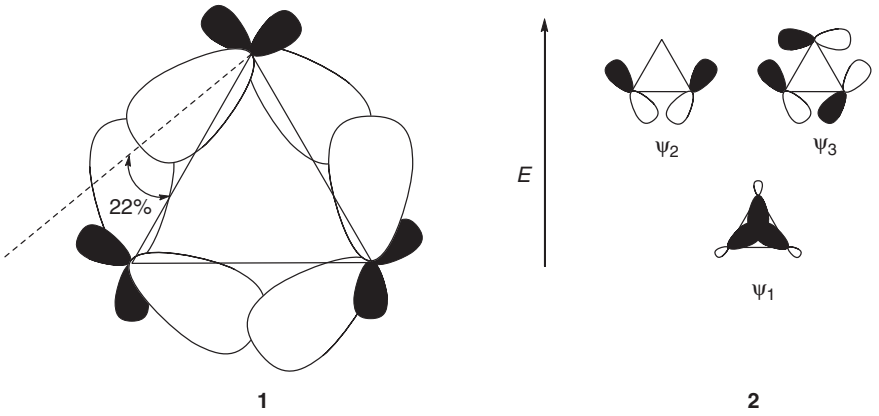
It has been more than 125 years since von Baeyer[1] and Perkin[2] reported the first syntheses of cyclopropane derivatives and von Baeyer[1] formulated of the "theory of ring strain." The chemistry of small-ring compounds has risen to prominence in the past 50 years. The popularity especially of three-membered rings as intermediates in synthetic transformations has been due primarily to their latent energy content and to the seemingly endless chemical transformations in which these compounds and their derivatives can participate. New applications and novel permutations of the basic systems continue to appear at a fast pace. The fascinating chemistry associated with the strain of these intermediates continues to find wide applicability in the field of synthetic methodology and in the total synthesis of complex molecules.

The following discussion highlights those transformations of vinylcyclopropanes and their derivatives that are selective with regard to the regio- and stereochemistry of products. The discussion of such transformations is done from the position of a synthetic practitioner interested in their actual use. At the end of both major sections, a survey of useful and general methodologies based on these transformations is provided along with a tabular compilation of total syntheses featuring these rearrangements as key steps.

5.22.1.2 Theoretical and Mechanistic Considerations of the Vinylcyclopropane System

5.22.1.2.1 Bonding and energetics of cyclopropane systems

The bonding in cyclopropane requires that the sp^3 hybrids be misaligned by approximately 22° from the imaginary line connecting the carbon atoms, as shown in Figure 1. The result is the so-called bent or banana bond, which has approximately 20% less orbital overlap than the corresponding bond in ethane. The Coulson–Moffitt[3] model **1** and the Walsh[4] model **2** use three sp^3-hybridized CH_2 groups and three sp^2-hybridized CH_2 groups, respectively. The overall hybridization of cyclopropane carbon–carbon bonds is thus $sp^{2.3}$; this greater *p*-character can be invoked in rationalizing the similarity of cyclopropane chemistry to that of alkenes. Because the bond angles are considerably less than the ideal 109.5°, cyclopropane suffers from significant angular (Baeyer) strain and hydrogen repulsions, as well as from torsional (Pitzer) strain from eclipsed carbon–hydrogen bonds.



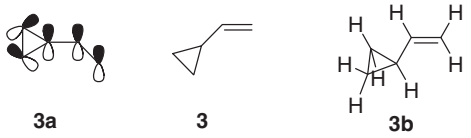


Figure 1 Bonding in cyclopropane.

A unique treatment of cyclopropane was advanced by Dewar,[5] who introduced the concept of σ-aromaticity, which explains some of its anomalous chemical and physical properties. The notion of σ-conjugation implies that three σ-bonds form a cyclic system of six electrons; thus cyclopropane is aromatic by the $(4n+2)$ rule. This explanation accounts well for its strain energy. The actual value (27.5 kcal mol^{-1})[6] is much lower than the predicted value of 104 kcal mol^{-1} (1 cal = 4.2 J), calculated from the C–C–C bending force constants obtained spectroscopically.[5,7] A similar comparison for cyclobutane (antiaromatic by the above notion and the $4n$ rule) underestimated the strain energy.[8] σ-Aromaticity also accounts for such observations as ^{1}H NMR chemical shifts and the reactivity of cyclopropane toward electrophiles.

The cyclopropane ring is subject to a number of chemical transformations that are only possible because of its unique bonding and high energy content. It is the energy content (27.5 kcal mol^{-1}) that drives the diradical opening of cyclopropane, especially so if one (or both) of the resulting radicals becomes a part of a delocalized allylic system, as in the case of vinyl- or divinylcyclopropanes. The resonance stabilization energy of an allylic radical system (12.6 kcal mol^{-1})[8] can be used to explain the lower activation energy for reactions involving vinylcyclopropane (34–55 kcal mol^{-1}) compared with the activation energy for reaction resulting from diradical processes that involve only the cyclopropane ring (59–66 kcal mol^{-1}).[9–13]

The vinylcyclopropane unit contains the strain energy of the cyclopropane ring (27.5 kcal mol^{-1}), and it is this energy content that is primarily responsible for its reactive options. Thermal ring fission can occur by any one of three mechanisms: [1,5] sigmatropic hydrogen shift, $[2\sigma_s+2\pi_s]$ concerted reorganization to cyclopentene, or a diradical fission followed by further reactions of the diradicals (recombination or hydrogen abstraction). This discussion has received considerable attention in both the mechanistic and the synthetic sense and has been the subject of several reviews.[9,14–25]

The bonding in vinylcyclopropane **3** is such that an *s-trans-gauche* conformational equilibrium exists to allow for maximum orbital overlap of the asymmetric component of cyclopropane orbitals with the π- or π^*-orbitals of the ethylene unit, as shown in **3a**. From thermochemical studies it appears that conjugation of an alkene with cyclopropane stabilizes the system by 1.2 kcal mol^{-1}.[26,27] The conformational equilibrium for vinylcyclopropane was shown to consist of an *s-trans* minimum **3b** and two *gauche* conformers that are equal in energy and destabilized by 1.43 kcal mol^{-1} with respect to the *s-trans* conformation. The barrier to interconversion has been determined to be 3.92 kcal mol^{-1}.[28]

3a **3** **3b**

The details of bonding and spectroscopic properties of cyclopropane derivatives have been reviewed.[13,27,29] In addition, the properties and energetics of cyclopropyl cations, anions, radicals, anion radicals, and cation radicals have been amply reviewed, and comparisons have been made with their corresponding alkenic counterparts.[13,27,30,31] Recently, theoretical calculations in a study of properties have been performed on vinylcyclopropyl cation radicals,[32] anion radicals,[33–35] and neutral radicals.[34]

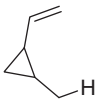
5.22.1.2.2 Reactive tendencies

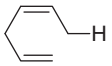
For a synthetic chemist the analogy between cyclopropanes and alkenes is an appropriate one. Virtually every reaction that an alkene undergoes has a counterpart in the repertoire of transformations possible with cyclopropanes. Thus, conjugation of a cyclopropane to an alkene makes it possible to invoke a number of reaction modes and reactive intermediates that can be compared directly to their alkenic counterparts.

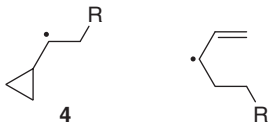
How a particular vinylcyclopropane will be electronically perturbed toward a specific mode of reactivity depends on the substitution of either the cyclopropane or the vinyl portion. All of the principal reactions of vinylcyclopropanes proceed via transition states that require stabilization by activating groups and/or release of the ring strain. To understand and to alter the reactive tendencies of substituted vinylcyclopropanes, we must understand the components of the possible transition state and the probable reactive intermediates involved. **Table 1** shows the principal reaction pathways of the vinylcyclopropane system in the context of their intermediates, products, and alkenic equivalents.

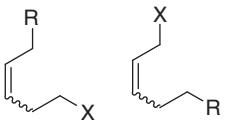
The cyclopropylcarbinyl radical **4**, the cyclopropylcarbinyl cation **5**, and the cyclopropylcarbinyl anion **6** all dominate the expected reactivity of vinylcyclopropanes as one of these forms will be expected to be a major contributor to either a radical or a polar transition state. It is important to consider the various reactive subunits in some detail in order to understand the "big picture" reactivity of a vinylcyclopropane system, especially as perturbed by additional substituents.

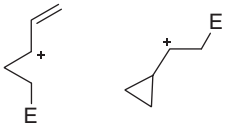
The dominant contributor to the reactivity of vinylcyclopropanes in any radical reaction is the form **4a**, the cyclopropylcarbinyl radical system. The opening of a cyclopropylcarbinyl radical to a butenyl radical is among the fastest radical processes known, with a rate constant of 1.3×10^8 s^{-1}.[36,37] The various stereoelectronic effects of this rearrangement have been reviewed.[38,39] The structure of **4a**, deduced from its electronic spin resonance spectrum[40,41] and in agreement with calculations (STO-36 basis set),[42] is in the bisected conformation shown, predicted to be 1.4 kcal mol^{-1} more stable than its perpendicularly oriented counterpart. Above −100 °C, only the butenyl radical **4b** can be detected. Substituent effects do not seem to operate when the substituents are on the cyclopropane (i.e., product stabilization).[43] The cyclopropylcarbinyl cation and anion have structures similar to **4a**, bisected conformations **5** and **6**, respectively. A concise summary of solvolytic and mechanistic data for system **5** has appeared.[27] Reviews of the chemistry of cyclopropylcarbinyl anions and carbenes are also available.[12,13]

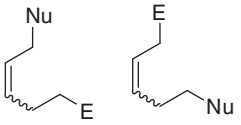


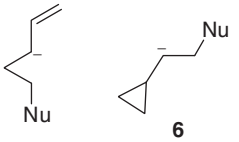


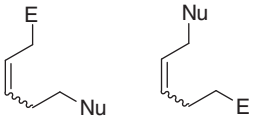


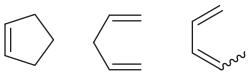


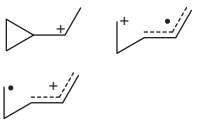




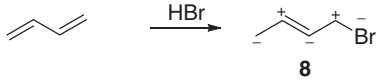




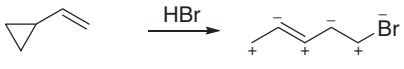




4a **4b**



5 **6**



To understand how substituents, especially heteroatoms, change the reactivity of these systems, the basic transformations shown in **Table 1** should be kept in mind. The number of possibilities is limitless, especially on the recognition that, depending on the substituents, any one of the above contributing structures **4**, **5**, or **6** can become operational on the mode of subsequent rearrangement of the vinylcyclopropane when such rearrangements occur from the homolytic or heterolytic manifolds. The question of concerted rearrangements, or $[2\pi_s+2\sigma_s]$ processes, is more difficult to address. Evidence exists on both sides of the argument with no clear-cut rules for or against a universally accepted mechanism. The next section presents the debate concerning this topic in more detail.

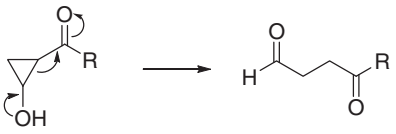


Table 1 Principal reaction modes of vinylcyclopropanes

Reaction type	*Reactive intermediate*	*Alkenic counterpart*	*Product(s)*
[1,X] Sigmatropic migration	 [1,5 shift]		
Radical addition	 **4** (Cyclopropylcarbinyl radical)		
Electrophilic addition	 **5** (Cyclopropylcarbinyl cation)		
Nucleophilic addition	 **6** (Cyclopropylcarbinyl anion)		
Radical cleavage			
One-electron oxidation	 **7** radical-cation		

In terms of retrosynthetic or disconnective reasoning, cyclopropane is an ideal molecular building block. Because it can be expected to act as an alkene, all of the standard reactions can be performed with it. As it has an extra carbon, however, it serves as a marvelous "synthetic wedge tool"[12] that can be used to either disrupt existing symmetry or consonance or to introduce it to the target. The concepts of synthetic consonance and dissonance formulated by Evans[44,45] or the "cyclopropane trick" analogy of Seebach[46] are ideal in understanding the synthetic utility of cyclopropanes. Thus, for example, equilibrium addition of HBr to 1,3-butadiene yields 1-bromo-2-butene **8** (equation 1), in which the halide enjoys an allylic relationship with the alkene. Similar addition to a vinylcyclopropane (equation 2) will, however, produce 1-bromo-3-pentene **9** where the same relationship is homoallylic. One can immediately see that the charge parity in the product alkenes has been inverted by the introduction of the odd carbon, and thus inverted reactivity of such alkenes can be expected in subsequent synthetic steps. This criterion is extremely important in synthetic schemes involving long-range planning and placement of functional groups. This property of cyclopropane has been exploited in the pioneering efforts of Wenkert, who developed 1,4-dicarbonyl compound synthesis based on the ability of oxycyclopropylcarbinyl systems such as **10** to act as pseudo enols (equation 3).[20,47,48]

8 (1)

9 (2)

10 (3)

Finally, the introduction of cyclopropane or vinylcyclopropane into organic compounds provides an opportunity to cross the odd/even manifolds in further synthetic steps aimed at the preparation of compounds of increased molecular complexity. Traditionally, any synthesis that involves cyclic intermediates with an odd number of atoms (or acyclic intermediates with an even number) is more difficult because proper charge parity or consonance cannot be observed. A cyclopropane unit then functions as a topological operator in those cases where such crossover is desired.[49–51]

The most fascinating features of vinylcyclopropane reveal themselves upon the introduction of not only substituents, but also heteroatoms. The number of possible permutations of molecular connectivity in a system such as **Z** (Figure 2) is virtually limitless. (Consider the series of connectivity operations for a chemical system composed of an odd number of atoms with an external operator X. Although there is only one way to connect A and X, there are now six ways to connect X through the ring opening of the three-membered ring system (**i**) and 120 such different connections in the ring opening of the heterovinylcyclopropane (**ii**) and its interactions with X.[52]) The complexity of connectivities of **Z** with an external operator X is related through the factorial (!) function and becomes even greater when the presence or the position of substituents in **Z** or the complexity of X is added for consideration. The success in predicting the reactivity of a system such as **Z** depends on the nature of component atoms, substituents, electronic perturbations, and the preference of some mechanistic pathways over others. To consider selective transformations of a system that has in excess of 120 possibilities may seem frivolous; fortunately there exists a number of simplifying parameters that provide for surprising selectivity as well as predictability of the rearrangements of any hetero-substituted system of type **Z**.

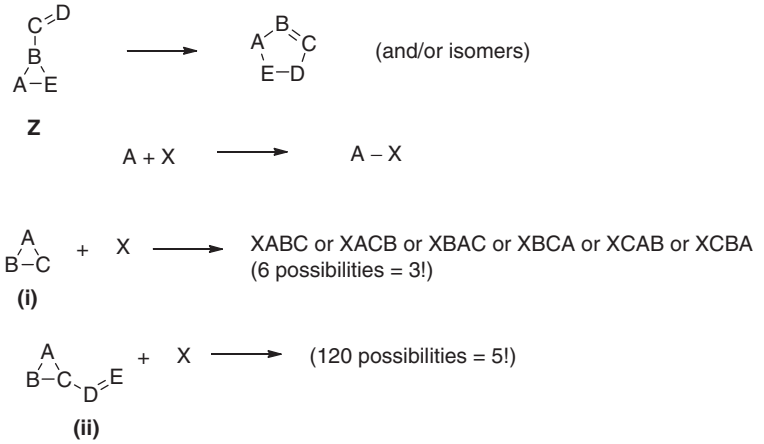

Figure 2 Permutations in connectivity.

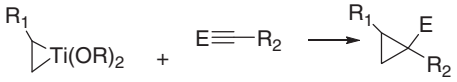
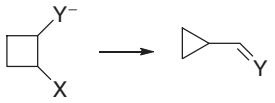
In the context of specific transformations, for example the vinylcyclopropane–cyclopentene rearrangement, substituent effects have been quantitatively addressed and are discussed in the appropriate sections. Donor/acceptor principles have been applied to thermal, heterolytic, and transition metal-catalyzed rearrangements and have been reviewed.[16,21,53–56] These take into account the possible intermediate structures listed in Table 1 and are used to explain the reactivity of a particular cyclopropane system. In the discussion that follows, emphasis is given to the processes that are uniformly selective with regard to regio-, stereo-, and enantiochemical integrity of the products.

5.22.1.2.3 Guide to preparation



The inherent energy content of the cyclopropane ring demands that the method of introduction of a cyclopropyl subunit itself relies either on highly reactive intermediates or on irreversible or energetically, if not entropically, favored processes. Thus the synthesis of cyclopropane derivatives can be classified into four major categories: 1,3 bond forming sequences (equation 4);[57–59] carbene or carbenoid routes (equation 5);[60–65] insertion of η^2 complexes of alkenes to electron-deficient unsaturated compounds (equation 7);[66–74] and rearrangement pathways (equations 8 and 9).[75–78]

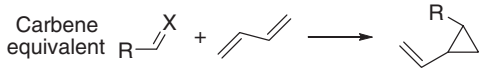


(4)

(5)

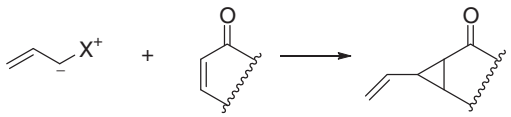
(6)

(7)



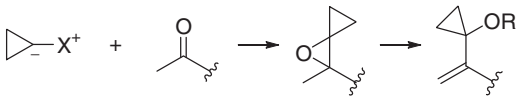
(8)

The procedures for the synthesis of cyclopropane derivatives, especially by the carbenoid route[57,59–63,79–84] or the ylide route (1,3-displacement),[19,20,59,85–88] have been amply reviewed.

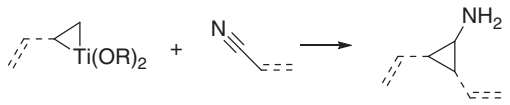


Equally well reviewed are the reactions of cyclopropanes and their use in synthetic methodology.[53,54–56,70,89] For the preparation of the more common cyclopropane derivatives, the use of suitably functionalized cyclopropyl building blocks that are commercially available is recommended.

Vinylcyclopropanes are most easily prepared by one of the following methods:



1. Cyclopropanation of conjugated dienes (inter- and intramolecular) by carbenes or carbenoids (equation 9)[51,83]
2. Permutations of the reactions of allylic ylides with Michael acceptors (equation 10)[19,20,59]
3. Ring opening of oxaspirocyclopentanes (equation 11)[19,20,90,91] and
4. Kulinkovich reaction of titanium diene intermediates with esters/amides/nitriles/thioacetals (equation 12)[69,70,73,74]

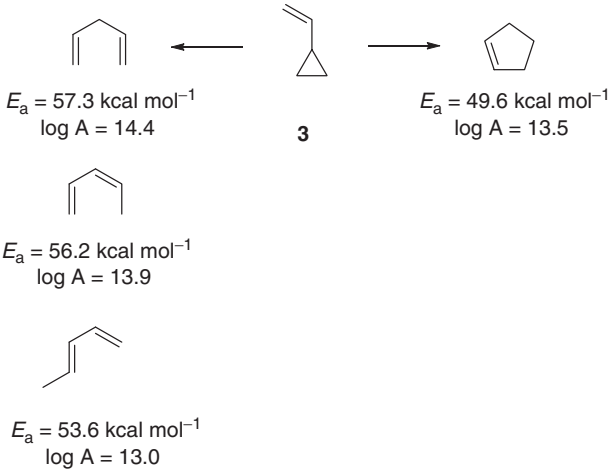


(9)

(10)

(11)

(12)

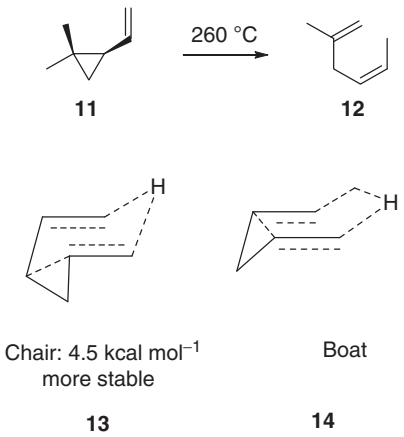


Indirect methods of formation can be used, for example, Wittig reaction of acylcyclopropanes and rearrangement pathways;[58,59] and in certain specific cases where the vinylcyclopropanes are immediately reacted further, by thermolysis of 1,4-dienes via [1,5] shift sigmatropic reactions.[51,92] The preparations of vinyloxiranes, vinylaziridines, cyclopropylcarbonyls, and cyclopropylimines have been reviewed in different contexts (addition of ylides to carbonyl compounds, interaction of azides or diazo compounds with alkenes, etc.), but their preparations have not been summarized under a common heading; however, any reference dealing with the use of these compounds will provide a guide to one or more methods of their synthesis.

5.22.1.3 Rearrangements of Vinylcyclopropanes

The vinylcyclopropane system is subject to a wide variety of transformations ranging from thermolysis and photolysis to nucleophilic, electrophilic, and radical ring-opening reactions as well as transition metal-catalyzed rearrangements and cycloadditions. A common trait in all such transformations is the release of the ring strain and further reaction of the intermediates thus generated. Until 1990s the most commonly recognized transformations of vinylcyclopropanes were those resulting from thermally induced bond reorganizations.

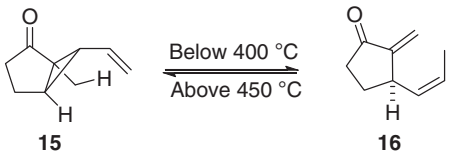
There are two major pathways available to vinylcyclopropanes on thermolysis: rearrangement to cyclopentene and ring opening to alkenes or dienes. The ability to predict which of these transformations is the most likely depends to a great extent on



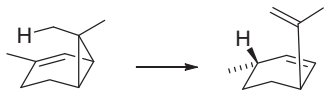
the substituents and on the precise conformational definitions and the orientation of the π-system of the vinyl group to the cyclopropane. The thermal cleavage of vinylcyclopropane can in principle provide any of the products depicted in Scheme 1. The analysis of the mechanistic pathways has been reviewed and widely accepted mechanism of such rearrangements includes a diradical intermediate/transition state.[22]

Scheme 1

5.22.1.3.1 [1,5] Shift pathways

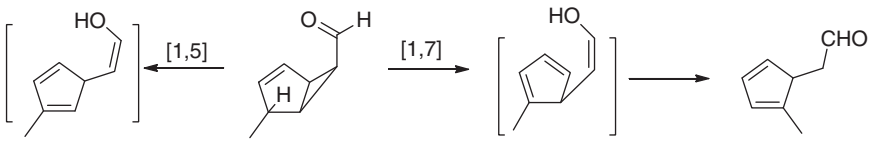


Under some circumstances, the [1,5] sigmatropic shift of a hydrogen from an alkyl group oriented *cis* to the vinyl group is the lowest energy pathway available to a vinylcyclopropane.[10,11,92] The classic experiments that led to the understanding of this process were performed by Winstein[93] and Frey.[92,94,95] The rearrangement of vinylcyclopropane **11** proceeded at 260 °C to furnish only the *cis*-alkene **12** (equation 13).[94] The rearrangement usually proceeds with an activation energy of 30–35 kcal mol^{-1} [9–11] and is thought to involve a chair-like (**13**) rather than a boat-like (**14**) transition state. Most of these rearrangements are stereospecific, yielding only the *cis*-alkene.



(13)

The transformation has been shown to be reversible by careful study of the temperature profiles of flash vacuum pyrolysis (FVP) of either *cis*-methylvinylcyclopropane **15** or diene **16** (equation 14).[96] Only above 400 °C did the vinylcyclopropane show the expected tendency toward diradical cleavage, a process that requires a substantially higher activation energy (15–20 kcal mol^{-1} higher) than the concerted [1,5] shift. This rearrangement also occurs stereospecifically in endocyclic vinylcyclopropanes such as **17** (equation 15).[97] The migration of the hydrogen atom is governed by the principles of sigmatropic rearrangements, that is, the pathway of the hydrogen atom is suprafacial.[98] The effect of substituents and their stereochemistry in this rearrangement was investigated.[99]



The fact that suitably sterically biased *cis*-alkylvinylcyclopropanes participate in these types of reactions attests to the ability of the cyclopropane ring to transfer conjugative properties and to act as a pseudo-ene unit. Competing pathways of higher order may become dominant in those cases where the transition state is stabilized by extended conjugation, as in the case of **18** and its predominant [1,7] hydrogen shift (Scheme 2).[100]

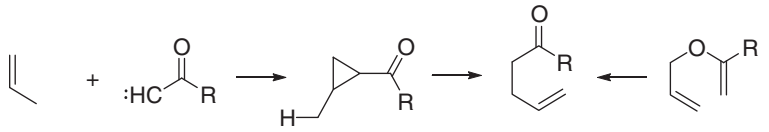
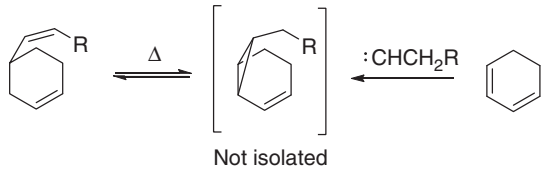
Scheme 2



Oxygen, nitrogen, and carbon atoms can equally well participate in the "vinyl" system. Table 2 provides a survey of some synthetically useful rearrangements of this type. In all cases shown in Table 2 the formation of the alkene is regioselective and in most cases it is stereospecific as well, according to the principles outlined below. The distinction between boat and chair transition states depends on the precise conformation of the reacting system, and this factor can be somewhat manipulated experimentally.

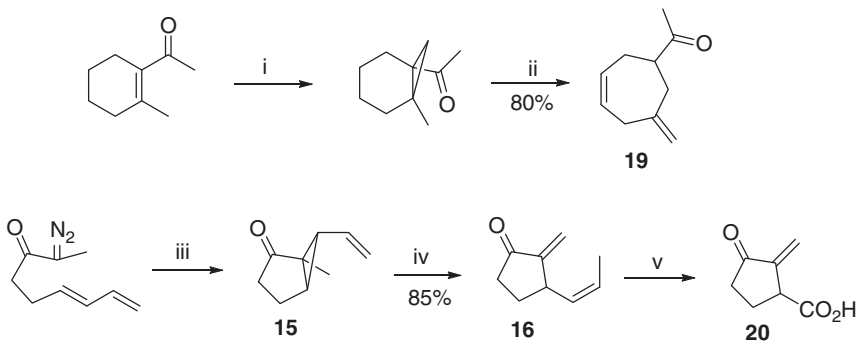
Table 2 Thermal rearrangements of *cis*-alkylvinylcyclopropanes

Cyclopropane	*Temperature (°C)*	*Alkene*	*Yield*	*References*
	300			95,101
	150		89.4	102
	280		82.5 (*trans*) 17.5 (*cis*)	102
	120			100,103,104
	200		80	105
	360		80	96



The synthetic utility of this process can be seen by evaluating the examples in Table 2. For example, because the cyclopropane serves as a pseudo alkene and because the [1,5] shift requires a six-membered transition state, it relates conceptually to the Cope and Claisen rearrangements. The γ,δ-unsaturated carbonyl compounds in Table 2 are those that would otherwise be obtained via

Claisen or orthoester Claisen rearrangements, which are normally effected under strongly acidic or strongly basic conditions (Scheme 3).



Scheme 3

For compounds of small molecular weight, the [1,5] shift pathway may therefore be superior in the ease of preparation, simplicity, and cost. In those instances where 1,4-dienes are easily constructed with the alkene predisposed *cis*, the resulting conversion to vinylcyclopropanes may in fact be superior to the use of carbenoid-based reagents in those instances where the resulting vinylcyclopropanes need not be isolated (Scheme 4). The retro-ene reaction of 1,4-dienes requires temperatures that induce immediate further reactive options in the vinylcyclopropane as soon as it is generated.[96]

Scheme 4

Two examples that show selectivity in synthetic applications are the synthesis of cycloheptanone **19**,[105] which involves ring expansion via a [1,5] hydrogen shift, and the synthesis of sarkomycin **20** (Scheme 5).[96,106] In both of these protocols, the intermediate cyclopropyl ketone or vinylcyclopropane system could be rearranged to dihydrofurans or cyclopentenes, respectively, by the appropriate adjustments in the experimental conditions.[9,51]

5.22.1.3.2 Vinylcyclopropane–cyclopentene rearrangements

The thermal rearrangement of vinylcyclopropanes to cyclopentenes is probably the most recognized mode of reactivity of the vinylcyclopropyl system and the one that has received the most attention. Discovered independently by Neureiter in 1959,[107] Vogel,[108] and Overberger and Borchert in 1960[109] it was scrutinized in detail during the 1960s. Mechanistic details of the thermal vinylcyclopropane–cyclopentene rearrangement have been reviewed.[22,23]

The fundamental issue at the time revolved around the concerted $[2\pi_s+2\sigma_s]$ versus diradical nature of the rearrangement. No resolution of this question materialized as both mechanisms were invoked to explain specific cases.[9–13] The experimental evidence in the majority of cases studied, however, supports a diradical-type cleavage of the vinylcyclopropane system and a reclosure of the allylic diradical with an average activation energy of approximately 45 kcal mol^{-1}, or approximately 15 kcal mol^{-1} higher than the competing [1,5] shift pathway discussed in the Sections 5.22.1.3 and 5.22.1.3.1. What is puzzling is the apparent stereospecificity

of the rearrangement of optically pure vinylcyclopropanes such as **21** (equation 16).[110] The presence of "forbidden" products, (−)-**23** and (+)-**23**, would suggest a biradical mechanism, but the high degree of retention of optical purity (80.1±0.4% at 60 °C, 68.8±0.5% at 120 °C) rules out any freely rotating diradical species.[110,111] This observation implies that if the regiochemistry of the rearrangement is controlled, the stereo- and enantiochemical consequences will follow.

(16)

Further studies conducted since 1990,[112–117] thus support, to a varying extent, a diradical-type cleavage of the vinylcyclopropane system and a reclosure of the allylic diradical with an average activation energy for unsubstituted vinylcyclopropane–cyclopentene rearrangement system of approximately 51.7±0.5 kcal mol^{-1}, as recently determined.[118] This value is approximately 6 kcal mol^{-1} higher than the one previously measured. Introduction of activating groups lowers the E_a for diradical opening by 5–20 kcal mol^{-1}.[114]

One of the major drawbacks is the apparent scrambling of enantiospecificity and sometimes stereospecificity. Opening and reclosure of vinylcyclopropane occurs more readily than the rearrangement to cyclopentene. Usage of *cis*- and *trans*-alkene can lead to the same manifold of products with different ratios. The use of optically pure vinylcyclopropanes indicated that both "allowed" (*antarafacial retention*, *ar*, and *suprafacial inversion*, *si*) and symmetry "forbidden" (*antarafacial inversion*, *ai*, and *suprafacial retention*, *sr*) products are formed although with different ratios. For example, for two cases of **21** and **22**, the distribution of products of (*sr*+*ai*) and (*si*+*ar*) pathways are shown in the **Table 3**.[119,120] In vicinally disubstituted donor–acceptor vinylcyclopropanes (i.e., functionalities on adjacent carbons), the transition state is believed to involve to some extent 1,3-zwitterionic intermediates.[54] The actual level of radical–zwitterionic character is likely influenced by the choice of solvent.[121]

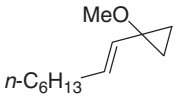
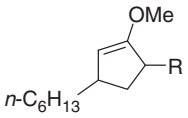
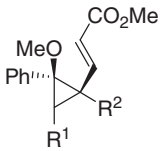
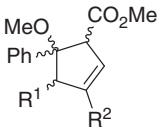
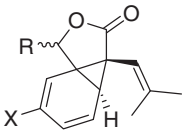
22, R^1=Me	90 (mix)		10 (mix)		119
22, R^1=Ph	91 (mix)		9 (mix)		120

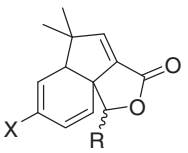


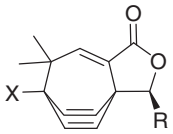


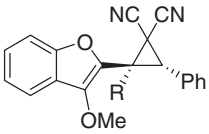


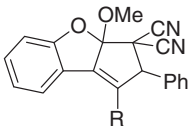


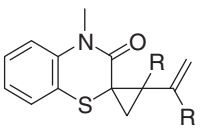


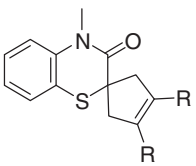


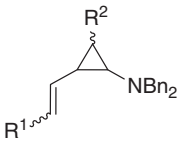


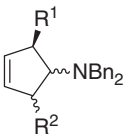


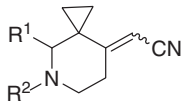


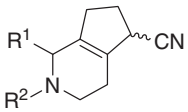








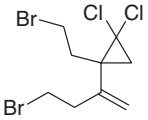


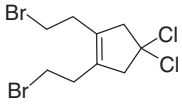


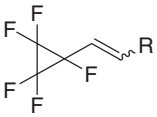
The molecular topology of this rearrangement is fascinating in its potentially limitless permutations. As indicated in Section 5.22.1.2.2, any one of the five atoms in the vinylcyclopropyl system may be replaced with almost any other atom (C, Si, P, N, O, S, etc.), and the overall reorganization to an unsaturated five-membered ring system remains operational. Thus cyclopropyl aldehydes, imines, ketones, and esters yield the corresponding heteroatom analogs of cyclopentene, as do vinyloxiranes, vinylaziridines, and vinylthiiranes. When electronegative elements are contained within the vinylcyclopropane framework, the mechanism may change from a diradical to a dipolar one.

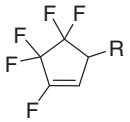
In the parent system **3**, only one bond is activated toward a cleavage that produces an allylic radical. In more substituted cases, however, different degrees of activation may exist, and these will control the rate as well as the regiochemistry of the rearrangement. Some examples of recent synthetic utilization of the thermal vinylcyclopropane–cyclopentene rearrangement are presented in **Table 4**.

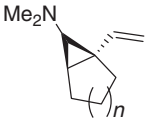
Nonthermal rearrangements can proceed under significantly milder conditions. For example, a radical-cation of vinylcyclopropane has a barrier of rearrangement of only 21.7 kcal mol^{-1}.[134] The photolytic vinylcyclopropane–cyclopentene rearrangement usually proceeds with the same stereoselectivity as the thermal rearrangement. It can be performed under direct irradiation or with photosensitizers and has been subject of several reviews.[135,136] It is interesting to note that, in some cases, the outcome of the photochemical rearrangement can be different: the vinylcyclopropane–cyclopentene rearrangement takes place in the presence of the photosensitizer and the cyclopropylcarbonyl–lactone rearrangement under direct irradiation conditions (see **Scheme 6**).[137]

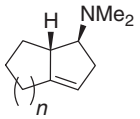


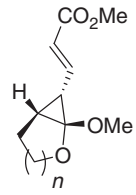


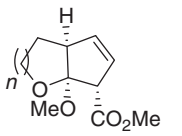


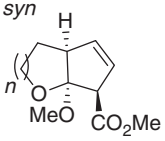












Photosensitized reactions are believed to proceed through single-electron transfer (SET).[138] Studies on cyclopropanes substituted with electron-withdrawing groups (EWGs) and electron-donating groups (EDGs) at position 1 (point of the connectivity of the vinyl group) of the cyclopropane ring showed that the former substrates tend to form an open-chain radical, which attacks

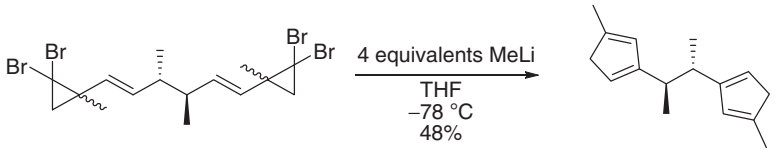
the aromatic ring and undergoes divinylcyclopropane–cycloheptadiene rearrangement to form compounds **28**. With electron-donating substituents on the cyclopropane, the products of the classical vinylcyclopropane–cyclopentene rearrangement, namely **27**, were formed (equation 17).

(17)



Cation–radical rearrangement mechanism and periselectivity have been studied.[139] Upon reaction with an amidyl radical source (i) in equation 18, the product of the rearrangement was formed. The same product was formed under conditions of one-electron oxidation in (ii) equation 18 and photochemical rearrangement (iii) in equation 18. Almost identical stereoselectivity and product distribution led to the conclusion that all three reactions operate under the same mechanism. These methods present a complementary approach to the thermal rearrangement. Formal periselectivity of the latter one is different and a main product of it would be the retro-ene product.

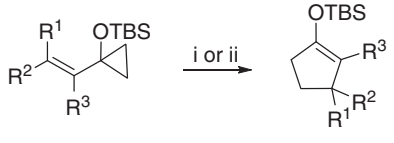
The Skattebøl rearrangement, shown in equations 19 and 20, constitutes a rare case of the vinylcyclopropane–cyclopentene rearrangement. It is used especially for the generation of cyclopentadienyl anions[140,141] and is believed to proceed through the formation of carbene intermediates.

(19)

(20)



Lewis acids are known to facilitate the vinylcyclopropane–cyclopentene rearrangement under mild conditions. For this protocol to be effective the cyclopropane ring must contain a functionality that can interact with the Lewis acid in order to stabilize charged zwitterionic intermediates. Some recent examples of these rearrangements are shown in **Table 5**.

5.22.1.3.2.1 Metal-catalyzed rearrangements

5.22.1.3.2.1.1 Vinylcyclopropane–cyclopentene rearrangements

The metal-catalyzed vinylcyclopropane–cyclopentene rearrangement has a much shorter history of development than the thermal version. The major difference from thermal rearrangement lies in the fact that the thermal rearrangement requires high temperatures to ensure cleavage of the C–C bond to diradicals with very similar energy, which in turn produce mixtures of products. Because metal insertion takes place at significantly lower temperatures through a concerted pathway, the stereoselectivity of the outcome can be controlled much more efficiently than in the case of thermal rearrangements. In addition, the use of chiral ligands provides an opportunity to control enantioselectivity, which cannot be achieved using other conditions unless at least one chiral center retains its original configuration. This aspect was sufficiently demonstrated through the early work of Hudlicky.[152] A general discussion on the topic of the transition-metal-catalyzed rearrangement of vinylcyclopropanes and related systems is provided in several reviews.[89,153,154]

Initially rhodium, low valent nickel, and copper catalysts were used.[155] Ryu and Sonoda[156] discovered that the catalytic system Ni(0)/PPh_3 can catalyze vinylcyclopropane–cyclopentene rearrangements of activated 1-silyloxyvinylcyclopropanes in good yields (equation 21).

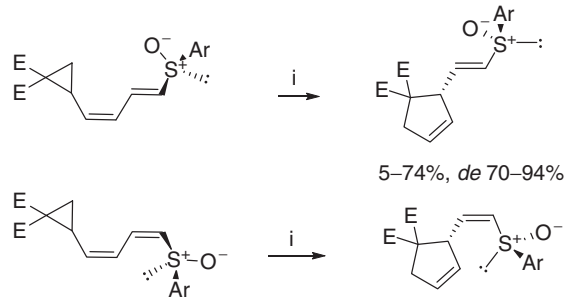
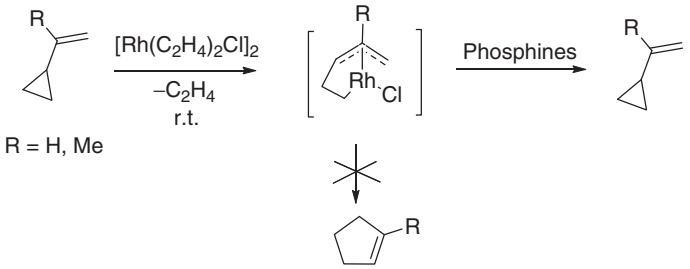
[a]Significant erosion of enantiomeric excess (*ee*) for monocyclic substrates, retention of *ee* for bicyclic substrates.
Abbreviations: TFE, trifluoroethanol; TIPS, triisopropyl silyl.



An enantioselective version of the vinylcyclopropane–cyclopentene rearrangement was developed by Hiroi,[157] who studied a wide range of metal catalysts, ligands, and solvent systems. Best results were obtained with Ni(1,5-cyclooctadiene; $COD)_2$/(+)-MOD-DIOP/DMSO, which produced the desired compound with 90% *ee*. It is interesting to note that the use of $Pd(PPh_3)_4$ under the same conditions[158] gave complete inversion of the enantioselectivity for the same substrates, albeit with lower *ee*. This suggests different modes operating in Ni- versus Pd-catalyzed rearrangements. Other metals, such as Cr, Mo, Pt, and W either failed to promote the rearrangement or their use did not lead to significant enantioselectivity (Scheme 7).

Scheme 7



A chiral sulfoxide auxiliary was used by Hiroi in the rearrangement shown in Scheme 8.[159] High levels of diastereomeric excess (*de*) (90–94%) were observed and the unexpected retention of configuration of the diene double bond was noted.

Most of the early discoveries of rearrangements catalyzed by Ni and Pd were made on "activated" vinylcyclopropane systems, either those containing EWGs on the cyclopropane ring, whose presence is thought to facilitate oxidative addition of the metal, or those containing an extended diene system, which would help precoordination of the transition metal. Rhodium catalysis did not require such additional functionalities in order to undergo C–C bond insertion, but in the case of simple unsubstituted vinylcyclopropanes a stable complex is formed that does not undergo a further transformation to cyclopentene, as shown in Scheme 9.[160] Cyclopropylallenes and cyclopropylalkynes can be considered to be activated systems. Examples of rearrangement of cyclopropylallenes with rhodium are known, as shown in equations 22, 23 and Table 6.[161,162]

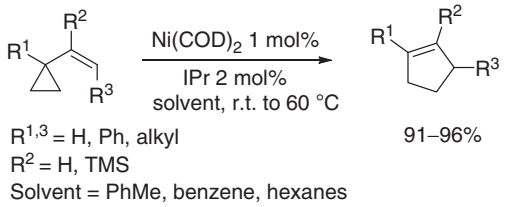
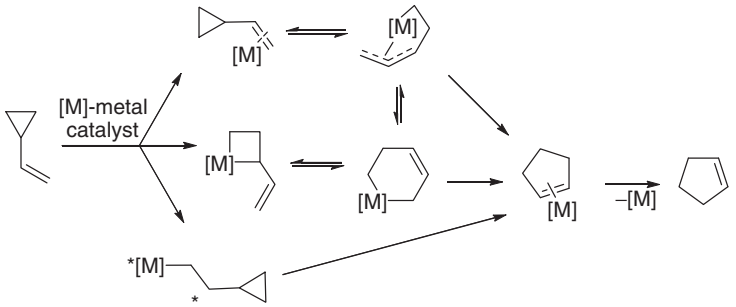
copper[163] and gold catalysis.[164,165] Both reactions are believed to proceed through similar allenic–metal complexes, as shown in Scheme 10.

Scheme 10



The unactivated vinylcyclopropane **29** was shown by Suginome and Ito to isomerize in the presence of Ni(pentane-2,4-dione; acac)$_2$/PCy_3/diisobutylaluminium hydride (DIBAL).[166] It is interesting to note that in an earlier chapter by Nishida[155f] the same substrate was shown to be inactive under $Ni(COD)_2$/PBu_3 conditions.



(24)

In 2004 Louie[167] discovered that the rearrangement of unactivated vinylcyclopropanes can be performed with a catalytic system consisting of $Ni(COD)_2$/N-heterocyclic carbene (NHC). (NOTE: Although the term "NHC" is widespread in the literature, the authors suggest refraining from the usage of this terminology. As there is no experimental proof that such species are true carbenes (they are in fact zwitter-ions!) the term NHC is misleading, inaccurate, and incorrect. It is only a resonance form of the zwitterion, not a true reactive entity. The metal complexes of such species should be referred to as carbenoids.) Utilization of sterically hindered "NHC" ligands allowed this reaction to proceed at significantly lower temperatures (room temperature to 60 °C) than with phosphine ligands, equation 25. Later this reaction was also utilized by Murakami[168] for bicyclic systems.

Louie and Tantillo studied the mechanism of the rearrangement under the Ni catalytic system.[169] They showed that the rearrangement is likely to proceed via sequential formation of an alkene complex followed by the opening of the cyclopropane and formation of complexes with different hapticity, as shown in Scheme 11.

(25)

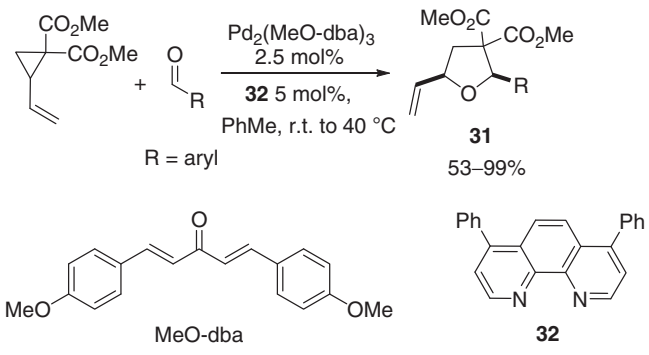
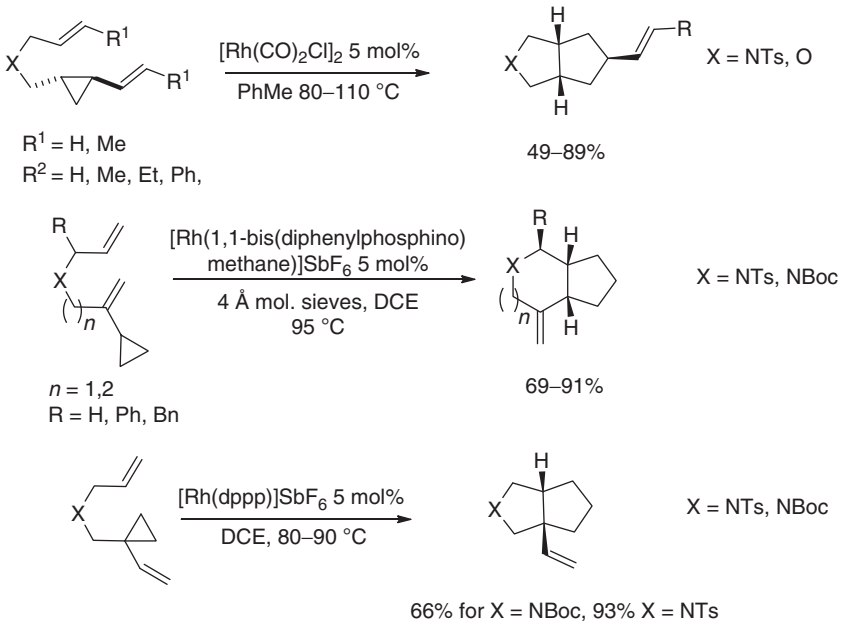
5.22.1.3.2.1.2 Metal-catalyzed opening and [3+2] cycloadditions



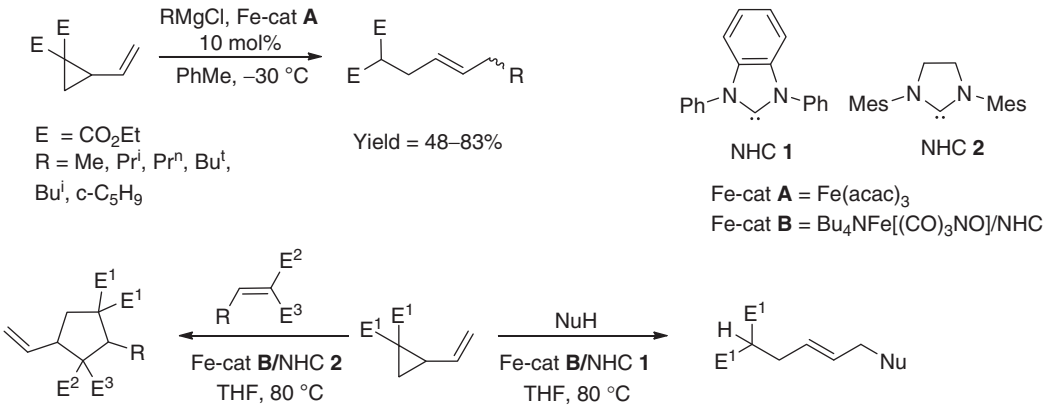
When a vinylcyclopropane is substituted with an electron withdrawing group (EWG), donor/acceptor symmetry causes the electrons to flow in one particular direction. Such a system, for example **30**, is susceptible to insertion of a transition metal followed by nucleophilic addition or cycloaddition of unsaturated compounds. Control of the outcome of the three possible modes of reaction is available by changing the metal and/or the ligand environment. As well, the use of chiral complexes can provide access to chiral compounds. Similar reactivity can be observed via Lewis acid mediated cycloaddition. This particular subject has been thoroughly covered in recent reviews.[54–56]

Most developed metal-catalyzed insertions involve palladium catalysis, proceeding via the formation of η^3-metal complexes. The regioselectivity of cycloaddition is dictated by the electronic effects of the second coupling partner as shown in Scheme 12.

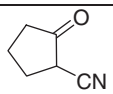


Scheme 12

The first example of such a [3+2] cycloaddition of an activated vinylcyclopropane as 1,3-dipolar equivalent with an activated alkene was described by Tsuji in 1985.[170] Different unsaturated fragments have been used as partners for coupling with activated cyclopropanes. Johnson[171] showed that aldehydes also undergo such cycloadditions. The main products are 2,5-disubstituted tetrahydrofurans (THFs) **31**. It was shown that electron-poor aldehydes perform better under the chosen reaction conditions (equation 26).

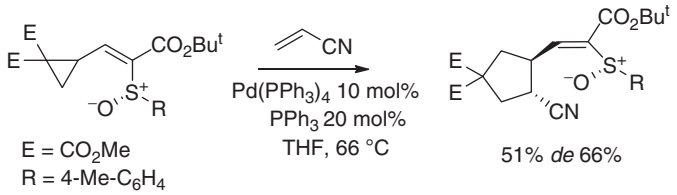


(26)



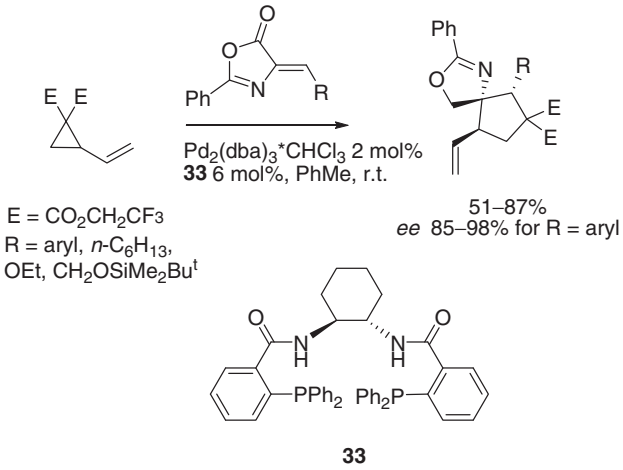
Rhodium-catalyzed [3+2] intramolecular cycloadditions of unactivated vinycyclopropanes were shown to proceed selectively[172] under the same conditions employed for the [5+2] cycloadditions (see Section 5.22.1.3.2.4). The configuration of the vinylcyclopropane plays a crucial role in the outcome of such process as shown in Scheme 13.

Scheme 13



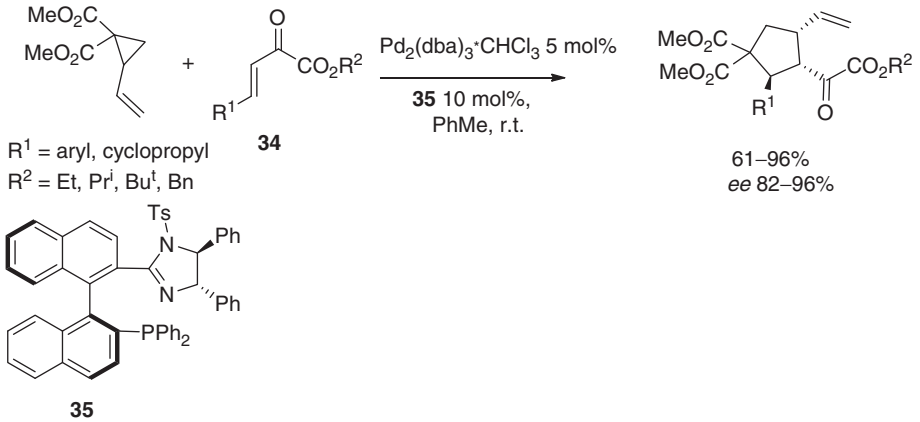
Complexes of iron[173,174] were shown to be efficient and inexpensive catalysts in formal [3+2] cycloadditions as well as in nucleophilic opening. Fürstner[173] has shown that activated vinylcyclopropanes undergo nucleophilic opening by Grignard reagents in the presence of $Fe(acac)_3$ to produce allylic products. A more recent study by Plietker[174] showed that the mode of reactivity catalyzed by the $Bu_4N[Fe(CO)_3NO]$/NHC system can be altered by modifying the NHC ligand as shown in Scheme 14.

	R, E^2, E^3	E^1	NuH	
		SO_2Ph		96%
95%	H, SO_2Ph, SO_2Ph	CO_2Me	$CH_2(CN)_2$	70%
79%	H, SO_2Ph, SO_2Ph	$CO_2CH_2CF_3$		
82%	Ph, CN, CN	CN		



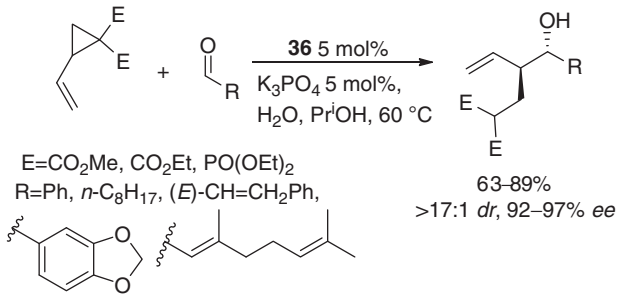
Scheme 14

Asymmetric versions of a formal [3+2] cycloadditions have a much shorter history. One of the first examples was performed by Hiroi who used chiral auxiliaries.[175] Despite the modest diastereoselectivity, the starting material can be easily accessed in an enantiodivergent way.



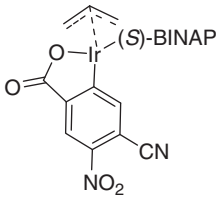
(27)

Trost[176] developed an asymmetric version of the [3+2] cycloaddition with alkylidene azalactones as the ene fragment. Additional activation of the cyclopropyl ring was required by introduction of electron-poor trifluoroethyl esters in order for the reaction to proceed in good yield. The reaction provided products with high enantioselectivity and high diastereomeric ratios (>19:1 for R=aryl) (equation 28).



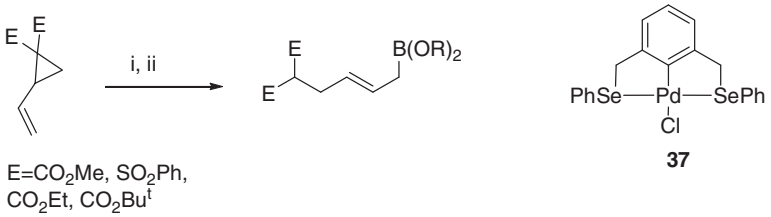
(28)

A similar approach was also described by Shi.[177] Palladium catalysis was shown to be quite efficient with the new type of chiral ligands **35**. Starting from standard activated cyclopropanes and activated alkenes **34**, chiral cyclopentanes were produced with good yields and high enantioselectivity (equation 29).



(29)

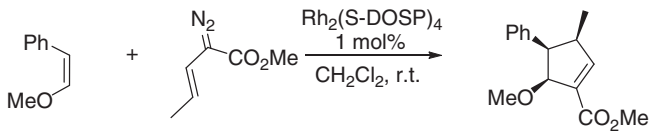
Unusual regioselectivity was observed with the iridium catalyst **36** during the coupling of aldehydes with activated vinylcyclopropanes. In contrast to the analogs coupling under palladium catalysis,[171] the introduction of iridium led to the opposite regioselectivity of aldehyde insertion. Homoallylic alcohols were produced with good yields and high enantioselectivity (equation 30).



(30)

36

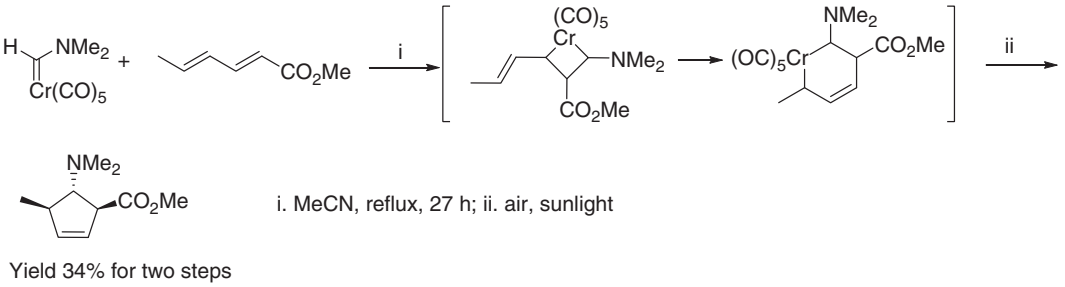
Different functional groups can be introduced via metal-catalyzed insertion. One of the most useful examples is the borylation of vinylcyclopropanes. The use of the palladium pincer complex **37** was shown[178] to lead selectively to *E*-allyl boronates. Similar transformations were also performed with the $Ni(COD)_2$/phosphine system under milder conditions and were shown to be less demanding with regard to the activation of the cyclopropane ring by EWGs (**Scheme 15**).[179]



37

Scheme 15

5.22.1.3.2.2 Formal [4+1] cycloadditions catalyzed by metals

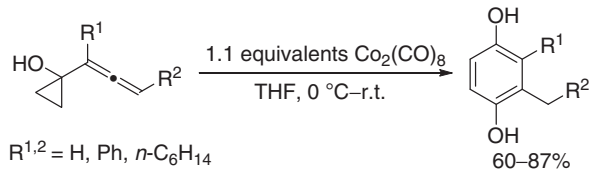


In some cases no cyclopropanes are isolated during attempted cyclopropanations of electron-rich enolates by vinyl carbenoids. Such a difference in the product outcome has been observed by Davies.[145] Depending on the nature of the rhodium catalyst, it was possible to isolate either a cyclopropane or a cyclopentene. The latter outcome was believed to proceed via charged intermediates, which lead directly to the cyclopentene, the product of a "formal" [4+1] annulation, (equation 31).

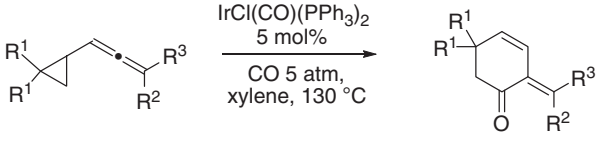
79%, 98% *ee*

(31)

Hegedus[180] discovered that the addition of an electron-rich chromium carbene to methyl sorbate provided the product of the formal [4+1] cycloaddition in one step. It is believed to form through sequential addition and rearrangement of a chromium complex, followed by reductive elimination, as shown in Scheme 16.



Scheme 16



5.22.1.3.2.3 [5+1] Cycloadditions

The formal [5+1] rearrangement has a significantly shorter history than other cycloadditions of the vinylcyclopropane system. Before 1990, only a limited number of examples of vinylcyclopropane–cyclopentene rearrangements with stoichiometric iron carbonyls were explored.

The first version of the [5+1] cycloaddition with metals other than Fe was discovered for "activated" vinylcyclopropane system containing allene and/or oxygen substituents on the cyclopropane ring. Cobalt [181] and iridium[182] catalysts were among the first to be investigated. Mechanistic studies of such cycloadditions were carried out with $Fe(CO)_5$.[183] Taber[184] showed that this transformation can be used for the synthesis of enantiopure cyclohexenones. A catalytic version of the [5+1] cycloaddition catalyzed by $Co_2(CO)_8$ was developed by de Meijere,[185] and similar activity was observed for $[Rh(CO)_2Cl]_2$ (equation 34). Only vinyl cyclopropanes with substituents on both the double bond and the cyclopropane ring undergo rearrangement under such conditions. Cationic rhodium catalysts, which were developed for [5+2] cycloadditions (*vide infra*), proved applicable in some cases to [5+1] cycloaddition with unactivated vinylcyclopropane systems[186] (equation 35 and Table 7). Yu and coworkers described[187] formal [5+1]/[2+2+1] cycloadditions (equation 36). The scope of this transformation is limited to 5-5-6 system. The product of such transformation possesses elements of homo-angular triquinane skeletons.

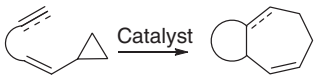
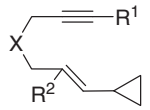
5.22.1.3.2.4 [5+2] Cycloadditions

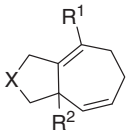
A [5+2] cycloaddition or rearrangement between vinylcyclopropane and an unsaturated two-carbon partner has been an attractive goal for synthetic chemists over the years, as it offers the possibility to generate multifunctionalized polycyclic structures containing seven-membered rings. This topic has been reviewed extensively over the past 10 years.[188] Seminal work was presented by Wender,[189] who described intramolecular cycloadditions of vinylcyclopropanes and alkynes with Wilkinson`s catalyst. The addition of AgO trifluoromethanesulfonate (Tf) has shown to lower the catalyst loading significantly and shorten the reaction time. More efficient catalysts were discovered,[190] such as $[Rh(CO)_2Cl]_2$ with higher functional group compatibility and improved selectivity. It has been shown that cationic Rh(I) complexes are most likely to be the active intermediates in such reactions. For example, other Rh catalysts that induced the [5+2] transformation at room temperature included those developed by Gilbertson[191] ((Rh(1,2-bis(diphenylphosphino)ethane; dppe)$(CH_2Cl_2)_2$]SbF_6) and Zhang ([Rh(1,4-bis(diphenylphosphino) butane; dppb)Cl]$_2$/$AgSbF_6$).[192] The recent development in this field is the discovery of the tendency of the arene complexes **42**[193] and **43**[194] to catalyze [5+2] cycloadditions with exceptional effectiveness and wide substrate scope at room temperature. Arene complex **42** allowed the migration of the double bond in the final product to be suppressed, which was a common problem with $[Rh(CO)_2Cl]_2$. [Rh(nbd)Cl]$_2$/$AgSbF_6$ (nbd=norbornadiene) was shown to accomplish successfully the transformation in water in the presence of the water soluble phosphine **46**.[195] The use of a water–methanol mixture as the solvent facilitated the isolation of nonpolar products. High formal dilution helps to suppress unwanted side reactions.

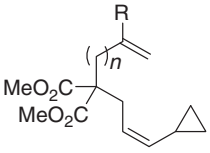


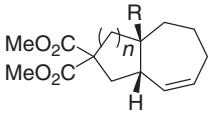
42 43 44 45

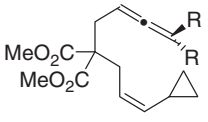
46 47

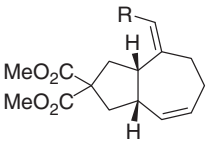












Because of the prohibitive cost of rhodium, other metal complexes have been investigated as alternatives in the catalysis of the [5+2] cycloaddition. Trost[196] found the commercially available $[CpRu(MeCN)_3]PF_6$ complex to be an effective catalyst at room temperature but with somewhat lower yields that the rhodium system **42**. Low-valent iron complexes of type **44** and **45** were utilized by Fürstner[197] for similar reactions. The $Ni(COD)_2$/SIPr system developed by Louie[198] was active in a limited number of cases (Table 8).

The scope of this reaction was later expanded to include alkenes and allenes as the cycloaddition partners.[199–201] The general reaction is depicted in Scheme 17, and representative examples of rhodium-catalyzed reactions are presented in Table 9. Only geminally disubstituted alkenes are suitable substrates for cycloaddition. Chiral allenes underwent the rearrangement enantioselectively. Vicinally disubstituted alkenes produced inseparable mixtures of products.[201]

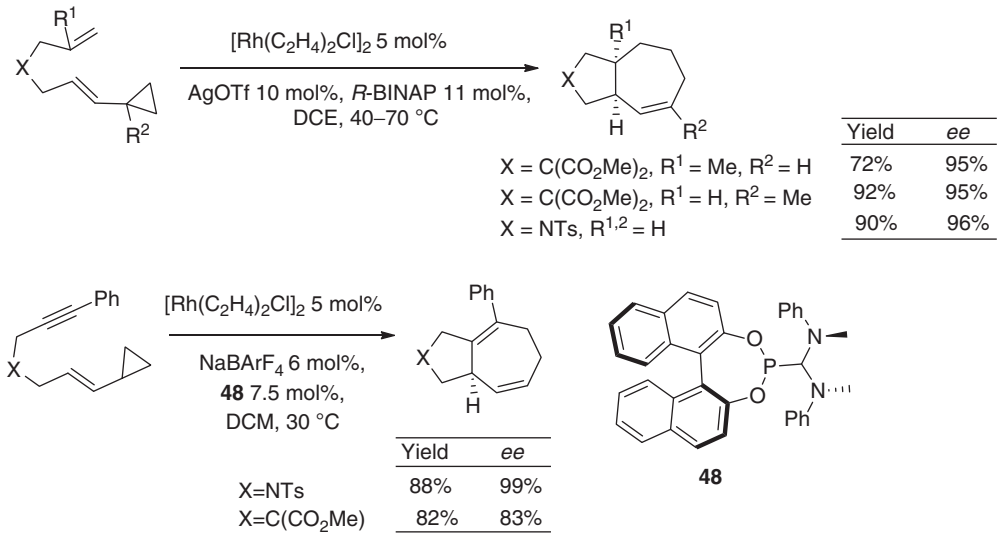
5.22.1.3.2.5 Intermolecular [5+2] cycloadditions

The intermolecular version of the [5+2] cycloaddition, first described by Wender[202] for alkynes and vinylcyclopropanes, poses a greater challenge than the intramolecular case. It was shown that additional coordinating siloxy or carboxy groups[203] on the vinylcyclopropane ring helped to facilitate such reactions. The scope of alkyne substrates has been shown to be quite extensive, including electron-rich, electron-poor, and terminal alkynes, as depicted in equation 37. The reaction has also shown to be chemoselective toward the alkyne moiety in enynes. The use of alkynes containing coordinating groups has led to higher yields of the cycloaddition products.

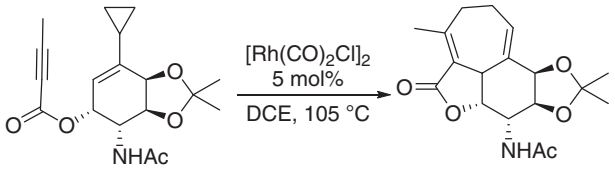
(37)

Reactions with "unactivated" vinylcyclopropanes are possible at higher temperatures; however, these vinylcyclopropanes must contain bulky substituents on position 1 of the cyclopropyl ring and/or oxygen coordinating substituents on the alkene portion of the vinylcyclopropane as shown in equation 38.[204]



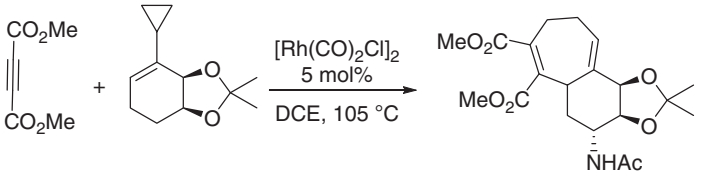
(38)

Wender[205] later discovered that intermolecular vinylcyclopropane–alkyne cycloadditions can be performed at room temperature and low loading (0.2–0.5%) with the cationic complex $[Rh(C_{10}H_8)cod]^+$ SbF_6^-. Simple allenes do not undergo cycloaddition, but it has been shown that extra coordinating groups such as alkynes, alkenes, and nitriles facilitate the cycloaddition.[206] Alkenes are not suitable substrates for intermolecular cycloadditions of this type.



5.22.1.3.2.6 Asymmetric [5+2] cycloadditions

There are very few examples of enantioselective [5+2] cycloadditions. Wender[201] observed the first example for the vinylcyclopropane–alkene system by using $[Rh(C_2H_4)_2Cl]_2$/AgOTf with (–)-CHIRAPHOS; however, only 63% *ee* was obtained. Later[207] he showed that the best ligand for such transformations is *R*-BINAP. The highest *ee* was achieved for *gem*-disubstituted alkene fragments. In case of an alkyne or an unsubstituted alkene moiety, low *ee*'s were obtained. Hayashi[208] discovered a new catalytic system which was useful in achieving high *ee*'s for vinylcyclopropane–alkyne coupling, as shown in **Scheme 18**.



Scheme 18 $NaBAr^F_4$, sodium tetrakis[3,5-bis (trifluoromethyl)phenyl]borate.

Recently, Hudlicky [209] studied the [5+2] cycloaddition with vinylcyclopropanes in which the olefin was constrained into a ring, as shown in equations 39 and 40; however, the yields were extremely low in both inter- and intramolecular applications. Calculations have shown a 16° misalignment of the olefin with the cyclopropane (see Figure 3). (Illustration provided by Dr. Travis Dudding (the structure was optimized with density functional theory (DFT) using B3LYP/6–31G(d)).) The yield of the cycloaddition was later improved to 22% for the intramolecular version.[210]

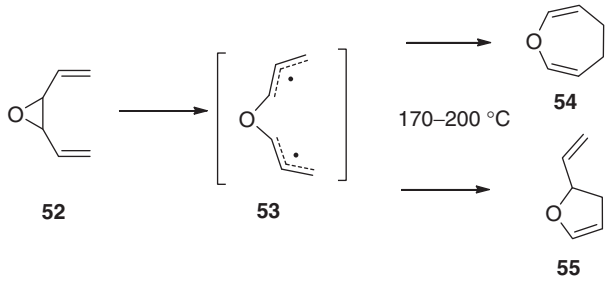
5.22.1.4 Rearrangements of Vinyloxiranes and Cyclopropyl Carbonyls

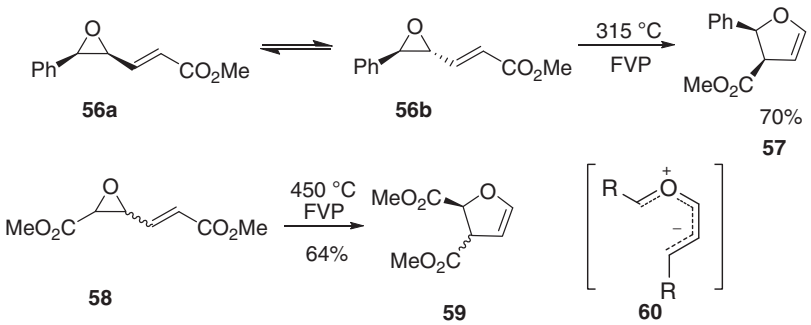
5.22.1.4.1 Vinyloxiranes



Rearrangements of vinyloxiranes proceed in an analogous fashion to those of the corresponding vinylcyclopropane, with two notable exceptions. First, they generally require a lower activation energy and therefore take place under milder conditions. Second, most of the thermal rearrangements proceed through zwitterionic or ylide-like intermediates, which are uncommon in carbocyclic cases. The nucleophilic opening of systems such as **51** is more complex because of the coordinative abilities of oxygen and the increased number of possible nucleophilic interactions (Scheme 19). Nevertheless, there is some parallel behavior and predictability in vinyloxirane rearrangements.

Scheme 19

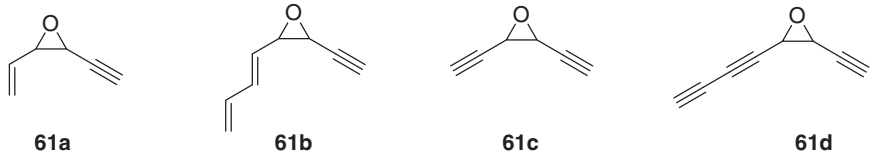
5.22.1.4.1.1 Thermal isomerization



The study of benzene oxide–oxepin tautomerism, reviewed in the late 1960s, revealed a competing pathway in the rearrangements of *trans*-divinyloxiranes of type **52** (Scheme 20).[211,212] The corresponding *cis* isomer gave only oxepin **54**, whereas the *trans* isomer gave a 7:3 mixture of dihydrofuran **55** and oxepin **54**. The activation parameters implied that the intermediate was biradical **53** (*cis*-oxide: $\Delta H^{\ddagger} = 24.6$ kcal mol^{-1}, $\Delta S^{\ddagger} = -11.3$ cal deg^{-1} mol^{-1}; *trans*-oxide: $\Delta H^{\ddagger} = 36$ kcal mol^{-1}, $\Delta S^{\ddagger} = -0.4$ cal deg^{-1} mol^{-1}).[211] These values indicate processes far lower in energy than those operating in the vinylcyclopropane rearrangement, whereas their difference (11 kcal mol^{-1}) led to the conclusion that the rearrangement was concerted for the *syn* isomer and biradical for the *trans* compound.

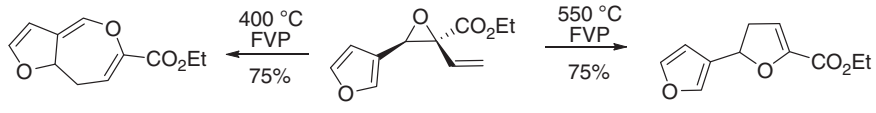
Scheme 20

The mechanism has since been studied on a number of occasions, and it is generally agreed that concerted, electrocyclic closures of ylides are operating in the formation of either oxepins or vinylfurans.[213–217] The rate of racemization of optically pure vinyloxiranes has been shown to be 6 times faster than the isomerization to the dihydrofuran.[213] Alternatively, cleavage of a vinyloxirane to a carbon–oxygen diradical pair or to a carbene–carbonyl pair has been considered for processes that do *not* usually lead to the formation of dihydrofuran[213,215,218] (though there is a notable exception, see ref.[218]). Corresponding [1,5] shift pathways are also known for those oxiranes that contain a *cis*-oriented alkyl group having at least one hydrogen.[215]



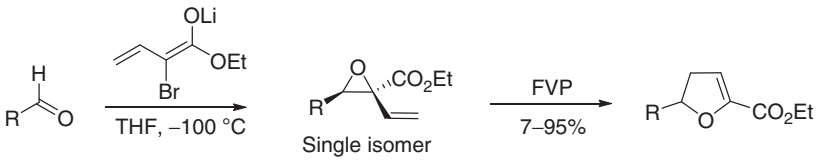
The regio- and stereoselectivity of this rearrangement was found to be excellent.[214] Thus the rearrangement of either isomer of vinyloxirane **56** yielded dihydrofuran **57** stereoselectively, whereas that of vinyloxiranes **58** led to a mixture of *cis* and *trans* isomers (Scheme 21); *cis*/*trans* isomerization was also accomplished photochemically.[219] The results were rationalized by involving ylides

Scheme 21



of type **60** and this allowed $[2\pi_s+2\sigma_a]$ or $[2\pi_a+2\sigma_s]$ closures for the former case and biradicals for the latter, although the epimerization may have taken place after the rearrangement because of the presence of an acidic proton.[214]

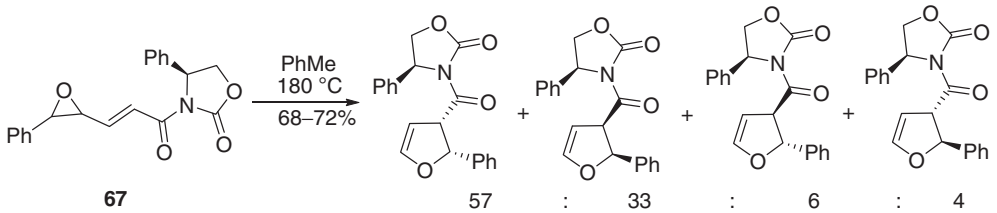
A number of substituents can be placed on the periphery of the vinyloxirane system. For example, alkynyl- and dienyl-oxiranes of the general structures represented by **61a** to **61d** were extensively studied. Their isomerization to various oxidation states of oxepins competed in some cases with the formation of the corresponding vinylfurans.[167,214,215,217,220]



61a **61b** **61c** **61d**

The control of furan versus oxepin manifolds has been addressed. Vinyloxiranes of type **62** yielded oxepins **63** at lower temperatures, whereas higher temperatures gave dihydrofurans (**64**; Scheme 22),[221] indicating that the Cope-type rearrangement of *cis*-divinyloxirane may be controlled by precisely defining the temperature profile of the FVP.[221,222] A [2+3] dihydrofuran annulation methodology was developed based on this rearrangement. Vinyloxiranes **65** were generated by the stereospecific addition of the lithium dienolate of ethyl α-bromocrotonate to aldehydes, and the subsequent pyrolysis to dihydrofurans **66** (Scheme 23) proceeded in excellent isolated yields (except for R = Bu^n, Pr^i).[221]

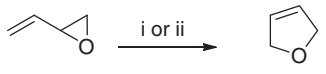
63 **62** **64**



Scheme 22

65 **66**

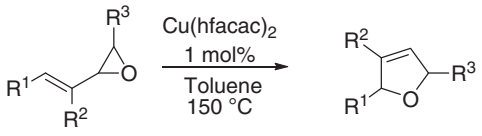
Scheme 23



The thermal rearrangement of vinyloxiranes equipped with a chiral auxiliary group, such as **67**, was studied by Steel,[223] but only limited chiral induction was achieved because of the small energy difference in the corresponding transition states (equation 41).

67 (41)

The 2-vinyloxirane–2,5-dihydrofuran rearrangement is a transformation of interest for industrial applications.[224,225] A combination of Lewis acids such as trialkyltin iodides,[225] zinc halides,[224] and iodide salts can be used as shown in Scheme 24.



Njardarson[226] found that Bis(hexafluoroacetylacetonato)copper(II) ($Cu(hfacac)_2$) is a convenient catalyst for laboratory application of the rearrangement to a wide range of vinyloxiranes **70** to 2,5-dihydrofurans **71**. The process occurs under milder conditions than those employed for the conventional thermal rearrangement. Complete stereoselectivity was observed in these rearrangements (equation 42).

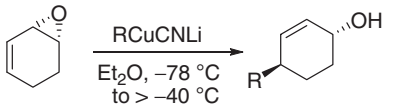
Yield 59–97%

Radical addition of alkenes to vinyloxiranes to yield THFs is analogous to the similar reaction of vinylcyclopropanes (equation 43),[227] with the same regio- and stereoselectivity, with a predominance of *syn* isomers having the regiochemistry indicated in **72**.[228] Radical polymerization of vinyloxiranes has also been reported.[229] The rearrangements of vinyl thiiranes proceed in a similar fashion to those of vinyloxiranes. The general field of thermal rearrangements of three-membered heterocycles containing oxygen, sulfur, or nitrogen was reviewed.[230] A vast majority of the literature on the rearrangements of vinyloxirane systems deals with those cases where Cope-like rearrangements of the divinyloxiranes are possible. The expansions of such systems to oxepins and further rearrangements and transmutations of, for example, vinylalkynyloxiranes to vinylcyclopropyl aldehydes have also been studied and reviewed.[222,228,230]

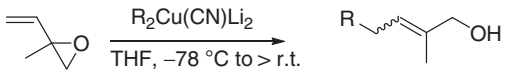
47%



(43)

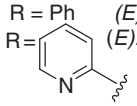
72

5.22.1.4.1.2 Nucleophilic opening



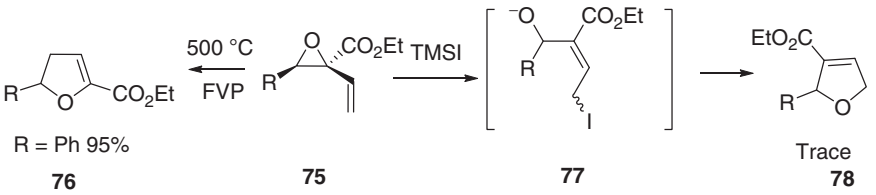
Vinyloxiranes react with nucleophiles in three regiochemically distinct ways: with α, β, and vinylogous modes of opening. The subject has been of considerable interest in the context of acyclic stereoselection and generation of allylic alcohols in an iterative fashion. Cyclic vinyloxiranes react with organocuprates with inversion of configuration (*anti*) and in a vinylogous mode (equation 44), not by the expected S_N2 reaction that simple oxiranes are known to undergo. This subject has recently been summarized.[231,232]

The conformation of cyclic vinyloxirane is restricted, whereas the acyclic vinyloxiranes, like vinylcyclopropanes, enjoy a conformational equilibrium, which determines the (*E*):(*Z*) ratio of the allylic alcohols that result from interactions with nucleophiles. For example, vinyloxirane **73** gave a *E*:*Z* = 4:1 ratio of allylic alcohols **74** (equation 45) with $Ph_2Cu(CN)Li_2$, but a 7:2 ratio when (2-$C_5H_5NCH_2$)$_2$Cu(CN)Li_2 was used.[233]



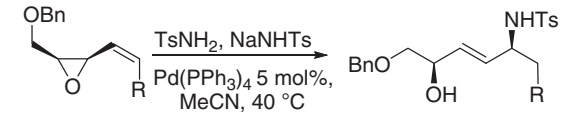
R = Ph 65%
Me 95%

(44)



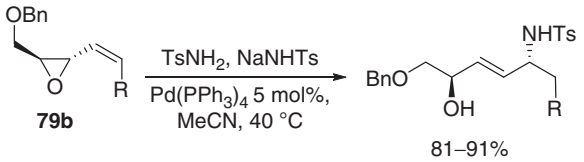
73 **74**

R = Ph (*E*):(*Z*) = 3.4:1 96%
R = (*E*):(*Z*) = 7:2 73%



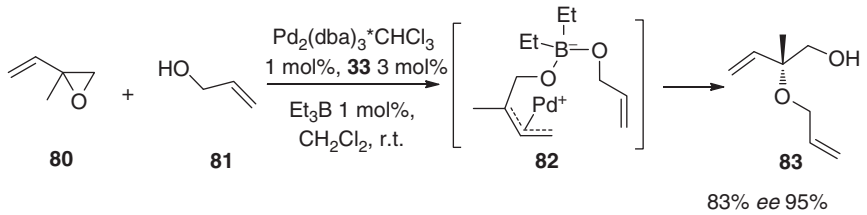
(45)

Although the 2,5-substitution pattern inherent in **76** is furnished through thermolytic rearrangements, the 2,3-isomer would result from an S_N2' opening of **75** to allylic iodide **77**, which would cyclize to 2,3-functionalized dihydrofuran **78** (Scheme 25).[221a,234] Only marginal results were obtained with vinyloxiranes under the conditions adapted from similar opening of vinylcyclopropanes with trimethylsilyl (TMS) iodide and titanium tetrachloride.[235]

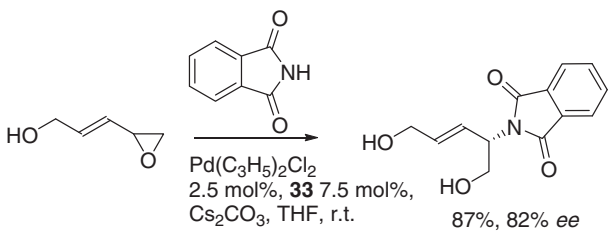


Scheme 25

Palladium-catalyzed nucleophilic opening of vinyloxiranes received attention in connection with the *cis*-dihydroxylation reported by Trost in 1985.[236] However, Pd-catalyzed S_N2' addition of nucleophiles is not a predominant mode for vinyloxiranes. Baeckvall[237] described opening of enantiomerically pure *cis*- and *trans*-vinyl epoxides **79** with NaNHTs in the presence of Pd $(PPh_3)_4$. The reaction proceeded with high regio- and stereoselectivity.

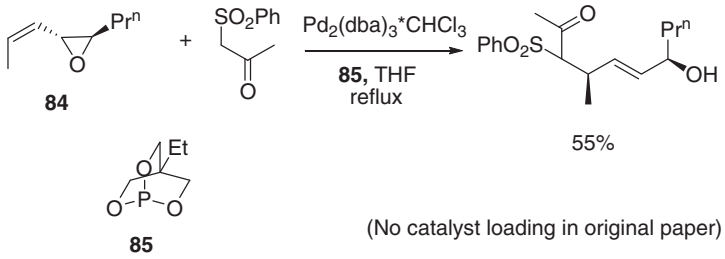


(46)

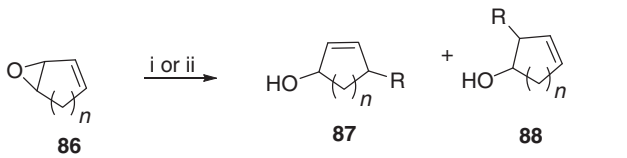


(47)

Trost[238] described a general approach for asymmetric opening of vinyloxiranes **80** with alcohols **81**. Starting from racemic epoxides, it was possible to achieve dynamic resolution with a wide range of alcohols. The reaction was believed to proceed via a π-allyl palladium complex **82**. In order to increase the nucleophilicity of the alcohol and change the reaction to an intramolecular mode triethylborane was added as cocatalyst. High enantiomeric excess (80–98%) was achieved. Trost[239] also showed that under similar conditions the opening of vinyloxiranes can be achieved with nitrogen nucleophiles containing acidic N–H bonds, such as the case of phthalimide, in good yields and with high enantiomeric excess (up to 98% *ee*) (equation 49).



(48)



(49)

Vinyloxiranes also undergo opening with carbon nucleophiles. With soft nucleophiles and products formed via π-allyl metal intermediates, S_N2' addition can be expected, whereas hard nucleophiles tend to form products of S_N2 addition. Certain methods can lead to the selective formation of either S_N2 or S_N2' products depending on the conditions and additives. Trost[240a] studied the addition of soft carbon nucleophiles to a chiral vinyloxirane **84** and showed that the reaction proceeds smoothly with retention of configuration (equation 50). He and his group[240b] also described conditions for selective asymmetric S_N2 opening of vinyloxiranes utilizing Pd-catalyzed conditions. Some alkynyl lithium salts can serve as soft nucleophiles and the mode of addition to the vinyloxirane can be controlled. A combination of copper salts and chiral phosphoramidite **48** (see Scheme 18) was utilized for the asymmetric resolution of cyclic vinyloxiranes **86** with alkyl zinc[241] and alkyl aluminum reagents.[242] Different ligands and sources of copper were studied (equation 51).

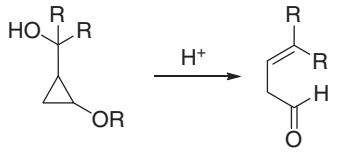
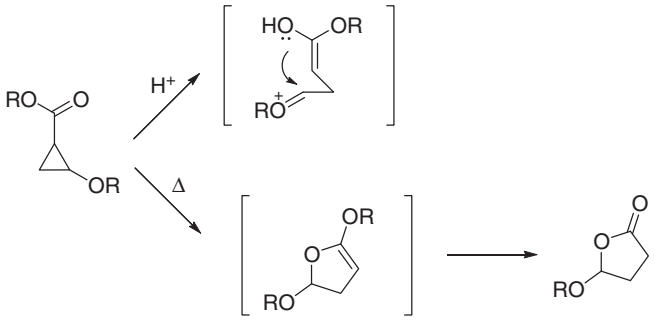
5.22.1.4.2 Cyclopropyl carbonyls

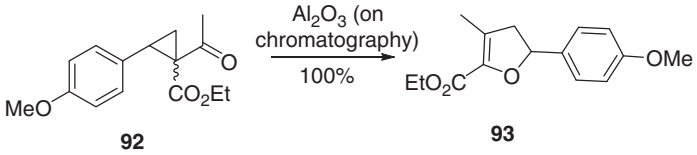


When the vinylcyclopropane system contains a heteroatom within the alkene portion, it is highly susceptible to rearrangements governed by donor–acceptor principles. Under appropriate conditions the ring closure of systems such as **89**, in addition to normal diradical pathways, can occur by two additional mechanisms: unraveling of a cyclopropylcarbinyl cation system (path a) or the action of a lone pair of an additional donor atom (or a full anion) resembling the unraveling of a cyclopropylcarbinyl anion (path b; Scheme 26). Ideally, both processes can reinforce one another to lead easily to rearrangements of systems such as **90** to the corresponding 1,4-dicarbonyl compounds, reported as early as 1938 (Scheme 27).[243] Recognition that the cyclopropylcarbinyl cation cleaves to provide additional unsaturation led to the methodology of acid- or base-catalyzed unraveling of systems of type **91** to the corresponding β,γ-unsaturated carbonyls (equation 52).[244] Only one review on the topic of synthesis and reactivity of cyclopropyl carbonyls and imines has been published in the past 20 years.[245]

Scheme 26

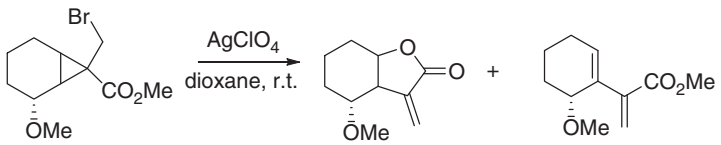


Scheme 27



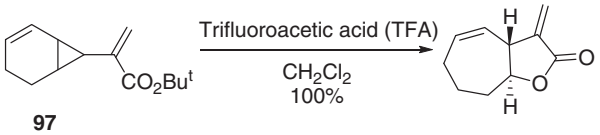
91 50% for R=Ph (52)

The above processes constitute the foundation on which Wenkert developed a general synthetic methodology applicable to terpenoid and alkaloid syntheses.[47,48] The carbonyl can be viewed as a hetero-vinyl moiety participating in the overall (hetero-vinyl)-cyclopropane–cyclopentene rearrangement, as shown in Scheme 28, even though the mechanism involves the cyclopropylcarbinyl rearrangement.

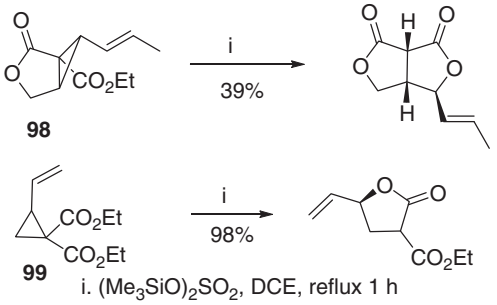


Scheme 28

Either isomer of **92** was converted into dihydrofuran **93** on alumina as an alternative to acid-catalyzed conditions (equation 53).[246] One methodology for α-methylene lactone synthesis relies on the solvolysis of cyclopropyl esters of type **94** to give α-methylene lactone **95** with Li_2CO_3 in dioxane (equation 54). The formation of the undesired diene **96** was diminished by the use of $AgClO_4$.[247]

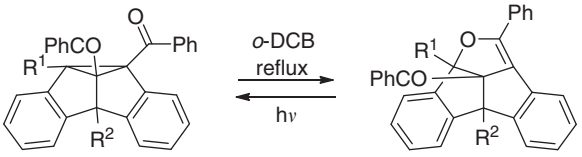


92 **93** (53)



94 **95** 85% **96** 15% (54)

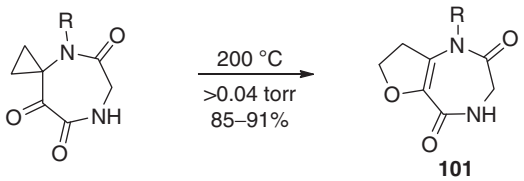
Vinylcyclopropanes containing carboxylates react selectively through the agency of the carbonyl group in acid-catalyzed rearrangements, as shown in equation 55.[248] It is noteworthy that neither of the two alternative pathways, the divinylcyclopropane Cope rearrangement of **97** or cyclopentene rearrangement(s), takes place. Further examples of carboxylate over vinyl selectivity are seen in the rearrangements of cyclopropanes **98** and **99** to the corresponding tetrahydrofuranones (Scheme 29).[249]



97 (55)

Thermal rearrangements of various dibenzosemibullvalenes have been described.[250] On heating, the compounds underwent clean rearrangements to the corresponding dihydrofurans **100**. It is interesting to note that under direct irradiation the products are converted back to the starting cyclopropyl ketones, in contrast to direct photoconversion of cyclopropyl carbonyl to

Scheme 29



gem-disubstituted dimethyl dihydrofurans,[137] (equation 56; compare to Scheme 6). FVP was applied by de Meijere[251] to produce complex diazepine products such as **101** (equation 57). Treatment of activated silylcyclopropyl ketones with acids[252] in aprotic conditions or with excess of TMS triflate[253] lead to conversion to the corresponding 2,3-dihydrofurans or cyclobutanones. Most substrates provided highest conversion with TMS triflate, as shown in Scheme 30 and Table 10.

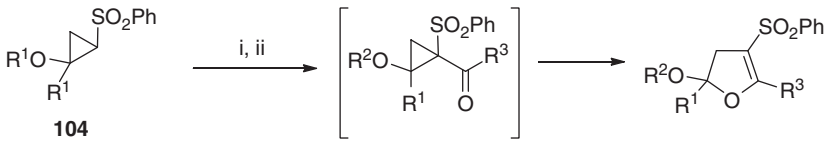
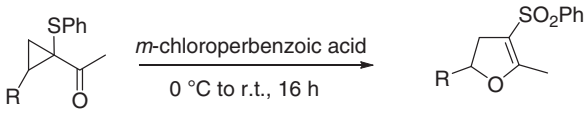
Theodorakis[254] utilized the acid-catalyzed rearrangement of bicyclic systems to produce bicyclic lactones (equation 58). Lewis acids have also been used for similar rearrangements in order to stabilize opened, charged intermediates. Yadav[255] and Johnson[256] showed that 1-acyl-2-vinylcyclopropanes can be rearranged with $Ni(cod)_2$[256] or with a range of Lewis acids[255] (equation 59). In analogy with the anion accelerated vinylcyclopropane–cyclopentene rearrangement, such as the one used in specionin synthesis (see **Table 12** and ref. 381) cyclopropyl carbonyls masked as silyl enol ethers rearrange, via the corresponding enolate anions, as shown in equation 60 and described by Davies.[257] The rearrangements proceed with good diastereoselectivity but with complete racemization in the absence of a chiral auxiliary.

(58)



(59)

(60)



5.22.1.4.2.1 *Transient cyclopropyl carbonyls*

Cyclopropane systems that contain donor and acceptor substituents on vicinal carbons are predisposed to undergo opening and rearrangement to more stable dihydrofuran moieties (equation 61). Suitable substrates can be generated by metalation of sulfonyl cyclopropanes such as **104**[123,258] and lithium salts can be quenched by acyl imidazoles (Im). On heating to room temperature, these compounds rearrange to dihydrofurans. Oxidation of cyclopropyl sulfides with electron-rich aryl substituents to the corresponding sulfones leads to rearrangement to dihydrofurans (equation 62).[259] Upon insertion of carbenoid intermediates to electron-rich enol ethers derived from α,β-unsaturated ketones the resulting cyclopropane intermediates can undergo further rearrangement to dihydrofurans.[260]

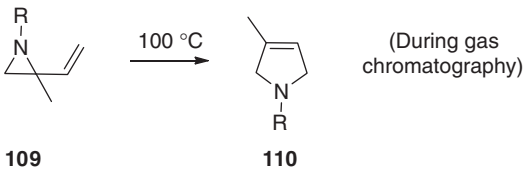
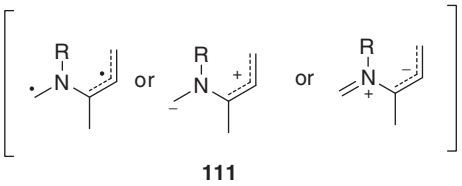
5.22.1.5 Rearrangements of Vinylaziridines and Cyclopropyl Imines

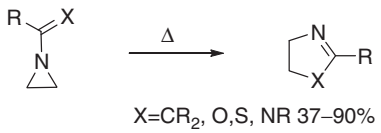
5.22.1.5.1 Rearrangement of vinylaziridines



Like vinyloxiranes, vinylaziridines are subject to a number of rearrangements that parallel the pathways available to vinylcyclopropanes. Unlike them, however, vinylaziridines undergo extremely well-controlled nucleophilic opening to furnish pyrrolines under nonthermolytic conditions. They are easily prepared from alkenes and azides via triazolines.[261] Because of the valency of nitrogen there are two topographical isomers possible, **105** or **107**, each leading to a different tautomer of pyrroline **106a** or **106b**, and an additional isomer, 3-pyrroline **108**, available through cleavage of bond **a** in **107** (Scheme 31). This remarkable property of vinyl- aziridines translates into the selective preparation of all possible isomers of pyrroline, 1-, 2-, and 3-pyrroline, by careful "tuning" of the reactivity of **105** and **107** through substituent effects and the knowledge of probable reaction intermediates. Much of the thermal and photochemical behavior of vinylaziridines may be rationalized through either diradical or zwitterionic (azomethine ylide) intermediates. This subject has been thoroughly summarized.[51,230,262,263]



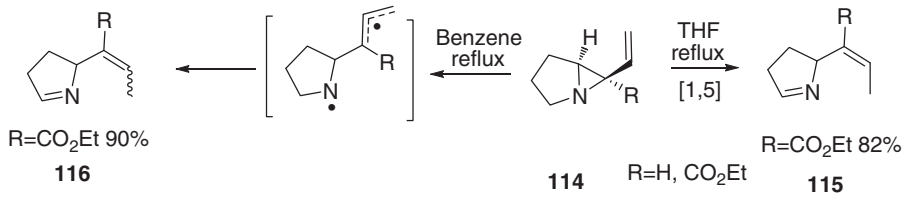
Scheme 31



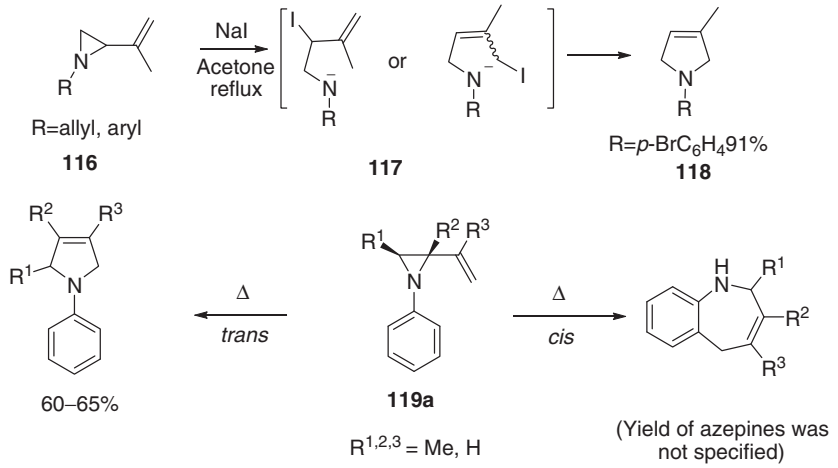
5.22.1.5.1.1 Thermal rearrangements of vinylaziridines

Vinylaziridines such as **109** have been rearranged thermally to 3-pyrrolines (equation 63),[264,265] presumably through one of the species **111**. Substituents play an important role in the likelihood of these intermediates.[266] The energy of activation for carbon–nitrogen bond cleavage has been estimated to be 12–14 kcal mol^{-1} (compared with 27 kcal mol^{-1} for cyclopropane).[267] Vinylaziridines of type **112** (R = alkyl) furnish 1-pyrrolines **113** or, if X is another heteroatom, the corresponding heterocyclopentenes (equation 64).[265,268]

(63)



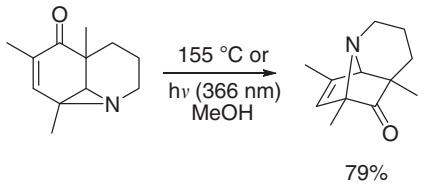
(64)



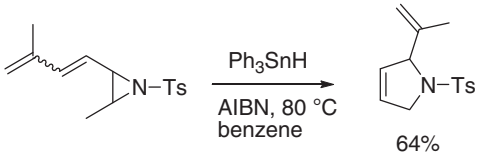
The competing reaction involves the formation of imines (presumably via diradicals and hydrogen migration), as proposed by Logothetis to account for the formation of imines in the thermolysis of aziridines.[269] Imine formation is sometimes observed as a competing pathway in the thermolysis of *N*-substituted vinylaziridines[270] and can also be rationalized by a process analogous to a [1,5] homodienyl shift.[230,271,272] In cyclic systems with proper stereochemistry (*endo*) this process may predominate, as evidenced by the isolation of only the (*E*)-alkene **115** (R = CO_2Et; Scheme 32).[271,272]

Reaction of vinylaziridines **116** with NaI in refluxing acetone led to 3-pyrrolines **118** (Scheme 33).[273,274] When the *N*-substituent contains an additional alkene as in the case of **119a**, the possibility of an intervening Cope-like rearrangement will complicate pyrroline formation. The selectivity between these two pathways usually depends on the stereochemistry of the

Scheme 32

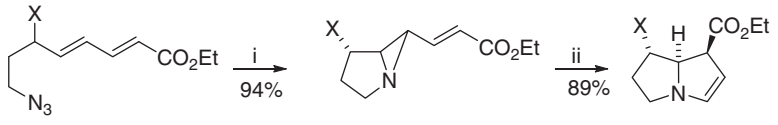


vinylaziridine, and the temperature of the rearrangement (higher temperatures favor the pyrroline formation as the Cope rearrangement is frequently reversible.) No *cis*/*trans* isomerization was observed in the case of **119a**.[275] The divinylaziridine rearrangement as well as the [1,5] shift pathways of vinylaziridines can be controlled according to the principles found valid with vinylcyclopropanes or vinyloxiranes. Some aspects of the rearrangements of vinylaziridines have been reviewed.[23,45,230,263,276]



Scheme 33

Photochemical rearrangements have also been reported, as shown in equation 65.[277,278] Transition-metal-catalyzed rearrangement [palladium(0)] of a dienylaziridine has been reported in one case,[279] and a radical opening of a dienylaziridine led to pyrroline formation under the conditions of radical initiation with azobisisobutyronitrile (AIBN)/Ph_3SnH (equation 66).[280] For those vinylaziridines that contain additional unsaturation, the corresponding aza equivalent of a divinylcyclopropane Cope rearrangement is the usual pathway.[281] The pyrroline–azepine pathways are usually controllable by determining temperature profiles for the reactions. Higher temperatures favor pyrroline formation.



Compared to vinylcyclopropanes, vinylaziridines have not enjoyed wide applicability in synthetic schemes or for annulation before the discovery and development of [4+1] pyrroline annulation (Scheme 34).[51,271,272,282–284] Activation of the dienes with EWGs proved necessary for the formation of vinylaziridines **121** (through intermediate triazolines and their thermal decomposition).[284] Noteworthy is the selectivity in bond activation in **121** (Scheme 34).

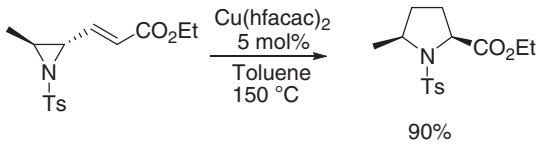
Scheme 34



Compounds of type **123** (Scheme 35) have been found to yield pyrrolines **125** through the vinylaziridine–pyrroline rearrangement of **124** (not isolated) in refluxing $CHCl_3$ or THF, albeit in moderate yields (31–62%).[285,286] The heteroatom substitution apparently accelerates the rearrangement. Somfai[287] showed that vinylaziridines may be rearranged to 3-pyrrolines under microwave radiation in presence of salts such as LiI or NaI. Njardarson[288] discovered that electron-deficient $Cu(hfacac)_2$ can promote a smooth rearrangement of electron-deficient vinylaziridines to the corresponding 2,5-dyhydropyrroles (equation 67). He extended the scope of this rearrangement to enantiopure aziridines,[289] in which the reaction proceeded with complete retention of optical purity unlike similar vinylcyclopropane–cyclopentene rearrangements. It is important to note that only electron-poor aziridines (R^1 = *p*-toluenesulfonate (Ts), *p*-nitrobenzenesulfonyl) can be transformed under such conditions.

5.22.1.5.1.2 *Nucleophilic opening of vinylaziridines*

The mechanistic details of the nucleophilic opening of vinylaziridines are similar to those operating on vinyloxiranes. Whereas thermolysis of **127** leads to pyrrolizidine **130**,[271,272,284] likely through the agency of azomethine ylide **129**, nucleophilic opening leads exclusively to **128** through intermediate allylic iodides **131**, which are produced as mixtures of (*E*)- and (*Z*)-isomers but are converted into **128** through equilibration and recycling of the (*Z*)-isomer (Scheme 36).[282]

It was shown by Ibuka and coworkers in 1994[290] that copper reagents can open acyclic vinylaziridines in a S_N2' fashion (Scheme 37). The same year Wipf[291] succeeded in opening of *N*-acyl aziridines with cyanocuprates in the presence of BF_3. High *anti*-selectivity was achieved (equation 68). Later Hudlicky[292] applied similar conditions to the opening of cyclic vinylaziridine **132**. The main product was formed as a result of selective *syn*-S_N2' addition. The predominance of the *syn* addition was explained by the high steric demand of the acetonide to proceed in *anti*-fashion (equation 69). Sweeney[293] showed that 2,3-*trans*-3-aryl-2-vinylaziridines can be opened with lithium dialkyl cuprates in exclusive S_N2' fashion (equation 70).

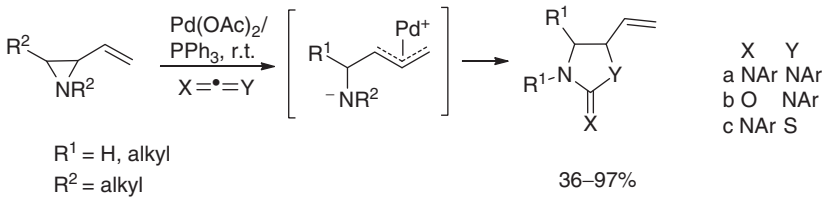
(69)

(70)

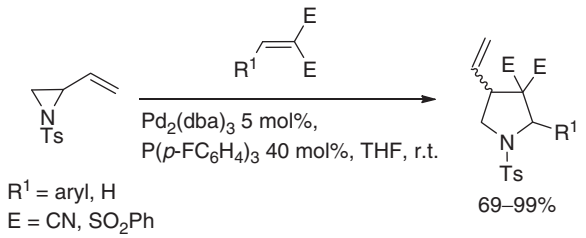


The catalytic enantioselective opening of vinylaziridines in the presence of copper catalysts has been studied by Pineschi.[294] During his work with cyclic vinyl epoxides (see Section 5.22.1.4.1.2), he discovered that cyclic 2-alkenyl *N*-carboxybenzyl (Cbz)-protected aziridines can be opened by alkylzinc reagents in the presence of $Cu(OTf)_2$/phoshoramidite ligands with an enantiomeric excess range of 5–83%. Without the ligand, there were unexpected amounts (50%) of the *syn* product observed, explained by the complexation of the copper with the Cbz group (equation 71). Comasseto[295] screened different organometallic reagents and showed that higher order cuprates gave the best selectivity for S_N2' addition for cyclic and acyclic aziridines.

(71)

5.22.1.5.1.3 Cycloadditions of vinylaziridines

Alper[296] showed that vinylaziridines can undergo cycloadditions with a variety of isocyanates, carbodiimides, and isothiocyanates with $Pd(OAc)_2/PPh_3$ as the catalytic system. The reaction proceeds via formation of a π–allylpalladium complex (Scheme 38, Table 11).



Scheme 38

Table 11 Cycloaddition reaction of vinylaziridines with different unsaturated partners

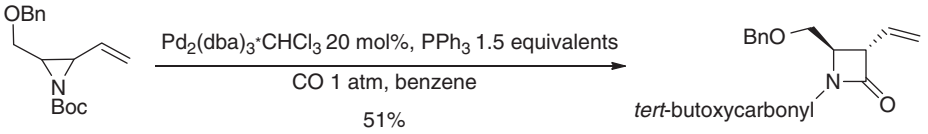
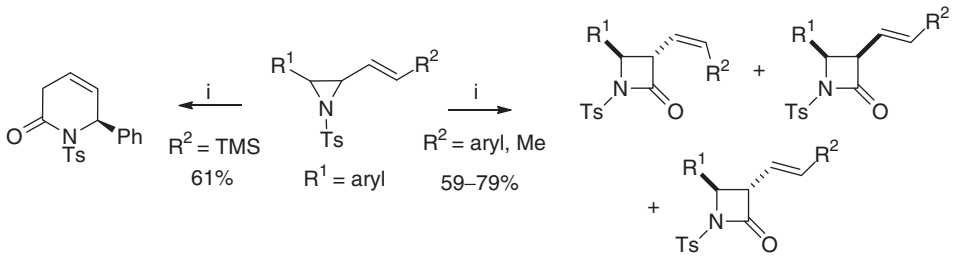
PhN, PhN	*c*-C_6H_{11}, H	60
PhN, S	*c*-C_6H_{11}, H	96

Yamamoto[297] described similar cycloadditions with olefins activated by EWGs. The reaction proceeded with high yields but low diastereoselectivities, with ratios of *cis* to *trans* in the range of 23:77–55:45 (equation 72).



(72)

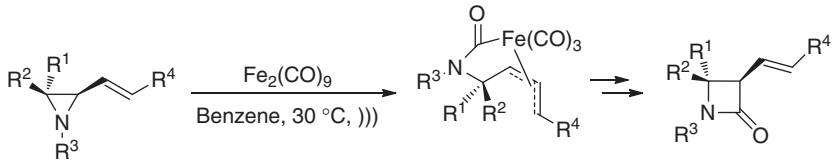
Trost[298] described the first example of an enantioselective version of the cycloaddition of isocyanates to vinylaziridines in the presence of $Pd(allyl)_2Cl_2/(R,R)$-**33**. The reaction proceeded with good yields and in reasonable enantiomeric excess in the presence of an acidic additive such as acetic acid. Later the same group utilized this transformation in total synthesis.[299] Alper[300] discovered that similar reactivity can be achieved also with BINAP and $CeCl_3$ as an additive (Scheme 39).



Scheme 39

The first example of a palladium-catalyzed cycloaddition of carbon monoxide to vinylaziridines was described in 1991 by Ohfune (equation 73).[301] Regardless of the configuration of the starting vinylaziridines, only the *trans* β-lactam was formed in moderate yield. Somfai and Tanner[302] utilized this transformation in the synthesis of the carbapenem antibiotic (+)-PS-5.

(73)



Expanding this methodology to a broader scope of substrates, Aggarwal[303] discovered that changing the solvent significantly alters the stereochemical outcome. He also discovered that silyl-substituted aziridines can produce δ-lactams as the only product of what seems to be a [5+1] cycloaddition, contrary to the typical reaction of such a system to produce β-lactams (Scheme 40).

i. $Pd_2(dba)_3$*$CHCl_3$ 5 mol%, PPh_3 60 mol%, CO 1 atm, PhMe, r.t.

Scheme 40

Iron-mediated processes were described by Ley.[304] Sonication of vinylaziridine with $Fe_2(CO)_9$ produces a stable iron complex that can be reduced and transformed to the β-lactam by oxidation with Me_3NO (Scheme 41).

Louie[305] discovered that a formal [5+2]-cycloaddition occurred up on heating electron-rich vinylaziridines with phenyl isocyanates in nonpolar solvents with formation of seven-membered cyclic ureas. Byproducts were five-membered ureas and oxazolidines. It has been shown that only *trans*-substituted aziridines form seven-membered cyclic ureas (equation 74). Recently Saito[306] showed that a similar reaction can proceed at 0 °C with activated mesyl and tosyl isocyanates (equation 75).

Yudin[307] described the reaction of *N*-unsubstituted vinylaziridines with dimethyl acetylenedicarboxylate (DMAD). The use of different solvents led to the formation of dihydroazepines or bicyclic 4,5-systems (Scheme 42).

Scheme 42

The Ni(0)/NHC catalytic system developed by Louie[308] was applied in the intramolecular cycloaddition reaction between alkynes and aziridines. In order to suppress the competing β-hydride shift, a large substituent on nitrogen was required. Screening of various ligands showed that the most efficient ones were SIPr and IMes (equation 76).

5.22.1.5.2 Cyclopropyl imines

The cyclopropylimine–pyrroline rearrangement (Cloke rearrangement) has been known since 1929, long before the discovery of the parent vinylcyclopropane system.[309] Rearrangements of cyclopropylimines have been studied recently in the context of the effects of heteroatom substitution on rearrangements of cyclopropanes.[245]

Dicyclopropylimine **133** rearranged to pyrroline **134** not to 2-pyrroline **137**, the product expected from the accelerating effect of the amino substituent (Scheme 43). Further reaction and hydrolysis led to pyrrolizidone **136**.[310] The effects of substituents (*N*, *S*) were investigated on substrates shown in equation 77.[247] Sulfur and nitrogen did not exert an effect of the magnitude expected from similar studies on vinylcyclopropanes. It may be attributed to the mechanistic duality of this rearrangement, which may involve nucleophilic opening followed by alkylation. The observed preference for the rearrangement of the less-substituted cyclopropane may have its roots in steric effects and the preference for the nucleophilic attack at the less-substituted site. Stevens obtained a different result.[311,312] The piperidinyl-substituted cyclopropane in **138** rearranged on thermolysis in the presence of an acid with a nonnucleophilic counterion and gave pyrrole **139** up on further acid-catalyzed elimination (equation 78).[311,312]

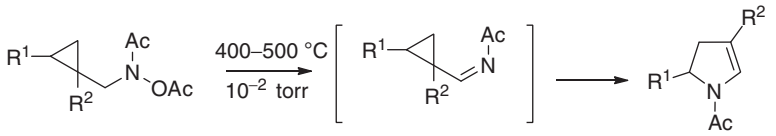
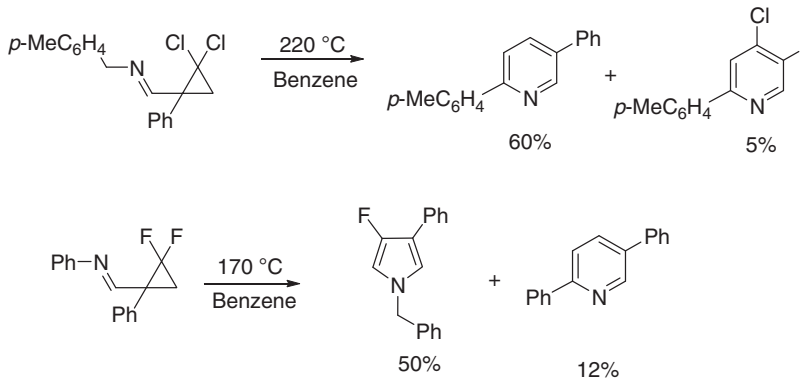
Cyclopropyl imines are usually generated by reduction of nitriles or condensation of carbonyl compounds with amines.[312,313] An alternative to this process involves the generation of cyclopropylimmonium salts such as **141** at room temperature from a cyanohydrin equivalent such as **140** (Scheme 44).[314]



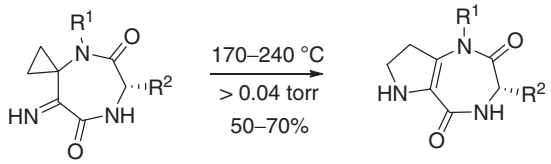
Scheme 44

The rearrangement proceeds thermally under acid catalysis by HBr, NH_4Cl, or via nucleophilic opening and reclosure as in the case of vinylaziridines. Sulfur substitution has been found effective in accelerating the rearrangement as well as serving as a site of further functionalization. This feature has been especially exhibited in the synthesis of pyrrolizidine and *Amaryllidaceae* alkaloids.[312,313]

The synthesis of cyclopropylimines was discussed in detail in a 2007 review.[315] Their rearrangement takes place under conditions similar to those employed for vinylcyclopropane–cyclopentene rearrangements; high temperatures (300–500 °C) are sometimes required. Unsubstituted C-cyclopropyl imine is stable toward heating up to 650 °C in the absence of acid. When Wu[316] studied the FVP of C-cyclopropyl imine, he discovered that *N*-acyl imines, with a stabilizing group on the cyclopropyl ring



generated *in situ*, undergo rearrangement with moderate yields. In case of unsubstituted and alkyl-substituted cyclopropanes decomposition was observed (Scheme 45).



R^1	R^2	%

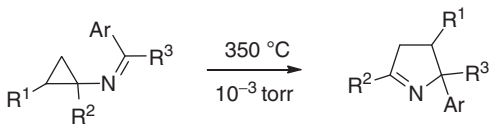
Scheme 45

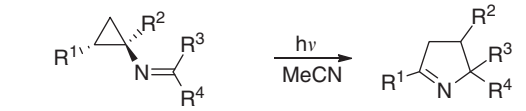
Kagabu[317] discovered that *gem*-dihalosubstituted cyclopropyl imines produce heterocyclic compounds under thermal conditions and with different additives (bases, metal oxides, inorganic salts). In the case of *N*-benzyl (Bn) substituted imines, the main products were pyridines. Pyrroles were generated from *N*-alkyl-substituted imines and *gem*-difluoro cyclopentene (Scheme 46). Later the same group[320b] published a more extensive study showing that *N*-substituents without α-protons undergo rearrangements to pyrroles. The mechanism is believed to vary for different substrates. In case of *gem*-difluorocyclopentene, radical cleavage occurs. *gem*-Dichlorocyclopropyl imines undergo the rearrangement via cationic intermediates. De Meijere[251] showed that this rearrangement can generate complex molecules starting from cyclopropyl ketimines (equation 79).



Scheme 46

(79)

N-Cyclopropyl imines undergo much smoother rearrangement. It has been shown by Campos and Rodriguez[318] that with FVP a variety of unsubstituted and aryl-substituted cyclopropyl imines undergo rearrangement to 1-pyrrolines (equation 80).



$R^{1,2}$ = H, Ph

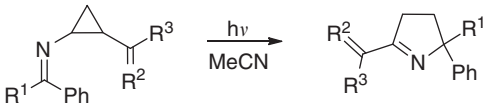
(80)



Photochemical rearrangement has been shown to work only for *N*-cyclopropyl imines.[315] The scope of substrates was investigated under direct irradiation and was shown to proceed with good to excellent yields (equation 81). The mechanism was shown to occur

via diradical intermediates,[319] but slow interconversion and control of chromophore excitation allowed greater stereoselectivity compared to thermal vinylcyclopropane–cyclopentene rearrangements. A further study[320] described the influence of substituents and solvents. Complete selectivity toward the cyclopropylimine–dihydropyrrole rearrangement was shown (equation 82).

Classical methods for the rearrangement of C-cyclopropyl imines (Cloke rearrangement)[309] entail high temperatures and acidic conditions. A typical reaction involves heating of the substrate to 140 °C in the presence of NH_4Cl;[321] however, milder catalysts may be used, for example TMSCl and NaI,[322] LiCl, LiI, and others. The generally accepted mechanism of the acid-catalyzed rearrangement is depicted in Scheme 47. The cyclopropyl iminium ion can also be generated with AgOTf (Scheme 48). Charged intermediates generated by alkylation of thioimidates were utilized for a similar rearrangement.[323] The mechanism for opening and reclosure is similar to the Cloke rearrangement (Scheme 49).

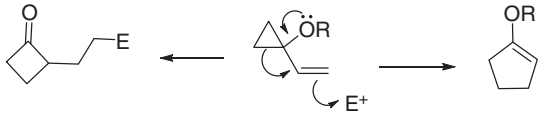
5.22.1.6 Miscellaneous Systems

It would be difficult to list all of the cases involving the various combinations of heteroatom substitution in a vinylcyclopropane system. It has been recognized that virtually any heteroatom or any degree of unsaturation can be incorporated into the parent vinylcyclopropane system for almost limitless variability in the type of products that can be expected on its rearrangements.[52,325] The general transformations depicted in equation 84 have been summarized and reviewed[18,230,326–329] in the context of the synthesis of five-membered heterocycles. Vinylcyclopropenes, methylenevinylcyclopropanes, and cyclopropylalkynes all undergo the requisite rearrangements to five-membered rings.[9] The products are the corresponding cyclopentadienes or methylenecyclopentenes and their heteroatom analogs. These topics have been reviewed.[9,13,18,329] The mechanism of these transformations ranges from diradical scission to carbene generation and rearrangement.[18,329–331]

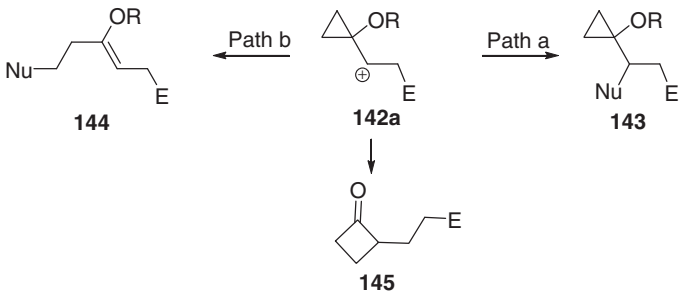


(84)

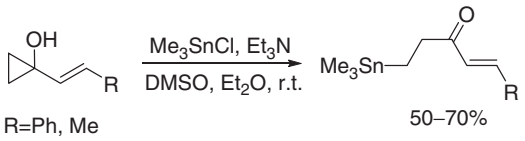
General discussions and reviews of rearrangements of heterovinylcyclopropane systems with one heteroatom and two or more heteroatoms not discussed in the previous sections (Sections 5.22.1.4 and 5.22.1.5) are available.[332,333] Their rearrangements are governed by principles discussed previously, that is, most stable diradical or ylide intermediate or the least-hindered site for nucleophilic attack in the case of nucleophilic openings. The electronegativity of the heteroatom and the conditions of rearrangement determine the regiochemistry of bond cleavage. With systems containing additional unsaturation, the divinylcyclopropane–Cope rearrangement remains a viable option (see Section 5.22.2).[222]

The use of vinylthiiranes as synthons for 2,5-dihydrothiophenes has been somewhat limited as they readily undergo thermal desulfurization to form dienes. Njardarson[334] recently discovered that vinylthiiranes may be rearranged into 2,5-dihydrothiophenes under conditions similar to those described above for vinyloxiranes and vinylaziridines.

5.22.1.6.1 Isomerizations of oxyvinylcyclopropanes to cyclobutanones



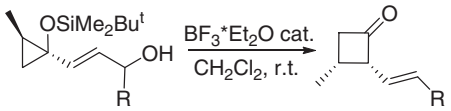
Vinylcyclopropanes substituted with oxygen (or sulfur or selenium) are susceptible to ring expansion to the corresponding cyclobutanone derivatives in addition to the expected rearrangement to cyclopentene (Scheme 50). The oxycyclopropane can be viewed as a pseudo enol in those interactions with electrophiles that involve the vinyl group. The resulting cyclopropylcarbinyl system **142a** will interact with nucleophiles either directly (path a) or through ring opening (path b; Scheme 51). The participation of either bond **a** or **b** in this opening will depend on the precise conformation of **142**, which is in turn dependent on the nature of the cation and its solvation, as well as on the tendency of the cyclopropylcarbinyl cation **142a** to unravel. When proper orbital overlap exists, one of these bonds will participate in opening the cyclopropane to yield **144**, or it will act as an internal nucleophile in its migration (and concomitant ring expansion to **145**).



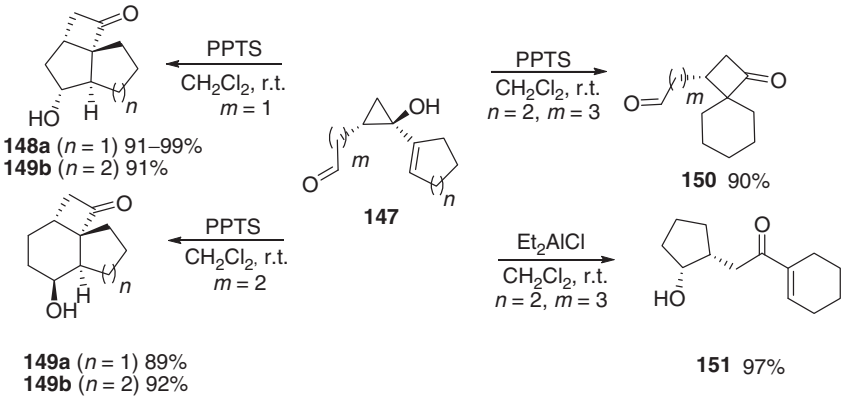
142

Scheme 50

This latter process was developed and extensively utilized by Trost in spirocyclobutanone annulation.[19,20] A less common reaction of oxyvinylcyclopropanes involves normal electrophilic opening of the oxycyclopropane, as, for example, that occurring in the generation of the β-stannyl enone (equation 85).[15]

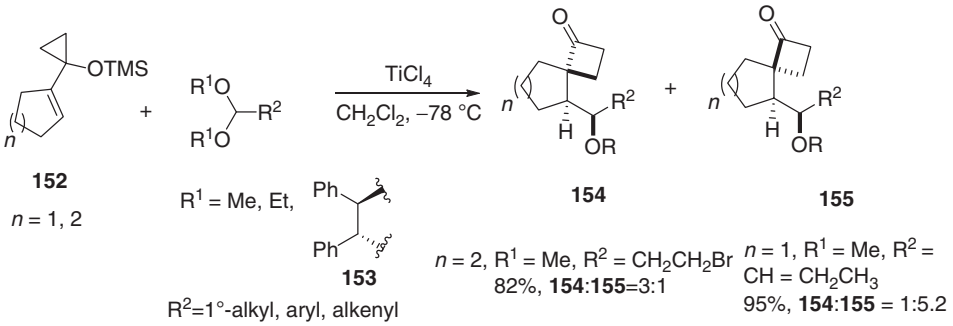


Scheme 51



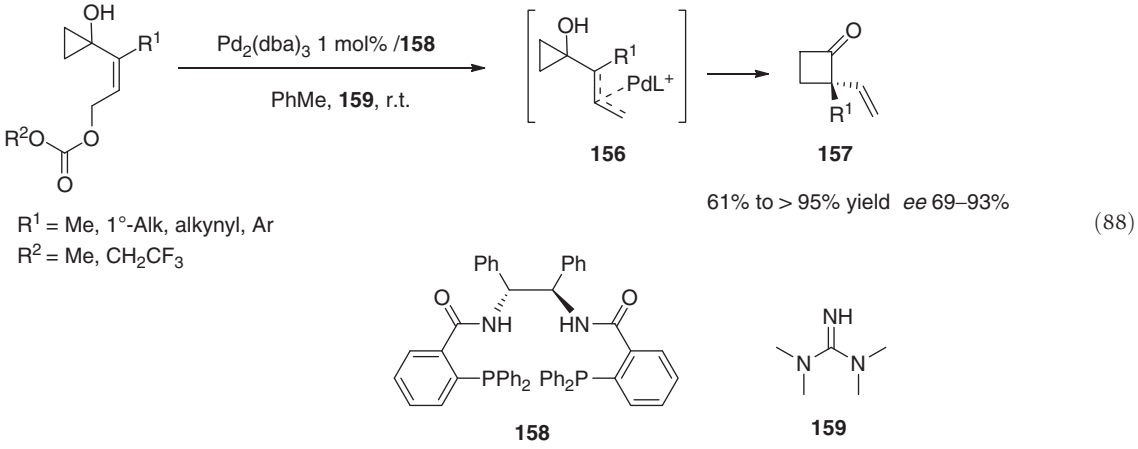
(85)

Salaun showed that optically active silyl ethers of vinylcyclopropanols can be rearranged under mild conditions with $BF_3{*}Et_2O$ with the retention of optical configuration (84–90% *ee*, equation 86).[335]



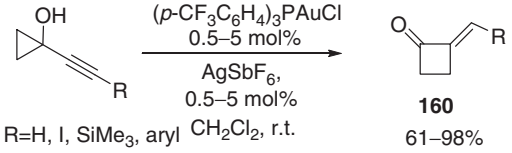
(86)

Cha[336] utilized the acid-catalyzed intramolecular cyclization of vinylcyclopropanols with tethered ω-aldehydes for the synthesis of polycyclic structures. Reactions proceed with good yield and diastereoselectivity. It was shown that, depending on the length of alkyl chain, different stereochemistry of the hydroxyl group can be observed (**Scheme 52**).

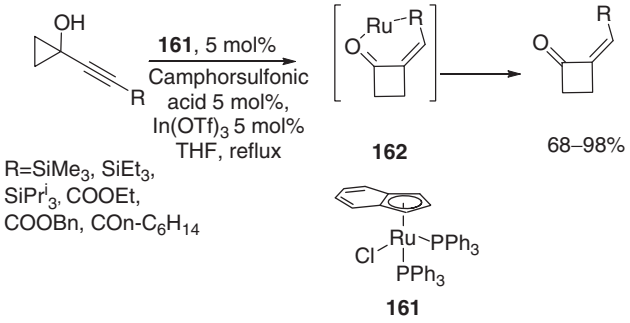


Scheme 52 PPTS, pyridinium *p*-toluenesulfonate.

Cha[337] also explored Lewis acid intermolecular reaction of acetals with vinylcyclopropanols. In the case of α,β-alkenyl substrates good diastereoselectivity was observed (>6:1), compared to modest diastereoselectivity (>3:1) observed in case of alkyl and aryl acetals (equation 87). The chiral auxiliary (*R,R*)-(+)-hydrobenzoin **153** was used[337b,c] in the form of a chiral acetal to provide access to the enantiomerically pure products.

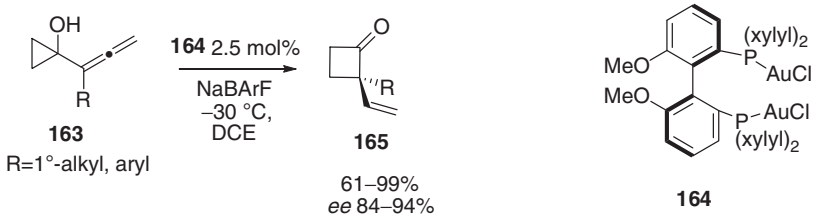


(87)

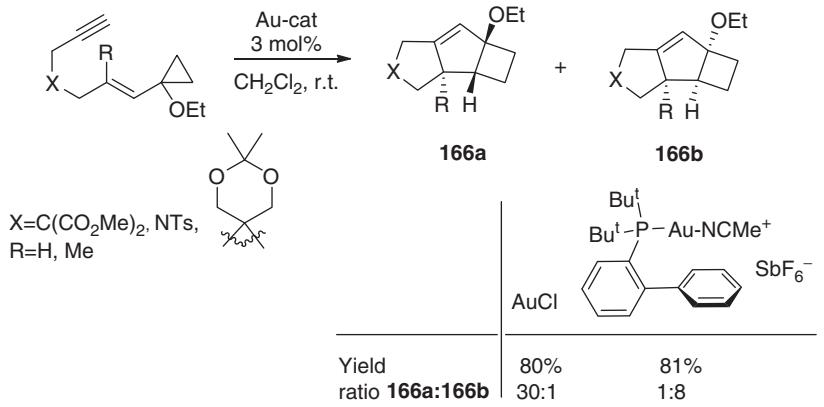


Cationic rearrangements can be performed in the presence of transition-metal complexes. Seminal work on the enantioselective variant of such rearrangements was published by Trost.[338] Reactions proceed in the presence of catalytic amounts of $Pd(dba)_2$ and the chiral bidentate phosphine **158** via formation of the π-allylpalladium complex **156** and proceed with good yields to give chiral vinylcyclobutanones **157** (equation 88). Addition of base such as tetramethylguanidine (**159**) was shown to increase the *ee* but significantly lowered the rate of conversion.

(88)



Gold[339] and ruthenium[340] were shown to promote rearrangements of alkynyl cyclopropanols to 2-alkylidenecyclobutanones. Triarylphoshine gold cationic species promoted the rearrangement of a wide range of substrates to *E*-alkene products **160** with high stereoselectivity. The indenyl ruthenium catalyst **161** promotes rearrangement to the sterically less favorable *Z*-alkene. A possible explanation of such an outcome is coordination of ruthenium to the R group in the proposed transitional state **162**, as shown in equation 89.

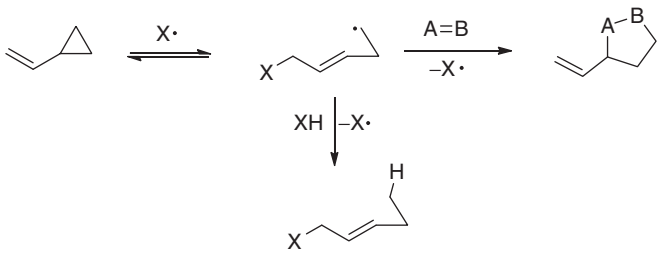


(89)

Toste[341] described enantioselective rearrangements in the presence of the cationic gold catalyst **164**. Allenyl cyclopropanols yielded vinylcyclobutanones under these conditions (equation 90).

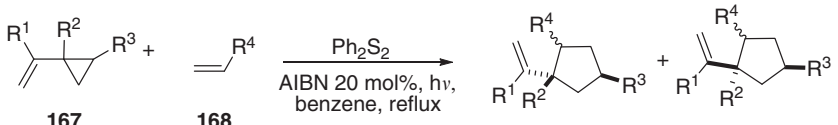
(90)

Electrophiles generated from alkynes on addition of gold catalysts were shown to undergo intramolecular annulation to produce [5.5.4] tricyclic systems.[342] The outcome of the reaction can be somewhat controlled by variations in catalysts (equation 91).



(91)

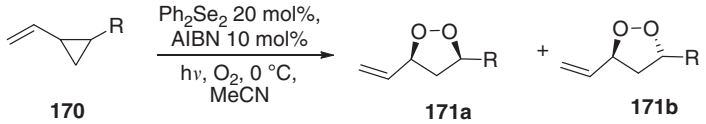
5.22.1.6.2 Radical reactions and cycloadditions of vinylcyclopropanes



Addition of free-radical species to vinylcyclopropane results either in the abstraction of a hydrogen atom from the cyclopropane or ring opening through the agency of the cyclopropylcarbinyl radical generated on the initial addition.[12]

Radical addition occurs with vinylcyclopropanes containing radical stabilizing group on the cyclopropane ring. There are two general types of reactivity derived from the radical activation of vinylcyclopropanes: the termination of a radical chain by a hydrogen atom source leading to an open-chain product or the addition of an unsaturated fragment A=B in a [3+2] manner leading to cyclic products (Scheme 53). Tin-, sulfur-, and silicon-based radicals add to the vinylcyclopropane system.

Scheme 53



Regioselectivity of radical additions was observed in general and follows the same pattern as metal-catalyzed formal [3+2] cycloadditions. Feldman[343] described radical activation of vinylcyclopropane rings with diphenyldisulfide under thermal and photolytic conditions. A mixture of *syn* and *anti*-isomers was formed. On introduction of an EWG to the cyclopropane ring, preferential formation of the *syn* product **169b** was observed (equation 92).

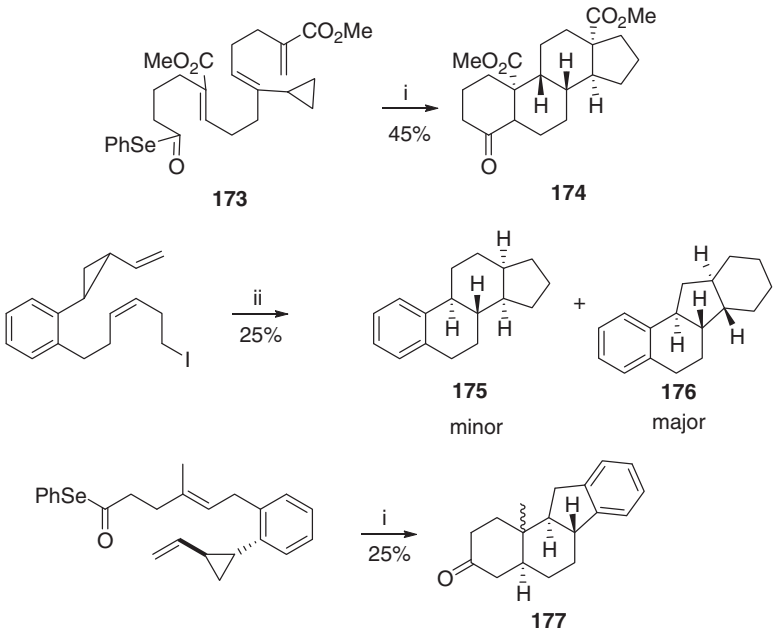
(93)



A study of intramolecular cyclizations showed[345] that the regioselectivity can be affected by the electronic configuration of the linker X in compound **172** (Scheme 54); different types of bicyclic systems can be produced starting from the same type of vinylcyclopropane **172**.

i. Ph_2S_2 1 equivalent, hν sunlamp, PhCl, reflux; ii. AIBN cat., benzene, reflux

Scheme 54

Free radical polymerization of substituted vinylcyclopropanes through both 1,2- and 1,5-type additions has also been reported.[346,347] Radical macrocyclization–transannulation in polyene systems containing a vinylcyclopropane moiety provided efficient access to manifolds of polycyclic compounds. Pattenden developed a general approach to diverse analogs of the steroid skeleton. By varying the position of the initial site of radical formation and the position of the vinylcyclopropane moiety in polyene system different types of polycyclic structures could be formed. An unusual type of steroid, **174**,[348] can be formed starting from acyl selenoate **173**. The estrone-type skeleton formation was studied, and conditions were found for the selective formation of **175** and **176**.[349] A similar type of skeleton of C-nor-D-homosteroid **177** was selectively prepared in moderate yield in one step (Scheme 55).[350]

Scheme 55

5.22.1.6.3 [2,3] Rearrangements of vinylaziridines and vinyl epoxides

The first example of an aza-[2,3]-Wittig rearrangement of vinylaziridines was described by Somfai.[351] It was shown that *N*-substituted aziridines with an anion-stabilizing group may be rearranged to piperidines on treatment with base. The best selectivity for formation of *cis*-disubstituted piperidines **179a** was achieved when a carboxylic ester was the stabilizing group and lithium diisopropylamide (LDA) was used as a base (Scheme 56).

Coldham[352] described a similar system that showed the same tendency to produce *cis*-disubstituted piperidines. Vinyl epoxides can be rearranged in a similar [2,3] fashion via oxonium ylides. Only two examples have been published on this rearrangement.[353,354] An oxonium ylide is produced on the attack by the metal carbenoid obtained from the decomposition of a diazo compound (equation 94).

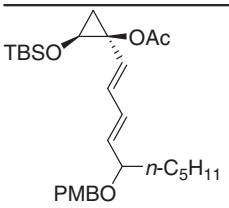
5.22.1.6.4 Rearrangements of silavinylcyclopropanes

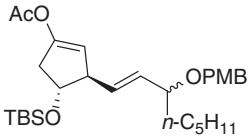
Thermal or photochemical[355] generation of silylenes in the presence of 1,4-dienes leads to 3-silolene. Stable vinylsiliranes can be prepared in high yield under mild conditions from bulky silylenes.[356] Such vinylsiliranes can be converted on heating to 3-silolene as shown in Scheme 57. It is unclear whether this reaction proceeds by a mechanism similar to the vinylcyclopropane–cyclopentene rearrangement or by decomposition to silylene and direct [4+1] cycloaddition. Computational studies for silylenes, germylenes, and hypothetical stannylenes have been performed.[357]

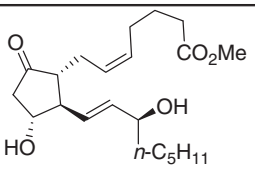
Scheme 57

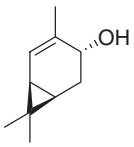
Vinyl phosphirane can be generated via the addition of the corresponding phosphinidene complex to a diene.[358] Rearrangement to the corresponding 3-phospholenes can occur under thermal conditions via a biradical intermediate similar to that in the vinylcyclopropane–cyclopentene rearrangement process, but such a rearrangement can also occur under CuCl catalysis as shown in Scheme 58. In the latter case the process possesses significant concerted features.[359]

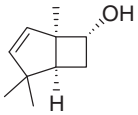
Scheme 58

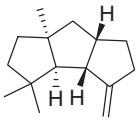


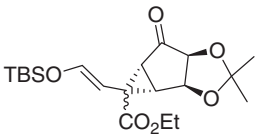


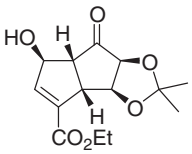


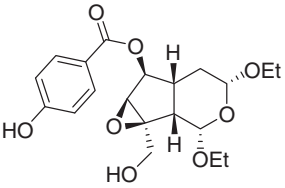


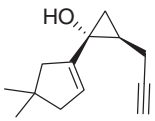


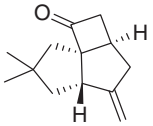


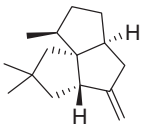


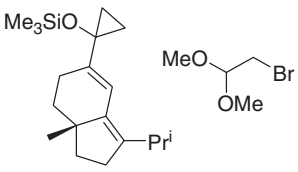


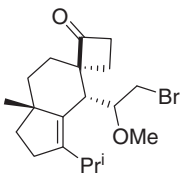


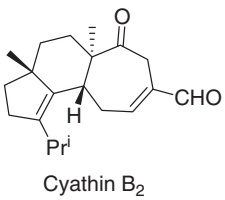








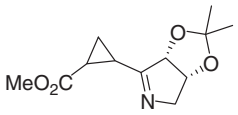


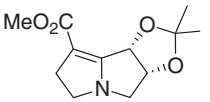


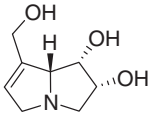
5.22.1.7 Total Syntheses

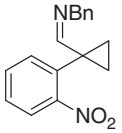
The vinylcyclopropane–cyclopentene rearrangement and its heterocyclic variants have been featured in a number of general methods of synthesis, most notably those developed by Wenkert, Stevens, Hudlicky, and Wender. Most of these developments were discussed in the first edition of this work published in 1991 or in the review that appeared at the anniversary of Neureiter's discovery.[485]

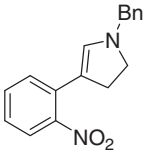
The list of syntheses performed before 1991 includes the core of prostaglandin by Trost,[360] aphidicolin by Trost,[361] zizaene by Piers,[362] hirsutene by Hudlicky,[363] 11-deoxyprostaglandin E_2 by Salaün,[364] α-vetispirene by Paquette,[365] hinesol by Piers,[366] isocomenic acid, isocomene, and β-isocomene by Hudlicky,[367,368] jasmone and dihydrojasmone by Salaün,[369] coriolin by Wender,[370] spirovetivane by Salaün,[371] silphinine by Wender,[372] dicraenone by Salaun,[373] antheridiogen-an by Corey,[374] epiisocomene by Hudlicky,[375] pentalenene by Hudlicky,[376,377] pentalenic acid by Hudlicky,[377] and retigeranic acid by Hudlicky.[378]

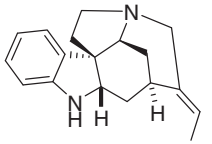


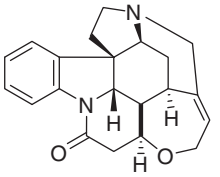


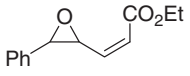


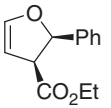


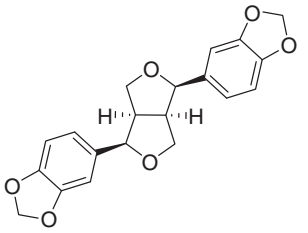


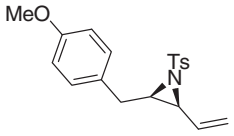


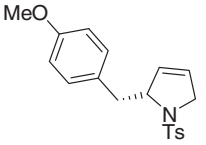


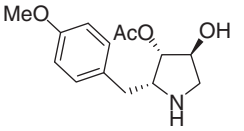












The use of these rearrangements in total synthesis continues and the tables below provide the update in accomplishments since the 1991 version (Tables 12–14).

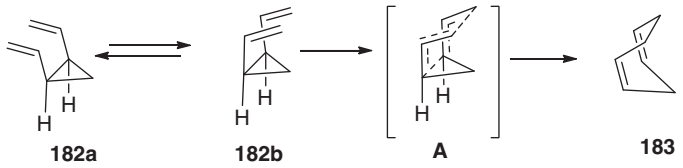
5.22.2 Divinylcyclopropanes

5.22.2.1 Introduction

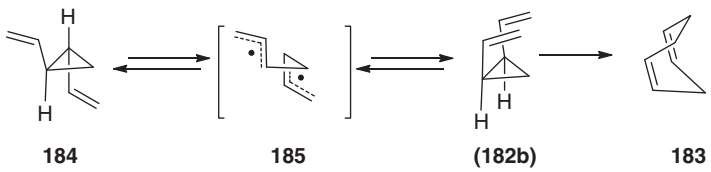
The facile thermal $\sigma^2s+\pi^2s+\pi^2s$ (Cope) rearrangement of *cis*-1,2-divinylcyclopropane **182** to 1,4-cycloheptadiene **183** was first reported in 1960 by Vogel.[416] In his experiments, Vogel did not isolate **182**, since, under the conditions of its formation (80 °C), **182** rearranges rapidly to **183**. Indeed, it was not until more than a decade later that **182** was isolated and shown to rearrange to **183** with half-lives of approximately 90 s and 25 min at 35 °C[417] and 11 °C,[417,418] respectively.



182 **183** **184**

Not unexpectedly, *trans*-1,2-divinylcyclopropane **184** is much more stable than the *cis* isomer **182** and is a readily isolable compound. Nevertheless, at elevated temperatures, for example, 190 °C, **184** undergoes smooth bond reorganization to provide 1,4-cycloheptadiene **183** in essentially quantitative yield.[416a,c] Thus, at the time the Cope rearrangement of 1,2-divinylcyclopropane systems was discovered,[416] it was already clear that both *cis* and *trans* isomers could, in principle, serve as suitable substrates for the reaction. As it turns out, this is an important reaction characteristic, since, in most cases, it makes unnecessary the stereoselective preparation of either the *cis* or *trans* starting material. Since 1960, the thermolysis of 1,2-divinylcyclopropanes has been studied quite extensively to from a mechanistic point of view. However, particularly since 1975, synthetic applications of the rearrangement reaction have been explored, and these studies have shown that the reaction provides a versatile, effective method for the construction of functionalized mono-, bi-, and tricyclic substances.[21,419] In this section, the mechanistic features of the rearrangement will be outlined briefly. The major portion of the discussion will deal with synthetic aspects of this interesting process.

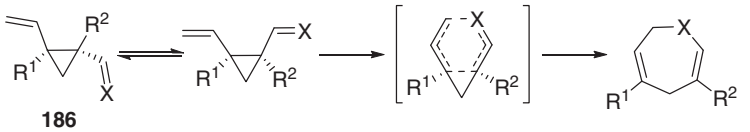
5.22.2.2 Mechanistic Considerations



5.22.2.2.1 Rearrangement pathways

It appears to be well accepted that the thermal rearrangement of *cis*-1,2-divinylcyclopropane **182** proceeds in a concerted fashion via a boat-like transition state, in which the vinyl groups lie over the three-membered ring.[10,420,421] Thus, conformational orientation of **182** as shown in **182b** (equation 95), followed by bond reorganization by way of a transition state represented by **A**, provides 1,4-cycloheptadiene **183**, in which both double bonds have *cis* stereochemistry. Concerted rearrangement of **182** via a chair-like transition state derived directly from conformation **182a** would lead to the highly strained *trans,trans*-1,4-cycloheptadiene, and it is clear that such a pathway would be of a much higher energy than that involved in the conversion of **182b**, via (**A**), into **183**.

182a **182b** **A** **183** (95)

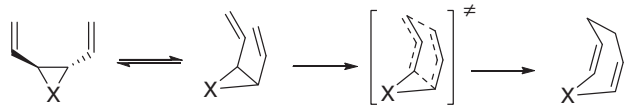


The thermolytic transformation of *trans*-1,2-divinylcyclopropane **184** into 1,4-cycloheptadiene **183** probably proceeds via the pathway shown in equation 96. Homolytic cleavage of the cyclopropane ring of **184** provides the resonance stabilized diradical **185**, which, in addition to reverting to **184**, can undergo bond rotation and subsequent ring closure to give *cis*-1,2-divinylcyclopropane **182**. The latter substance then rearranges, by way of conformation **182b**, into **183**.

184 **185** **(182b)** **183** (96)

The energy of activation E_a for the overall conversion of **184** into **183** has been reported[421,422] to be in the range 32.1–34.3 kcal mol^{-1} (1 kcal≈4.2 kJ). In comparison, the data reported by Brown et al.[417] and Schneider and Rau[423] show that E_a for the rearrangement of **182** to **183** is approximately 19–20 kcal mol^{-1}. Thus, for the conversion of **184** into **183**, the rate-determining step is the isomerization of **184** into **182**, presumably via the diradical **185**. This characteristic is common to most of the known rearrangements of 1,2-divinylcyclopropane systems. That is, for a given pair of isomers, *trans* to *cis* isomerization is generally slower than Cope rearrangement of the *cis* isomer. However, it must be noted that there are exceptions to this generalization, since thermolysis of certain substituted *cis*-1,2-divinylcyclopropanes results only in *cis-trans* isomerization and not in sigmatropic rearrangement (*vide infra*).

The mechanism of rearrangement has been studied by DFT methods. Fabian[424] explored systems containing a heteroatom in the double bond **186**. The activation barrier calculated for the known vinylcyclopropane carbaldehyde–dihydrooxepin rearrangement corresponded well with known data, 23.4 and 23 kcal mol^{-1}, respectively. The barrier for rearrangement of *cis*-divinylcyclopropane, a strongly exothermic reaction, was calculated at 18.8 kcal mol^{-1}. This result corresponds with experimental evidence that *cis*-divinylcyclopropane rearranges below room temperature. Substituents such as OH and CHO lower the activation barrier for rearrangement (equation 97).

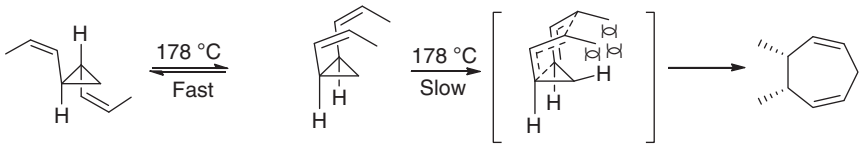


186

X = CH_2, O, S, NH
$R^{1,2}$ = H, OH, CHO

(97)

For systems **187** Zora calculated the barrier of rearrangement and nuclear independent chemical shifts (NICS) for the all-carbon skeleton[425] and for heterocyclic analogs.[426] It was shown that the activation barrier decreases in the series $CH_2 < NH < O < PH < S$, which can be justified by decreasing ring strain of the parent three-membered compounds (equation 98).

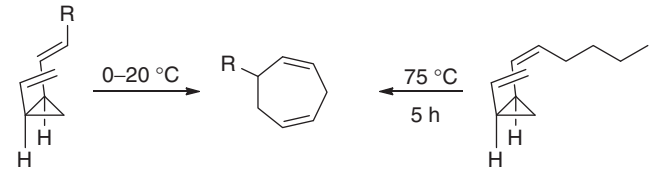


187

X = CH_2, O, NH, NMe, NEt, PH, S

(98)

5.22.2.2.2 Substituent effects



Substituents attached to the terminal carbons of the vinyl groups can have a profound effect on the rate of the Cope rearrangement of *cis*-1,2-divinylcyclopropane systems, Schneider and Rau[423] showed that the *cis,cis,cis* substrate **187** undergoes reversible *cis-trans* isomerization, **188** to **187**, much faster than it undergoes Cope rearrangement to **189** (Scheme 59). In a related study, Baldwin and Ullenius[427] reported that, at 165 °C, the **188**:**187** ratio at equilibrium is approximately 1:4. Furthermore, heating **187** at 178 °C for 4.2 h or 75 h gives, in addition to an equilibrium mixture of **188** and **187**, minor (4%) or significant (35%) amounts of the Cope rearrangement product **189**. Thus, although the sigmatropic bond reorganization of **188** is not precluded, the steric interactions present in the transition state (**E**; Scheme 59) make this a higher energy pathway than the isomerization of **188** to **187**.

187 **188** **E** **189**

Scheme 59

Other studies have also qualitatively demonstrated the effect of substitution patterns on the ease of *cis*-divinylcyclopropane rearrangements. For example, at temperatures in the range 0–20 °C, the substrates **190**–**192** are readily transformed into the cycloheptadienes **193**–**195**, respectively (Scheme 60).[428–430] The rearrangement of **192** to **195** occurs with a half-life of approximately 50 min at 15 °C[430] and is thus marginally slower than the thermal conversion of the parent *cis*- 1,2-divinylcyclopropane **182** into 1,4-cycloheptadiene **183** (Section 5.22.2.1).[417,419] However, complete transformation of **196** into **193** requires heating at 75 °C for 5 h (Scheme 60),[428] again demonstrating the notable rate-retarding effect of a *cis*-substituent.

196

Scheme 60

The highly substituted *cis*-divinylcyclopropanes **199** and **200** do not undergo sigmatropic rearrangement at all.[431] Apparently, the highly sterically congested nature of the transition states (**F**) precludes this possibility. Thermolysis of **199** and **200** at 170–180 °C produces only equilibrium mixtures of these substances and the corresponding *trans* isomers **197** and **198**, respectively (Scheme 61).[431]

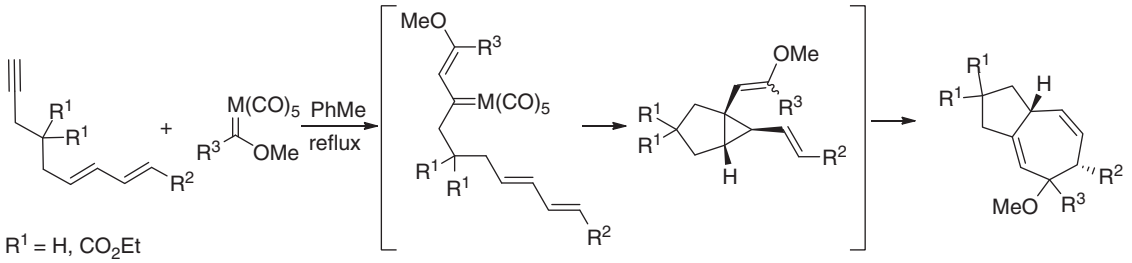
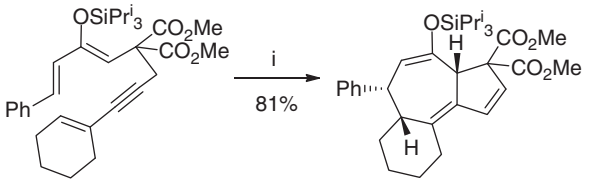
5.22.2.2.3 Guide to preparation

There are a variety of methods for generating divinylcyclopropanes. Some are analogous to those used for the preparation of vinylcyclopropanes (*vide supra*). The following methods are unique to divinylcyclopropane systems, in particular *cis*-divinylcyclopropane systems. Some general approaches are presented in Scheme 62.



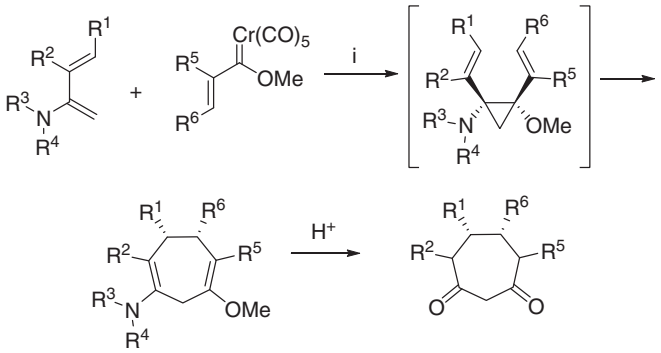
Scheme 62



Olefination of cyclopropyl aldehydes of general type **201**[432–434] provided access to a variety of substituted divinylclyclopropanes. Addition of cyclopropyl-containing organometallic reagents of general type **202** to appropriate electrophiles provided yet another means of access to the divinylcyclopropane core. These reagents include Cu,[435] Zn,[436] Zr,[437], and Li[438,439] derivatives.

One of the most developed and general modern methods involves the addition of vinyl carbenoids of type **203** to a diene system. Early examples of use of such carbenoids include addition of Fischer-type carbenes of VI group metals. Harvey[440] utilized insertion of these to alkynes. The vinylcarbenoid **205** formed in this way undergoes intramolecular cyclopropanation to the diene, which in turn rearranges to the cycloheptadiene system **206**. The reaction proceeds in moderate yields in both electron-neutral and electron-poor diene systems (Scheme 63).

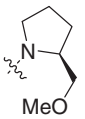
A similar approach was utilized by the group of Iwasawa.[441] Insertion of a tungsten complex into the enyne led to the formation of a vinyl carbenoid, which was subjected to cyclopropanation and rearrangement as shown in equation 99.



Scheme 63

(99)

i. 5 mol% $W(CO)_6$ 5 mol%, Et_3N 10 mol%, hν, 4 Å sieves, PhMe, r.t.



The addition of chromium carbene complexes to electron-rich dienes was studied by Barluenga.[442] The reaction occurred under mild conditions and provided *cis*-divinylcyclopropanes with complete regio- and stereoselectivity. In some cases, the reaction required heating to 60 °C, and some *trans*-product was observed. Studies of reactions in the presence of chiral proline-based auxiliaries showed significant enantioinduction[442b,c] (**Scheme 64**, **Table 15**). Barluenga described similar reactivity for 2-azadiene systems,[443] with preferential insertion into the C=N bond.

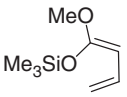
[a]For chiral auxiliaries.

One of the most convenient methods for generating such carbenoids is by the decomposition of diazo compounds of type **207** in the presence of metal catalysts such as salts of rhodium and copper. The rhodium-based approach developed and studied by Davies has been the subject of several reviews.[83,84,444–447]



The advantage of this method is that it proceeds with high levels of stereoselectivity and the major product is a *cis*-divinylcyclopropane **209**, which can undergo direct rearrangement to the cycloheptatriene skeleton (Scheme 65, Table 16). The regioselectivity of carbenoid insertion into acyclic dienes can be controlled somewhat by changing the substitution pattern. Preferential cyclopropanation occurred on the least substituted double bond. The reaction can be selectively performed on a *cis*-alkene in presence of the *trans* isomer. Better control can be achieved by substitution with electron-rich functionalities.

[a]For chiral version of the transformation.

In most cases, divinylcyclopropanes are transient species and cannot be isolated. Under the reaction conditions they tend to undergo subsequent transformation to cycloheptadienes **210**; however, sterically congested divinylcyclopropanes can sometimes be isolated.

A wide range of substrates has been studied. Cyclic dienes[448], furans,[449] pyrroles[450] have been used; these open access to functionalized bicyclic systems including biologically active tropanes. The addition of metal carbenoids to an aromatic ring with disruption of aromaticity (Büchner reaction) leads to bicyclic norcaradiene structures.[445,451] The reaction also proceeds under copper/rhodium catalysis from diazo compounds. In most cases the intermediate divinylcyclopropanes undergo immediate rearrangement to the corresponding cycloheptatriene system.

Less common methods of preparation of divinylcyclopropanes include oxidative cyclization of allyl iron complexes. Donaldson[452] discovered that vinyl Grignard reagents **211** can be stereoselectively added to a cationic iron complex such as **212**. The product of such reaction, namely **213**, can be oxidized by one-electron oxidants such as cerium ammonium nitrate (CAN) or H_2O_2. Oxidation of the complex leads to decomplexation of iron and rearrangement to *cis*-divinylcyclopropane **214**. After reduction of the ester, this compound undergoes the rearrangement to cycloheptadiene **215** (Scheme 66).

Scheme 66

Extrusion of SO_2 from tricyclic sulfolanes **216** was explored by Aitken.[453] Fused tricyclic sulfolanes produced the corresponding 7-membered-ring compounds up on FVP in moderate to good yields via formation of *cis*-divinylcyclopropanes (equation 100). Acyl-silanes of general type **217** undergo sequential Brook/Cope rearrangement on addition of dienolates **218** (Scheme 67) as was described by Takeda.[454,455] Matsubara reported that vinylic 1,2-diketones **219** can be transformed into *cis*-divinylcyclopropanes with Zn carbenoids.[456] The reaction proceeded with high stereoselectivity, and the transient divinyl species **167** underwent smooth rearrangements to cycloheptane diketone **221** (Scheme 68). Stephenson[457] studied the utility of a photoredox catalyst in the reaction of cyclopropyl-centered radicals with alkynes. It was shown that radicals are formed under mild conditions and undergo an addition–Cope rearrangement sequence with good yield. The scope of substrates was somewhat limited as only propargylic amides **170** were found to participate in such reactions (equation 101).

5.22.2.3 Monocyclic Divinylcyclopropanes

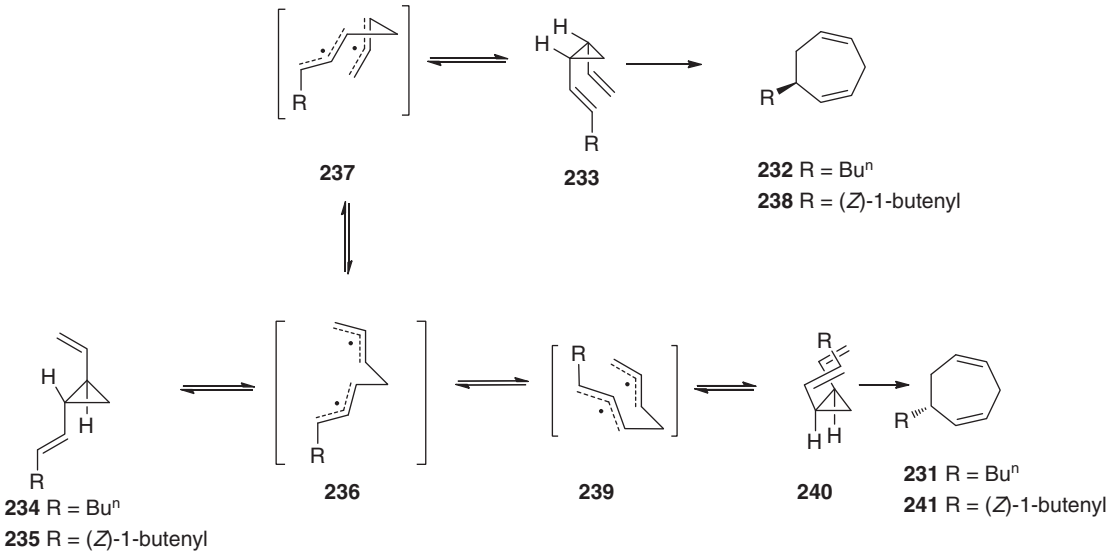
5.22.2.3.1 Stereospecificity

Rearrangement of **224** from –10 to 30 °C provides quantitatively *cis*-6,7-dimethyl 1,4-cycloheptadiene **189**.[423] Furthermore, prolonged heating of **188** at 178 °C produces, in addition to the *trans* isomer **187**, the same sigmatropic rearrangement product

(**189**; Scheme 69).[427] Other studies have shown that thermolyses (178 °C, 4.2 h) of substrates **225** and **226** give, in quantitative yields, the epimeric cycloheptadienes **189** and **228**, respectively.[427] Presumably, these transformations proceed by way of the corresponding *cis*-1,2-di(1-propenyl)cyclopropanes **224** and **227**.[427]

Scheme 69

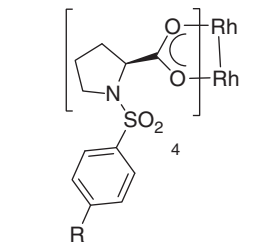
Collectively, the results summarized above show that, with respect to the stereochemistry of appropriately substituted vinyl groups, the (reversible) *trans* to *cis* isomerization (e.g., **187** to **188**; **224** to **225**; **226** to **227**) and the sigmatropic rearrangement of the *cis*-1,2-divinylcyclopropane systems (e.g., **224** or **188** to **189**; **225** to **228**) are completely stereospecific. In connection with carrying out stereoselective syntheses, the importance of this reaction characteristic is obvious. Indeed, the stereospecific nature of the Cope rearrangement of 1,2-divinylcyclopropanes has been demonstrated with substrates that are structurally more complex than those discussed above. Specific examples will be presented later in this chapter (see Sections 5.22.2.3–5.22.2.6).



5.22.2.3.2 Enantiospecificity

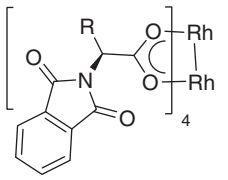
Relatively little work has been done in this area. In studies related to the total synthesis of the marine natural product (*R*)-(−)-dictyopterene C′ (**231**), Jaenicke and coworkers[458] showed that the enantiomerically pure substrates **229** and **230** rearrange cleanly to the corresponding enantiomerically pure products **231** and **232**, respectively (Scheme 69). Nonnatural (*S*)-(+)-dictyopterene C′ (**232**) is also obtained by rearrangement of (1*R*,2*S*)-1-[(*E*)-1-hexenyl]-2-vinylcyclopropane (Scheme 69).[459] These results show, not unexpectedly, that the Cope rearrangements of rather simply substituted *cis*-divinylcyclopropanes are enantiospecific.

With monocyclic *trans*-1,2-divinylcyclopropanes, chirality transfer is, apparently, poor. Thermolysis of (+)-dictyopterene A (**234**) at 165 °C for 48 h and of (−)-dictyopterene B (**235**) at 103–108 °C for 40 h gives, in each case, a mixture of the two enantiomeric Cope rearrangement products, **231**, **232** and **238**, **241**, respectively (Scheme 70).[460] Although the uncertainty associated with the optical purities and (or) rotations of the various substances involved[458,460] made a quantitative determination of the product ratios difficult, it is evident from the results that enantiomers **232** and **238** predominated marginally over **231** and **241**, respectively. This observation has been rationalized[461] by postulating that, in the intermediate diradical **236**, the allyl system rotates more rapidly, to give **237**, than the more bulky heptenyl or heptadienyl groups, to produce **239**. Ring closure of **237** and **239**, followed by bond reorganization of the (enantiomeric) *cis*-divinylcyclopropanes **233** and **240**, produces the final products.



Although further work in this area is desirable, it appears that in the Cope rearrangement of simple *trans*-divinylcyclopropanes, such as **234** and **235**, enantioselectivity is poor. Despite the biradical character of the rearrangement, transfer of chirality can sometimes occur in more complex substrates, such as polycyclic systems.

The enantioselective generation of divinylcyclopropanes is of utmost importance. Because of the concerted nature of the rearrangement, enantioselective cyclopropanation leads to chiral products, according to the well-studied transition state. Davies has expanded the scope of the insertion of vinyl carbenoids to an asymmetric version. Chiral auxiliaries have been utilized[462] with some success, but the diastereomeric excess of products was not high (30%).



Scheme 70

Later investigations focused on chiral rhodium catalysts. The use of amino acid-based rhodium dinuclear ligands such as **242** and **243** led to impressive levels of enantio- and regiocontrol. Low temperatures and nonpolar solvents such as pentane and toluene were required.

5.22.2.3.3 Synthesis of functionalized cycloheptanes

The use of the Cope rearrangement of 1,2-divinylcyclopropanes for the synthesis of functionalized seven-membered rings has been illustrated in a number of studies. For example, thermolysis of **245** (mixture of *cis* and *trans* isomers), followed by cleavage of the enol silyl ether function in the resultant product **246** provides the natural product karahanaenone (**247**; Scheme 71).[438a] In this

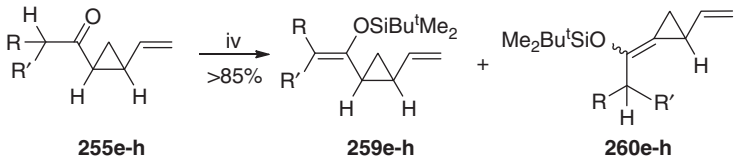
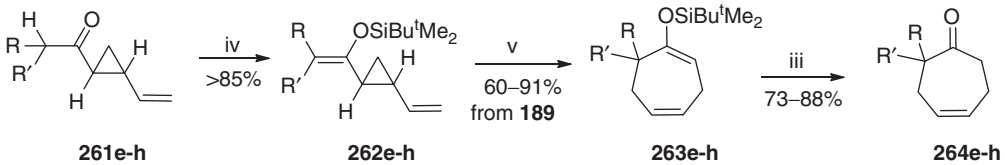


Scheme 71



case, as in many others, the fact that **245** was not stereochemically homogenous was of no consequence, since both isomers of **245** cleanly afford the same rearrangement product. Similarly, sigmatropic rearrangement of the isomers **248** and **249** and subsequent hydrolysis of the resultant vinyl sulfide **250** also produces karahanaenone (**247**).[464] The efficient conversion of substrate **251** into the keto ester **254** via a route in which the Cope rearrangement of **252** played a key role has been reported.[465]

In an investigation related to the synthesis of substituted 4-cyclohepten-1-ones,[466] the stereochemically homogenous *cis*-2-vinylcyclopropyl ketones **255a–255d** were converted cleanly into the enol silyl ethers **256** (**Scheme 72**). Thermolysis of the latter substances, followed by acid hydrolysis of the resultant products **257**, gives excellent yields of the ketones **258a–258d**. Interestingly, however, kinetic deprotonation of each of the *cis*-ketones **255e–255h** is not regioselective. Treatment of these substrates with LDA–TBSCl provides mixtures of the enol silyl ethers **259** and **260**, in ratios varying from 4:1 (substrate **255g**) to 1:9 (substrate **255f**). Fortunately, the *trans*-ketones **262e–262h** give synthetically more satisfactory results, since these substances can be converted chemoselectively into the *trans*-divinylcyclopropanes **263**. As expected, Cope rearrangements of compounds **262** require temperatures considerably higher than those employed for the conversion of **256** into **257**. However, the reactions are clean and the products **264**, obtained in good to excellent yields, are readily hydrolyzed to the ketones **258e–258h**.

In a study of Nakamura, an interesting application of the chemistry of the cyclopropenone acetal **265** was achieved (equation 103).[437] Although this conversion was the only reported example of this novel process, it seems likely that the use of other functionalized and (or) stereochemically modified reagents would provide efficient syntheses of a wide variety of interestingly substituted seven-membered rings.

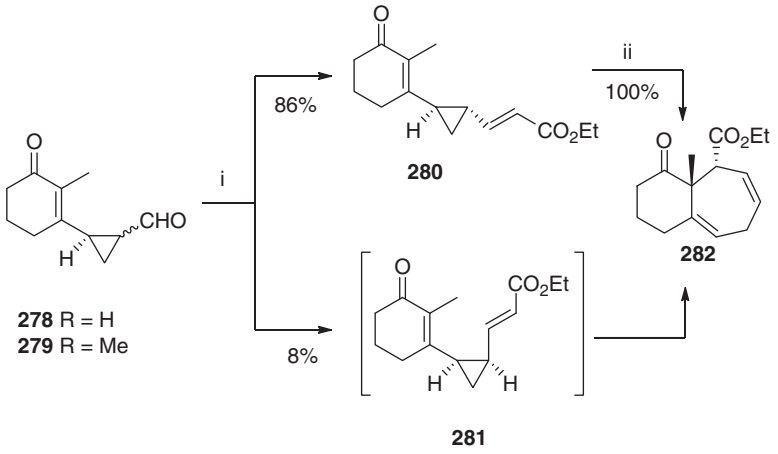
5.22.2.4 β-(2-Vinylcyclopropyl)-α,β-Unsaturated Ketones

5.22.2.4.1 Synthesis of functionalized bicyclo[5.n.0]alkanes and related substances

The Cope rearrangement of 1,2-divinylcyclopropane systems in which one of the vinyl groups is part of an *α,β*-unsaturated ketone moiety has found considerable use in synthesis. A significant number of substrates have been prepared and subjected to thermal rearrangement and some of the products have been employed effectively for natural product syntheses.

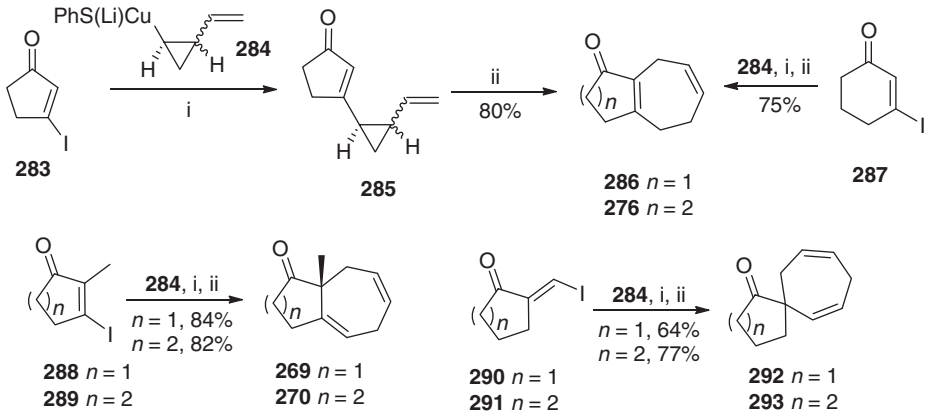
The reaction of 2-vinylcyclopropyllithium reagents with *β*-alkoxy enones has served well as a method for preparing *β*-(2-vinylcyclopropyl) enones.[438,439] For example, treatment of **266** with a mixture of *cis*-and *trans*-2-vinylcyclopropyllithium, followed by mild acid hydrolysis of the resultant products, provides the epimeric divinylcyclopropanes **267** and **268** (Scheme 73).[439a] Although **267** rearranges slowly at room temperature, the *trans* substrate **268** requires, as expected, elevated temperatures for rearrangement. Indeed, heating of the mixture of **267** and **268** at 170–180 °C provides **269** cleanly and efficiently.[439a] Thus, not unexpectedly, the stereoselective preparation of the requisite divinylcyclopropane substrates is unnecessary, since both **267** and **268** are readily converted into the same product **269**. In a similar fashion, the enones **271–273** are smoothly transformed into the rearrangement products **270**, **276** and **277**, respectively.[439a] Under the rearrangement reaction conditions, the primary products **274** and **275**, derived from **272** and **273**, undergo isomerization to the more stable enones **276** and **277**, respectively.



i. 7:3 mixture of *cis*- and *trans*-2-vinylcyclopropyllithium, Et_2O; ii. HCl, H_2O; iii. 170–180 °C, PhH

Scheme 73

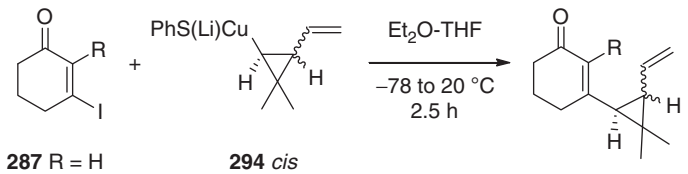
Chemoselective Wittig reactions on keto aldehydes, such as **278** and **279**, also provide substrates suitable for sigmatropic rearrangement.[432,433] For example, treatment of **279** (mixture of epimers) with $Ph_3P{=}CHCO_2Et$ provides the *trans*-divinylcyclopropane **280** (86%) and the keto ester **282** (8%), the latter being derived from room temperature Cope rearrangement of the initially formed intermediate **281** (Scheme 74).[433] Thermolysis of **280** produces **282** quantitatively. The efficient conversions of **280** and **281** into the stereochemically homogenous keto ester **282** again illustrates the highly stereoselective nature of the sigmatropic rearrangement of *cis*- and *trans*-1,2-divinylcyclopropane systems.



The reaction of cyclopropylcuprate reagents with *β*-iodo enones has proven to be a useful method for preparing *β*-(2-vinylcyclopropyl) enones. For example, reaction of **283** with the cuprate reagent **284** (7:3 mixture of *cis* and *trans* isomers, readily prepared from the corresponding mixture of 1-bromo-2-vinylcyclopropanes), followed by thermal rearrangement of the resultant product **285**,

i. $Ph_3P{=}CHCO_2Et$, THF, 20 °C; ii. 140 °C, xylene, 6 h

Scheme 74

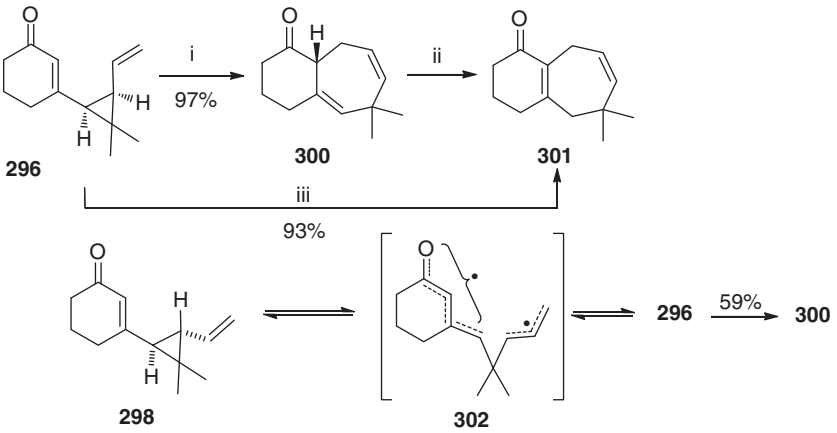


gives the ketone **286** (Scheme 75).[467] Similarly, the substrates **287**–**289** are smoothly transformed into the bicyclic ketones **276**, **269**, and **270**, whereas subjection of the (*E*)-2-(iodomethylene)cycloalkanones **290** and **291** to the same reaction sequence affords the corresponding spirodienones **292** and **293**. Because the iodo enones are readily prepared from 1,3-dicarbonyl compounds[468] and the cuprate reagent **284** is obtained via a separate synthetic route, the overall annulation sequences are convergent, short, and efficient.

i. THF, –78 °C, 1 h; –20 °C, 1 h; 0 °C, 1–2 h; ii. Heat, 180 °C, 30–45 min

Scheme 75

Cuprate methodology can also be used to prepare more highly substituted substrates. Thus, treatment of the 3-iodo-2-cyclohexen-1-ones **287** and **289** with the epimeric, stereochemically homogenous cuprates **294** and **285** produces the divinylcyclopropanes **296**–**299** in excellent yields (equation 104).[468]



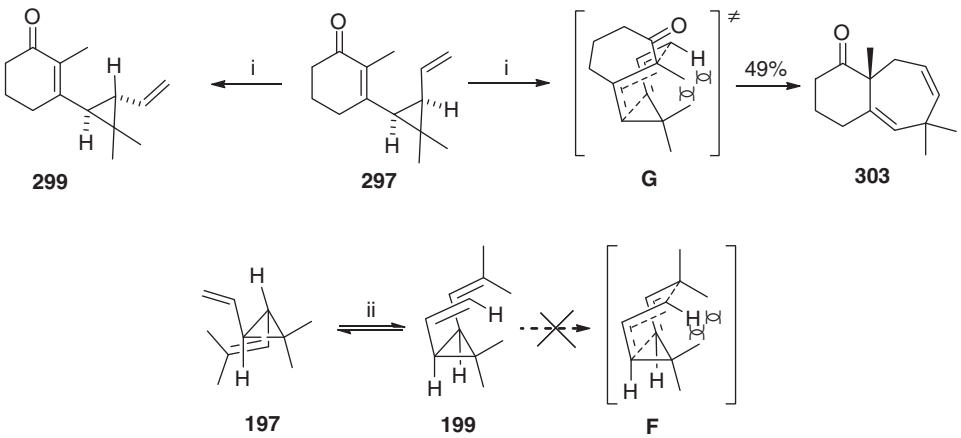
287 R = H
289 R = Me

294 *cis*
295 *trans*

296 R = H, *cis* (88%)
297 R = Me, *cis* (76%)
298 R = H, *trans* (95%)
299 R = Me, *trans* (82%)

(104)

Rearrangement of the epimers **296** and **298** is, in each case, unexceptional (Scheme 76).[468] Thermolysis of **296** in hexane provides the dienone **300**, whereas heating either **296** or **300** at 110 °C (neat) affords the conjugated ketone **301**. Although, as expected, rearrangement of **298** requires much higher temperatures, the same product **301** is formed in good yield. Presumably, this conversion proceeds by way of the stabilized diradical **302** and the *cis*-divinylcyclopropane **296**.

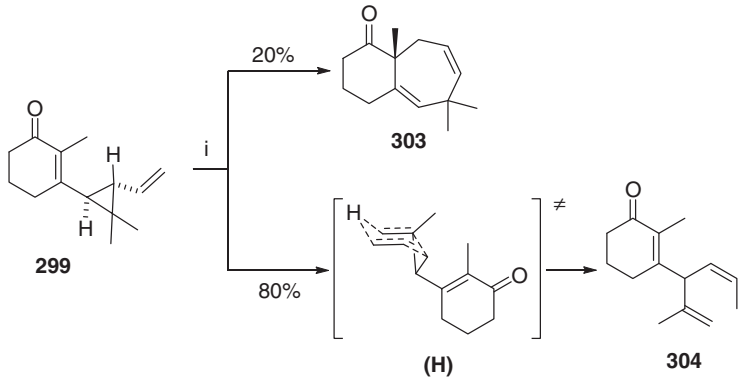


i. hexane, reflux, 4 h; ii. Heat, 110 °C, 10 min; iii. o-dichlorobenzene, 220 °C, 14 h

Scheme 76

The *cis* substrate **297** represents an interesting case. Thermolysis of this material under a variety of conditions produces mixtures of **299** and **303**, in which the latter substance nearly invariably predominates (Scheme 77).[468] For example, heating of **297** in collidine at 140–150 °C gives **299** and **303** in a ratio of approximately 1:2. Under these and other thermolysis conditions, the *trans*-divinylcyclopropane **299** is stable.

As mentioned in Section 5.22.2.2.2, Scheme 61, thermolysis of **199** at 180 °C does not result in Cope rearrangement but provides an equilibrium mixture of **199** and its epimer **197**.[431] Interestingly, in terms of steric congestion, the transition states for Cope rearrangement of **199** and **297**, **F** and **G**, respectively, are similar (Scheme 77). Therefore, it is noteworthy that **297** does undergo sigmatropic rearrangement (albeit in competition with isomerization to **299**), whereas **199** does not. In **297**, of course, one of the substituted vinyl groups is part of an α,β-unsaturated ketone function and, apparently, this structural feature lowers the activation energy of the Cope rearrangement process.

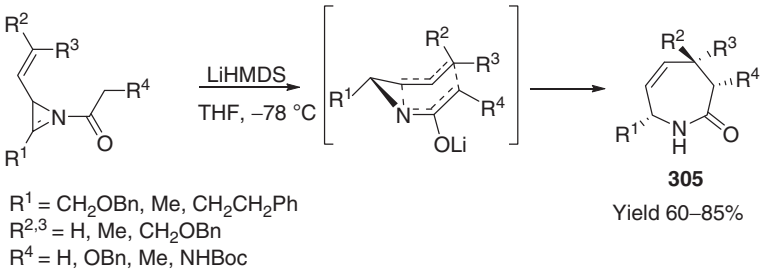


i. Collidine, 140–150 °C, 43.5 h; ii. 180 °C, 3 h

Scheme 77

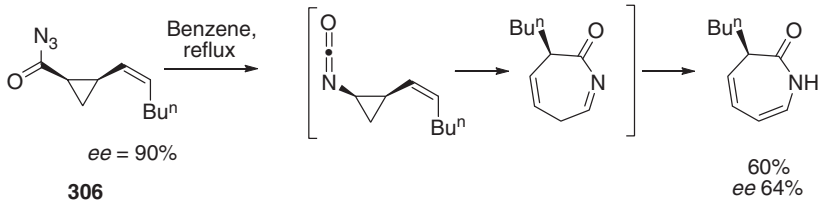
The *trans* substrate **299** is quite resistant to thermal rearrangement. However, thermolysis of this substance at 220 °C (Scheme 78)[468] provides the Cope rearrangement product **303** and the trienone **304**, in a ratio of 1:4. Product **304** results from a [1,5] sigmatropic hydrogen migration, presumably via a transition state that can be represented by **H**.[421,98] Interestingly, in the thermolysis of **299**, the latter process is energetically more favorable than the alternative Cope rearrangement pathway.

From a synthetic viewpoint, a comparison of the thermolyses of the epimers **297** and **299** (Schemes 77 and 78) illustrates the point, previously mentioned, that, in certain cases in which alternative modes of rearrangement are possible, the stereoselective



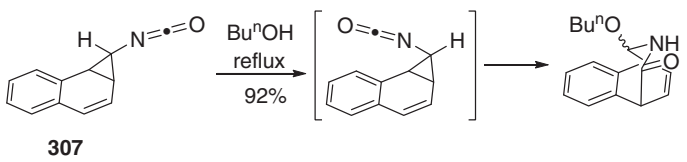
Scheme 78 *o*-DCB, 1,2-dichlorobenzene.

formation of the *cis*-divinylcyclopropane substrate is important. Thus, whereas thermal rearrangement of the *cis* substrate **297** provides the Cope rearrangement product **303** in reasonable yield, thermolysis of the *trans* isomer **299** does not.



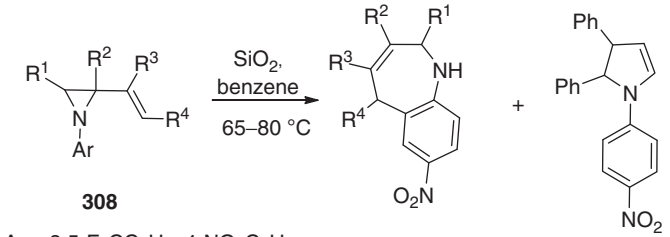
5.22.2.5 Heterocyclic Divinylcyclopropanes

Somfai[469,470] studied rearrangements of *N*-acylvinylaziridines. On their treatment with LiHMDS, the resulting enolate underwent a rearrangement to lactam **305** via a boat-like transition state leading to conservation of chirality in the sp^2-sp^3 transfer of stereochemical information (equation 105).



(105)

Müller described a Curtius–Cope rearrangement sequence.[471] It is interesting to note that, despite the mostly concerted character of this rearrangement, some erosion of *ee* occurred in case of **306**, probably because of participation of a biradical mechanism (equation 106). In case of the more substituted compound **307**, complete conservation of stereoselectivity was observed (equation 107).



(106)

(107)

N-Aryl vinylaziridines **308** can be rearranged to benzoazepines **309** on heating with silica gel. Gallo[472] studied the formation of such aziridines and their pathways of rearrangement. In case of sterically encumbered aziridines or under strictly thermal conditions without silica gel, dihydropyrroles of type **310** are formed (equation 108).

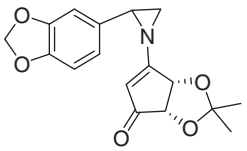
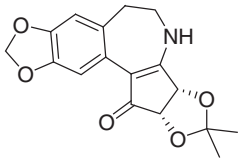
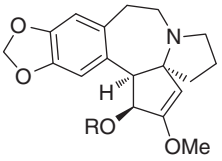
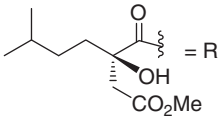
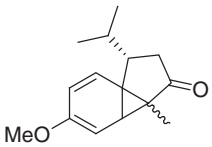
5.22.2.6 Total Syntheses

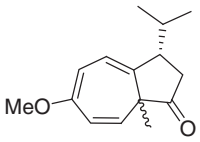


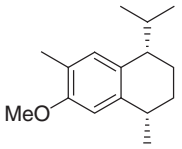


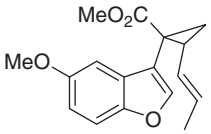


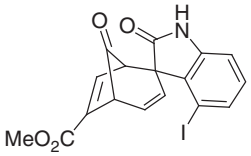


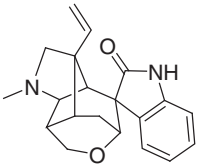


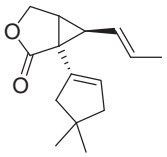


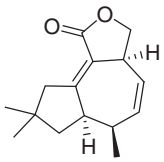


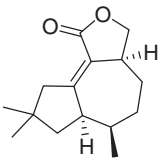


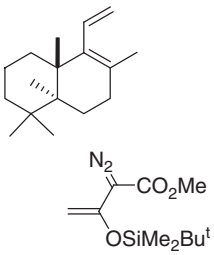


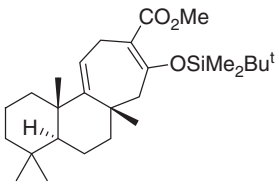


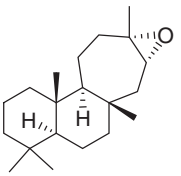


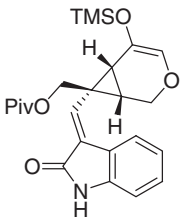


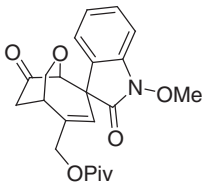


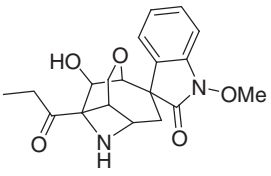












The divinylcyclopropane–cycloheptadiene rearrangement has not been featured in total syntheses as frequently as the vinylcyclopropane–cyclopentene rearrangement. Since the publication of the first edition of this work, only a few applications were reported. These are summarized in Table 17. For previous utilization of this rearrangement see the 1991 edition; notable accomplishments include the syntheses of β-himachalene by Piers[473] and of confertine by Wender.[474]

5.22.3 Outlook

More than 50 years have passed since Neureiter's discovery of the vinylcyclopropane rearrangement. In the golden age of physical organic chemistry, 1950–70, this rearrangement and the divinylcyclopropane rearrangement were subjected to detailed

mechanistic scrutiny. The applications of both rearrangements to synthesis followed shortly thereafter. Many useful and general methods were derived from these rearrangements and their heteroatom variants. The total synthesis community was also quick to recognize their value, as evidenced by many applications to the synthesis of natural products in both the terpene and alkaloid domains.

After the publication of the chapters dealing with these two rearrangements in the first edition of *Comprehensive Organic Synthesis* in 1991 the frequency of applications in synthesis diminished, perhaps indicating the maturity of the methods. An update published in 2010[485] as a tribute to Neureiter's historical contribution reported a few new applications that surfaced since 1991.

Organometallic chemistry significantly changed the landscape of, especially, the chemistry of vinylcyclopropanes. The attention of the synthetic community has been more focused on the application of transition-metal catalysis especially in the design of new modes of reactivity, such as the higher order cycloadditions discovered by Wender and the redesign of old reactions under enantioselective conditions.

The topology of these reactive substrates offers almost endless combinations of products when one considers the almost infinite combinatorial possibilities resulting from the incorporation of heteroatoms into the reactive manifold. Few of these combinations have been truly exploited in synthesis, and it is the authors' hope that the publication of this chapter will inspire interest in further development of some of the most fascinating transformations in organic synthesis.[486,487]

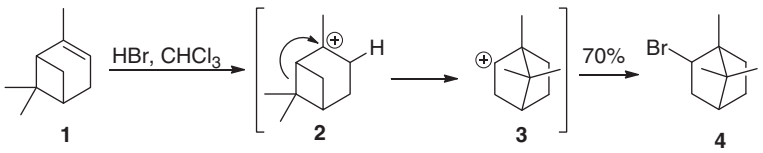
Glossary

β-Carbon elimination Formation of a carbon–metal species by elimination of the carbon atom in the β-position to the metal. Reversal of the migratory insertion reaction.
Carbon–carbon bond cleavage Rupture of the bond between two carbon atoms.
Charge acceleration Faster reaction rate due to the presence of a positive or negative charge.
Cyclobutane Four-membered carbocycle.
Cyclopropane Three-membered carbocycle.
Strain acceleration Enhanced reaction rate due to the release of ring strain.

5.23.1 Charge-Accelerated Rearrangements: Background

5.23.1.1 Introduction

Exploitation of ring strain as enabling force to promote molecular rearrangements, which do not proceed (or at least not as facile) with conventional substrates, is a well-appreciated strategic tool in organic synthesis. In particular, this encompasses ring-expansion and -cleavage reactions of three- and four-membered rings. Although the exact quantification of the energy benefit of breaking the small ring depends on the specific substrates and reactions, a rough overview of the strain energies is helpful to estimate reactivities. The strain energy of cyclopropane (27.5 kcal mol^{-1}) is very similar to that of cyclobutane (26.5 kcal mol^{-1}) and dramatically higher than that of cyclopentane (7.4 kcal mol^{-1}) (Scheme 1). Despite this similarity, the cyclopropane ring is more susceptible toward ring-cleavage. This can be rationalized by a dissection of the strain in C–C and C–H bond energy contributions. The amount deriving from C–C bonds is 10.1 kcal mol^{-1} higher in cyclopropane than in cyclobutane.[1] This difference is compensated by the stronger C–H bonds (8.0 kcal mol^{-1}) of cyclobutane.[2] Care needs to be taken to estimate the ring strain of substituted substrates. For example, geminal disubstitution reduces the ring strain of cyclobutane by more than 8 kcal mol^{-1} because of the Thorpe–Ingold effect.[3]



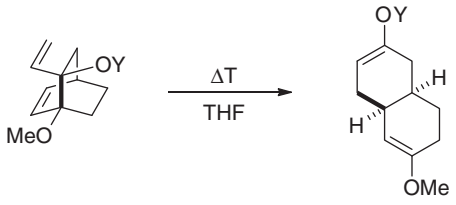
Scheme 1 Strain energies of selected carbocycles.

Although the ring strain is an important feature to increase reactivity, many substrates still suffer from drawbacks of poor reactivity, selectivity, and scope limitations. These shortcomings can often be addressed by exploiting the accelerating properties of a charged substituent on the small-ring compound. In the first edition of Comprehensive Organic Synthesis (COS) in 1991, the

majority of the featured reactions fell in the category of anionic pericyclic rearrangements. Most often, these reactions were stoichiometric comprising a first or second row metal cation. The reaction outcome is dictated by the substrate and the rate is modulated by the nature of the charge. Generally, the faster the reaction, the greater their charge separation and higher their ionic character. Although some additional applications of these reactivities have been reported in the following two decades, the most significant advances were made in the area of transition-metal catalyzed reactions. The transition-metal catalyst enables a host of conceptually new methods, with intermediary appearing charges. These may be more accurately described as coordination complexes or organometallic species. The chapter's main focus is placed on illustrating the possibilities that these new methods enable in combination with strained ring compounds.

5.23.1.2 Cationic Rearrangements

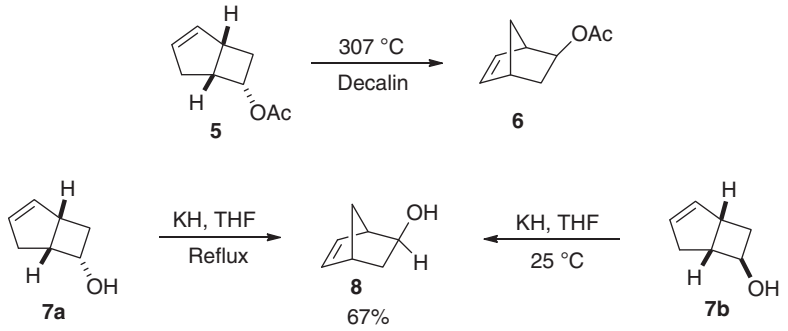
The history of cationic rearrangements of the Wagner–Meerwein type of strained molecules is long. In general, the reaction follows the mechanistic pathway of a 1,2-carbon shift. A generated cyclopropyl methyl or cyclobutyl methyl carbenium ion rearranges into a cyclobutyl or cyclopentyl carbenium ion, which in turn can react further. An important illustration and a classic example is the acid-promoted rearrangement of α-pinene (**1**) (Scheme 2). Simplified, it is the ring-expansion of a vinyl cyclobutane into a cyclopentane. Protonation leads to the tertiary cyclobutyl methyl carbenium ion **2** which rearranges to the camphane cation **3**, which gets subsequently trapped to give 2-bromo camphane **4** in 70% yield.[4]



Scheme 2 Prototypical Wagner–Meerwein type of cationic rearrangement.

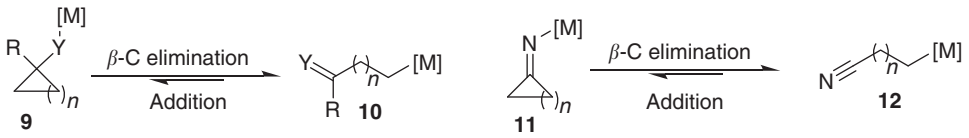
This reactivity principle has been utilized many times, exploiting the different aspects of this chemistry. It should be noted that these types of purely cationic rearrangements are not covered in this chapter and are treated separately with the appropriate depth in the chapters specifically concerned with Wagner–Meerwein type and related rearrangements in Volume 3 of COS2. A recent review focusing on cyclobutane substrates is available as well.[5]

5.23.1.3 Aza- and Oxyanion-Accelerated Rearrangements



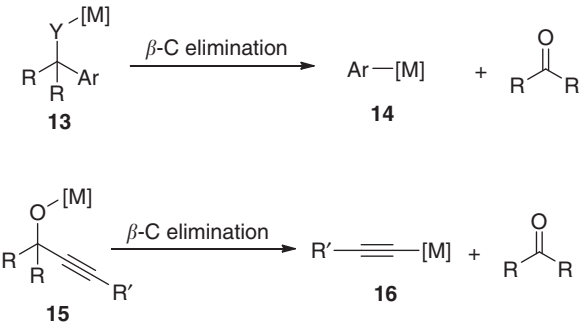
The classical example for anionic-charge accelerated processes is the oxy-Cope reaction. Spectacular rate enhancements of 10^{10}–10^{17} are observed with anionic oxy-substituents compared to their neutral congeners (Scheme 3). Although the neutral process generally requires reaction temperatures between 200 and 400 °C, the corresponding anionic reaction often proceeds at ambient temperature or below.[6] The effect stems both from reactant destabilization and transition state stabilization. Since its discovery, anionic oxy-Cope reactions have been widely utilized in synthetic organic chemistry (*see* Chapter 5.19 of COS2).

Y	Half-life	T (°C)
H	(66 yrs)	66
Na	1.2 h	66
K	1.4 min	66
K	11 h	10
K (HMPA)	4.4 min	10



Scheme 3 Rate accelerations and half-lives of anionic oxy-Cope reactions.

A popular prototype of oxyanion-accelerated rearrangements of strained rings is the vinylcyclobutane-to-cyclohexene rearrangement. As exemplified for the rearrangement of **5**–**6**, the notoriously high temperature for the reaction has severely limited synthetic applications (Scheme 4).[7] These limitations can be largely overcome by exploiting the accelerating properties of an appended alkoxide group.[8] Depending on the utilized diastereomer **7a** or **7b**, different mechanistic pathways of the rearrangement are operative, all ending with the same thermodynamic *exo*/*endo* ratio, favoring largely the depicted isomer **8**.



Scheme 4 Anion-accelerated vinyl-cyclobutane rearrangement.

The mechanistic details and synthetic applications of this and related reactions are discussed in detail in the corresponding chapter of COS1. Here, the main focus is placed on new developments of transition-metal oxy- and aza-anions. In this scenario compound **9** builds an important starting point for rearrangements of strained cyclic compounds (Scheme 5). Their softer and less oxyphilic character compared to main group anions, enables a rearrangement process – the β-carbon elimination – giving rise to either a C=O and C=N double bond or a nitrile and an alkyl-metal species.[9] In turn, intermediate **10** undergoes a myriad of valuable follow-up processes, often involving a π-unsaturation in vicinity. However, these π-unsaturations are generally not essential to induce the rearrangement reactivity. However, the reaction requires most often tertiary alcoholates/amides to avoid the concurrent process of β-hydride elimination. For β-carbon elimination of sp^3-hydribized carbon substituents, the energy release of ring opening is required to compensate for the relatively weak C(sp^3)-metal bond (**10** and **12**). In contrast, substrates with sp- and sp^2-hydribized residues (**13** and **15**) give species with significantly stronger carbon-metal bonds (**14** and **16**) and do not mandate this additional driving force. In several cases the relevant alkoxides can be generated as reactive transients by the addition of organometallic species to the strained ketones. This, and alternative methods to their generation as well as the possible downstream reactivities of the species **10** and **12** are overviewed in the following sections.

[M] = Transition metal

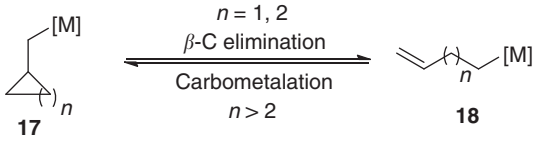
n = 1, 2

C(sp^2)-[M] and C(sp)-[M] do not require strain release:

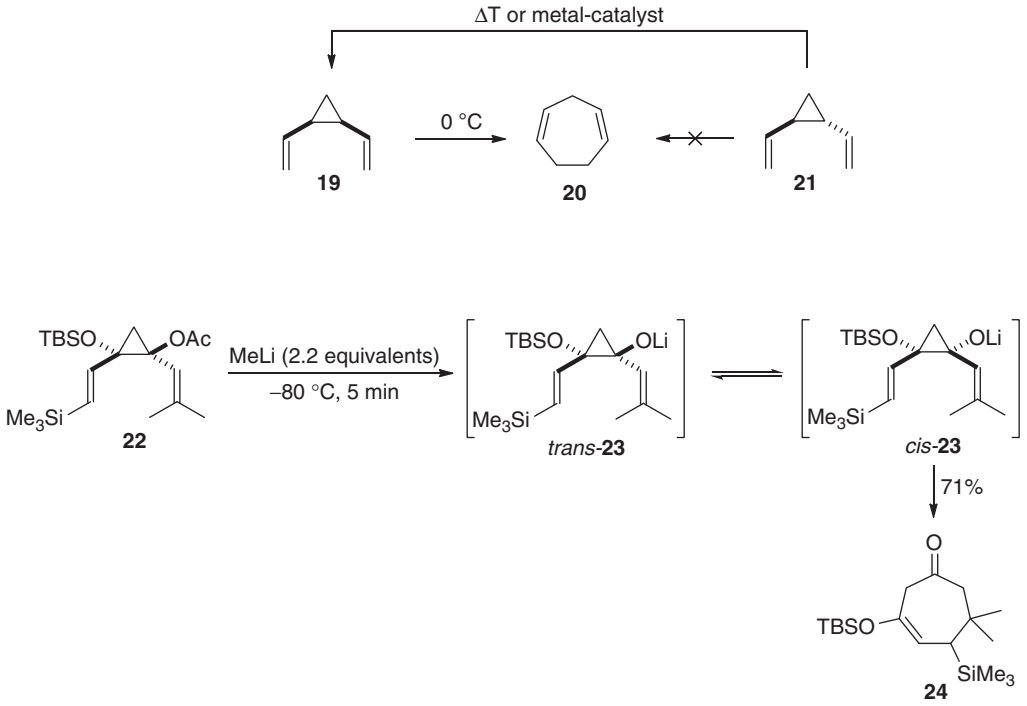


Scheme 5 β-Carbon eliminations from *tert*-alcohols with and without strain.

5.23.1.4 Carbanion-Accelerated Rearrangements

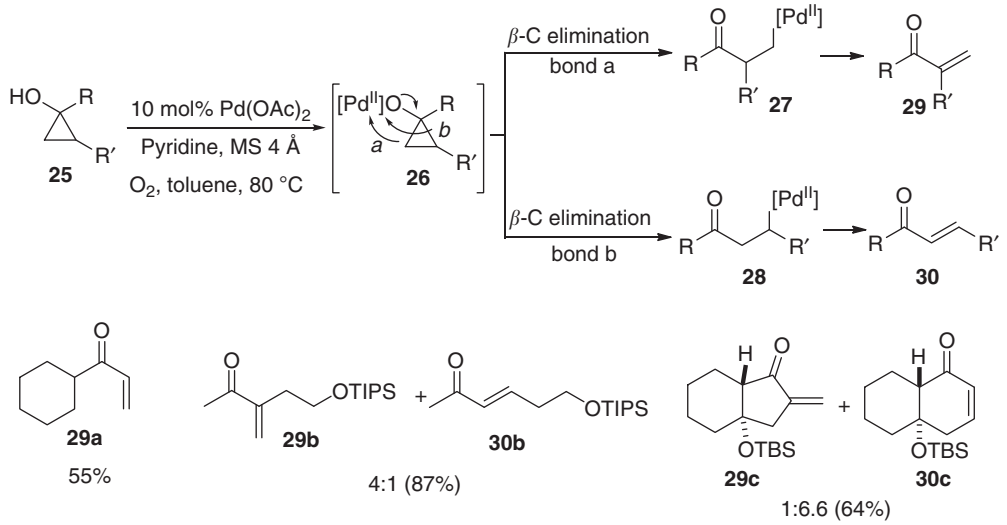
Similar to aza- and oxyanions, major progress in the field of carbanion-accelerated rearrangements has been made with transition-metal catalysis involving discrete carbon-metal bonds. In particular, β-carbon eliminations benefit from the release of ring strain (equation 1). For $n > 2$, the equilibrium largely favors the cyclic form **17**, whereas cyclopropylmethyl and cyclobutylmethyl

intermediates rapidly rearrange to their open forms **18**. Often, the ring opening is preferred over β-H elimination when the appropriate geometrical constraints are met. The range of methods to obtain the crucial intermediates **18** and their subsequent reactivity are discussed. For example, this concept has been applied to higher order cycloadditions such as [5 + 2].



(1)

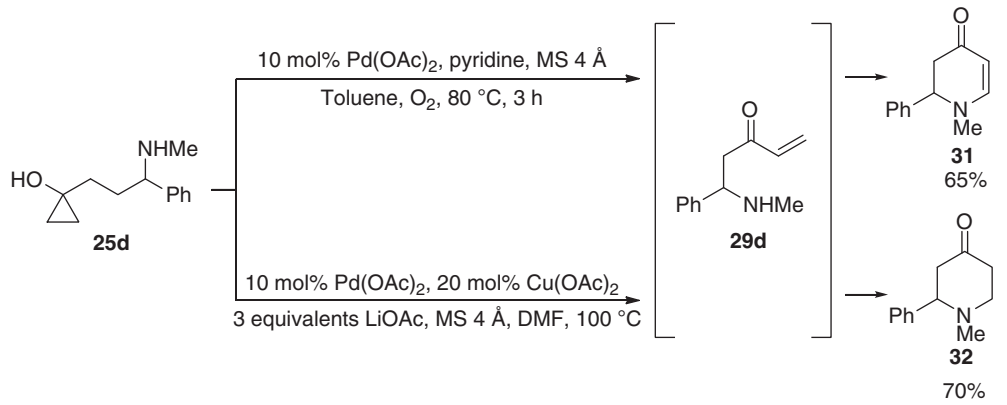
5.23.2 Charge-Promoted Rearrangements of Cyclopropanes



5.23.2.1 Oxyanion-Induced Rearrangements of Cyclopropanes

The divinylcyclopropane rearrangement is a special form of the Cope-rearrangement and provides access to 1,4-cyclohepadienes **20** (Scheme 6).[10] Owing to the release of ring strain, the rearrangement of *cis*-divinyl cyclopropane **19** proceeds already at ambient temperature and below, making it very difficult to isolate **19**. Usually, formation of the divinylcyclopropane and the rearrangement is carried out in the same pot. In contrast, the corresponding *trans*-isomer **21** is stable and does not undergo the rearrangement unless an isomerization (excessive heat or transition-metal-catalysts) to the *cis*-isomer **19** occurs. Similar to anionic oxy-Cope reactions, divinyl cyclopropane rearrangements are also accelerated by appended oxyanions. Takeda found that generation of the lithium alkoxide *trans*-**23** from the unreactive *trans*-acetate **22** promotes a rapid equilibration to *cis*-**23**, which directly cyclizes to cycloheptenone **24**.[11] All steps are fast and take place at −78 °C within 5 min.

Scheme 6 Oxyanion-accelerated divinylcyclopropane rearrangement.

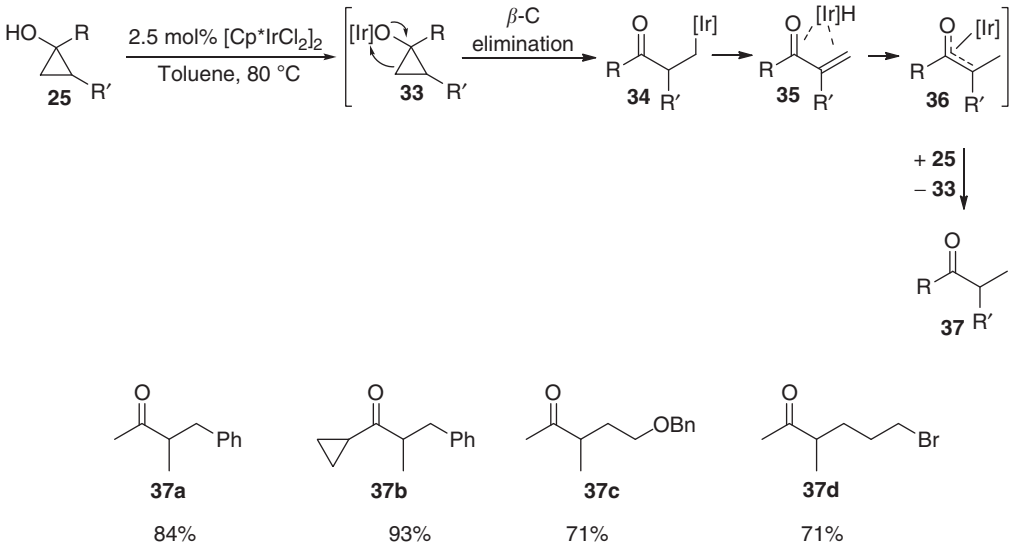


Free *tert*-cyclopropanols are readily accessible from the corresponding esters by the titanium-mediated Kulinkovich reaction.[12] They are a versatile class of substrates for a set of rearrangements initiated by a range of transition-metal catalysts. For instance, Cha reported palladium(II)-catalyzed openings of cyclopropanols **25** under oxidative conditions (Scheme 7).[13] The reactions proceed with molecular oxygen as the terminal oxidant, using catalytic amounts of $Pd(OAc)_2$ and pyridine as base. At first, formation of the palladium(II) alkoxide **26** occurs. Depending on the substitution pattern, a β-carbon elimination – cleaving either bond *a* or *b* – leads to intermediates **27** or **28**. Subsequent β-hydride elimination gives rise to enones **29** or **30**. Oxidation of the formed Pd(0)-species by oxygen turns over the metal complex. For acyclic substrates, cleavage of the

Scheme 7 Palladium(II)-catalyzed β-carbon elimination from *tert*-cyclopropanols.

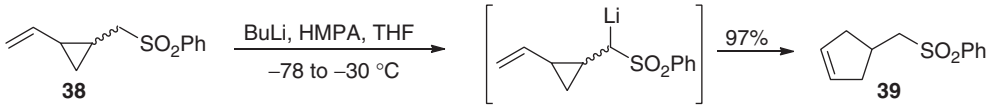
less substituted bond *a* dominates, whereas for constrained cyclic substrates, selectivities can be reversed, favoring cleavage of bond *b*.

Independently, Okumoto described a similar process with Pd(0)-catalysts.[14] Brandi exploited the reaction further, capitalizing on the formation of the enone **29d** for an aza-Michael addition, leading either to enaminone **31** or to the saturated product **32** (Scheme 8).[15]



Scheme 8 Palladium(II)-catalyzed β-carbon elimination followed by cyclization.

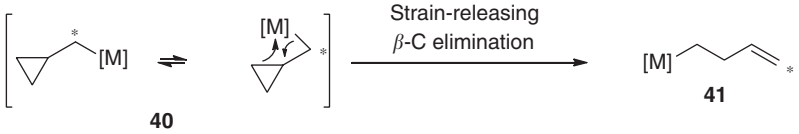
With other catalysts, similar cyclopropanol substrates can be transformed into saturated ketones as well. In this respect, Funk reported a Ir(III)-catalyzed process using catalytic amounts of $[Cp^*IrCl_2]_2$ (Scheme 9).[16] Contrasting the work of Cha, the less substituted C–C bond of **33** is cleaved selectively, leading strictly to the more stable primary iridium intermediates **34**. β-Hydride elimination leads to enone **35** and an iridium-hydride species, which in turn adds in a 1,4-fashion, leading to the saturated ketone **37** via the oxa-π-allyl species **36**. The reaction is functional group tolerant and generally high yielding.



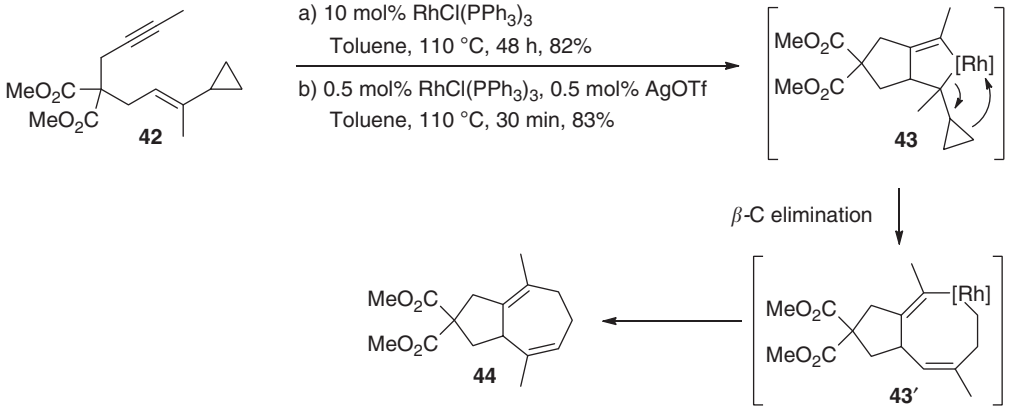
5.23.2.2 Carbanion-Induced Rearrangements of Cyclopropanes

The acceleration potential of carbanionic substituents for small-ring rearrangements was first demonstrated by Danheiser with the vinylcyclopropane (VCP) rearrangement of **38** into cyclopentene **39** (Scheme 10).[17] The potential and the limitation of such lithiated intermediates were covered in the first edition of COS.

Since then, most exciting progress has been made by using transition-metal carbanionic intermediates complementing the classical main group carbanion reactivity. In general, these reactions follow the same principle as the one for oxyanions. The metalated cyclopropylmethyl intermediate **40** undergoes a strain-driven opening to form a homoallyl metal species **41** (equation 2).

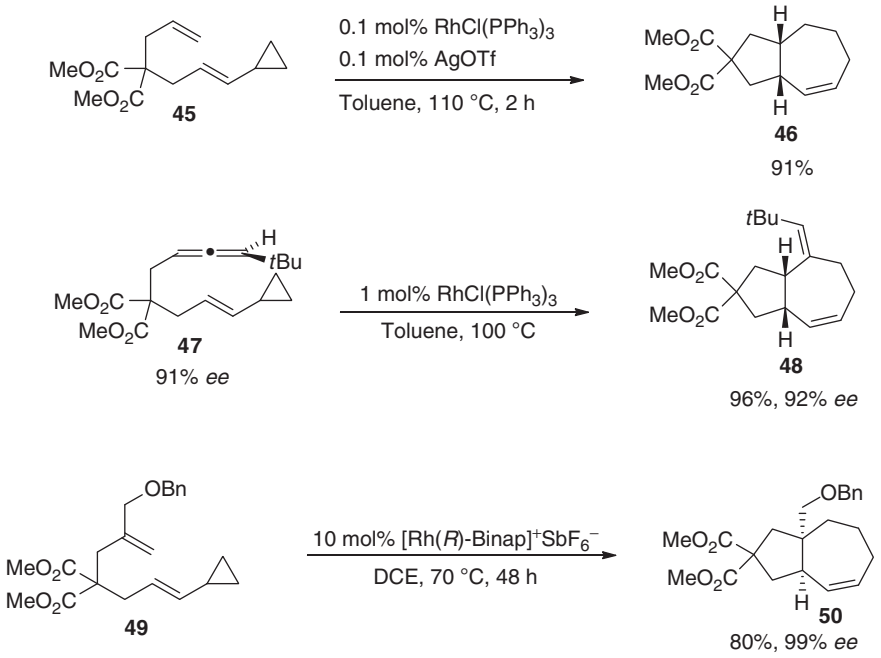


Scheme 9 Iridium(III)-catalyzed β-carbon elimination from *tert*-cyclopropanols.



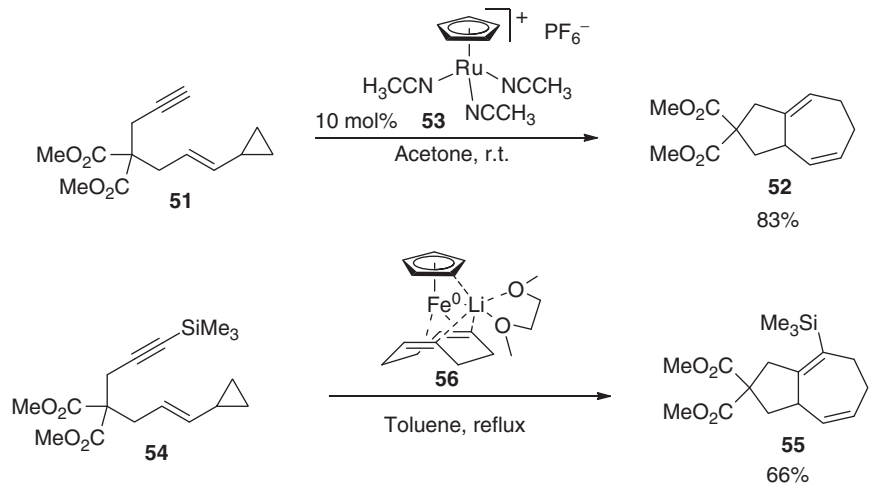
Scheme 10 Carbanion-accelerated vinylcyclopropane rearrangement.

Depending on the catalyst and metal, **41** undergoes specific downstream processing to the individually observed product branches. The generation of the initiating anionic intermediate **40** can be achieved by several methods.



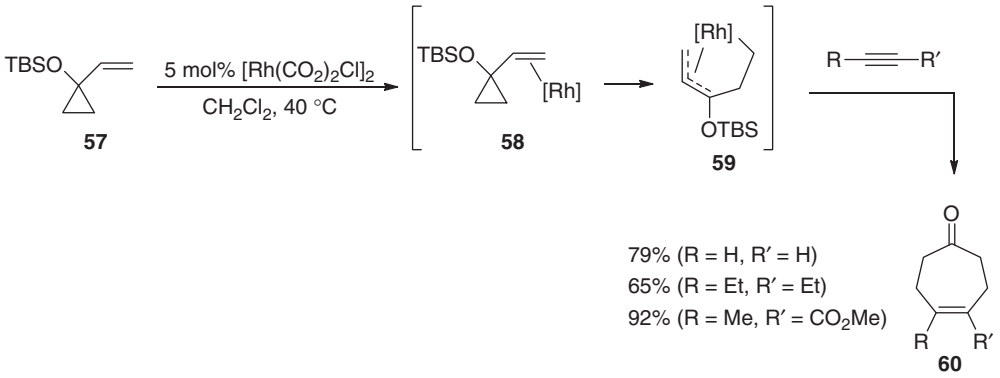
(2)

Common methods for its generation are metal-catalyzed cycloisomerization reactions. Especially Wender's large body of work on rhodium-catalyzed [5 + 2]-cycloadditions of a VCP moiety tethered by a three atom spacer to an alkyne expanded this field vastly. In early studies, Wilkinson's catalyst was utilized, whereas later it was found that a cationic rhodium(I) species is much more reactive (Scheme 11).[18] At first, oxidative cyclization of **42** forming rhodacyclopentene **43** proceeds. Then, strain-driven ring opening by β-carbon elimination leads to a transient rhodacyclooctadiene **43′**, which undergoes reductive elimination to give cycloheptadiene **44**.



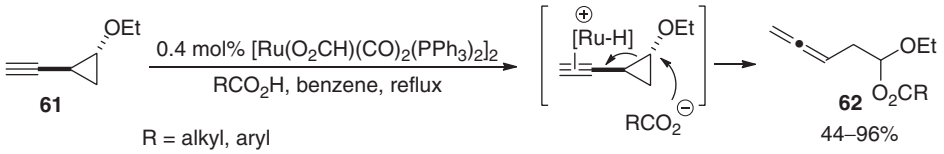
Scheme 11 Wender's rhodium(I)-catalyzed [5 + 2]-cycloadditions.

Subsequently, it was demonstrated that the reaction proceeds as well with olefins instead of alkynes (Scheme 12).[19] As shown for **45**, cycloheptene **46** is obtained. The transformation of a trisubstituted allene **47–48** is enantiospecific.[20] Some enantioselective versions have also been developed.[21] For instance, substrate **49** gave, with *(R)*-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (Binap) as chiral ligand, cycloisomerized product **50** in excellent optical purity.



Scheme 12 General scope of rhodium(I)-catalyzed [5 + 2]-cycloadditions.

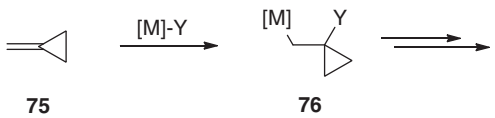
Although rhodium complexes are until now the most general and best explored metal catalysts for [5 + 2]-cycloadditions, other metal-catalysts promote this transformation as well. For instance, Trost showed that similar substrates **51** undergo the reaction with the cationic ruthenium(II) complex $[CpRu(CH_3CN)_3]PF_6$ (**53**) providing product **52** (Scheme 13).[22] The reaction has a broad scope and proceeds at mild conditions, comparable to the rhodium-catalyzed process. Fürstner reported the use of the well-defined ferrate complex **56**, showing that it is possible to catalyze the cycloisomerization of substrate **54** to bicycle **55** also with a nonnoble metal catalyst.[23]



Scheme 13 [5 + 2]-Cycloadditions catalyzed by ruthenium- and ferrate-complexes.

Wender has further developed an intermolecular version (Scheme 14). VCPs **57** needs to be activated by an alkoxy or siloxy group. The scope for the alkyne is broad (acetylene, internal alkynes, and propiolates are tolerated).[24] However, to achieve the reaction, one has to use $[Rh(CO)_2Cl]_2$; Wilkinson's catalyst is not competent. Calculations for this reaction have shown that coordination of a Rh(CO)Cl fragment to the vinyl group (**58**) leads to a cleavage of the cyclopropane delivering intermediate **59**. Insertion of an alkyne and subsequent reductive elimination provides cycloheptane derivative **60**.[25] Further details on these and related metal-catalyzed [5 + 2]-cycloadditions[26] can be found in Chapter 5.14 of COS2, dealing with higher order cycloadditions.

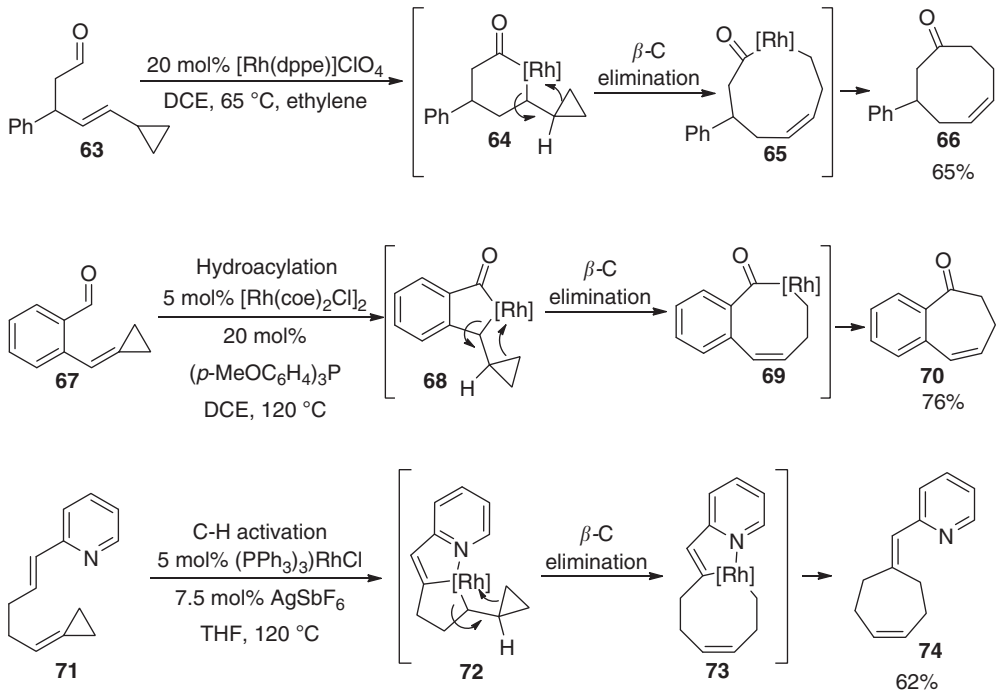
Scheme 14 Intermolecular rhodium-catalyzed [5 + 2]-cycloaddition.



Similarly to the reactions outlined above, activated alkynyl cyclopropanes such as **61** can be activated by ruthenium catalysts (Scheme 15).[27] Dixneuf showed that coordination of a ruthenium hydride species to the alkyne make the cyclopropane moiety susceptible toward nucleophilic attack by a carboxylate. The ring-opening reaction yields allenes **62** and proceeds in fair to excellent yields.

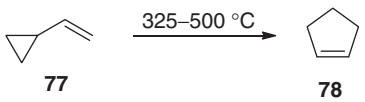
Scheme 15 Ruthenium catalyzed ring-opening of alkynyl cyclopropanes.

Besides these pathways, other strategies to access the cyclopropylmethyl metal intermediates were reported. Shair used aldehydes **63** with an appended vinyl cyclopropane unit as starting materials for an intramolecular hydroacylation, leading to the cyclopropylmethyl intermediate **64** (Scheme 16).[28] β-Carbon elimination opens the cyclopropane ring and gives **65**. Reductive elimination provides access to the cyclooctanone derivative **66**. In general, the reaction is tolerant to a variety of substitution patterns and functional groups. However, the catalytic efficiency is moderate and the yields are often fair. A related approach was reported by Fürstner and Aissa, using vinylidene cyclopropanes **67** and **71** as substrates for the intramolecular hydrorhodation to access the critical intermediates **68** and **72**.[29] Similarly, these reactive species ring open subsequently to compounds **69** and **73**, respectively, before reductive elimination forms products **70** and **74**.



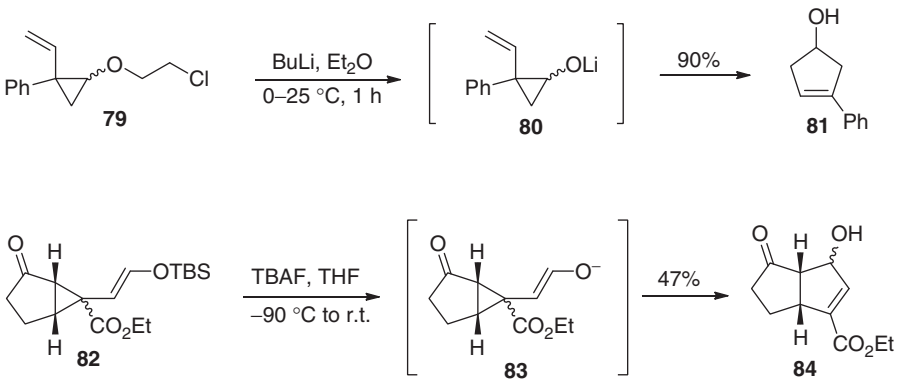
In general, methylenecyclopropanes (MCPs) **75** are highly strained molecules and undergo a variety of addition and ring-opening reactions. Although some of these reactions pass by cyclopropylmethyl metal intermediates like **76** (equation 3), their discussion will go beyond the scope of this chapter and more detailed information can be found in recent reviews.[30]

(3)



5.23.2.3 Rearrangements of Cyclopropanes Promoted by π-Coordinated Metals

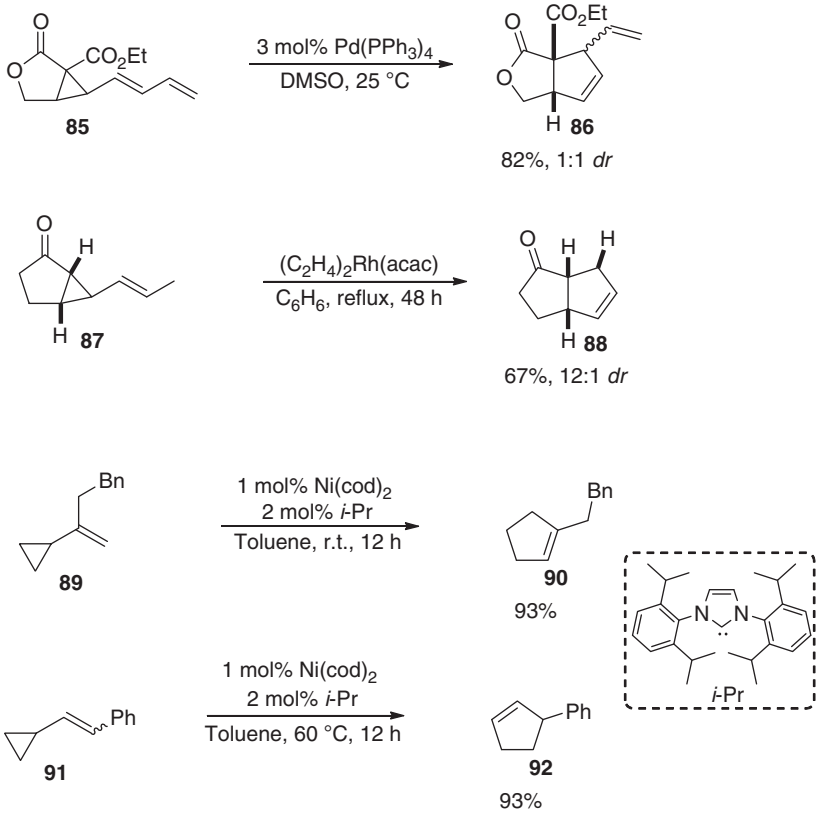
The VCP, (77)-to-cyclopentene (**78**) rearrangement is a classic application field for flash vacuum pyrolysis, capable of delivering the necessary high reaction temperatures (frequently over 500 °C) (Scheme 17).[31] A reasonable reaction temperature and a solid functional group tolerance as well as cleaner stereochemical outcome has been achieved by charge-acceleration. Analogous to the tremendous acceleration effect observed in anionic-oxy-Cope rearrangements, similar observations have been made by Danheiser



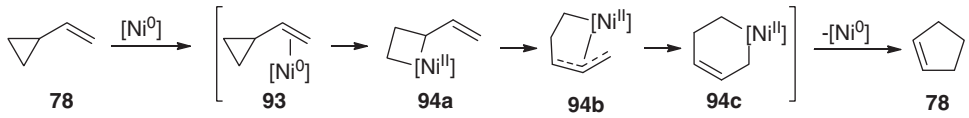
Scheme 16 β-Carbon elimination induced by hydrorhodation.

Thermally promoted parent VCP rearrangement:

Oxyanion accelerated VCP rearrangements:



Scheme 17 Thermal and charge-accelerated VCP rearrangements.

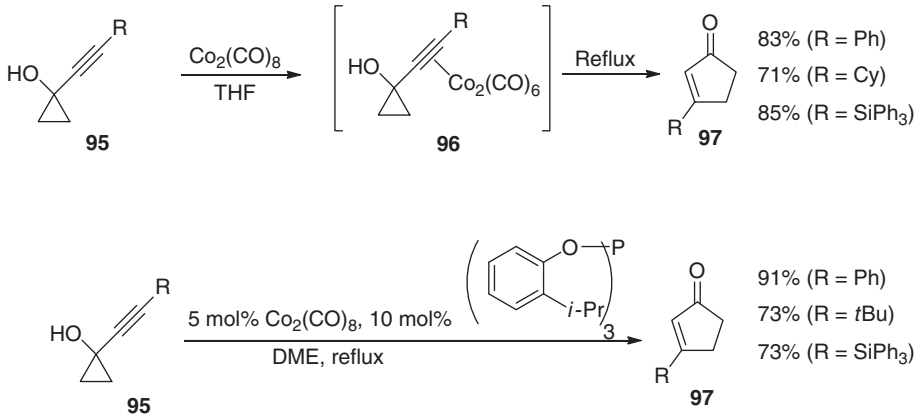


for VCPs bearing deprotonated hydroxyl functionalities.[17] For instance, generation of the lithium alkoxide **80** from **79**, allows for a clean rearrangement to cyclopentenol **81** at ambient temperature. Activated substrates such as **83**, obtained by desilylation from **82**, are even more reactive and readily rearrange to **84**.[32]

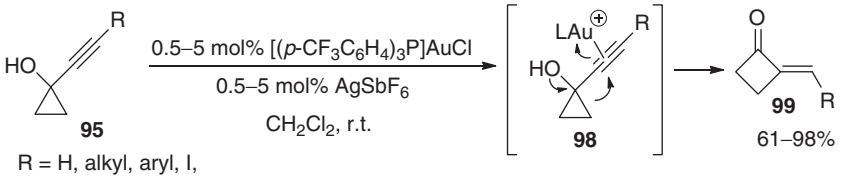
In contrast to these advances, substrates lacking the appropriate handle to place a charge remained problematic and required the development of different activation strategies. Transition-metal complexes (Ni, Pd, Rh, Cu, Cr, Mo, and Fe) were reported to catalyze rearrangements from VCP, dramatically lowering the required reaction temperature.[33] In this respect, Pd(0), Rh(I), and Ni(0)-catalyst were the most versatile (for selected examples see Scheme 18). The scope for palladium- and rhodium-catalysts

reactions is limited by and large to activated VCP (**85** and **87**) having an electron-withdrawing substituent, which enhances their propensity for oxidative addition and/or stabilization of anionic ring-opened intermediates. Alternatively, cyclopropyl dienes are well behaved substrates because of their good coordination ability to the metal complexes. These limitations were addressed by a nickel system with a carbene ligand described by Louie.[34] It proved to be highly efficient for completely unactivated VCPs. With a 1,1-disubstituted olefin (**89**), the reaction proceeds at ambient temperature with a catalyst loading of 1 mol%. A 1,2-disubstituted olefin (**91**) requires heating to 60–100 °C. Mechanistically, calculations suggest that coordination of the nickel complex to the double bond (**93**) and, subsequently, a proximity-induced insertion into the strained C–C bond of the cyclopropane gives **94a**. Isomerization to **94c** and finally reductive elimination gives rise to the cyclopentene derivative **78**.[35]

Mechanism of the Ni^0-catalyzed VCP rearrangement:

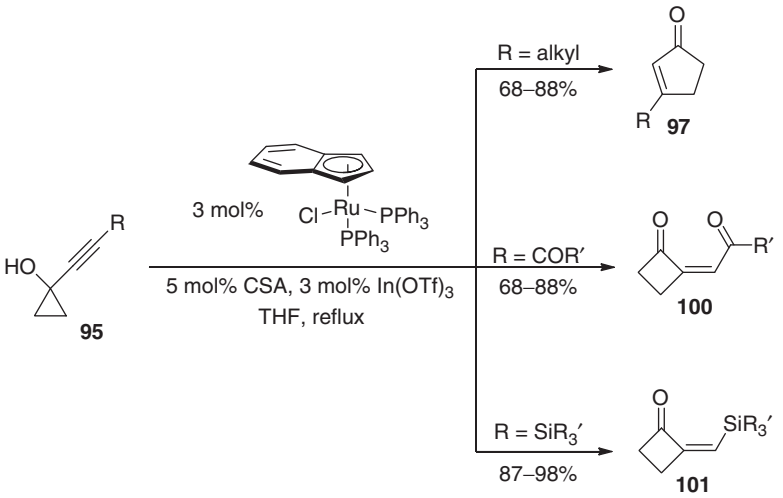


Scheme 18 Transition-metal catalyzed VCP rearrangements.



The metal-catalyzed VCP rearrangements were reported along the way of related activation strategies leading to a host of versatile new transformations. The activating nature of the hydroxyl group of cyclopropanol derivatives possessing an adjacent degree of unsaturation (olefin, allene, and alkyne) render them readily rearrangeable on treatment with transition-metal complexes. In an early example, Iwasawa demonstrated the ring opening of 1-alkynylcyclopropanols **95** mediated by dicobalt octacarbonyl (Scheme 19).[36] On heating, the intermediate cobalt complex **96** undergoes a rearrangement delivering cyclopentenone **97** in moderate to excellent yields. The same group later established an efficient catalytic version using a bulky triarylphosphite ligand.[37]

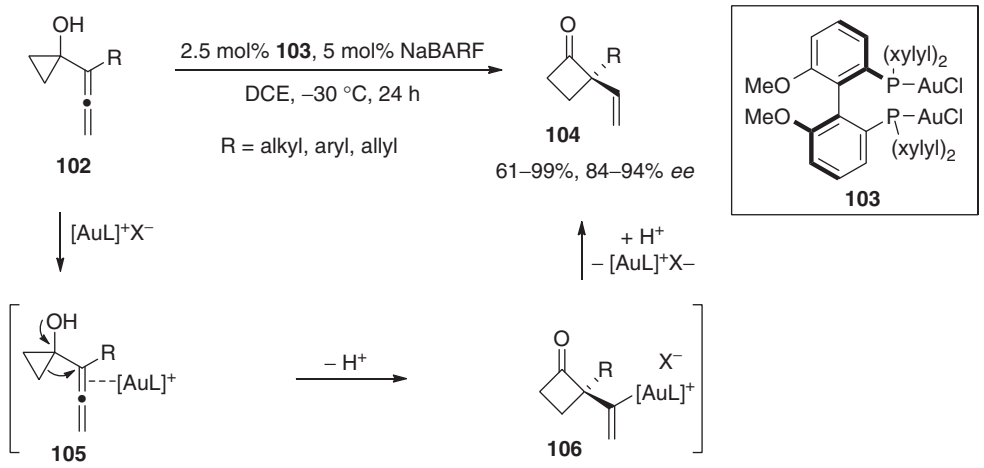
Toste found that exposure of the same substrates **95** to an *in situ* generated cationic gold(I)-catalyst induces a 1,2-shift leading to *trans*-cyclobutenones **99** (Scheme 20).[38] The reaction is induced by π-coordination of the gold(I) complex to the triple bond (**98**). The rearrangement proceeds at ambient temperature and is generally very high yielding.



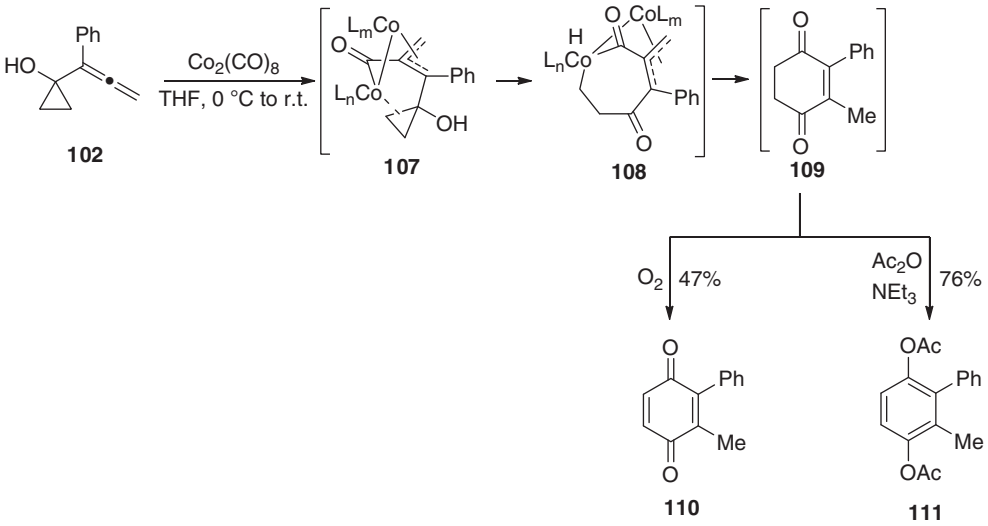
The reaction of 1-alkynylcyclopropanols **95** with a ruthenium(II)-catalyst was reported by Trost.[39] Interestingly, divergent reaction pathways were observed depending on the substituent R (Scheme 21). Electronically 'neutral' alkyl substituents are prone to a C–C insertion providing, similar to the cobalt-catalyzed process, cyclopentenones **97** via a suggested ruthenacyclohexenone.

Scheme 19 Cobalt-promoted rearrangement of 1-alkynylcyclopropanols.

Scheme 20 Gold-promoted rearrangement of 1-alkynylcyclopropanols.



Scheme 21 Ruthenium(II)-promoted rearrangement of 1-alkynylcyclopropanols.



In contrast, electron-donating silyl groups or electron-withdrawing carbonyl groups yield selectively *cis*-cyclobutenones **101** and **100**, respectively. The observed olefin geometry is complementary to the one obtained by the gold-catalyzed process.

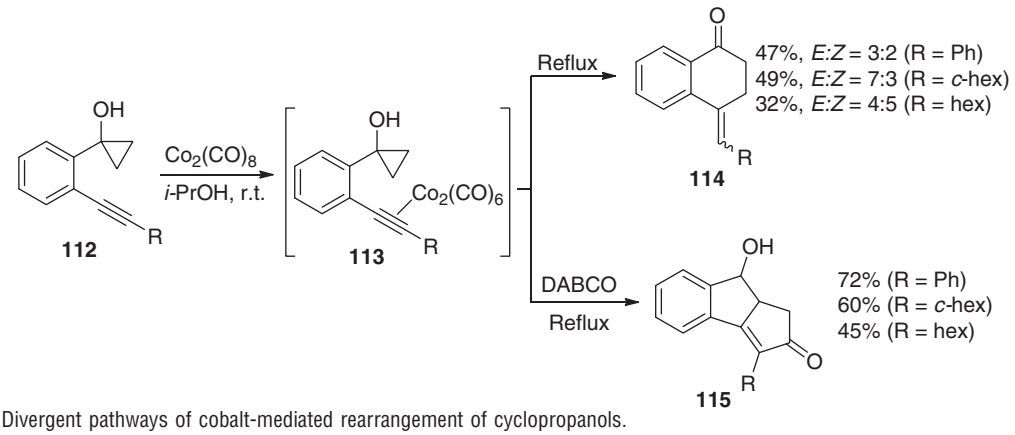
Toste reported in 2009 a highly enantioselective rearrangement of 1-allenylcyclopropanols **102** using the chiral bis-gold(I) complex **103** (Scheme 22) to give cyclobutanones **104**.[40] On generation of a competent cationic gold species by anion metathesis with sodium tetrakis[(3,5-trifluoromethyl)phenyl]borate, the reaction proceeds at temperatures as low as $-30\,^{\circ}C$. The reaction tolerates different substitution pattern and works efficiently with a wide range of R-groups. Although coordination of the metal to the allene moiety of **105** induces ring enlargement via vinyl gold species **106**, the reaction can as well becatalyzed in a racemic fashion by simple Bronsted-acids such as $HNTf_2$.

Treatment of similar 1-allenyl cyclopropanols **102** with dicobaltoctacarbonyl at ambient temperature leads to a totally different reaction pathway (Scheme 23). Iwasawa reported the formation of diketone **109**, which rapidly enolizes to the corresponding hydroquinone.[41] Owing to its oxidation sensitivity, this primary product is *in situ* acylated to give **111** in good yield. Alternatively, deliberate exposure to molecular oxygen delivers benzoquinone **110**. The reaction is believed to proceed first by a carbonylation of

Scheme 22 Enantioselective gold-catalyzed rearrangement of allenylcyclopropanols.

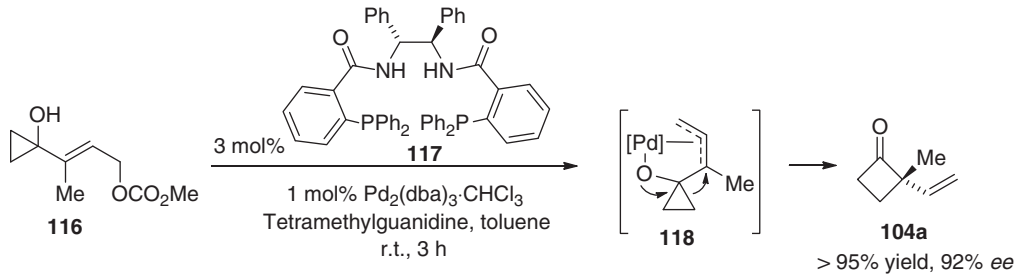
Scheme 23 Cobalt-mediated rearrangement of allenylcyclopropanols into hydroquinone derivatives.

the allene moiety leading to **107**. Cleavage of the cyclopropane ring gives rise to intermediate **108**, and subsequent reductive elimination delivers diketone **109**.



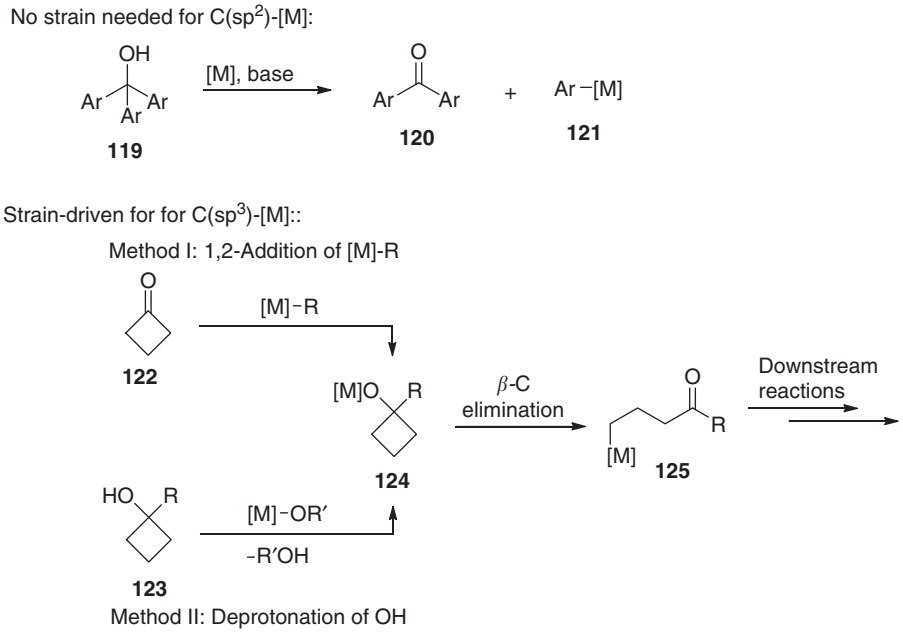
Iwasawa also reported cobalt-mediated rearrangements of 1-aryl cyclopropanols **112** with an appended internal alkyne (Scheme 24).[42] After formation of the alkyne cobalt complex **113** at ambient temperature in isopropanol, heating initiates a *β*-carbon cleavage and promotes subsequent cyclization to ketones **114** in fair yields. The *E*/*Z*-ratio is dependent on the substituent R of the alkyne. When the reaction is carried out in the presence of a base 1,4-diazabicyclo[2.2.2]octane (DABCO), a different pathway becomes operative and Pauson–Khand like products **115** are obtained in fair to good yields.

Trost reported in 2001 an enantioselective rearrangement of cyclopropanols such as **116** equipped with an allylic carbonate-leaving group (Scheme 25).[43] With a palladium(0) species formed with the Trost ligand **117** ionization to intermediate **118** occurs. The addition of tetramethylguanidine is beneficial for the rate of the reaction. From **118**, a selective migration of one of the enantiotopic cyclopropane C–C bond leads to cyclobutanone **104a** in excellent yield and selectivity.



5.23.3 Charge-Promoted Rearrangements of Cyclobutanes

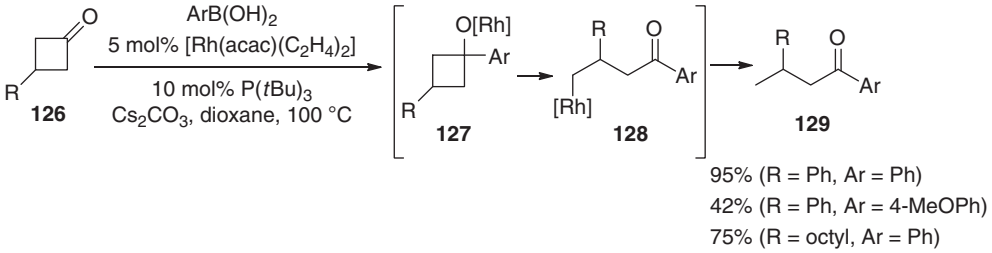
5.23.3.1 Oxyanion-Induced β-Carbon Eliminations



Hartwig has shown that triarylcarbinols **119** undergo a *β*-carbon elimination in the presence of a rhodium(I) catalyst to give aryl rhodium species **121** and benzophenone **120** (Scheme 26).[44] For a similar reaction leading to an alkyl-(instead of the aryl-) rhodium intermediate, additional energy input in the form of ring-strain release is required. In this respect, cyclobutanolates have

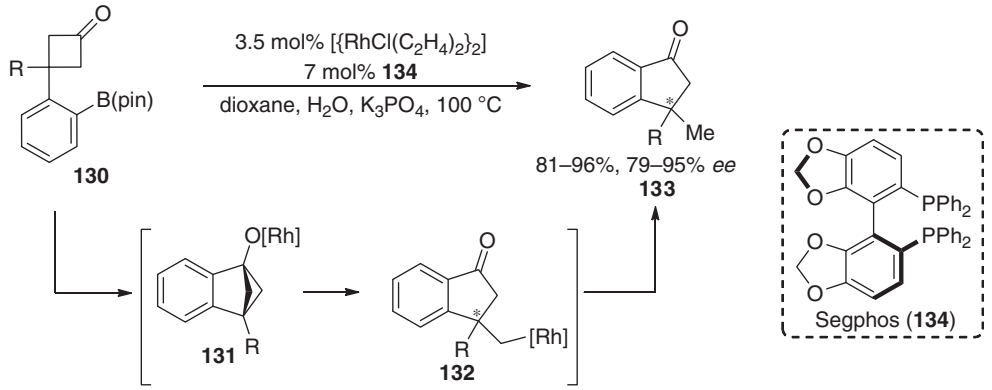
Scheme 24 Divergent pathways of cobalt-mediated rearrangement of cyclopropanols.

Scheme 25 Enantioselective palladium(0)-catalyzed rearrangement of cyclopropanols.



Scheme 26 Anion-promoted β-carbon elimination of *tert*-cyclobutanolate intermediates.

the right balance between reactivity and stability of the starting material and this method became a relatively robust reaction to access, in a complementary way, highly reactive alkyl-metal species **125**. Two general approaches have been described to obtain the metal cyclobutanolate intermediate **124**. It can be either obtained by the addition of an organometallic reagent to a cyclobutanone precursor **122** (Method I) or directly from the corresponding cyclobutanol **113** through deprotonation of the hydroxyl

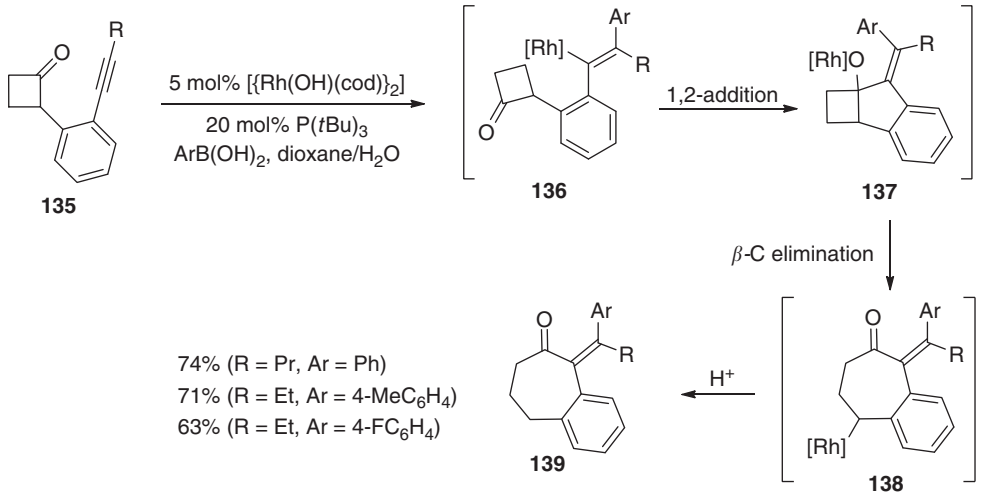


group (Method II). Both methods and the rich downstream chemistry of the alkyl-metal intermediates are discussed in this section.[45]

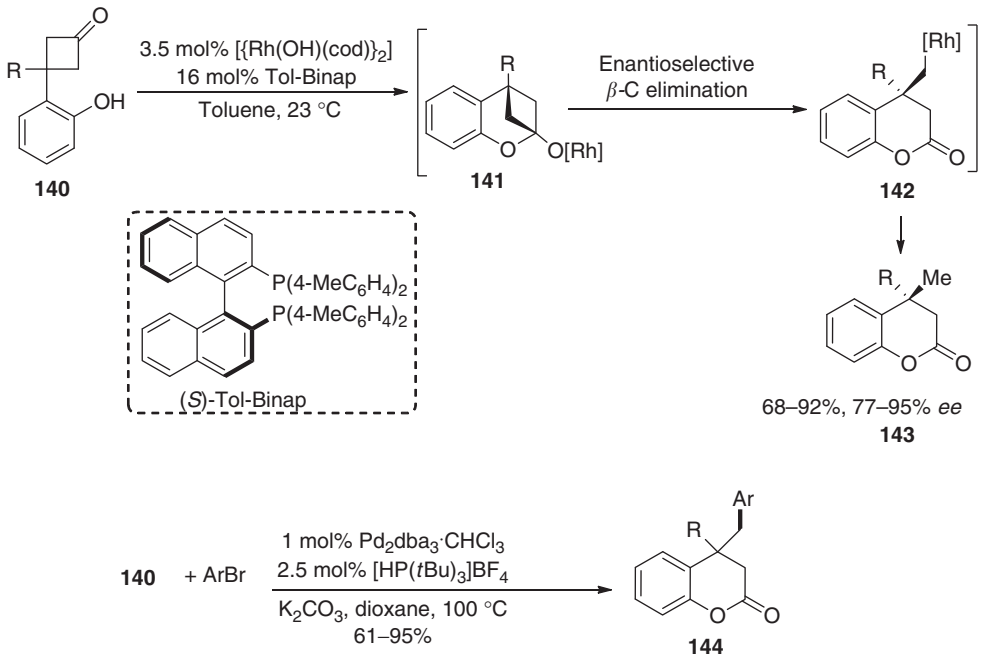
Following the first approach, Murakami disclosed rhodium(I)-catalyzed intermolecular 1,2-additions of aryl boronic acids to cyclobutanones **126** (Scheme 27).[46] Normal ketones are poor electrophiles in rhodium(I)-catalyzed 1,2-additions, but the higher carbonyl reactivity of a cyclobutanone compared to an unstrained ketone enables this process. However, only a single substituent is tolerated in the 3-position of the cyclobutanone. The rhodium-cyclobutanolate intermediate **127** is then undergoing a β-carbon cleavage reaction to give **128**. Sequential β-hydride eliminations and readditions afford an oxa-π-allylrhodium which is finally protonated to yield arylketones **129**.

Scheme 27 β-Carbon elimination induced by intermolecular 1,2-addition of arylrhodium species.

3,3-Disubstituted cyclobutanones are unreactive toward 1,2-additions of aryl rhodium species. So far, this could only be overcome by performing the reaction in an intramolecular fashion (Scheme 28).[47] Starting from boronic acid **130**, a 1,2-addition leads to the highly strained rhodium-alkoxide **131**, which in turn undergoes a β-carbon elimination to give complex **132**. Protonation via a 1,4-rhodium shift leads to indanones **133**. A differentiation of the two enantiotopic C–C bonds of **131** during the β-carbon elimination step enables the resulting quaternary carbon center to be formed with high enantioselectivity. Segphos (**134**) proved to be the best ligand for this purpose.



Scheme 28 Intramolecular 1,2-addition followed by enantioselective β-carbon elimination.

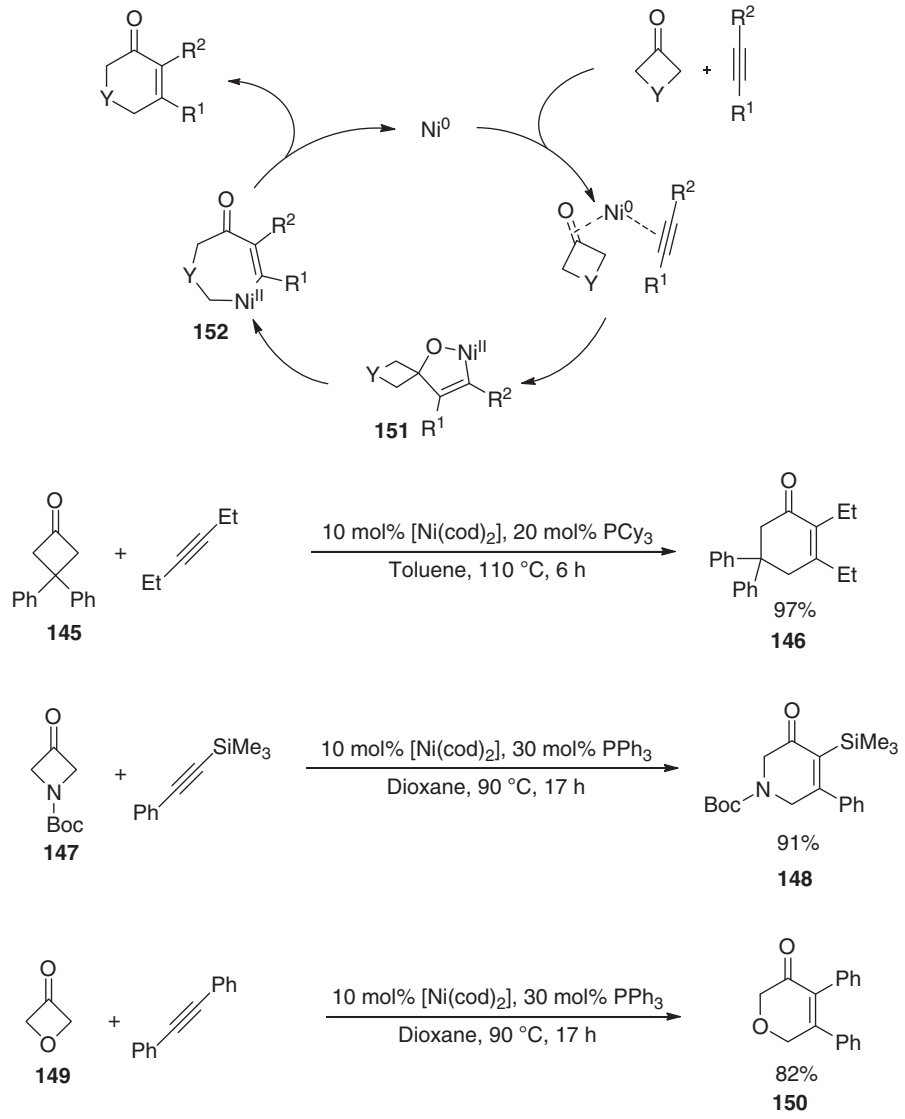


The same authors further designed another handle to render the additions intramolecular. First, regioselective carbo rhodation of the internal alkyne of **135** gives rise to vinyl rhodium species **136** (Scheme 29).[48] A facile intramolecular 1,2-addition across the carbonyl group of the cyclobutanone generates the requisite cyclobutanolate **137**. Regioselective β-carbon elimination leads to the benzylic rhodium species **138**. Two consecutive β-hydride eliminations/readditions provide medium-sized benzoheptanones **139** as the terminal products.

Murakami also reported the generation of the cyclobutanolate intermediates from a cyclobutanone by deprotonation of an *in situ* formed hemiacetal (Scheme 30).[49] The initial step of the reaction is believed to be the deprotonation of the phenolic hydroxyl group of **140**. Cyclization delivers lactolate **141**. The use of Tol-Binap as chiral ligand results in an enantioselective β-carbon elimination. Protodemetalation of the alkylrhodium species **142** gives dihydrocoumarine **143** in good to excellent enantiomeric excess. Arylated dihydrocoumarines **144** were obtained with similar substrates by performing the reaction with a palladium catalyst.[50]

Murakami reported a nickel(0)-catalyzed process using cyclobutanones **145** and internal alkynes. In this reaction, the cyclobutanone serves as a four-carbon atom component in a formal [4 + 2]-cycloaddition providing cyclohexenones **146** (Scheme 31).[51] In 2012, Aissa has extended this reaction to 3-azetidinones **147** and 3-oxetanones **149**, leading to the corresponding heterocycles **148** and **150** in high yields.[52] Like for many other nickel(0)-catalyzed reactions between alkynes and

Scheme 29 Cyclobutanolate formation induced through carborhodation of appended alkynes.

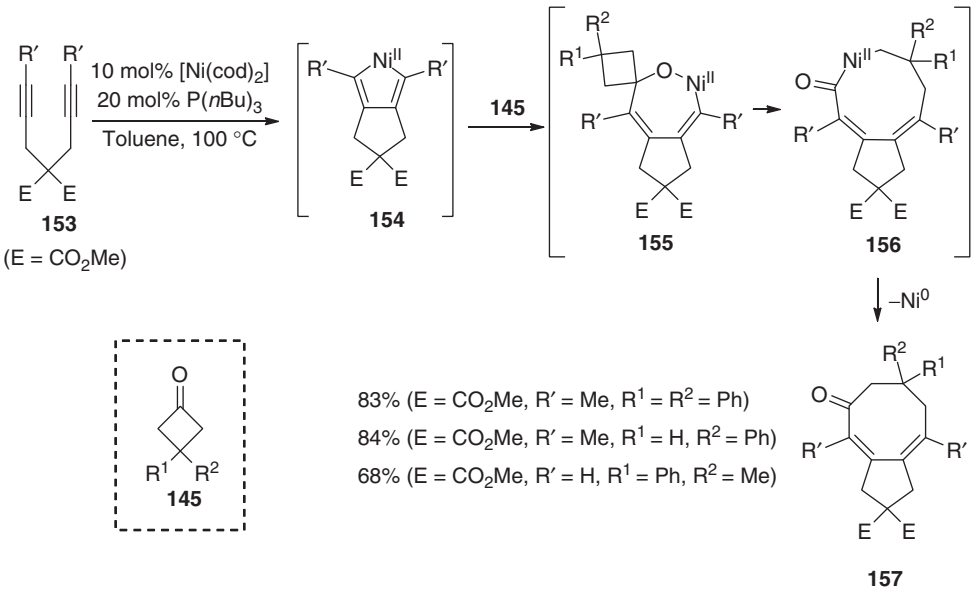


Scheme 30 Deprotonation of lactols promotes enantioselective β-carbon elimination.

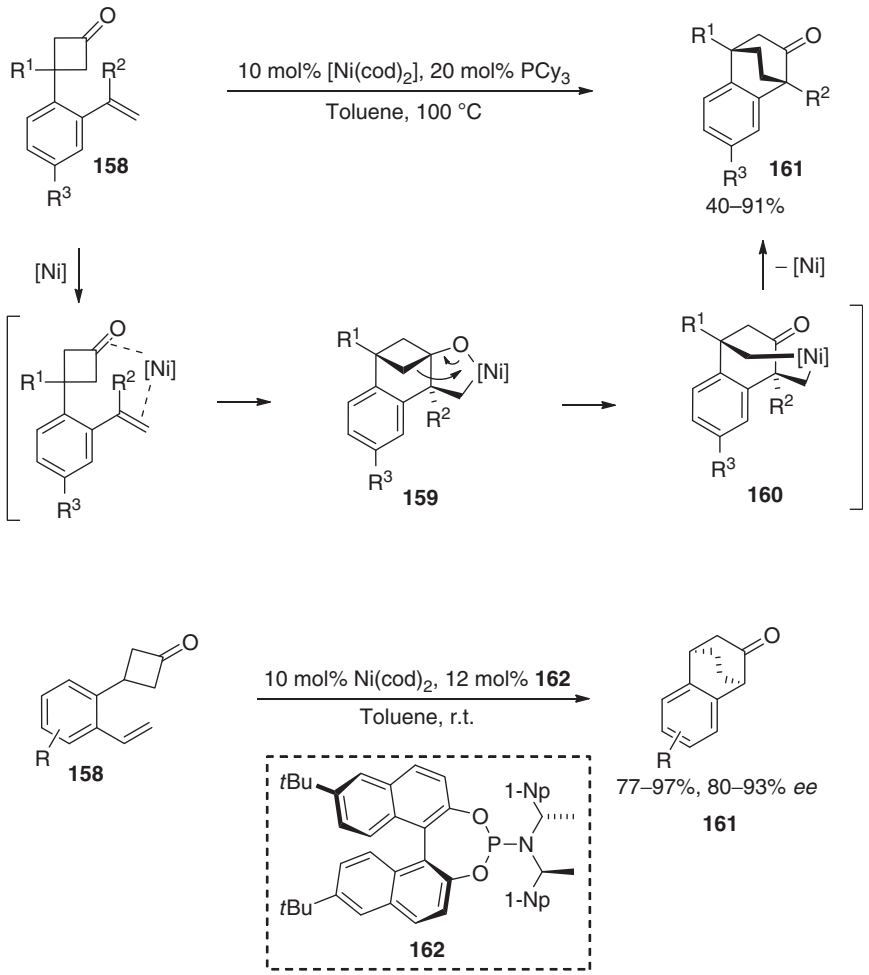
carbonyl moieties, oxidative cyclization to form an oxanickelacyclopentene is the central part of the mechanism. A similar intermediate is proposed for the reaction with the strained four-membered ring ketone. Hence, the proposed catalytic cycle is initiated by a simultaneous coordination of the carbonyl group and the alkyne to the Ni(0)-catalyst resulting in a cyclization, which leads to the crucial spiro-oxanickelacycle **151**. The nickel cyclobutanolate collapses subsequently by β-carbon elimination, cleaving the four-membered ring and forming the seven-membered nickelacycle **152**. Reductive elimination forms the observed six-membered rings in moderate to excellent yields and expels the Ni(0)-complex to close the catalytic cycle.

This principal reaction concept was extended to a formal [4 + 2 + 2]-cycloaddition leading to cyclooctadienones **157** (Scheme 32).[53] Tethered diynes **153** provided, on reaction with the nickel(0) catalyst, a nickelacyclopentadiene **154** which reacts in a similar manner with the strained cyclobutanone, now leading to spirocycle **155**. Once again, the *tert*-cyclobutanolate collapses via β-carbon elimination to give **156**, which on reductive elimination yields cyclooctadienones **157**.

Although the nickel-catalyzed reactions do not proceed with olefins instead of alkynes in an intermolecular fashion, a corresponding intramolecular version can accommodate the less reactive olefins as coupling partners (Scheme 33).[54] As before, oxidative cyclization of **158** forms oxanickelacyclopentane intermediate **159**, which undergoes β-carbon elimination to

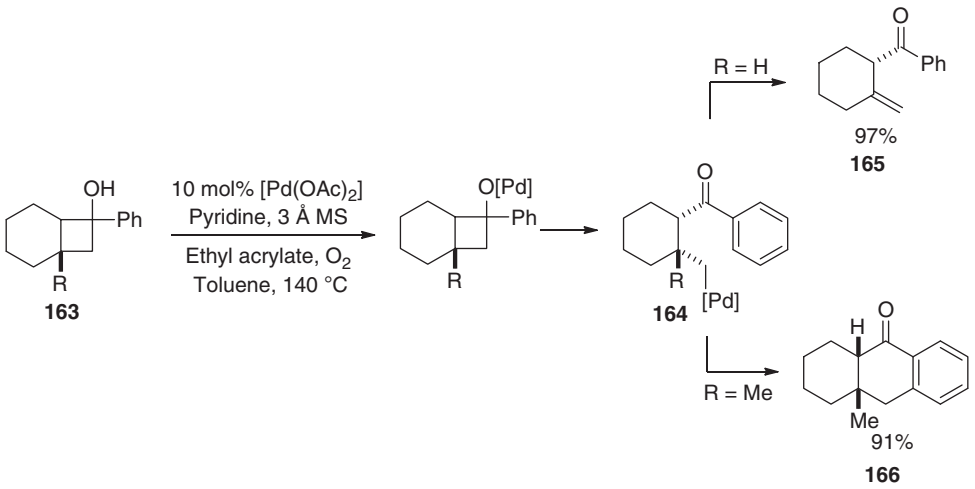


Scheme 31 Nickel-catalyzed [4 + 2]-cycloaddition of strained four-membered ketones and alkynes.

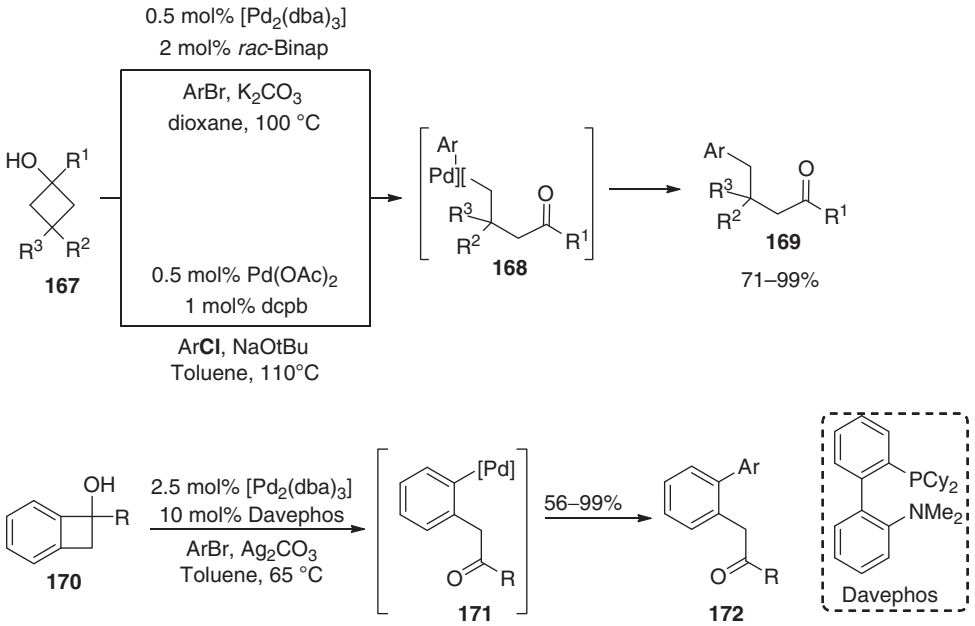


nickelacycles **160**. Reductive elimination closes the catalytic cycle and gives benzobicyclo[2.2.2]octenones **161**. In 2012, an enantioselective version of this reaction has been reported.[55] With the Binol-derived phosphoramidite ligand **162**, high enantioselectivities ranging from 80 to 93% *ee* are obtained for styrene substrates **158**.

The second method to obtain transition-metal cyclobutoxides as precursors for the *β*-carbon elimination process is the direct deprotonation of a preformed cyclobutanol derivative. Although this method requires more elaborated tertiary alcohols as starting materials, its independence from tethered 'enabling' functionalities such as alcohols, alkynes and olefins offsets this shortcoming. Uemura demonstrated in 1999 the viability of this approach. Under oxidative conditions, cyclobutanol **163** was cleaved in the presence of a palladium(II) catalyst to intermediate **164** (Scheme 34).[56] Depending on the substitution R, different pathways are operative. If a *β*-hydrogen atom is present (R = H), *β*-hydride elimination is preferred, resulting in the formation of the *β*,*γ*-unsaturated ketone **165**. If no *β*-hydrogen atom is available (R = Me), a cyclization by a direct arylation of the phenyl group leads to the tricyclic ketone **166**. Reoxidation of the formed palladium(0) species occurs under oxygen atmosphere.

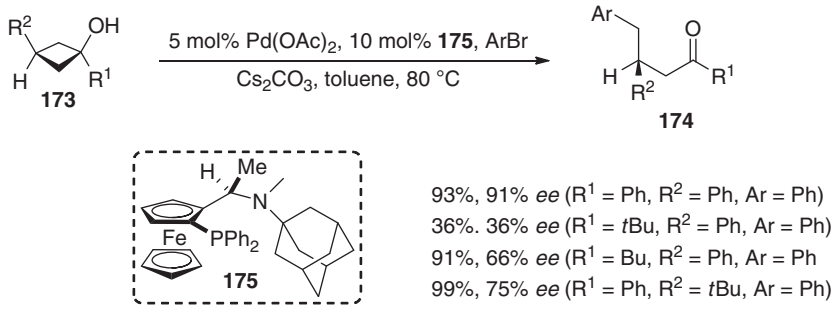


The same group demonstrated that the formed alkylpalladium intermediate can be coupled to aryl halides (Scheme 35).[57] In this scenario, reoxidation of the Pd(0)-species proceeds by an oxidative addition of an aryl bromide or iodide leading to an aryl palladium(II) species. This complex is competent to induce ring-cleavage of **167** and forms the aryl alkylpalladium intermediate **168**. Reductive elimination forms *γ*-arylated ketones **169**. The scope of this process was recently extended by Martin, now allowing an efficient use of aryl chlorides as well as 3,3-unsubstituted cyclobutanols as substrates.[58] Orellana further showed that benzocyclobutanols **170** are selectively cleaved to form the more stable C(sp^2)-Pd bond (**171**) providing ketone **172**.[59]

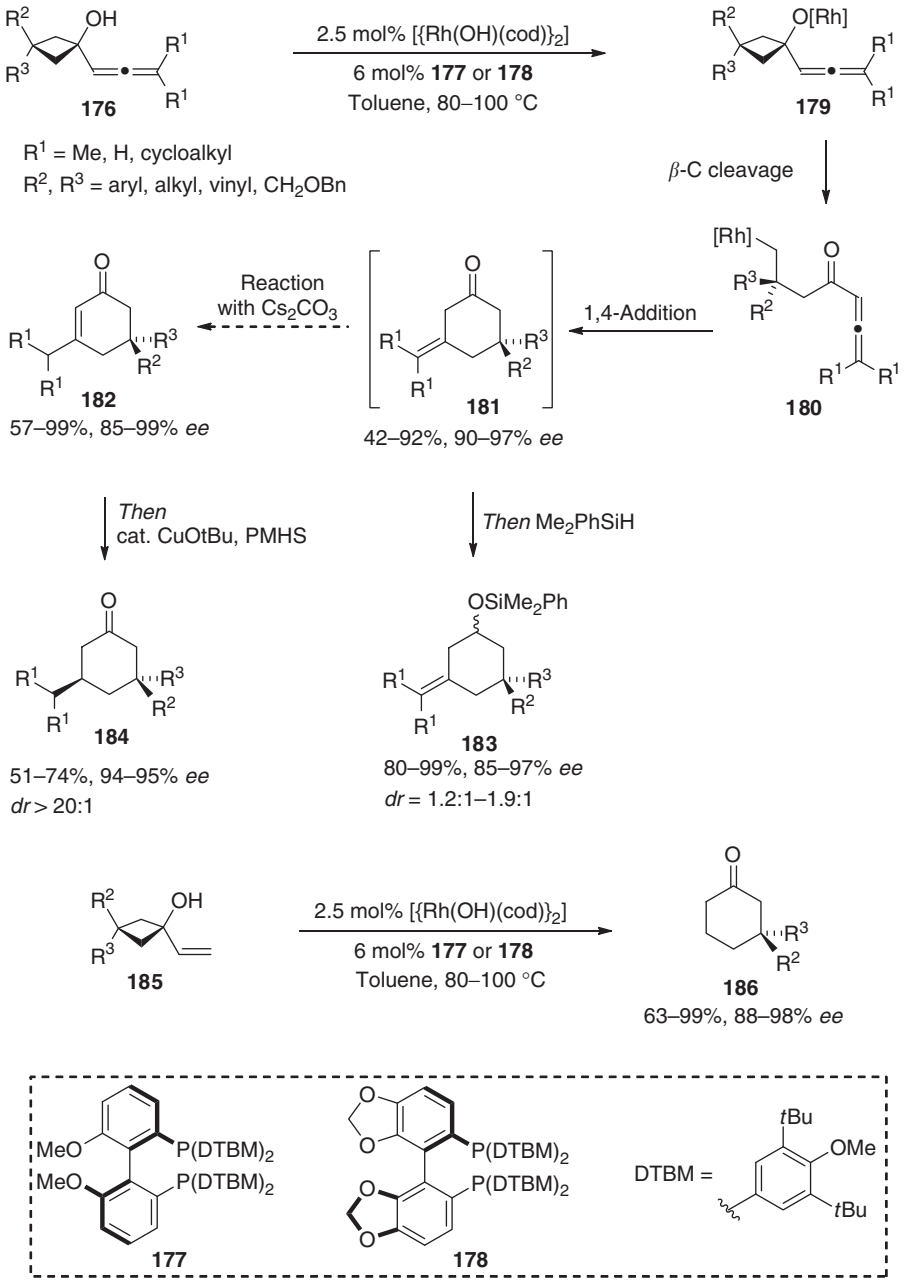


Scheme 32 [4 + 2 + 2]-cycloaddition of cyclobutanones and diynes.

Scheme 33 Intramolecular cyclization/rearrangements with olefins. 1-Np, 1-naphthyl.



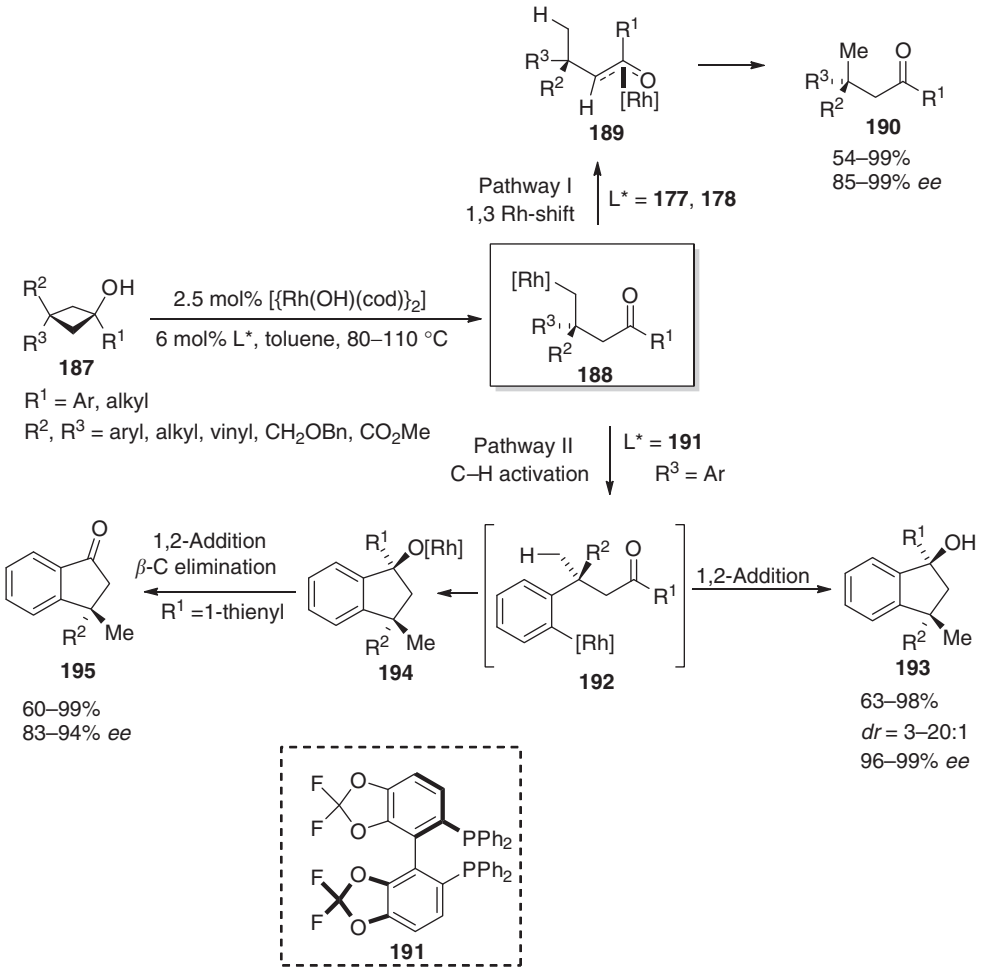
Scheme 34 Uemura's pioneering Pd(II)-catalyzed ring-cleavage of *tert*-cyclobutanols.



Scheme 35 β-Carbon elimination and trapping of the intermediate by subsequent arylation.

Uemura and coworkers developed an enantioselective version of this process.[60] With the engineered bulky bidentate *P,N*-ferrocenyl ligand **175**, γ-arylated ketones **174** with a tertiary stereogenic center were obtained in excellent enantioselectivities of up to 95% *ee* (Scheme 36). However, 3,3-disubstituted cyclobutanol substrates reacted less selectively, and the selectivity was dependent as well on the substitution pattern.

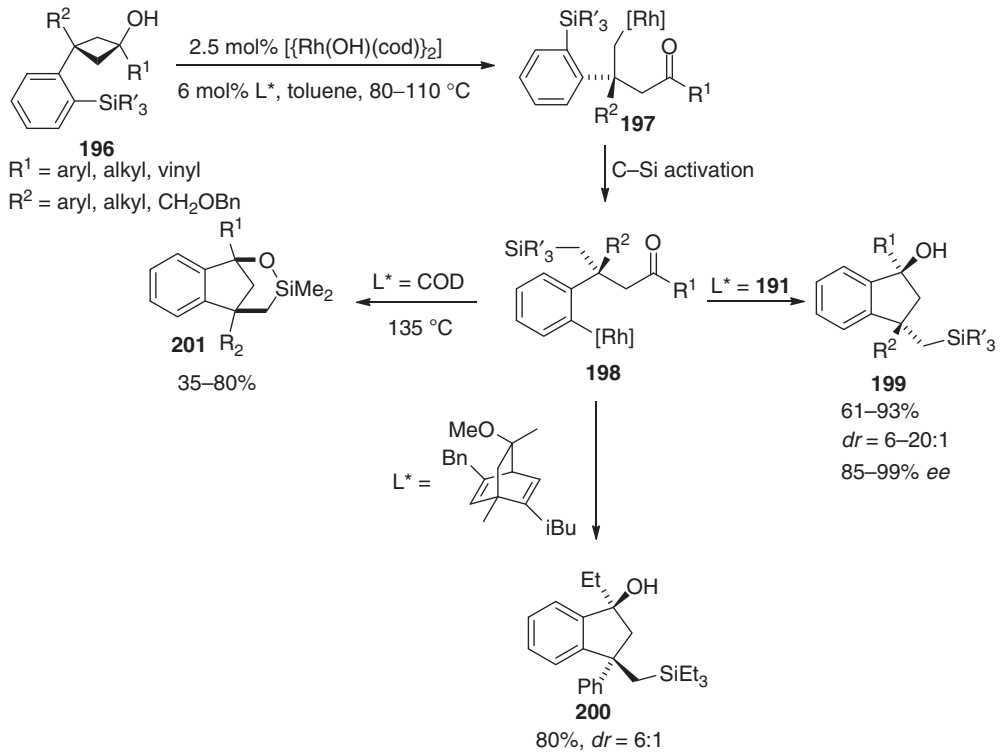
Rhodium(I) catalysts are also well suited to initiate β-carbon cleavages from metal cyclobutanolates, showing a complementary reaction profile of the arising alkyl-metal intermediate. In 2008, Cramer reported a highly enantioselective rearrangement of allenyl cyclobutanols **176** (Scheme 37).[61] Once the rhodium alkoxide **179** is formed, an enantioselective β-carbon cleavage is triggered, leading to an alkylrhodium intermediate **180** bearing an all-carbon quaternary stereogenic center. Chiral bulky biphosphine ligands such as di(3,5-di-*tert*-butyl-4-methoxyphenyl (DTBM)-MeOBiphep (**177**) or DTBM-Segphos (**178**) allow for excellent enantioselectivities. Subsequent cyclization of **180** by 1,4-addition across the now activated allenyl ketone moiety provides access to cyclohexanones **181** with an exocyclic double.[62] Without auxiliary bases in the reaction mixture and careful work-up, these products can be isolated. In the presence of cesium carbonate, double bond isomerization occurs, leading to enones **182**. As the addition across the allene moiety is faster than β-hydride elimination, cyclobutanols that are only monosubstituted at the 3-position can be used as well. One-pot and cascade pathways were developed, enabling an access to different products. For instance, *in situ*



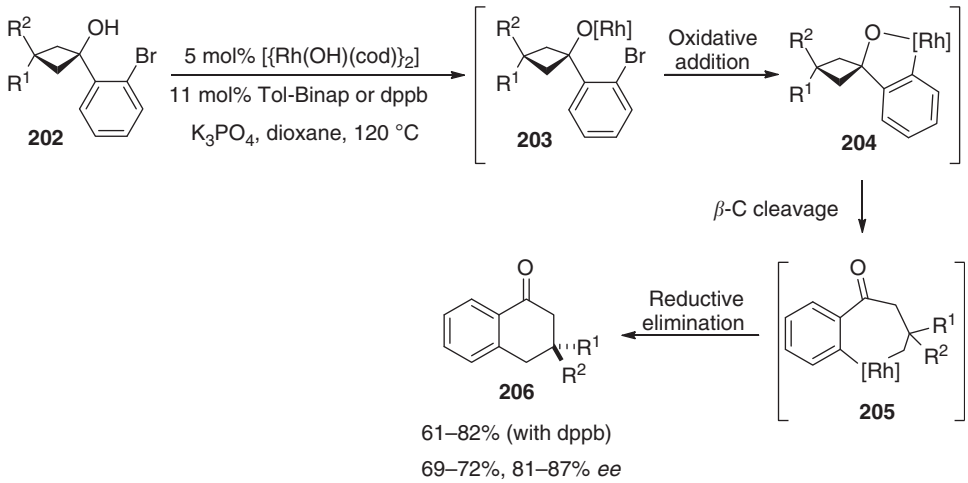
Scheme 36 Enantioselective version of the Pd-catalyzed β-carbon elimination/arylation.

Scheme 37 Reactions of alkylrhodium species formed by β-carbon elimination of *tert*-cyclobutanols.

hydrosilylation providing a protected secondary alcohol **183**, occurs with a silane in the presence of the rhodium catalyst. 1,4-Reduction can be selectively induced with an added copper(I) catalyst and a silane leading to saturated ketone **184**. Vinyl *tert*-cyclobutanols **185**, forming intermediary vinyl ketones cyclize as well, giving rise to cyclohexanones **186**.



The β-carbon cleavage does not require vinyl or allenyl groups in proximity to proceed. Aryl- or alkyl-substituted cyclobutanols (**187**) rearrange to alkylrhodium intermediates seeking downstream stabilization by other pathways. Apparent protodemetalation of intermediate **188** afford acyclic ketones **190** (Scheme 38, pathway I).[63] However, Cramer showed with labeling experiments that the formation of **190** proceeds by a 1,3-Rh-shift, forming oxa-π-allylrhodium species before protonation. Cramer and Murakami independently found that β-aryl substituted substrates undergo a formal 1,4-rhodium shift, which is supposed to proceed via a C–H bond activation/reductive elimination pathway of hydride (pathway II).[64] An intramolecular addition of the arising aryl rhodium species **192** across the formed carbonyl group yields heavily substituted indanols **193** in a highly enantio- and diastereoselective manner using difluorphos **191** as steering ligand. Remarkably, electron-rich aromatic substituents R^1, e.g., a 1-thienyl group, induced another β-carbon elimination from the rhodium indanolates **194** providing finally indanones **195**.[65]

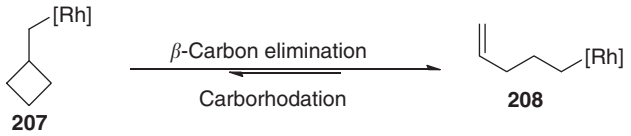


Scheme 38 Ring-cleavage followed by pathways induced by C–H activations.

The transposition of the aromatic hydrogen atom limits the reachable product portfolio strictly to methyl-substituted quaternary stereogenic centers. Addressing this shortcoming, Cramer showed further that functionalizable silyl groups (**196**–**198**) can be used alternatively. Oxidative cleavage followed by reductive elimination leads to silyl-substituted products **199** (Scheme 39).[66] In general, silyl groups with two methyl substituents ensure complete C–Si over C–H activation. For bulkier silyl groups, rhodium catalysts bearing solely a diene as ligand provide selective C–Si activation, whereas phosphine ligands favor C–H activation. In addition, the diastereoselectivity is dependent on the nature of the ligand. Phosphines give rise to indanols **199** and diene ligands to indanols **200** with the opposite diastereoselectivity. Higher reaction temperatures induced a second C–Si activation, thus providing access to tricyclic silyl ethers **201**.

Murakami developed a Rh(I)–Rh(III) redox cycle which allows bromo aryl-substituted *tert*-cyclobutanols **202** to be converted into tetralones **206** by a β-carbon cleavage process (Scheme 40).[67] The suggested mechanism involves oxidative addition of the

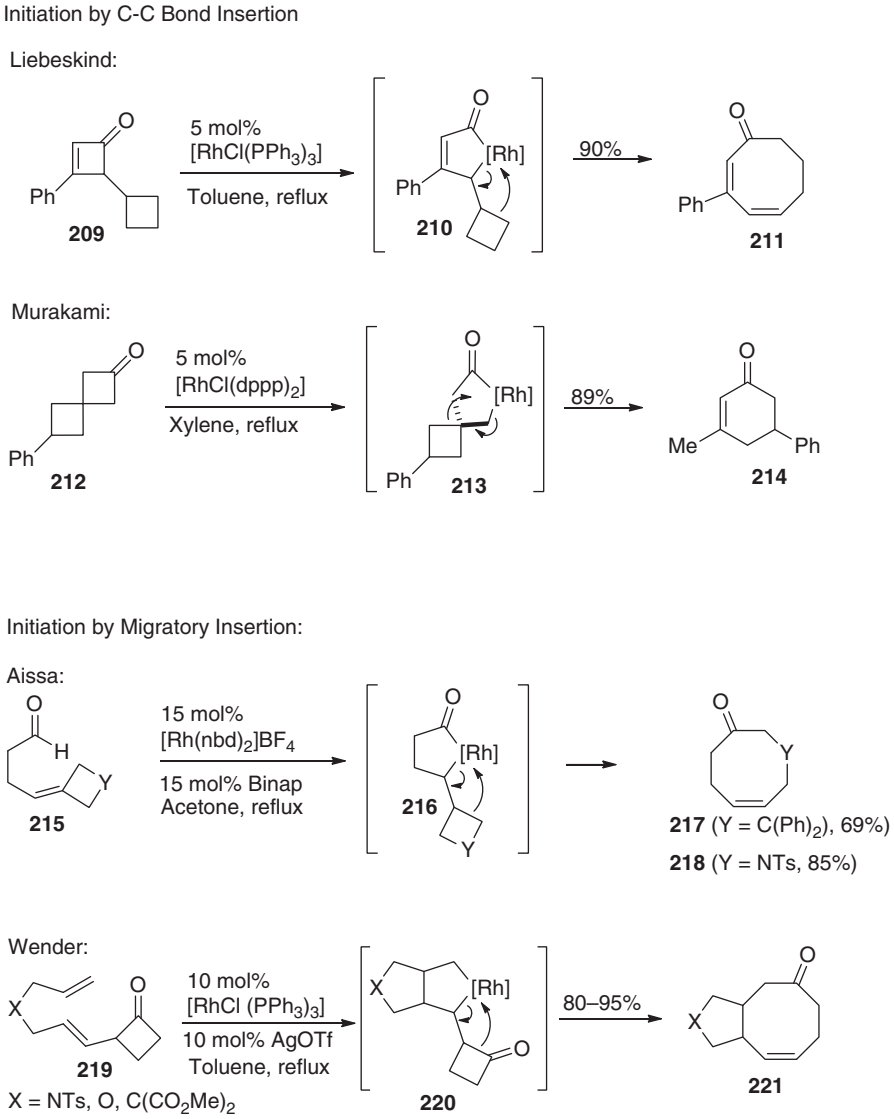
Scheme 39 Ring-cleavage, followed by C–Si activation.



Scheme 40 Cyclobutanol cleavage leading to tetralones.

rhodium alkoxide **203** to give Rh(III)-species **204**. Subsequent *β*-carbon elimination forms **205** and reductive elimination provides **206** in good yields. The process can be conducted asymmetrically and gives good selectivities with Tol-Binap as the chiral ligand.

5.23.3.2 Carbanion-Induced β-Carbon Eliminations

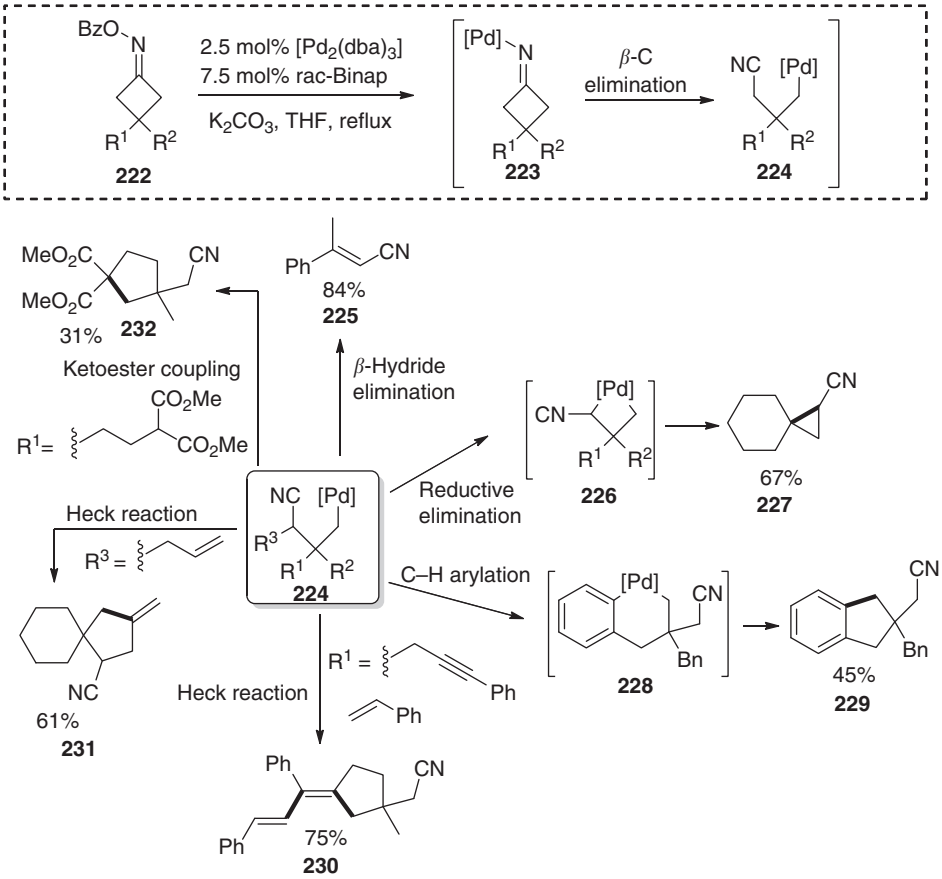


β-Carbon eliminations from cyclobutylmethyl metal species is an unconventional method to access unusual organometallic intermediates from cyclobutane derivatives. This reaction can be seen as the reversal of the carbometalation of a C–C double bond, a '*retro* 4-*exo-trig*' event (equation 4). Compared to the previous Section 5.23.2.1, where a very strong carbonyl bond was

concomitantly generated during the ring opening, the formation of an olefin provides less energy. In contrast to rearrangements of cyclopropyl metal intermediates, the homologous ring-opening reaction of cyclobutyl metal species is already less favored. Owing to the stronger carbon–rhodium bond compared to other transition metals, rhodium catalysts are the favored metal for this process, although a few other examples exist. The β-carbon elimination is nevertheless often faster than other pathways of the organometallic intermediate, namely reductive- and β-H-eliminations, so that its synthetic potential could be explored.

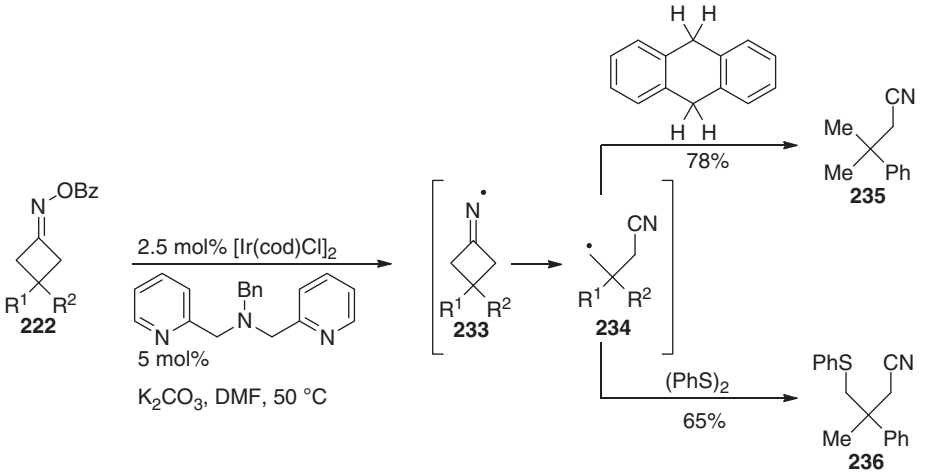
(4)

The crucial organorhodium intermediates can be accessed by several indirect methods involving either an addition across a double bond or a C–C bond activation process (**Scheme 41**). In a leading example, Liebeskind investigated the C–C insertion of rhodium(I) complexes into cyclobutenone **209** in 1993.[68] Rhodacycle **210** is formed with catalytic amounts of Wilkinson's catalyst in refluxing toluene. In turn, this intermediate undergoes β-carbon cleavage of the adjacent cyclobutane and subsequent reductive elimination provides access to cyclooctadienone **211**. Exploiting the insertion of rhodium(I) complexes into the acyl bond of strained ketones, Murakami disclosed a related reaction starting from spirocyclobutanone **212**.[69] The initial C–C bond insertion delivers the cyclobutylmethyl rhodium intermediate **213** and sets the stage for the β-carbon elimination. Final reductive



Scheme 41 β-Carbon eliminations induced by cyclobutylmethyl-metal transients.

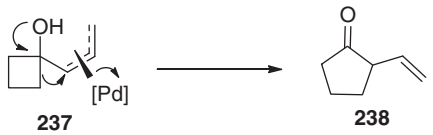
elimination gives rise to cyclohexenone **214**. A conceptually different method to obtain the direct cyclobutylmethyl metal precursor is the addition of an organorhodium species across a suitable double bond, which consists either of a vinylcyclobutane or a vinylidenecyclobutane. Following the latter approach, Aissa used an intramolecular hydroacylation of **215** to obtain **216**, which collapses under ring-strain release to cyclooctenone **217**.[70] The method is also suited for azetidine derivatives **218** in the place of a cyclobutane. Wender accessed rhodacycle **220** via cycloisomerization of dienes **219**.[71] In contrast to his work on [5 + 2]-cycloadditions with vinyl cyclopropane substrate, the ring opening of the cyclobutylmethyl intermediate is significantly more sluggish. Without the appended carbonyl group on the cyclobutane providing an additional driving force, no ring-opening proceeded. However, in some instances this carbonyl causes side reaction. CO extrusion can take place, leading to the formation of seven-membered rings as side products instead of the desired cyclooctenone **221**.



5.23.3.3 Azaanion-Induced β-Carbon Eliminations

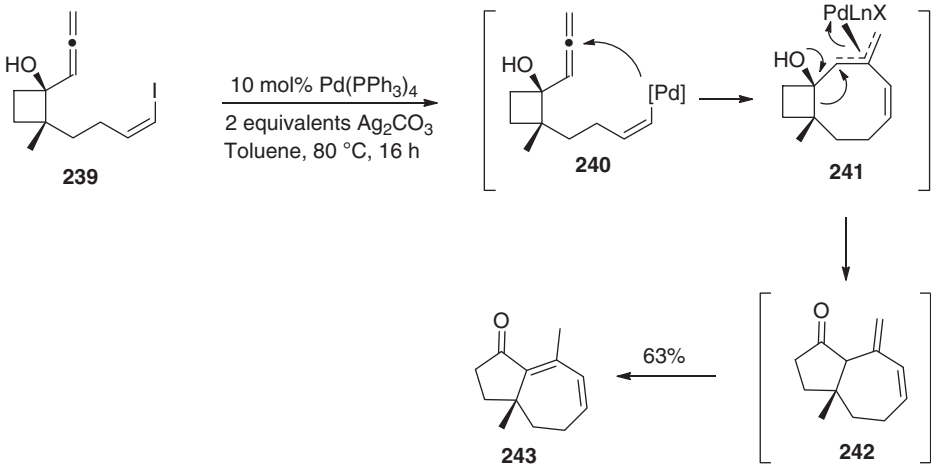
The use of metal-nitrogen intermediates to trigger rearrangements has so far received less attention. In addition to the energy released by ring opening, cleavages from C=N double bonds to form nitriles are a good driving force. For instance, Uemura reported an attractive method capitalizing on the generation of a strong CN-triple bond of a nitrile from benzoylated cyclobutanone oximes **222** using a Pd(0)-catalyst (Scheme 42).[72] This process still represents a *β*-carbon elimination (in this case a '*retro*-4-*exo*-*dig*' event). Oxidative addition of the N–O bond generates an iminopalladium(II) species **223**, which is the competent intermediate to undergo *β*-carbon cleavage giving nitriles **224**. In the absence of a suitable acceptor, *β*-hydride elimination and migration of the formed double bond into conjugation yields acrylonitriles **225** (for R^1 and/or R^2=H). In cases where the *β*-hydride elimination pathway is blocked (R^1 and $R^2 \neq H$), cyclopropanecarbonitriles **227** are obtained instead. The reaction is presumed to proceed via an activation of the acidic methylene group in *α*-position to the nitrile to give palladacyclobutane **226**; reductive elimination yields the products **227**. Alternatively, an activation of an aryl-H bond can proceed to yield benzocyclobutane **229** via palladacycle **228**. However, offering a suitable acceptor to intermediate **224** can trigger many of the common reactivities of organopalladium(II) species. For instance, Heck-type processes were obtained when an alkene or alkyne moiety is at a distance for a 5-*exo*-*trig*/5-*exo*-*dig* cyclization (**230** and **231**). Similarly, appended malonates react as C-nucleophiles forming cyclopentane derivatives **232**, though in rather modest yields.

Scheme 42 *β*-Carbon elimination from iminyl Pd(II)-complexes and their reaction manifold.



A related ring-cleavage reactivity has been reported by the same authors using iridium complexes (Scheme 43);[73] reduced products **235** are obtained. However, the reaction does not proceed via anionic metal intermediates but is believed to proceed through radical pathways involving species such as **233** and **234**. This conclusion is based on trapping reactions which gave products **236** with diphenyldisulfide in good yields, and enhanced yields of **235** in the presence of a hydrogen donor.

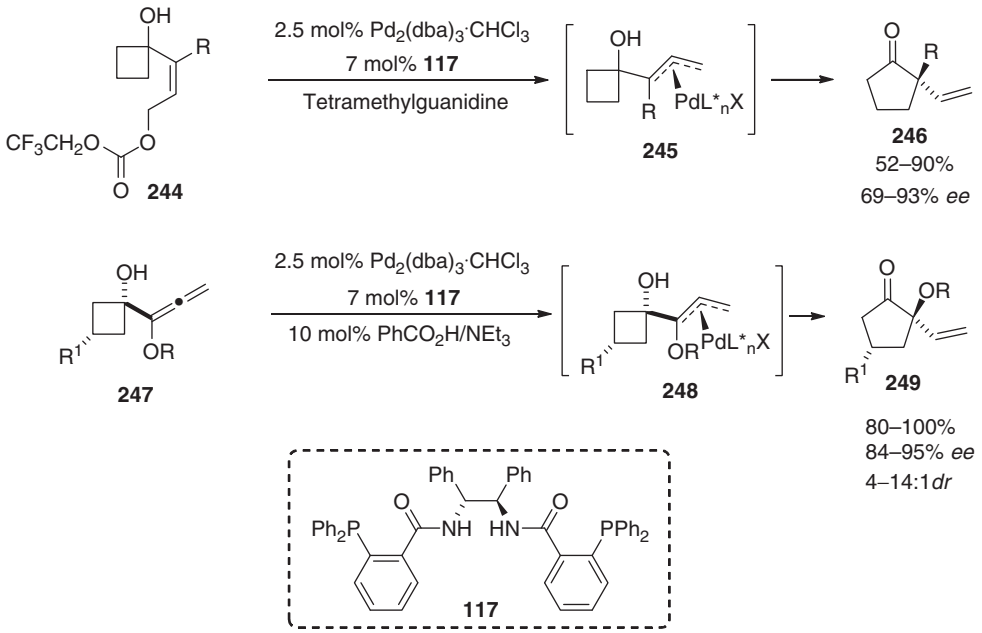
Scheme 43 Iridium-catalyzed ring-cleavage proceeding by radical pathways.



5.23.3.4 Allylmetal-Induced Rearrangements of Cyclobutanols

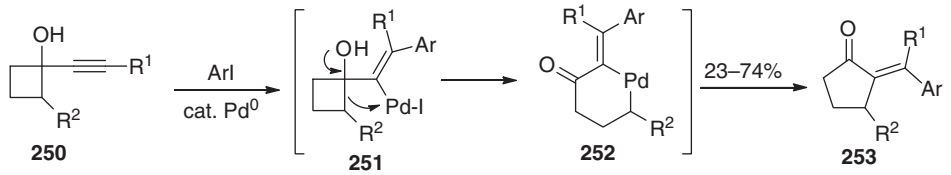
tert-Cyclobutanols can be triggered to ring expand by activating adjacent C–C double or triple bonds by a range of transition-metal complexes. Very often, this reactivity can be achieved by the generation of an allylmetal intermediate in α-position to the hydroxyl group, typically involving palladium catalysts (equation 5). Formally, the ring-expansion of **237** can be seen as Wagner–Meerwein type of reactivity, which can be modulated by the metal and its surrounding ligand sphere and delivers cyclopentanone derivatives **238**.

(5)



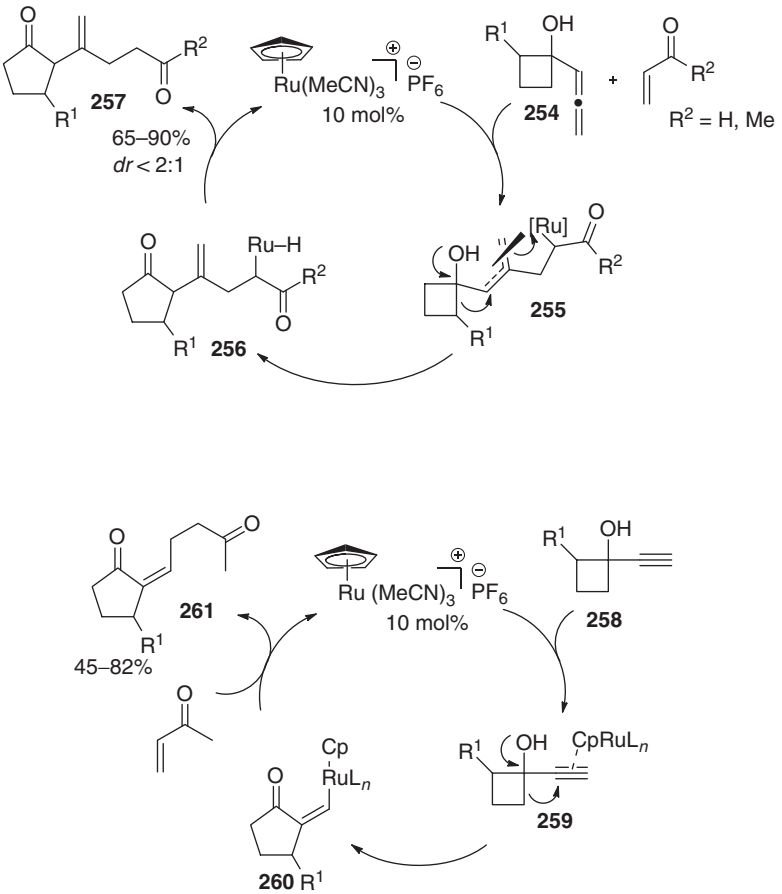
Nemoto proved the viability of this approach using allenyl cyclobutanol **239** as substrate (Scheme 44).[74] An intramolecular carbopalladation initiated via vinylpalladium species **240** from the appended *Z*-vinyl iodide moiety across the allene functionality generates the π-allyl palladium intermediate **241**. This 4,8-bicyclic system primarily formed rearranges to the 5,7-ring system **242**.

Scheme 44 Ring enlargements induced by carbo-palladations of allenyl cyclobutanols.



Under the reaction conditions, the *exo*-methylene group is not stable and migrates into conjugation to give the more stable enone **243** as the final product. The scope of the reaction was subsequently extended to an intermolecular version with aryl halides.[75] Based on these findings, related transformations were reported in which the key π-allyl palladium species was generated by a carbopalladation of conjugated dienes[76] or alternatively from propargylic carbonates.[77]

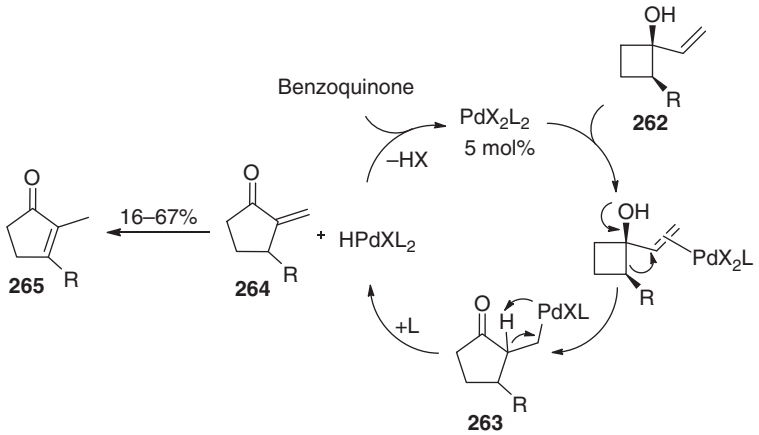
Trost developed an asymmetric version of this kind of ring expansions (Scheme 45). In the initial approach, the requisite π-allyl palladium intermediate **245** was generated from allyl carbonate precursors such as **244**.[43] Good to excellent levels of enantioselectivity were achieved with the Trost ligand **117**. Later, the process could be extended to cyclobutanol substrates **247** bearing an electron-rich alkoxy allene group. Hydropalladation leads to the formation of the allyl palladium species **248** and triggers the enantioselective ring enlargement to give access to a wide range of α-alkoxy cyclopentanones **249** in high diastereo- and enantioselectivity.[78]



Scheme 45 Palladium-catalyzed enantioselective ring enlargements of cyclobutanols.

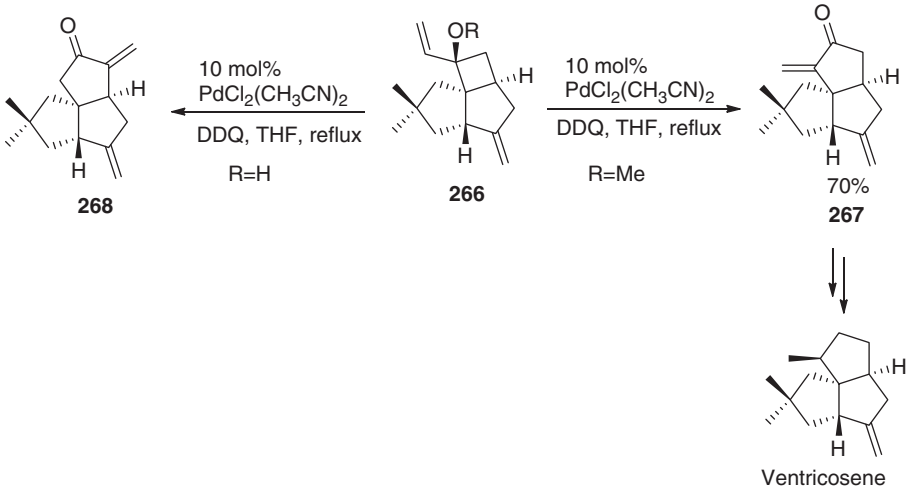
Larock reported a related, but mechanistically distinct process for the synthesis of 2-alkylidenecyclopentanones **253** from alkynyl-substituted cyclobutanols **250** (Scheme 46).[79] The authors suggest that the process is initiated by a regioselective carbopalladation of the internal alkyne moiety of the cyclobutanol **250**, giving rise to the vinyl-Pd(II) intermediate **251**. In turn, this vinyl metal species ring expands to give the six-membered palladacycle **252**. Finally, reductive elimination forms cyclopentenones **253** in fair to good yields.

Scheme 46 Cyclobutanol ring-expansion initiated by carbopalladation of internal alkynes.



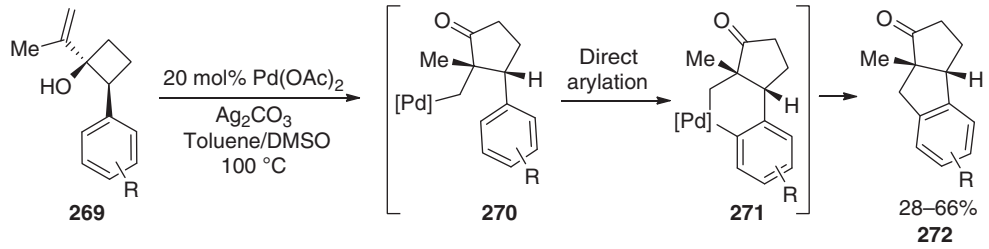
Besides palladium-catalyzed rearrangements via π-allyl intermediates, Ihara showed that ruthenium complexes are competent catalyst for this task (Scheme 47).[80] The required π-allyl intermediate is obtained by an intermolecular reaction of an α,β-unsaturated carbonyl compound (acrolein or methyl vinyl ketone, MVK) and allenylcyclobutanols **254**. It is assumed that an allyl ruthenacyclopentane **255** is formed with the ruthenium(II) complex $[CpRu(CH_3CN)_3]PF_6$. Subsequently, ring-expansion followed by reductive elimination leads to **256** which evolves into cyclopentanones **257** in good yields. Later, the same authors demonstrated as well the feasibility of this transformation with alkynyl-cyclobutanol substrates **258** as the strained ring component.[81] Contrasting the allene substrate **254**, they suggest a π-coordination of the ruthenium catalyst (**259**) promoting the rearrangement to the vinyl ruthenium species **260**. A 1,4-addition to MVK closes the catalytic cycle and gives product **261**.

Scheme 47 Ruthenium(II)-catalyzed intermolecular coupling/rearrangement reactions.



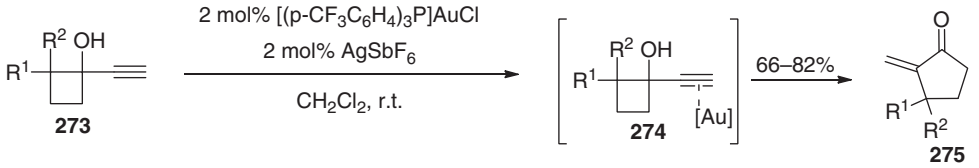
5.23.4 π-Coordinated Metal-Promoted Rearrangements of Cyclobutanes

In a seminal publication, Clark reported in 1985 that Pd(II) salts are active catalysts able to rearrange vinyl cyclobutanols **262** into cyclopentenones **265** (Scheme 48).[82] From a mechanistic perspective, coordination of the Pd(II) to the olefin promotes a Friedel–Crafts type reactivity, leading to cyclopentanone **263** bearing an alkylpalladium group. In turn, *β*-hydride elimination generates cyclopentenone **264**. Under the reaction condition, internalization of the olefin takes place to give **265**. Benzoquinone is often used as stoichiometric oxidant, which is required to reoxidize palladium(0) back to palladium(II) to close the catalytic cycle.



Scheme 48 Palladium(II)-salts promoted rearrangements of vinyl cyclobutanols.

Since the original publication, related methods were reported[83] and the reaction was sporadically employed in the context of natural product synthesis.[84] For example, Toste converted **266** into **267** for a total synthesis of ventricosene (Scheme 49). For the substrate with a free hydroxyl group, migration of the less substituted bond giving the undesired isomer **268** was observed. Protection of the hydroxyl group as its methyl ether induced a selective migration of the more highly substituted C–C bond, producing the required intermediate **267** for the completion of the synthesis of ventricosene.



Scheme 49 Synthesis of ventricosene using a Pd(II)-catalyzed ring-expansion.

When substrates bearing 1,1-disubstituted olefins are used, the commonly observed *β*-hydride elimination of the alkylpalladium intermediate is blocked. This feature was recently explored by Orellana, who coupled the ring-expansion process to a downstream direct arylation reaction with a tethered aryl substituent (Scheme 50). This strategy provides access to *cis*-benzoquinanes **272** in moderate yields.[85] Starting with substrates **269**, coordination-promoted rearrangement gives rise to intermediate **270**, which undergoes (in the absence of a more favorable pathway) an activation of the aromatic C–H group leading to palladacycle **271**. Reductive elimination closes the second five-membered ring and gives the benzoquinanes **272**.

Scheme 50 A domino ring-expansion/direct arylation sequence.

Besides the activation of olefin-bearing cyclobutanols, the corresponding reactivity of alkynyl-substituted cyclobutanols was investigated as well. For instance, Toste exploited the strong propensity of gold complexes to act as carbophilic Lewis acids capable of activating carbon–carbon triple bonds, in conjunction with cyclobutanols **273** (Scheme 51). By coordination of an *in situ*

Scheme 51 Gold-catalyzed ring-expansion of alkynyl-cyclobutanols.

formed cationic gold(I) catalyst to the alkyne moiety of the substrate (**274**), the ring rearrangement is triggered forming cyclopentenones **275** in good yields.[38]

Glossary

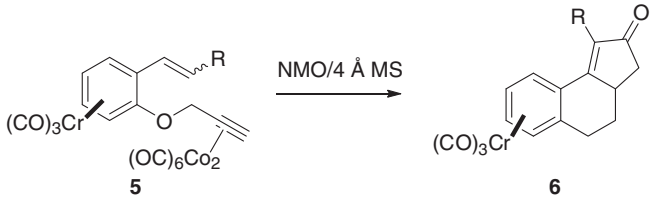
Desymmetrization reaction Reaction creating stereogenic center(s) by chiral catalysts from symmetric achiral substrates, such as *meso*-compounds.
Diversity-oriented synthesis A strategy for quick access to molecule libraries with an emphasis on skeletal diversity.
Promoter An additive, which expedites a reaction by activation of either the catalysts or the reagents.
Reagent-controlled reactions A reaction, the stereoselectivity of which is controlled by chiral catalysts or reagents.
Substrate-controlled reaction A reaction, the stereoselectivity of which is controlled by preexisting stereogenic center(s) in the substrates, not by the catalyst or the reagent; usually achiral catalysts or reagents are employed.
Tandem reaction A consecutive series of reactions completed in one batch. It can be affected by either employing more than one catalyst or reagent, where the product of one reaction is the substrate for another reaction, or by employing a single catalyst.

5.24.1 Introduction to the Pauson–Khand Reaction

Five-membered rings are found as a key portion of the skeleton in many biologically interesting natural products. Of the numerous methods for the preparation of this building block, the transition metal-mediated [2 + 2 + 1] carbocyclization of three components, an alkyne, an olefin, and carbon monoxide (CO), is uniquely straightforward and efficient. This reaction was first discovered and reported during the early 1970s by Pauson and Khand as an unexpected result of their study on the reaction of various (alkyne)hexacarbonyldicobalt compounds with strained olefins (Scheme 1). Shortly thereafter, it was named after its discoverers and so became known as the Pauson–Khand reaction (hereafter, PKR or PK-type reaction).[1]

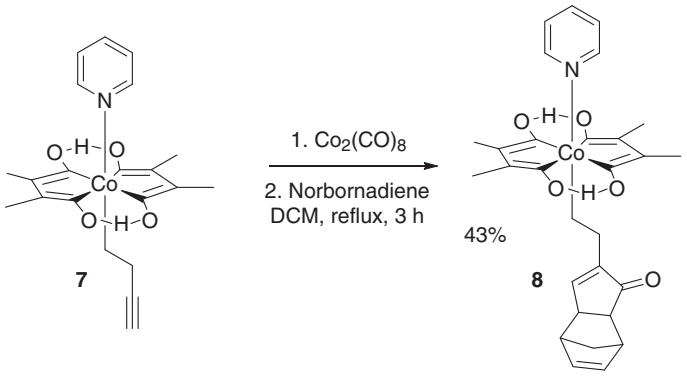
Scheme 1

Since then, it has attracted a great deal of interest from the synthetic community over the past four decades, because of its distinctive virtues, providing a straightforward synthetic strategy for various natural products, operational simplicity, and compatibility with a wide range of functional groups. In addition, many variations using metals other than cobalt, improvements of the reaction efficiency by promoters, and the development of catalytic versions with a stereoselectivity issue have appeared in the literature. These subsequent developments are complementary to each other, make the transformation better and expand the application scope. Naturally, one can find a number of review articles and easily refer to them for more ideas and details about the reaction.[2]



The purpose of this chapter is to update and highlight the recent advances regarding this reaction with critical comments, instead of duplicating the previous review articles.

Despite the fact that the reaction is conceptually straightforward and operationally simple, the original protocol exhibited some distinct limitations together with several virtues. We start our discussion by summarizing the scope and limitations of the original version, with respect to the substrate scope, regiochemistry, and stereochemistry. Then, a discussion of the possible solutions to nearly all of the issues raised regarding the original protocol will be given.



5.24.1.1 Substrate Scope

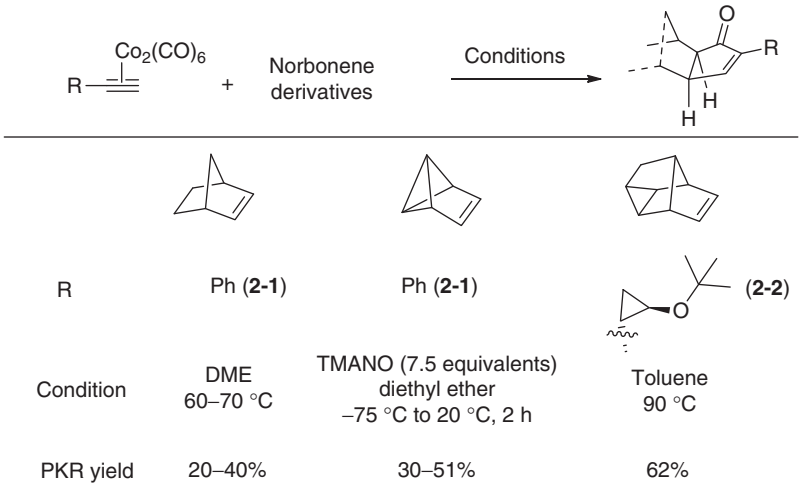
This reaction tolerated many functional groups, such as ethers, alcohols, carbonyls, acetals, esters, amides, tertiary amines, and even halides as previously summarized.[1b] It is worth mentioning here that even organometallics, including alkynyl allylamino

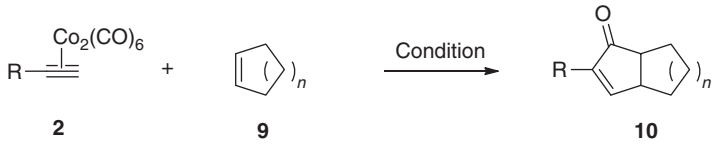
chromium and/or tungsten Fisher–carbene complexes,[3a] arene–chromium carbonyl complexes **5**,[3b] ferrocene,[3c] and cobalt complexes **7**[3d] are compatible with this reaction. A couple of examples are illustrated in equation 1.

85% (Based on the consumed substrate)

(1)

However, the efficiency of the reaction depends on the nature of the substrates. For example, electron-deficient olefins and/or alkynes were not adequate under the original thermal protocol. Also, it is well known that, from the inception, only strained olefins like norbornene provided reasonable chemical yields in the intermolecular PKR (**Figure 1**).[1,4]





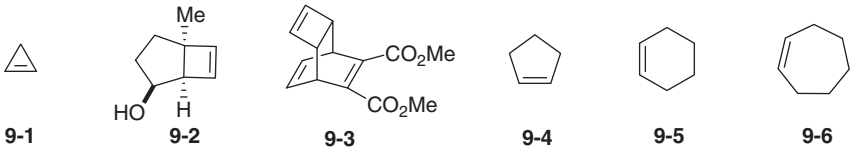


Figure 1 Intermolecular PKR of the strained olefins.

A theoretical study by Milet and coworkers[5] showed that there is a correlation between the reactivity of olefins with a given hexacarbonyldicobalt alkyne complex and the lowest unoccupied molecular orbital (LUMO) of the olefin substrate. They carried out charge decomposition analysis (CDA) calculations and found an excellent correlation between the level of back donation of electrons from the d-orbital of the cobalt atom and the barrier to cobaltacycle formation, which is thought to be the rate-determining step. The back-donation of electrons from the metal to the olefin is facilitated as the LUMO level of the olefin is lowered.[6]

The study also notes that the energy of the LUMO is lowered as the C=C–C angle of the alkene becomes smaller.[7] Based on this argument, the higher reactivities observed with smaller cycloalkenes (cyclopropene to cyclopentene),[5,8,9] than those with larger rings (cyclohexene and cycloheptene),[10] is readily explained (**Figure 2**). For a reasonable reaction with a less reactive cycloalkene, a special promoter is required (see Section 5.24.2.2).

	Catalytic	–	–	>98%[10]	–	–	–

Figure 2 Intermolecular PKR of the endocyclic olefins.

In addition, it is also understandable that, although ethylene a substrate free from any strain, is notoriously unreactive, *exo*cyclic olefins are reasonably reactive (Figure 3).

Figure 3 Intermolecular PKR of the exocyclic olefins.

5.24.1.2 Stereoselectivity

The relative stereoselectivity is high in this intermolecular reaction (Scheme 1).[1] Norbornene or norbornadiene (**3**) reacted with the alkyne–cobalt complex (**2**) to give the *exo* product only. More details about the stereoselectivity for the intramolecular reaction, including the control of the absolute stereochemistry, will be discussed in Section 5.24.4.2.

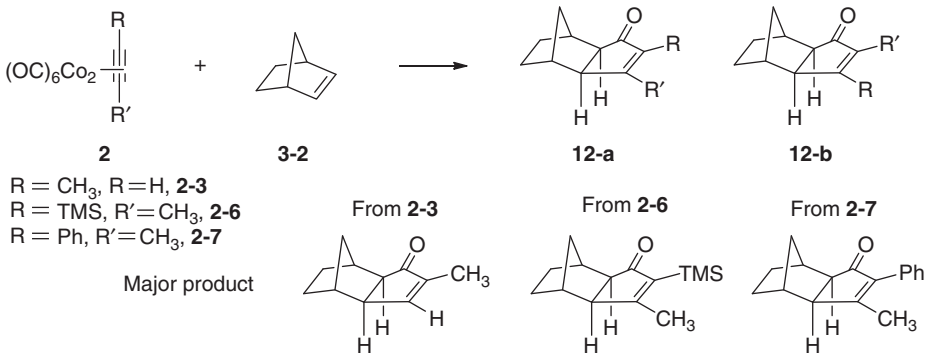
5.24.1.3 Regioselectivity

The regioselectivity in the PKR is one of the more complicated issues, if the intermolecular reaction is considered.[1b,c] The outcome depends on two factors, the substitution pattern and the electronic nature of the alkynes or alkenes.[11–14]

5.24.1.3.1 Regiochemistry with respect to the alkynes

In the reaction with a given alkene like norbornene (**3-2**), the regiochemical outcome is again controlled by steric and electronic factors. If an unsymmetrical alkyne such as **2** in Figure 4 bearing substituents of different size with similar electronic character is

employed, the major product would be the one having a larger substituent on the α-position with respect to the carbonyl of the product cyclopentenone (**12-a**) (Figure 4).[15]



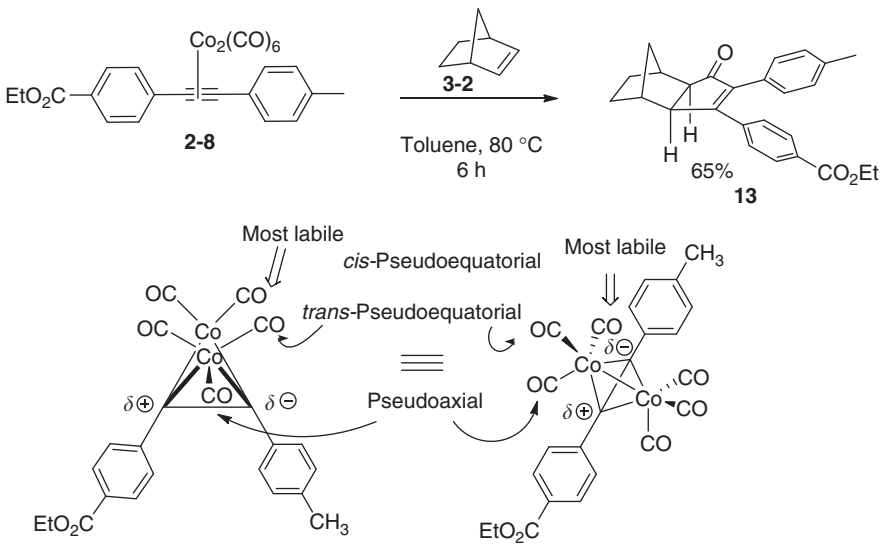


Figure 4 Regioselectivity with respect to alkyne substitution pattern.

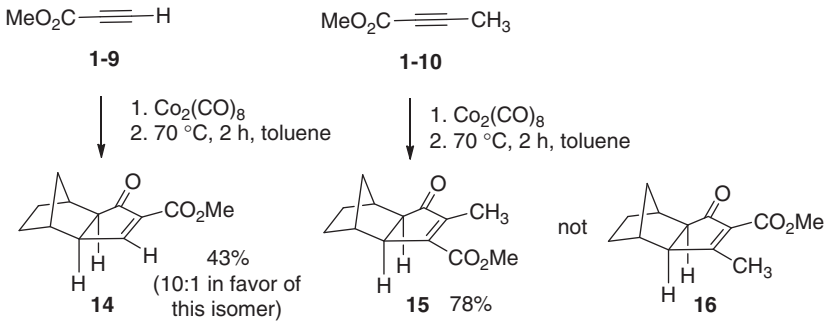
However, if the substituents at both ends of the alkyne have different electronic characters but similar size, as in **2-8**, the more electron-deficient substituent prefers to sit on the β-position of the enone in the resultant cyclopentenone **13**. This electronic bias can be accounted for by the facile loss of CO at the *cis*-pseudo equatorial position affected by the '*trans* effect,' as shown in Scheme 2.[16]

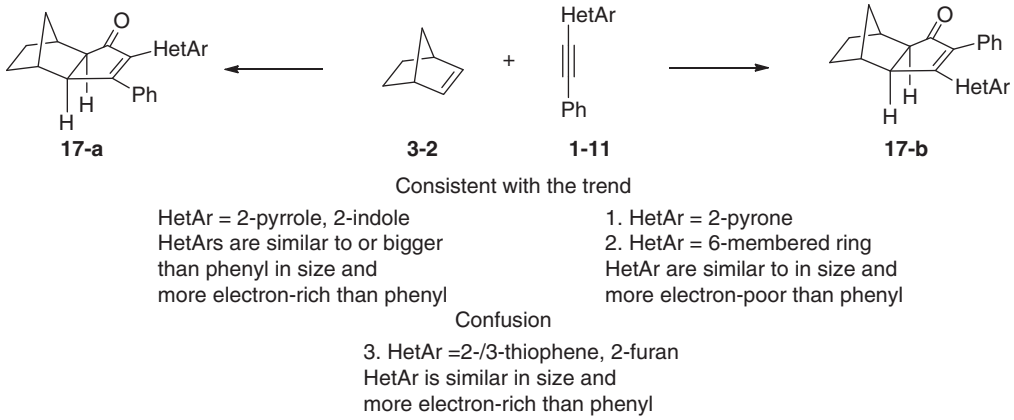
Scheme 2

When both effects enforce the same trend, the results apparently reflect the sum of each. In other words, a larger and more electron-rich substituent prefers to be at the α-position of the enone.

However, when both effects act against each other, the outcome will be more difficult to predict. A couple of examples is illustrated in Figure 5. First, when the terminal alkyne (**1-9**) was used, the carboxylate is considered to be the larger group and, thus, only the α-substituted cyclopentenone (**14**) was obtained, regardless of the electronic character of the substituent. However, if the terminal proton is replaced by a methyl group, the effect of the electronic character becomes more influential: **15** is the major product, in contrast to the cases of 1-trimethylsilyl (TMS) propyne (**1-6**) and 1-phenylpropynes (**1-7**), where the steric factor is more significant (compare Figure 5 with Figures 3 and 4).[15]

The bothersome aspect of the regiochemistry is demonstrated more clearly by the reaction between (2-phenylethynyl)heteroaromatic compounds (**1-11**) and norbornene (**3-2**) reported by Fairlamb and coworkers.[17] In most cases, the regioselectivity seemed to follow the general trend previously mentioned. When the counterpart heteroaromatic ring HetAr is similar to or bigger than the phenyl in size, the electronic character seemed to control the reaction pathway; compound **17-a** is obtained as the major product if the heteroaromatic is more electron rich than phenyl, but compound **17-b** if it is more electron poor.





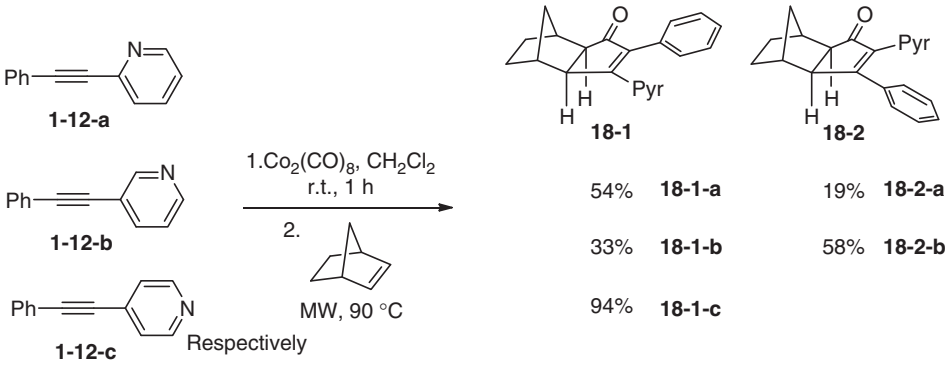


Figure 5 The competition of electronic and steric effects in determining the regiochemistry during the intermolecular PKR.

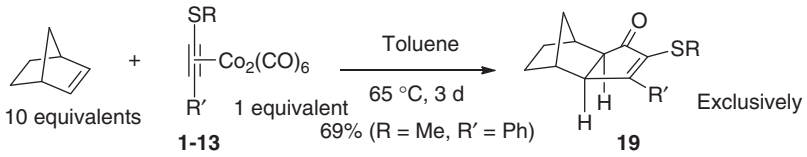
2-/3-Thiophene and 2-furan, whose sizes are similar to and which are more electron-rich than phenyl, are supposed to give **17-a** as the major product. Experimentally, however, it was found that this is not the case, and it is not easy to give a rationale for the observed results (Scheme 3).

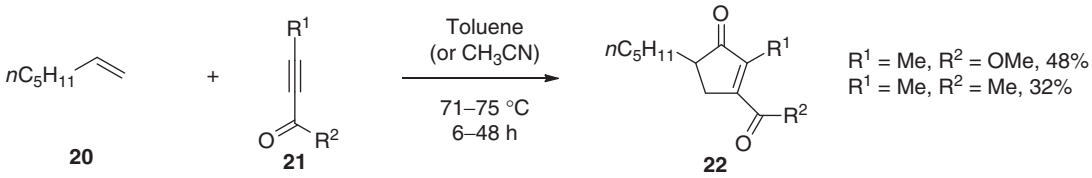


Scheme 3

Furthermore, even with a fixed heteroaromatic like pyridine in **1-12**, not only the electronic character of the heteroaromatic ring but also the position of the heteroatom within the ring seems to influence the regioselectivity. When the nitrogen atom in pyridine is remote from the alkyne, the exclusive formation of **18-1-c** is observed, as expected, but when the nitrogen moves toward the alkyne group, a mixture of regioisomers is obtained (equation 2).

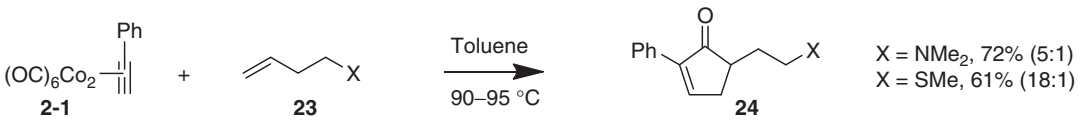
(2)

Heteroatoms directly bonded to the alkyne also exhibit an influence on the regioselectivity. The PKR of the *S*-alkyl-substituted alkyne (**1-13**) with norbornene provided the single regioisomer, in which the *S*-alkyl sits on the α-position in the cyclopentenone **19**, regardless of the electronic character of the other substituent R′ (equation 3).[18] No plausible rationale for this effect has been suggested.



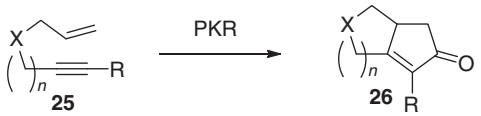
(3)

R, R′ = Me, Me; Me, *t*-Bu; Me, Ph; Me, CO_2Et; *t*-Bu, Me



5.24.1.3.2 Regiochemistry with respect to the alkenes

The regiochemistry with respect to the alkene is more complicated than that in the case of the alkyne. Even with terminal alkenes like **20**, nearly equal amounts of the regioisomers are obtained. One exception is the coupling of 1-heptene (**20**) and the dicobalt hexacarbonyl complex of an alkyne **21** conjugated with an electron-deficient group, in which a single product was formed (equation 4).[19]



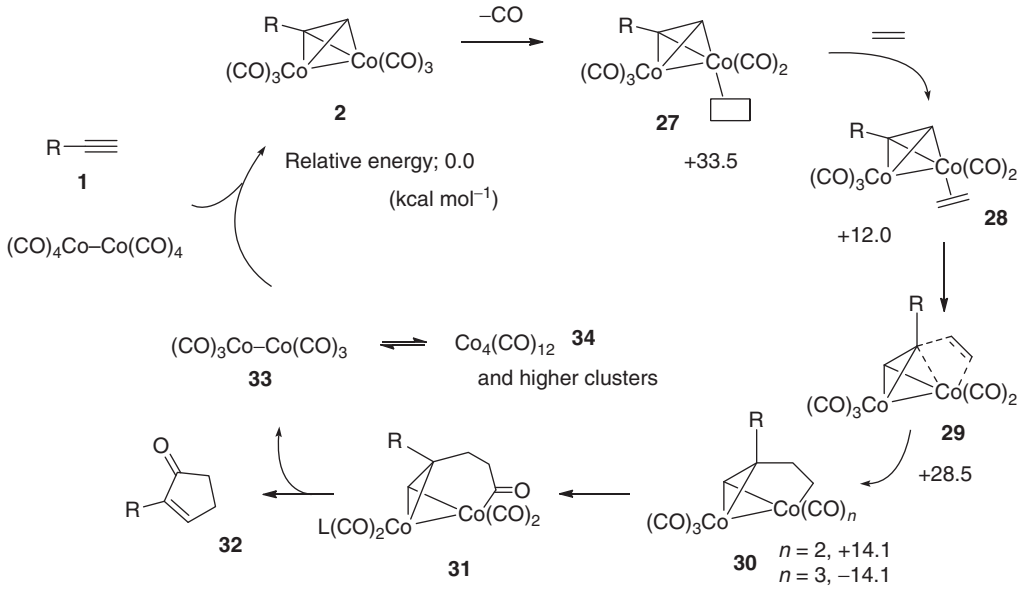
(4)

Krafft showed that the presence of a heteroatom in the substrate **23** that can coordinate the metal will guide the regiochemistry. These examples are thought to be a result of the coordination of the heteroatom to the metal before the insertion of the olefin, thereby fixing the orientation of the alkene to favor the 5-substituted product (equation 5).[20]

(5)

Despite the existence of several successful examples of regioselective PKRs, the formation of a mixture of regioisomers is inevitable in most intermolecular PKRs and a serious drawback when unsymmetrical alkenes and/or alkynes are employed. The synthetic utility of this reaction can be considerably improved by utilizing the intramolecular version. Schore introduced the first intramolecular version forming several rings simultaneously.[21] This has become the most popular synthetic strategy in the synthesis of natural products, because the reaction is more efficient than the intermolecular version and can reduce the complications related to the regiochemistry (Scheme 4).

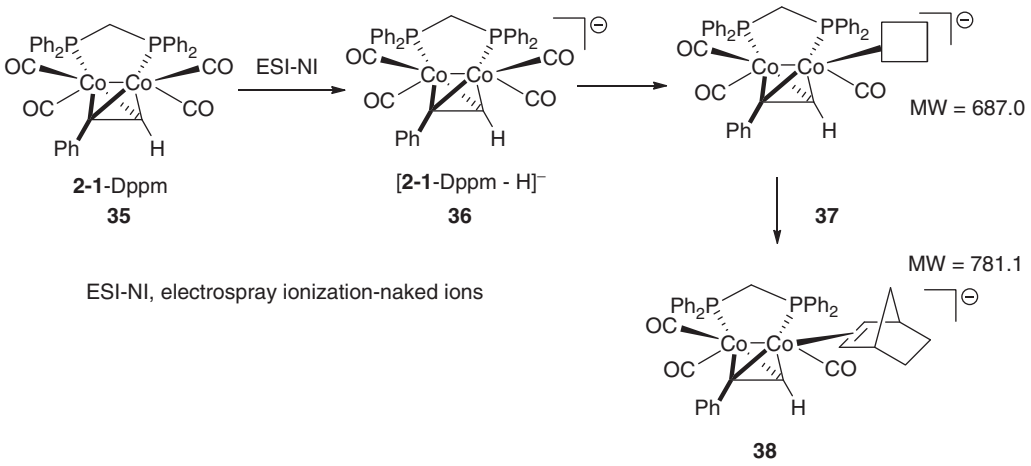
Scheme 4



5.24.2 Improvement of the Original Protocol

5.24.2.1 A Proposed Mechanism

Some of the problems mentioned previously can be accounted for by the widely accepted mechanism given in Scheme 5, which was proposed by Magnus[22] and is supported by many theoretical studies.[23]



The alkyne–cobalt carbonyl complex (**2**) formed from the alkyne (**1**) and dicobalt octacarbonyl should lose at least one of the CO moieties on the metal to provide the vacancy required for the incoming olefins. Subsequently, the olefin-bound complex (**28**) is oxidatively rearranged to yield a metallacycle intermediate **30** via transition state **29**. The migratory insertion of the CO ligands in **30** provides the homologated-ring intermediate **31**, and the following two successive reductive eliminations afford the cyclopentenone product **32** and the unsaturated dicobalt-carbonyl species **33**.

In this multistep process, the decarbonylation from complex **2** is thought to be the rate-determining step of the overall process and this hypothesis is supported by a couple of experimental data, albeit they are still circumstantial. One piece of evidence is that the overall reaction rate is given as $k = [CO]^{-1.9}[\text{olefin}]^{0.3-1.2}[Co_2(CO)_8]^{1.3}[\text{alkyne}]^{0}$.[24] The process is -1.9th order with respect to

Scheme 5

CO, which means that higher CO concentrations retard the reaction. The concentration of alkyne is irrelevant to the reaction rate. Other evidence comes from the identification of the proposed intermediate. Gimbert and Greene carried out an experiment to trace the proposed intermediates by a tandem mass spectroscopic study coupled with electrospray ionization. Starting from precursor **35** with a modified bisphosphine ligand, the decarbonylated species **37** (*m*/*z* 687) and the olefin complex **38** (*m*/*z* 781) were identified (Scheme 6).[25]

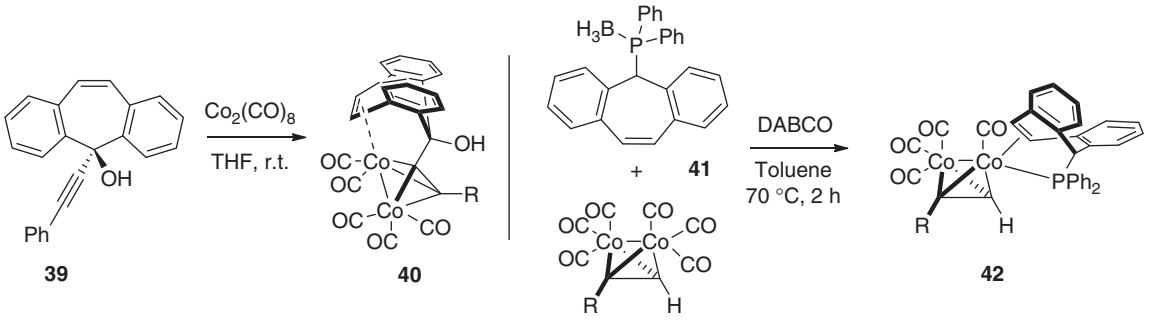
Scheme 6

Nonetheless, none of the proposed intermediates beyond **2** has been isolated and characterized. Very limited cases of trapping of any of the proposed intermediates have been reported.[26] Compounds **40** and **41** were isolated and fully identified by spectroscopic data and crystal structure analysis (Figure 6).[27] Ironically, these isolated intermediates fail to react further to provide the corresponding PKR product even under forcing conditions. This means that the isolable compounds are accidentally interrupted intermediates of the PKR rather than the real active species involved in the cycloaddition reaction. These reactions may represent an example of 'Halpern's law,' that is, only those intermediates are isolable which are not involved in the reaction pathway.[28]

5.24.2.2 Promoter-Assisted PKR

5.24.2.2.1 Physical means

As already mentioned, the requirement of harsh reaction conditions is mainly associated with the first decarbonylation of complex **2**. The first practical and significant rate acceleration had been achieved by the dry support-adsorption method on silica



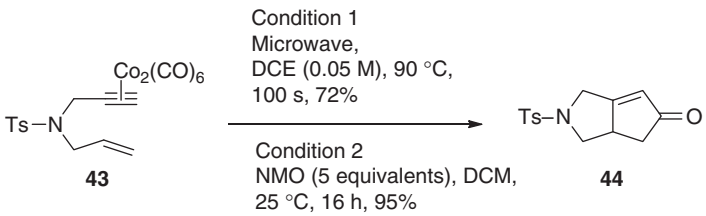


Figure 6 Trapped intermediates during the PKR.

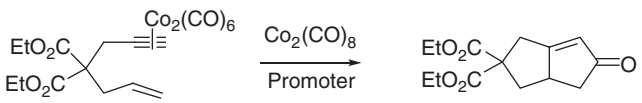
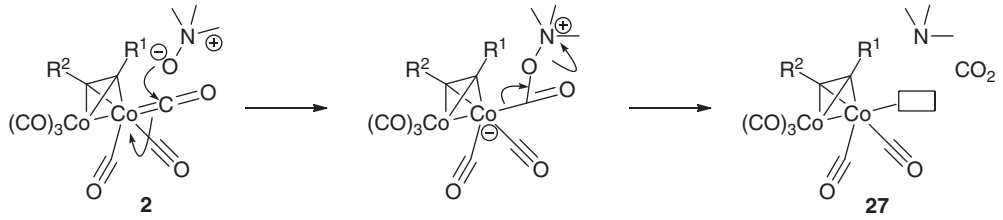


gel or alumina. Smit and Caple used cobalt-complexed enynes adsorbed on silica gel (2 on SiO_2) and obtained the cyclopentenones in good yields by gentle heating for several hours.[29]

The other physical means included irradiation with ultraviolet light and sonication with ultrasound. These methods have been tested and shown positive effects.[30] Most noticeably, Evans and coworker demonstrated excellent promotion by microwaves to expedite the reaction to completion in a minute (equation 6). Nevertheless, the beneficial effect in terms of the chemical yield is not spectacular[31] (**Table 1**).

(6)

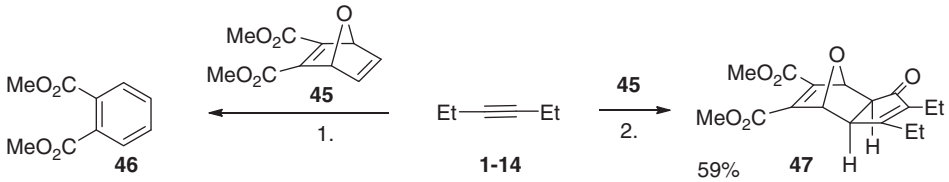
Table 1 The promoter-assisted Pauson–Khand reaction with cobalt



Promoter-assisted condition				*Yield (%)*	*References*
Promoters	*Solvent*	*Temperature (°C)*	*Time (h)*		
By physical means					
SiO_2	–	60	4	74	29
Visible light, UV	Toluene	r.t.	45	78	3c
Microwave	DCE	90	0.3	98	31
By oxidative promoters					
N-Methyl morpholin *N*-oxide	CH_2Cl_2	0–r.t.	3–20	95	32a
Trimethylamine *N*-oxide	CH_2Cl_2	0–r.t.	3	95	32b
TMANO with 4 Å MS	CH_2Cl_2	−10–r.t.	3	45–90	36
Amine *N*-oxide on solid support	THF	r.t.	0.5	91[a]	37
Dimethylsulfoxide	Benzene	40–50	3–20	83–92	38
By nonoxidative promoters					
$RSCH_3$	1,2-DCE	80	0.5–2	22–99	39,40
Sulfide on solid support	1,2-DCE	83	0.5	76[a]	41
TEMPO	Toluene	99	3 days	99	43

[a]The yields were taken from the intermolecular reaction.

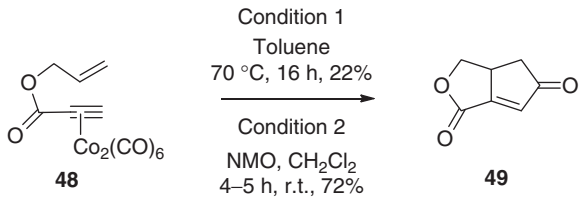
Recently, an example was reported in which a stoichiometric PKR was promoted solely by visible light, although the result was not impressive. Only two examples with TMS-acetylene and ferrocenyl acetylene dicobalt-hexacarbonyl complexes were reported to give 78% yield at 59% conversion, with an *endo*/*exo*-ratio of 3:97.[3c]



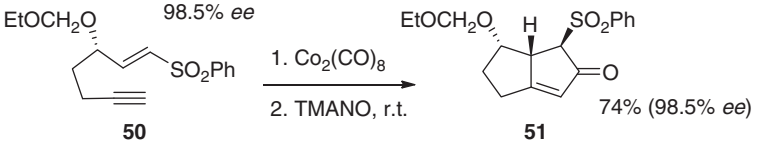
5.24.2.2.2 Oxidative promoters

More general methods have been devised. Schreiber[32a] and Jeong[32b] independently showed that amine *N*-oxides could promote the reaction substantially, affording high yields within a short reaction time. It is thought that these amine *N*-oxides, such as *N*-methylmorpholin *N*-oxide (NMO) and trimethylamine *N*-oxide (TMANO), oxidize at least one of the CO moieties to CO_2 even at ambient temperature. The latter binds much more weakly to the metal and, thus, dissociates readily to afford a vacant site for the incoming olefins (Scheme 7). As a result, the reaction proceeds even at ambient temperature. In addition, after the completion of the reaction, deep purple-colored cobalt oxide clusters are formed, which can be removed by simple filtration.

Scheme 7 An amine *N*-oxide promoter anchored to a solid support.



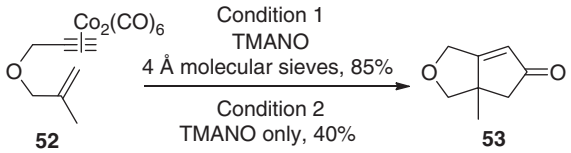
This general approach has now become the method of choice. The beneficial effects of amine *N*-oxide promoters are well documented in the example given in equation 7.[33] Although the aromatized product **46** was obtained instead of the PKR product from the reaction of diethylacetylene **1-14** and compound **45** under thermal conditions, only the desired PKR product **47** was formed with the aid of the amine *N*-oxide (equation 7).



(7)

1. Toluene, 70–80 °C (yield not reported); 2. NMO (6 equivalents), CH_2Cl_2, 0–20 °C, 10–24 h

This condition is good for reactions of electron-deficient alkynes and alkenes as well. The allyl alkynoate **48**[34] and sulfonyl-substituted substrate **50**[35] stereospecifically afforded the corresponding PKR products **49** and **51** in high yield (equations 8 and 9). Especially, a comparison between the thermal and promoter-assisted PKR clearly showed the difference (equation 8).



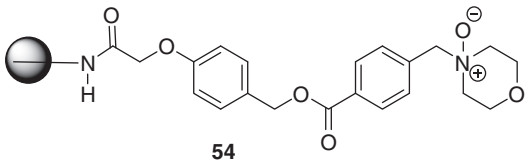
(8)

(9)

The promotion of the cycloaddition reaction by amine *N*-oxides was further improved by addition of molecular sieves (equation 10).[36] Molecular sieves are assumed to retain CO molecules and, thus, increase the conversion without the destruction of the metal clusters. This condition is applicable to less reactive substrates like **52**, which carry a trisubstituted olefin.

(10)

Subsequently, Kerr introduced a promoter anchored to a solid support to facilitate the workup after the reaction. For example, the PKR proceeds to completion when the amine *N*-oxide is anchored to a solid support (**54**) and then the polymeric amine can be recovered by simple filtration (Figure 7). The recovered polymer is cleaned, oxidized again, and then reused without any loss of activity.[37]



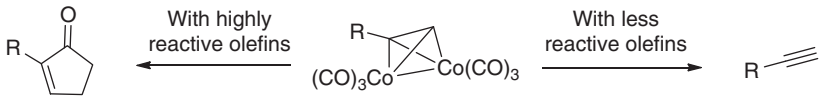


Figure 7 An amine *N*-oxide promoter anchored to a solid support.

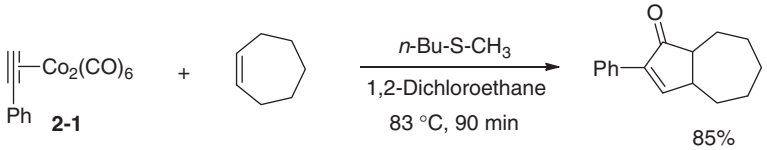
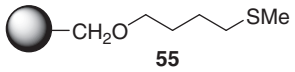
Jeong and Pauson revealed that sulfoxides are milder than amine *N*-oxides, but still excellent promoters for the reaction. The slight warming (50 °C) of the mixture was required.[38] Under this condition, the competition between the PKR and demetallation of the alkyne–metal carbonyl complex (see Scheme 8) is substantially suppressed.



Scheme 8

5.24.2.2.3 Nonoxidative promoters

Although oxidative promoters have been shown to be quite effective, the reaction with less reactive olefins is still troublesome in the presence of an oxidative promoter. The PKR inevitably competes with the demetallation of the alkyne–cobalt carbonyl complex to give the metal-free alkynes. This competition is insignificant if reactive olefins are employed, but prominent if less reactive olefins are used, most likely because the decarbonylation is not discriminative.

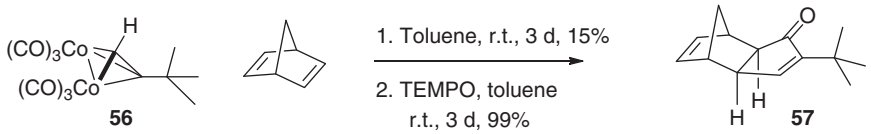


As a result, further optimization to identify milder promoters is critical to make the PKR more favorable. Sugihara reported that dialkylsulfides were effective as nonoxidative promoters in stoichiometric reactions.[12,39] This finding is rooted in the dimethylsulfoxide (DMSO) promoter[38] and Krafft's demonstration[20,26] that a suitably positioned sulfur moiety tethered to the PK precursor increases the reaction efficiency. Although the reaction conditions with these promoters generally require noticeably higher reaction temperatures than those with oxidative promoters, the transformation is completed in substantially shorter periods and gives high chemical yields. Moreover, the sulfur additive promotes the intermolecular PKR with even unstrained and less reactive olefins. A prominent example is the reaction between phenyl acetylene and cycloheptene (equation 11).[12]

(11)

This result has to be compared with the observation that only phenyl acetylene (**1-1**) was obtained with an NMO promoter, whereas the PKR product was formed in only 23% yield under thermal conditions after 3 days. The odorless sulfide, *n*-dodecyl methyl sulfide (DodSMe), was introduced by Kerr to make the reaction innoxious.[40] A sulfide anchored on the solid support (**55**) was also successfully used (Figure 8).[41]

Sugihara et al. demonstrated the enhancement of the reaction rate by using primary amines as a promoter, and this will be discussed in conjunction with the 'hard Lewis base'-catalyzed reaction (Section 5.24.3.1). Before that, it is worth mentioning that ammonia can serve as a promoter in a biphasic system consisting of an aqueous solution of ammonium hydroxide and dioxane. The reaction provided nearly quantitative yields in less than an hour under optimized conditions.[39]

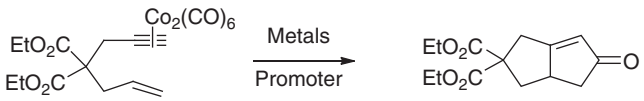


55

Figure 8 A sulfide promoter anchored to a solid support.

5.24.2.2.4 Promotion by single-electron transfer

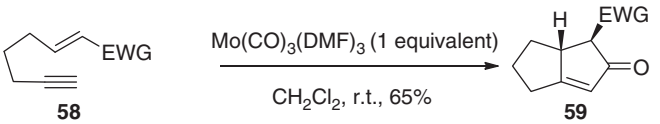
Ab initio calculations using the complete active space (CAS) method indicated that the Co–Co bond in the alkyne-bridged dicobalt hexacarbonyl complex (**2**) has a singlet diradical character.[42] Based on this study, the PKR was successfully promoted by single-electron transfer. Co–Co bond dissociation in a dicobalt alkyne complex is induced by 2,2,6,6-tetramethylpiperidine *N*-oxide (TEMPO) to afford (η^2-TEMPO)Co(CO)$_2$ without oxygen transfer to CO, which undergoes the PKR efficiently. This protocol is especially efficient for sterically demanding acetylenes such as *tert*-butylacetylene **56** (equation 12).[43]



56 57 (12)

5.24.2.2.5 Other metals coupled with a promoter

Group 16 metal carbonyls are also effective in the PKR reaction. Hoye prepared a pre-activated tungsten catalyst (W(CO)$_5$THF) by photochemically replacing one of the CO moieties of W(CO)$_6$ with THF, and successfully applied this complex to the PKR. Only substoichiometric amounts were required and this semicatalytic system constitutes one of the early examples of a metal/promoter couple. It is useful even for substrates bearing electron-withdrawing groups.[44]



Jeong et al. reported the activation of molybdenum hexacarbonyl *in situ* by DMSO.[45] A mixture of the substrate and Mo(CO)$_6$ (1.0 equivalent) together with more of DMSO (10 equivalents) in toluene and/or benzene was heated to give the corresponding PK products. DMSO can be replaced by tributylphosphine oxide (TBPO).[46] Recently, Carretero showed that Mo(CO)$_3$(DMF)$_3$, obtained by mixing molybdenum hexacarbonyl with DMF for several months, efficiently promotes the PKR reaction (Table 2).[47]

Table 2 The promoter-assisted Pauson–Khand type reaction with other metals

Promoter-assisted condition				*Yield (%)*	*Reference*
Promoters	*Solvent*	*Temperature (°C)*	*Time (h)*		
W(CO)$_5$(THF)	THF	65–110	6–20	60	44
Mo(CO)$_6$/DMSO	Toluene	100	8	76	45
Mo(CO)$_6$/Bu$_3$P=O	Toluene	100	3.5	71	46
Mo(CO)$_3$(DMF)	CH_2Cl_2	r.t.	15 min	83	47

The molybdenum-assisted version made some formidable PK reactions possible. In particular, substrates **58** having electron-deficient olefins, including the phosphonate-conjugated substrate **58d**, work nicely to give the corresponding products **59** (equation 13).[48]

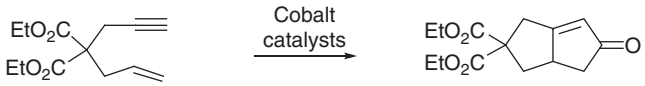
(13)

An allene moiety is an interesting substitute for an olefinic unit and, thus, the application of the PKR to allenes has flourished in recent years. However, the results of the early trials of the PKR with cobalt carbonyl were inconclusive.[49] Brummond et al. demonstrated the efficiency of the combination of molybdenum carbonyl and DMSO in the PKR of allenes.[50] They also showed that the regioselectivity of the reaction could be controlled by the substitution pattern on the allenes. For example, when the 1,3-disubstituted allene **60** was subjected to this condition, the product **61** resulting from the reaction with the internal double bond of the allene was obtained. However, the reaction took place at the terminal double bond when the 3-substituted allene **62** was employed, giving product **63** (equation 14).[50]

(14)



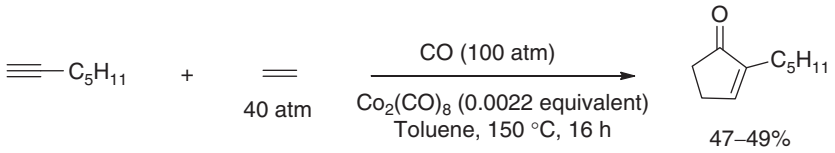
More discussion about the PKR with allenes is found in Section 5.24.5.1.

5.24.3 Catalytic PKR

5.24.3.1 Based on Cobalt

From the very beginning, the catalytic version of the PKR had been envisioned. In fact, Pauson reported an early success in the intermolecular catalytic reaction employing a continuous supply of ethylene (Table 3).[1]

Table 3 The cobalt-catalyzed Pauson–Khand reaction



Catalytic condition				*Yield (%)*	*References*

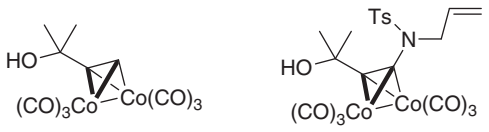
[a]The yield was based on the used alkynes during the intermolecular reaction.

It has been suggested that the difficulty in making the reaction catalytic is mainly associated with the facile formation of higher cobalt clusters like **34** from the unsaturated cobalt carbonyl species **33** relieved after a catalytic cycle (Scheme 5). Once **34** is formed, high pressure of CO is required to dissociate it to produce $[Co_2(CO)_8]$ again. However, the portion of unsaturated cobalt carbonyl $[Co_2(CO)_{8-n}]$ ($n = 1$ or 2) as the real catalytic species for the next cycle of the reaction would be severely discouraged

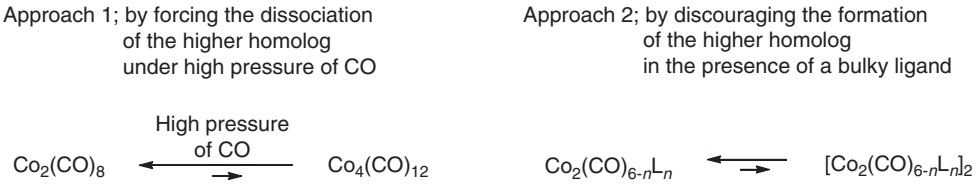


under such condition, and the second cycle would be even more difficult. As a result, many early attempts involving the simple use of a catalytic amount of dicobalt octacarbonyl provided erratic results.

The first successful catalytic reaction was reported in 1990 by Rautenstrauch et al. (Table 3). In their report, the reaction between ethylene (40 bar) and 1-heptyne in toluene was performed in the presence of a catalytic amount of $Co_2(CO)_8$ under a high pressure of CO (100 bar).[51] Although this constitutes the first truly catalytic reaction with a high turnover number (>220), this result was not reproducible. The reported chemical yield did not exceed a certain limit (<50%) and the trimerization of 1-heptyne competed with the desired reaction (equation 15).

(15)

In this endeavor, the purity of $Co_2(CO)_8$ should be high to ensure reproducible results. Many attempts have been made to realize this catalytic reaction. Finally, Livinghouse and coworkers refined the conditions and expanded the scope of the catalytic version.[52] Their first report used photochemically activated $Co_2(CO)_8$ under atmospheric pressure of CO. Next, they found thermal conditions by keeping the reaction temperature in a very narrow range (50–55 °C). For both studies, $Co_2(CO)_8$ must be rigorously purified. An alternative way to ensure the formation of highly purified unsaturated [$Co_2(CO)_6$] is the use of alkyne–dicobalthexacarbonyl complexes. The early attempts of Billigton to use ethyne–[$Co_2(CO)_6$] and recent examples using **64** and **65** are representative (Figure 9).[53]



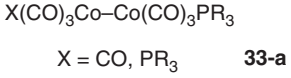
64 **65**

Figure 9 Precursors providing pure unsaturated cobal-carbonyls in a practical manner.

5.24.3.1.1 Various ligand-modified cobalt catalysts

More reliable catalytic PKRs were devised. The bottom line in devising the catalytic PKR is identifying the way to discourage the formation of higher cobalt clusters **34** and to allocate enough time to the unsaturated cobalt carbonyl species **33** for binding the new substrates before making the aggregated clusters (Scheme 9). A highly congested environment was introduced around the cobalt metal by using a sterically bulky external ligand. Once the catalyst is sterically encumbered, it would discourage the dimerization or oligomerization of the unsaturated metal carbonyls (Figure 10).

Scheme 9



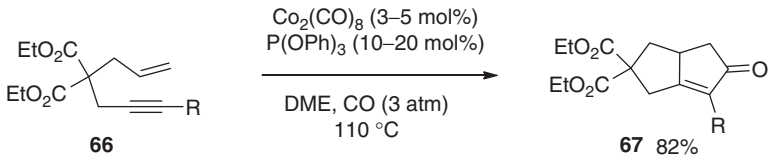


Figure 10 Dicobalt carbonyls armed with bulky ligands.

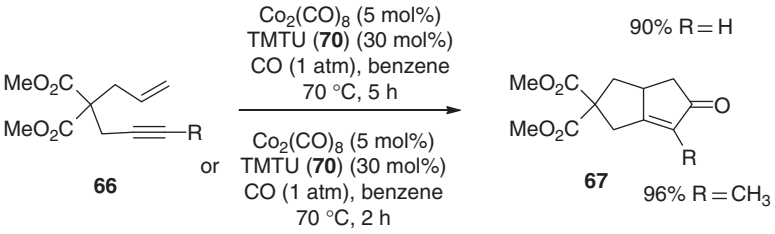
Jeong et al. made a phosphite-modified cobalt catalyst **33-a** (X=P(OPh)$_3$) which was prepared *in situ* by mixing dicobalt-octacarbonyl (3 mol%) and triphenylphosphite (10 mol%) before the PKR. The best results were obtained when the reaction was carried out at elevated temperature (110 °C) under mild pressure of CO (3 atm) (equation 16).[54]



(16)

Although phosphites were used in the original work, it was found that other phosphorus ligands including phosphanes are also effective as long as the solubility of the catalysts in the reaction media is guaranteed. Subsequently, it was shown that the use of premade robust catalysts by coupling with phosphanes and phosphites was effective under a CO atmosphere (1 atm).[55]

Since the successful introduction of catalysts modified by phosphine ligand, the efforts were focused on the identification of other ligands. Hashimoto showed that the addition of phosphane sulfides also results in higher yields and faster conversions for the PKR under atmospheric pressure of CO. This mild promoter provided high TONs and can be applied to an intermolecular PKR under 1 atm of CO.[56]

In addition, thiourea turned out to be a very effective additive.[57a] Among the various thioureas tested, including the bulky and optically pure **71**, tetramethylthiourea (TMTU, **70**) turned out to be the best choice and provided the best results if the metal/ligand ratio was carefully controlled (1:6) (equation 17). Subsequently, the tris-thiourea compound **72** was also introduced for the same purpose (**Figure 11**).[57b]

(17)

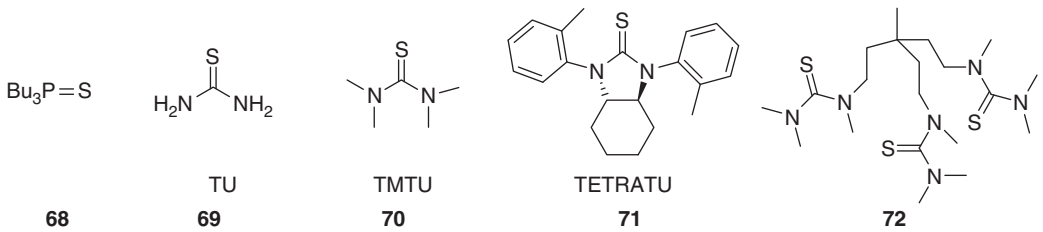


Figure 11 Representative promoters of PKR by cobalt carbonyl bearing sulfur.

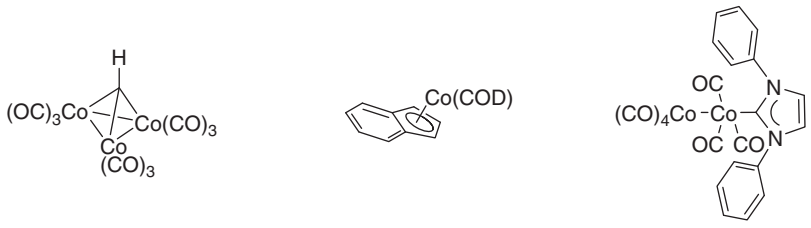


The catalysts modified by phosphorus ligands made the transformations reliable, but this consistency was obtained at the expense of the reaction rate. This is mainly attributed to the electron flow from the ligands to the metal, making the π-back bonding of the metal to the CO much stronger and thus the removal of CO more difficult. The use of 'hard Lewis bases' would be a solution to overcome this problem, because these kinds of ligands are assumed to make the CO of low-valent organotransition metal complexes more labile.[58] However, there is a rather contradictive explanation for the role of the hard Lewis base. The DFT calculation carried out by Milet and Gimbert indicated that the rate effects exerted by most Lewis bases are due to preventing the reversibility of olefin insertion rather than by facilitating the departure of the CO ligand to create a vacant site for the incoming olefin.[59] Anyway, whatever the reason is, the beneficial effect of the 'hard Lewis base' seems to be evident.

It was already discussed that the use of 1,2-dimethoxyethane (DME) as a hard Lewis base additive in toluene was critical to the success in the microwave-promoted PKR (see equation 6).[31] Nevertheless, the use of DME as the solvent is detrimental and the formation of the demetallate parent alkyne **1** was the problem. Water was less efficient under the same conditions, but gave a comparable yield at higher concentrations.

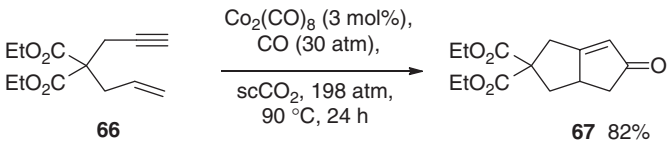
Cyclohexylamine, which was found to be one of the best promoters for the stoichiometric reaction, failed to give a catalytic version under CO pressure (7 atm). However, Krafft et al. elegantly combined cyclohexylamine and cobalt carbonyl (in the form of dicobalt octacarbonyl or tetracobalt dodecacarbonyl (**34**)) in DME and demonstrated its efficiency in catalytic cyclizations. Cyclohexylamine is a sterically bulky amine and is presumed to remain intact on the unsaturated dicobalt species during the catalytic cycle, discouraging the formation of higher homologues and making CO more labile.[60]

Interestingly, cobalt clusters such as alkylidynetricobalt nonacarbonyl, which are easily prepared by the reaction of dicobalt octacarbonyl with trihaloalkane, were utilized for the PKR reaction.[61] Among the clusters investigated, the one having a relatively

small substituent on the bridging carbon, $Co_3(CO)_9(\mu^3\text{-}CH)$ (**68**), turned out to be the best choice (Figure 12). However, a relatively high pressure of CO (7 atm) is required for consistent results.

68 **69** **70**

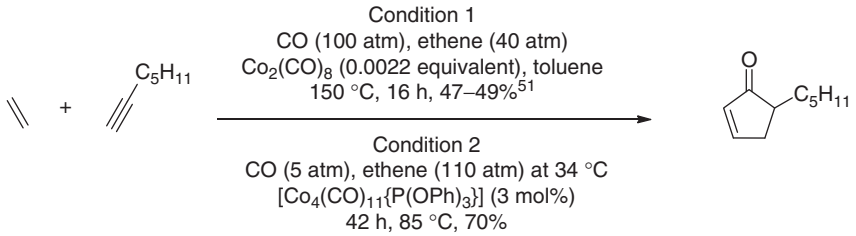
Figure 12 Cobalt based catalysts other than dicobalt octacarbonyl.



In another study, a mono cobalt(I) species proved its utility for the catalytic PKR. Chung and Jeong reported a new catalyst, [(indenyl)(cod)cobalt(I)] (**69**) (Figure 12), to promote the reaction. Although this catalyst required a high pressure of CO (15 atm) to obtain excellent results, the TON was as high as 97.[62]

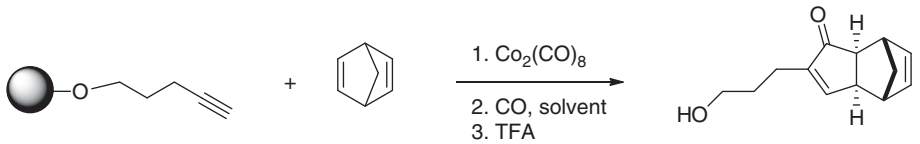
The robust NHC–cobalt complex **70** has been used, albeit with slightly inferior efficiency, which might be due to the highly electron-donating character of NHC ligands (Figure 12).[63]

Studies using alternative sources of cobalt have been the subject of research as well, because of the relative instability of $Co_2(CO)_8$. The generation of Co(0) can be effected either by the reduction of $Co(acac)_2$ with $NaBH_4$ in CH_2Cl_2 or the reduction of $CoBr_2$ by Zn in toluene/*t*-BuOH.[64]



5.24.3.1.2 Cobalt-mediated catalytic PKR in unconventional media

Compressed carbon dioxide, either as a supercritical fluid ($scCO_2$) or expanded liquid (XPL), can be used as a solvent for this reaction. Jeong et al. first demonstrated that the efficiency of the PKR is substantially improved in supercritical CO_2 fluid.[65] The advantages may be due to the high solubility of gaseous reactants including CO, the rapid diffusion of the solutes, and the weakening of the solvation around the reacting species (equation 18).



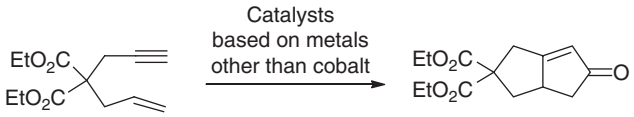
66 **67** 82% (18)

In a subsequent study, the same authors used ethylene both as a substrate and supercritical fluid solvent.[66] This notoriously poor substrate in the PKR served nicely to give 2-substituted cyclopentenones. The reaction efficiency of each alkyne substrate can be tuned by changing the catalyst precursors. Not only $Co_2(CO)_8$ but also the two cobalt clusters $[Co_4(CO)_{12}]$ and $[Co_4(CO)_{11}\{P(OPh)_3\}]$ were used case by case to obtain optimal yields. A comparison with Rautenstrauch's result[51] clearly shows the superiority of this approach (equation 19).

(19)

Furthermore, these media turned out to be especially good for solid-phase organic synthesis, in which efficient mass transfer is critical to success. Leitner and his coworkers demonstrated that the PKR between norbornadiene and the alkyne substrate **71**, which is bound to a solid support, proceeded well in compressed carbon dioxide (equation 20). In this specific case, the reaction in XPL provided better results than that in a supercritical fluid, because the concentrations of both the catalysts and soluble substrate were significantly improved in XPL compared to that in the supercritical phase.[67]

(20)



Ionic liquids are a versatile class of solvents for transition metal-mediated reactions, because of their many advantages compared to conventional media, including their nonvolatility. The catalytic PKR was also tested in these media, but only found to provide reasonable chemical yields for a narrow range of substrates.[68]

To reduce the environmental impact of organic solvents in industrial-scale applications, water is considered as a possible alternative, because it is cheap, readily available, nonflammable, and nontoxic. The PKR can also be realized in water in the presence of detergents and surfactants to solubilize the cobalt carbonyls, $Co_2(CO)_8$ and/or $Co_4(CO)_{12}$. The water–Triton X medium using $Co_4(CO)_{12}$ rendered the catalytic thermal PKR in aqueous conditions possible. The efficiency of this protocol exceeds that of the aqueous reactions using stoichiometric amounts of $Co_4(CO)_{12}$ and $Co_2(CO)_8$.[69]

5.24.3.2 Based on Metals Other Than Cobalt

The use of other metals for the PKR has attracted much attention recently in the search of new possibilities (Table 4).

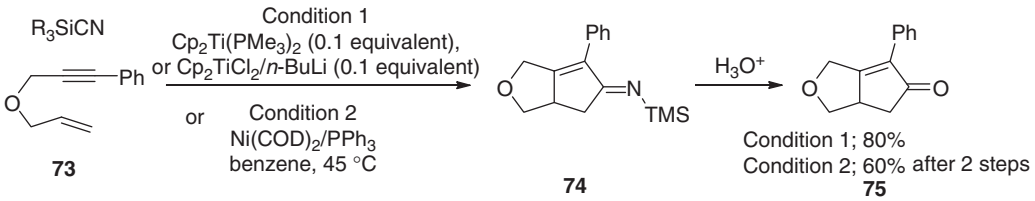


Table 4 The catalytic Pauson–Khand reaction using metals other than cobalt

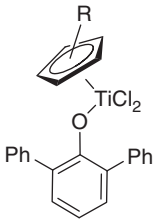
Catalytic condition				*Yield (%)*	*References*
Catalysts	*Solvent*	*CO (atm)*	*Temperature (°C)*		
$Cp_2Ti(CO)_2$	Toluene	1.2	90	98	70,72
$CpTi(OAr)X_2$	Toluene	1	95	79	73
$Ni(COD)_2/PPh_3$	DMF	Isocyanide	120	85[a]	71
$[Ru_3(CO)_{12}]$	DMAC	15	140	79	74,75
$[RhCl(CO)_2]_2$	Toluene	0.1	80	90	77
$[RhCl(PR_3)_2]/CO$	Toluene	1	110	96	78
$[Rh(COD)(TRIA)]_2$	Xylene	5	130	80	81
$PdCl_2$/TMTU (**70**)	THF	1	50	81	82
$[IrCl(COD)]_2$	Toluene	1	110	75	120

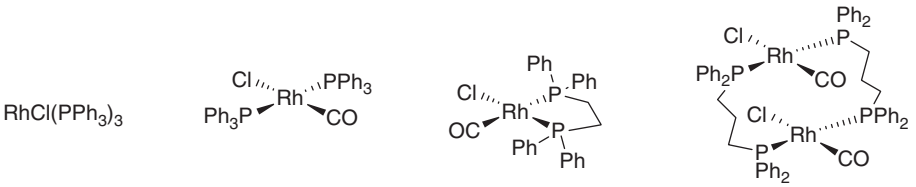


[a]The yield of the PK product was determined after hydrolysis of the resultant imines.

The initial success with early transition metals, such as zirconium and titanium, reported by the Buchwald group, included an indirect cycloaddition between an enyne and isocyanides. The first protocol using catalytic $[Cp_2Ti(PMe_3)_2]$ or Ni(cod) together with CO and triphenylphosphine failed to cyclize the enynes. However, the cyclic imine **74** was obtained when trialkylsilyl isocyanides were used, which eventually hydrolyzed to give the PK product **75**.[70,71] For the nickel-catalyzed PKR, it was revealed that a diamine ligand was superior to the commonly used phosphane ligand. In addition, it was necessary to use sterically bulky isocyanides for the catalytic version. The poisoning of the nickel catalyst by the formation of a nickel–isocyanide complex was an obstacle in this reaction (equation 21).

(21)

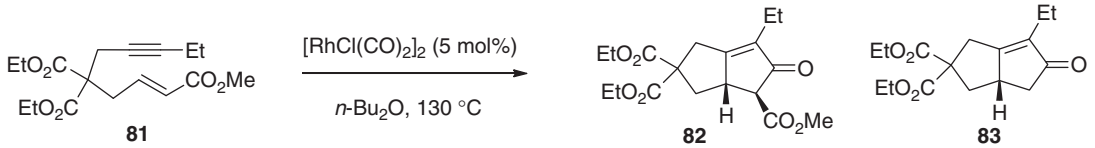
Subsequently, the direct incorporation of CO by the titanocene(II) catalyst, $Cp_2Ti(CO)_2$, under a CO atmosphere was accomplished.[72] This catalytic system showed a substantially higher TON and broader functional group compatibility. However, this catalyst failed to react with sterically hindered olefins and alkynes. A subsequent contribution from the same group revealed that the series of aryloxide titanium complexes of type **76** could promote the PKR even with sterically hindered enynes (Figure 13).[73]



76

Figure 13 Ti-based catalysts for the PKR.

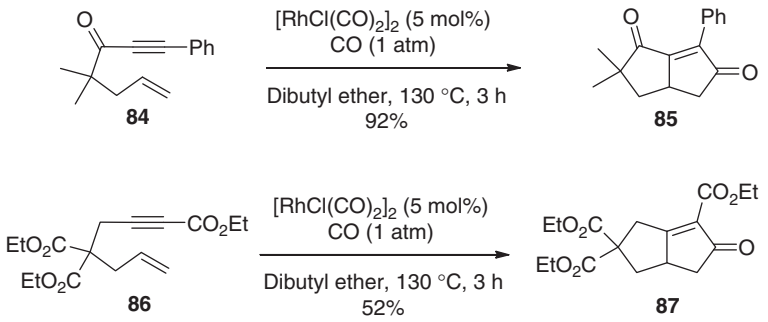
Furthermore, late transition metals such as ruthenium, rhodium, and iridium showed their ability to catalyze the PK reaction. In 1997, two groups reported independently that $[Ru_3(CO)_{12}]$ can be used. The group led by Murai reported the use of dioxane as the solvent,[74] whereas the other led by Mitsudo employed *N*,*N*-dimethylacetamide (DMAC).[75] Both conditions required a high pressure of CO (10–15 atm) and the scope extended only to disubstituted alkynes.



The rhodium catalyzed PKR was also reported by two groups simultaneously and has attracted much more attention.[76] Early studies by Narasaka and coworkers employed $[RhCl(CO)_2]_2$ as a catalyst in dibutyl ether,[77] whereas the report by Jeong et al. employed various phosphine-modified Rh(I) catalysts in noncoordinating solvents such as toluene.[78] The latter has the potential for further development toward the enantioselective version. The requirements for efficient transformation, when phosphine-ligated catalysts are used, are well defined. For example, while complexes such as $RhCl(PPh_3)_3$ (**77**), *trans*-$RhCl(CO)(PPh_3)_2$ (**78**), or RhClCO(dppe) (**79**) require the co-use of silver(I) salts for a faster reaction by making cationic catalysts, the complex *trans*-$[RhCl(CO)(dppp)]_2$ (**80**) efficiently promotes the reaction without the need for any additives (Figure 14).

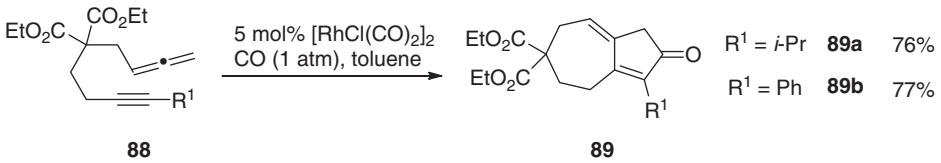
77 **78** **79** **80**

Figure 14 Various Rh(I) catalysts initially screened for the PKR.



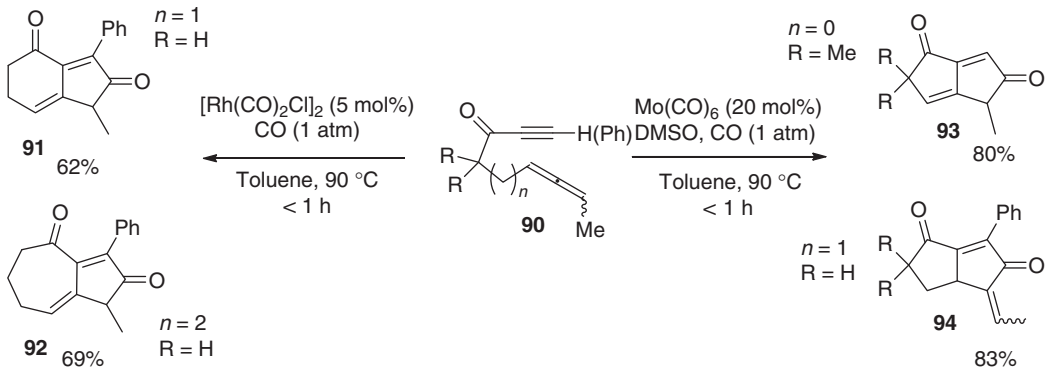
Rhodium catalysts demonstrated some additional unique features, which cobalt catalysts do not have. Electron-deficient alkenes and alkynes were among the previously challenging substrates in the PKR assisted by oxidative promoters. The situation is more favorable when a rhodium(I) catalyst is utilized. The inherently electron-rich rhodium(I) is able to provide a more significant π-back-bonding into the electron-deficient multiple bonds. Thus, it initiates the reaction to furnish the cycloaddition products in a highly efficient manner.[77] It is interesting to note that the concentration of CO should be kept as low as possible to achieve a higher chemical yield in a shorter reaction time (equation 22).

1 atm CO	18 h	19%	68%
0.1 atm CO and 0.9 atm Ar	4 h	59%	31%



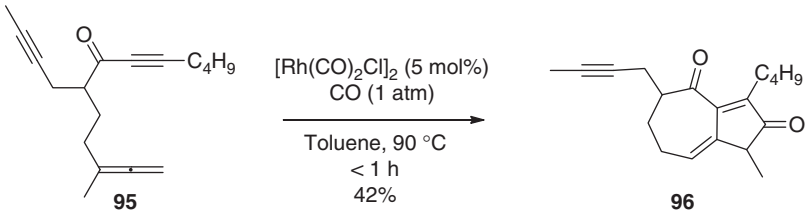
(22)

In addition to the example given above, the alkynone **84** and the alkynoate **86** also gave the PKR products in moderate to excellent yield (equation 23).[77]



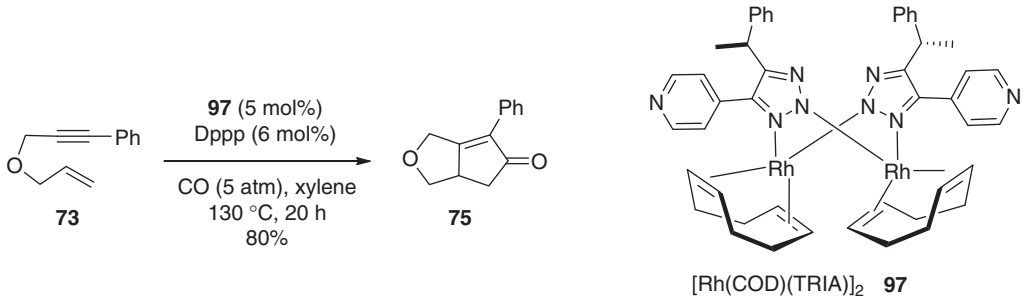
(23)

Another advantage of the Rh(I) catalyst is the preparation of a bicyclo[5.3.0]-decenone system by the PKR. The preparation of a larger ring system than bicyclo[3.3.0]- and [4.3.0] rings remained a big challenge for a long time. The breakthrough came with Rh catalysts, when allenes were used as a substitute for the olefin moiety. The treatment of substrate **88** with either $[RhCl(CO)_2]_2$ or $[RhCl(CO)dppp]_2$ in toluene under 1 atm of CO furnished the bicyclo[5.3.0] compounds **89** in excellent yields (equation 24) (see Section 5.24.6.1).[79]



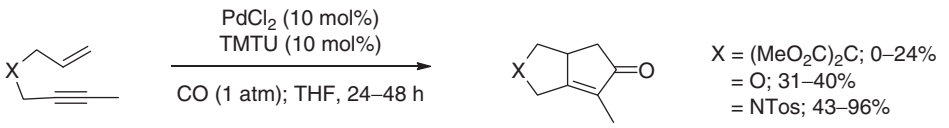
(24)

Interestingly, the regioselectivity of the cycloaddition of the allene–alkynone **90** depends on the catalyst used, for example, Mo versus Rh(I) (equation 25). With compound **90** ($n=1$, R=H), Rh(I) afforded **91** as the product, whereas Mo(0) yielded **94**.



(25)

More interestingly, it was found that the carbonyl-conjugated alkyne in **95** was more reactive than the normal alkyne. Compound **95** afforded **96** exclusively in 42% yield (equation 26).[80]

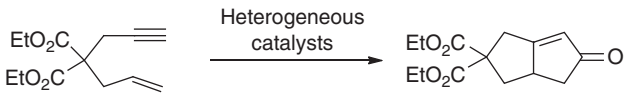


(26)

$[Rh(COD)(TRIA)]_2$ (**97**), obtained from a mixture of $[Rh(COD)Cl]_2$ and 4,5-disubstituted NH-1,2,3-triazole (TRIA) in the presence of KOH, constitutes a new class of Rh(I) catalysts for the PKR. Together with dppp, this complex exhibited decent reactivity under CO pressure (5 atm) (equation 27).[81]

(27)

Palladium(II) coupled with TMTU (**70**) was also introduced as a catalyst for the PKR. The efficiency of this combination is very sensitive to the tethering of the substrates and only substrates having an *N*-Tos tether turn out to be effective (equation 28). In addition, the diastereoselectivity of the reaction is extremely high, and the reaction more effective with electron-deficient alkynes, contrary to the conventional notion. The use of LiCl as an additive expanded the substrate scope widely and improved the efficiency of the reaction significantly.[82]



(28)

Catalysts based on iridium(I) were discovered and will be discussed later in the context of enantioselective transformations in Section 5.24.4.2.2.

5.24.3.3 Heterogenized (Immobilized) Catalysts

In view of their environmental advantages and operational simplicity, heterogeneous catalytic systems have been strongly suggested (Table 5). To this end, Gibson and coworkers first introduced polymer-bound cobalt species (**98** and **99-a**).[83a] Subsequently, Portnoy and coworkers immobilized cobalt on dendrimeric phosphane ligands, which have a partial structure of **99-b**.[83c–e] Leitner introduced poly(ethylene glycol) stabilized Co nanoparticles for this transformation (Figure 15).[84]

Table 5 Heterogeneous catalysts for Pauson–Khand reactions

Catalytic condition				*Yield (%)*	*References*
Catalysts	*Solvent*	*CO (atm)*	*Temperature (°C)*		
Polymer-bound Co	THF	1	70	61	83,84
Co on PEG	THF	23	130	89

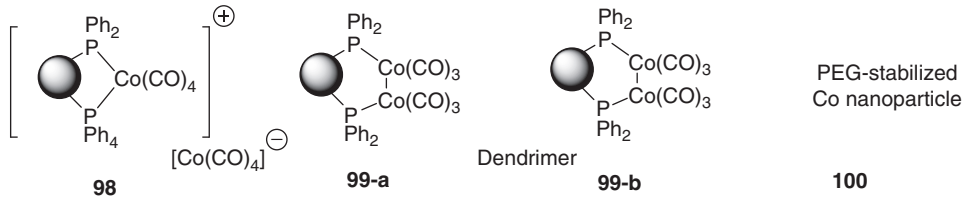
Raney Co	THF	23	130	95	87
Zr-mesoporous silica	Toluene	30	130	20	88

Chung and Hyeon developed a variety of heterogeneous catalysts, using cobalt metal immobilized on mesoporous silica[85a] or charcoal.[85b] Although these catalysts generally require harsh conditions (high CO pressure and high catalyst loading) to effect the reaction, the reuse of the catalysts without loss of activity may compensate for such drawbacks.

Substantial improvements were made by using cobalt nanoparticles.[79a] Contrary to the previous cases, a much lower CO pressure (5 atm) is sufficient for the completion of the reaction. However, the high loading of catalysts (45 mol%) is still a drawback. Nevertheless, this system can be reused, and one of them is even compatible with water as the solvent.[85]



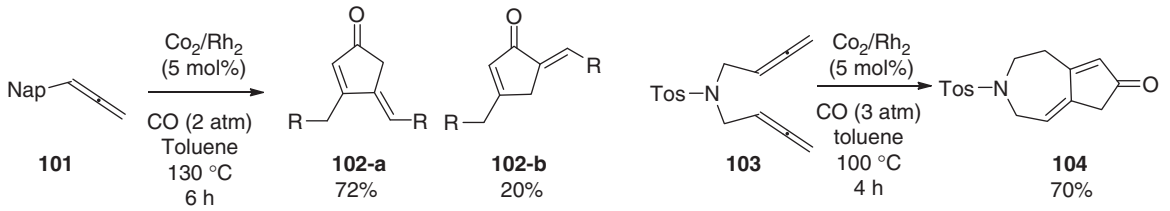


Figure 15 Representative cobalt carbonyl catalysts immobilized on solid supports.

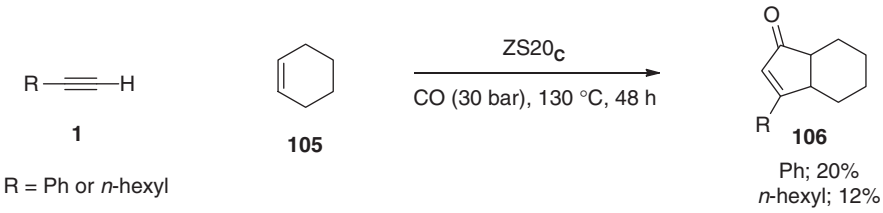
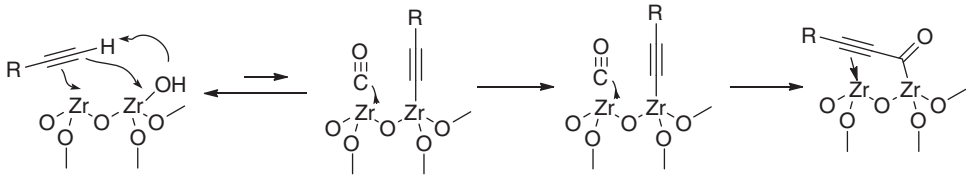


Immobilized Co_2Rh_2 heterobimetallic nanoparticles on charcoal were identified and used for the catalytic reaction either under CO atmosphere or in the presence of crotonaldehyde as the CO source.[86] This catalyst was further used for the carbonylative dimerization of two allenes intra- and intermolecularly (equation 29).[86]

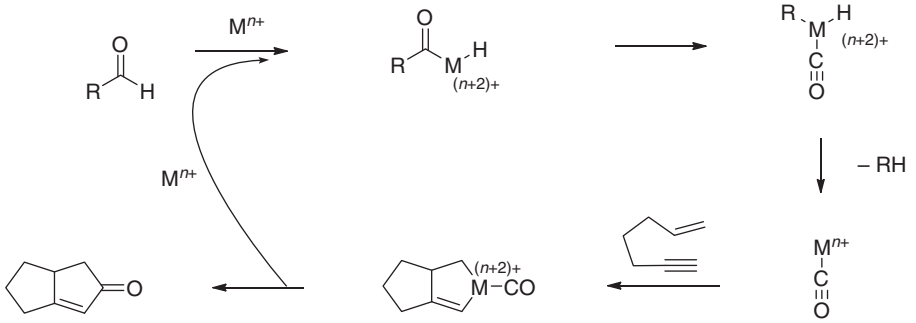


(29)

Commercially available Raney cobalt has also been used for this cycloaddition.[87]

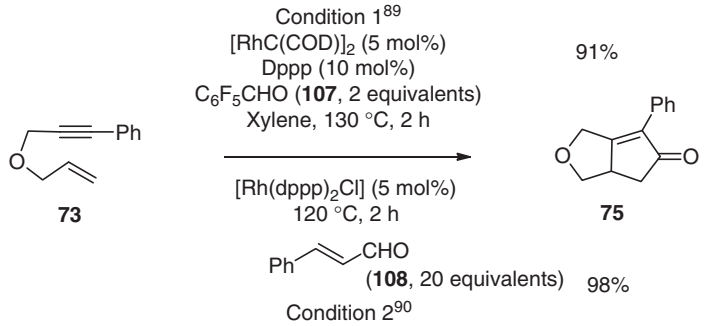
Zirconium–silica mesoporous powders ($ZS20_C$) were found to act as a moderate catalyst for hydroformylations and the PKR. Although the reaction using this catalyst was far less efficient than that with other immobilized catalysts, this is one of the first examples of the use of zirconium for this transformation. Besides this aspect, there are a couple of points worth mentioning. The reaction is good only for terminal alkynes. Even though the chemical yield is not impressive at all, this condition provided *β*-substituted cyclopentenones **106** in contrast to the previous results (equation 30). Based on these observations, the authors proposed the mechanism described in Scheme 10.[88]

(30)



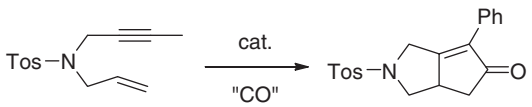
Scheme 10

5.24.3.4 PKR using Alternative CO Sources



Facile formation of metal carbonyl complexes makes rhodium a very useful catalyst for both the hydroformylation of multiple bonds and the decarbonylation of aldehydes (Scheme 11). Two groups have independently utilized rhodium carbonyl complexes obtained by decarbonylation of aldehydes in the PK reaction.[89]

After an extensive screening of various aldehydes to optimize the conditions, Kakiuchi and Morimoto reported that most of the aromatic aldehydes tested are able to serve as a CO source and that the electronic nature of the aldehydes is responsible for the CO-transfer efficiency. Aldehydes bearing electron-withdrawing substituents are more effective than those bearing electron-releasing substituents. As a result, pentafluorobenzaldehyde (**107**) is chosen for this purpose. No complication by hydroacylation of the alkenes and/or alkynes was observed.[89]



Scheme 11

In a subsequent study, Shibata found that cinnamaldehyde (**108**) can be employed as a CO source as well as a solvent.[90] Refluxing of the enynes **73** greater than cinnamaldehyde (**108**) (20 equivalents) together with 5 mol% $Rh(dppp)_2Cl$ (prepared *in situ* by mixing $[Rh(cod)Cl]_2$ and 2 equivalents of dppp) under argon provided the corresponding bicyclopentenones **75** in nearly quantitative yields (equation 31). The reaction time in the case, where **108** is used, is substantially shorter than that when **107** was used (Table 6).

(31)

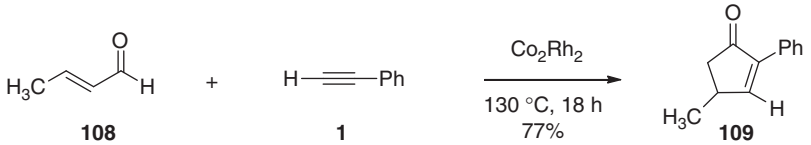


Table 6 The catalytic Pauson–Khand reaction using aldehydes as CO source

Catalyst (mol%)	*Additive (mol%)*	*RCHO (equation)*	*Yield (%)*	*References*
$RhCl(cod)_2$ (5)	Dppp (11)	C_6F_5CHO (2)	95	89a

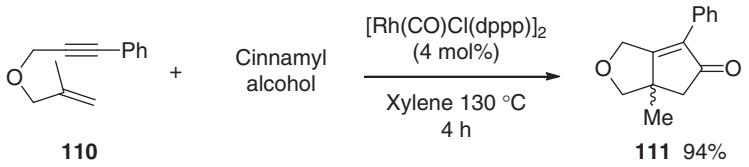
$[RhCl(cod)]_2$ (5)	BINAP	Acetylated carbohydrates	51 (61% *ee*)	92a,b



[a]TPPTS, triphenylphosphine-3,3′,3″-trisulfonic acid trisodium salt.

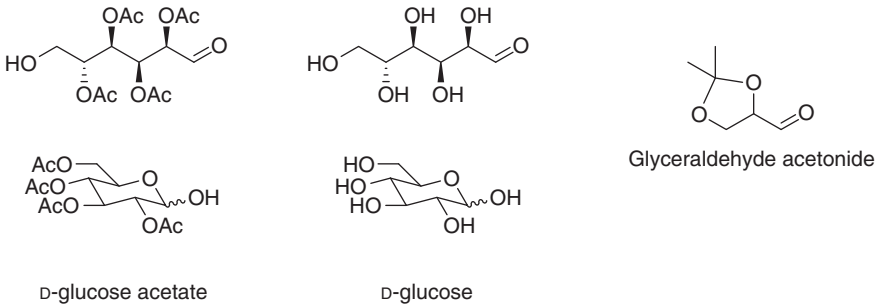
Chung successfully used cinnamaldehyde not only as a CO source but also as a reactant styrene source. This PK reaction was achieved using Rh/Co colloidal nanoparticles (equation 32).[91]

(32)

Since aldehydes are formed from alcohols through the metal-assisted dehydrogenation, this tandem process can be further extended. The same catalyst is used for the dehydrogenation of alcohols to aldehydes, then decarbonylation of the resultant aldehyde yields the metal carbonyl, which finally serves in for the PKR (equation 33).[91b]

(33)

Various carbohydrate derivatives with acetate-protected alcohol groups derived from D-glucose, D-mannose, D-galactose, D-xylose, D-ribose,[92a] or glyceraldehyde acetonide[92b] were used as CO sources, albeit the results were modest. Multiple successive CO generations from single carbohydrates such as D-glucose and/or xylitol was tried, but the efficiency is not impressive (Figure 16, see Section 5.24.4.2.2 for more discussion).[91b]



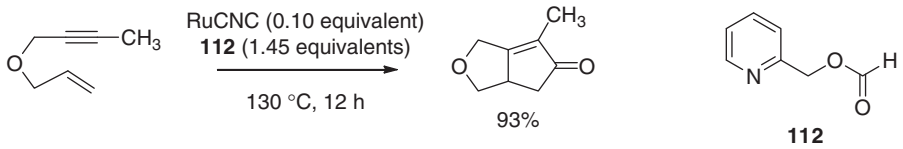


Figure 16 Sugars as CO source for the neutral Rh(I) catalyzed PKR.

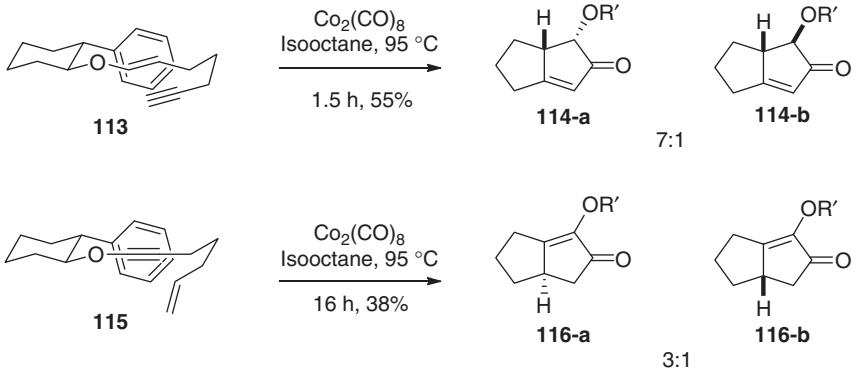
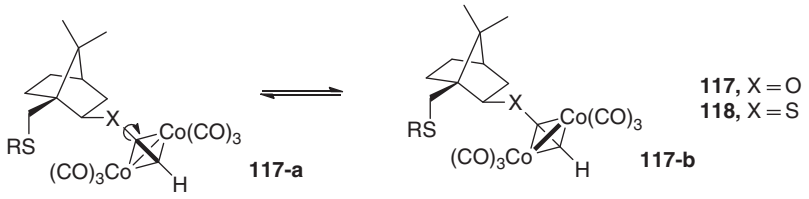
Chung introduced a combination of the well-designed CO surrogate **112** and ruthenium colloidal particles (RuCNC) (equation 34).[93]



(34)

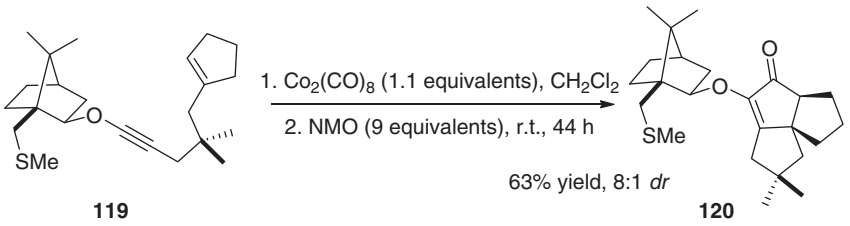
5.24.4 Asymmetric PKR

In the past two decades, there have been extensive efforts to prepare optically pure PKR products. These efforts include the following two categories: (1) substrate-controlled asymmetric reactions and (2) reagent-controlled asymmetric reactions.



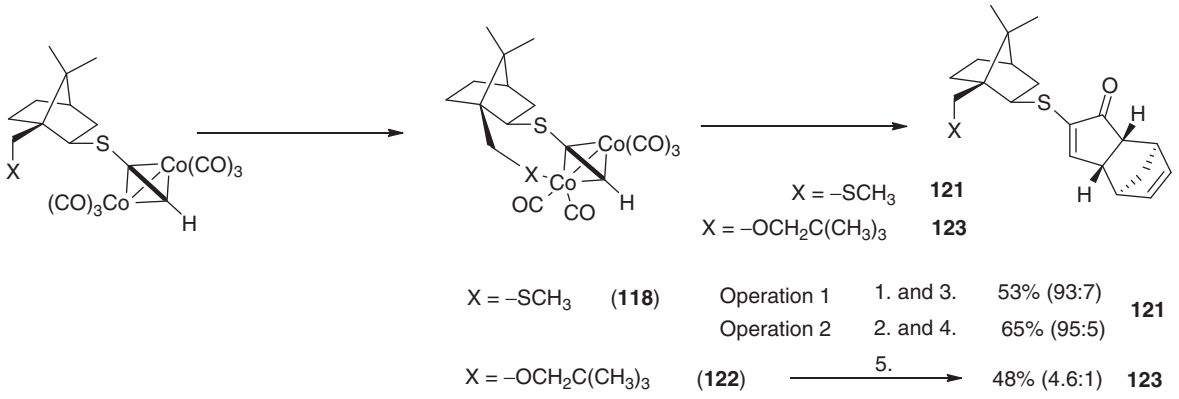
5.24.4.1 Substrate-Controlled Asymmetric PKR

The use of substrates having a removable chiral auxiliary: Early attempts utilizing the substrates **113** and **115**, with the expectation of the blocking of one face of the olefin by a phenyl group, led to modestly diastereoselective PKRs (equation 35).[94]



(35)

Moyano and Pericas used the chiral alcohols **117** (X=O) or sulfides **118** (X=S) bearing a suitably positioned extra sulfur appendage. This would make the intermediate structure rigid by a secondary ligation from the auxiliary. As a result, the free rotation of the alkyne cobalt complex moiety along the axis between the alkyne carbon and the heteroatoms would be restricted and high diastereoselectivity be ensured (Scheme 12) when a highly strained olefin such as norbornadiene (**3**) is used.[95a] Otherwise, when a less reactive olefin such as cyclopentene was employed, a 1:1 mixture of diasteromers was obtained in low yield (14%).[95b]



Scheme 12

The tricyclic ring compound **120** was prepared from **119**, an analog of **117**, with high stereoselectivity (equation 36).[96]

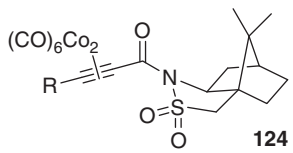
(36)

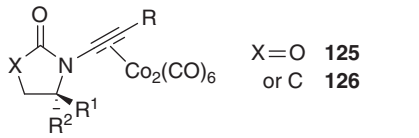
The significance of the secondary prechelation is again supported by the report that compound **118** having a more strongly donating sulfur atom on the appendage provided a substantially higher diastereoselectivity than **122** containing a weaker binding O-atom (equation 37).[97]

(37)

1. (a) $Co_2(CO)_8$, (b) heating at 55 °C; 2. (a) $Co_2(CO)_8$, (b) NMO (3 equivalents) in CH_2Cl_2 3.; 4. norbonadiene, –10 °C;
5. (a) $Co_2(CO)_8$, (b) NMO (6 equivalents), –20 °C, CH_2Cl_2

Substrates bearing other chiral auxiliaries such as Oppolzer's bornanesultam **124** gave excellent results in terms of stereocontrol and yield (Figure 17).[98]





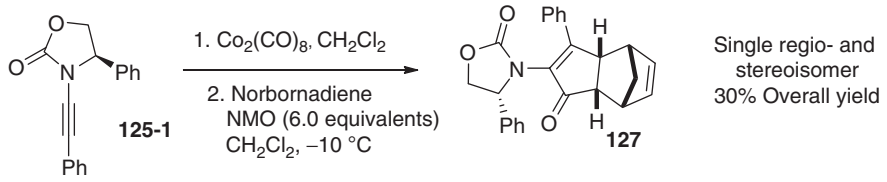


Figure 17 Chiral alkyne-cobalt complex bearing Oppolzer's bornanesultam.

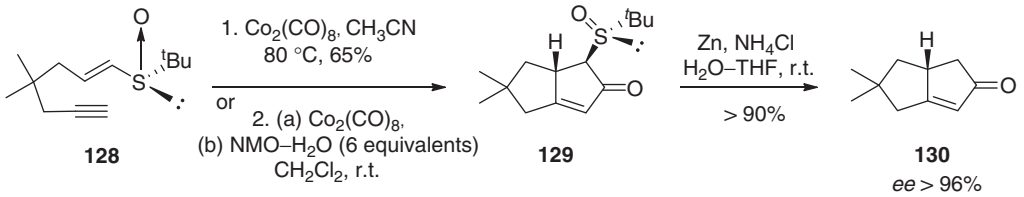
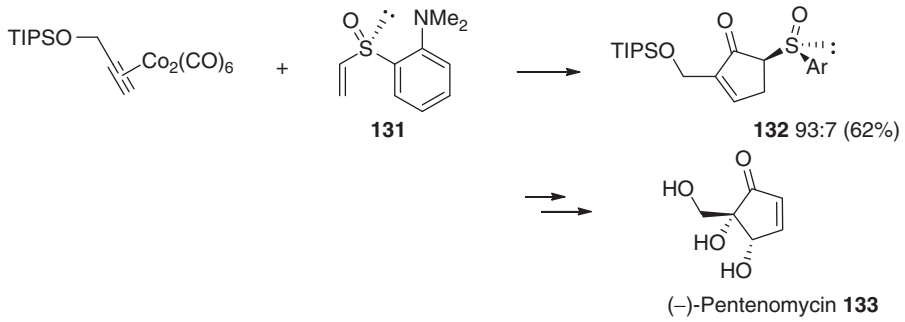
A chiral imidate (**125**) or chiral amides (**126**) were successfully employed for the intermolecular PKR to provide a single diastereomeric product, albeit in low yield.[99]

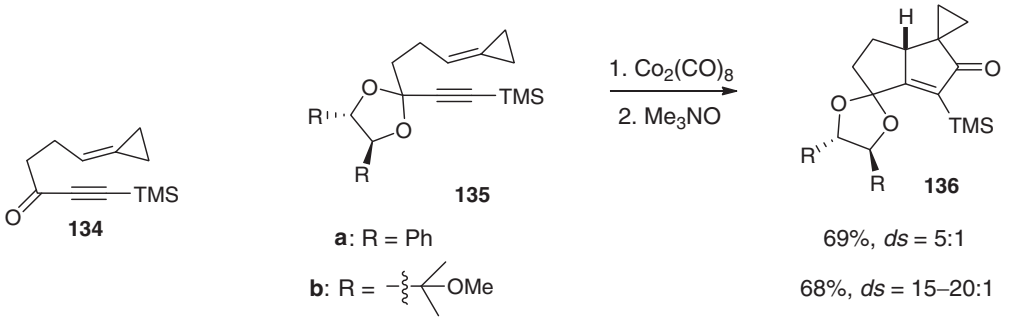


An example of the use of an imidate is summarized in equation 38 and another example using the chiral amide **581** will be given later in equation 155.



(38)

The chiral sulfoxide group next to the olefinic moiety in **128** controls the stereoselectivity efficiently and provides **129** with high diastereoselectivity. In addition, the mixture of *E* and *Z* vinylsulfoxides **129** gives the same final product **130**, if they are treated with zinc to remove the sulfoxide moiety (equation 39).[97c]

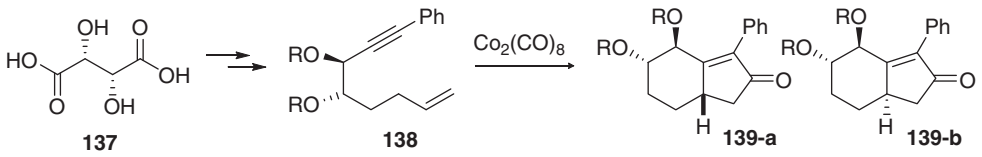


(39)

The chiral sulfoxide in compound **131** could control the diastereoselectivity in an intermolecular PKR as well (equation 40).[100]

(40)

De Meijere introduced a chiral ketal for the ynone substrate **134**. The authors tried to offer a solution for two problems in the PKR of the electron-deficient alkyne **134**. By introducing a chiral ketal on the carbonyl, the newly formed alkyne **135** was then no longer a poor substrate, and a chiral environment was imposed at the same time.[101a] The PKR of substrate **135a** provided **136a** as the major diastereomer. Later, Krafft used a bulkier chiral auxiliary. Compound **135b** gave rise to improved results (ds from 5:1 to 15–20:1) (equation 41).[101d]

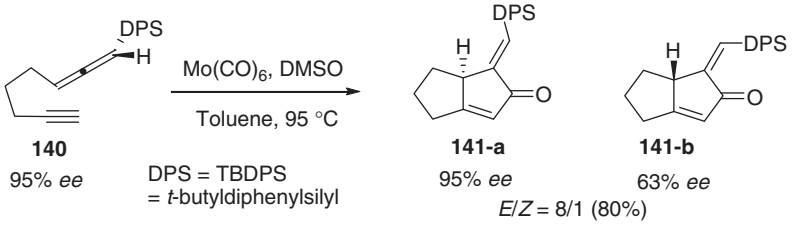


(41)

5.24.4.1.1 Chirality transfer from the preexisting stereogenic center on the substrates

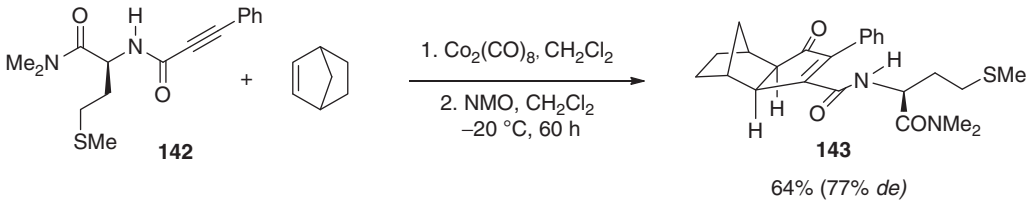
Relative stereocontrol by preexisting stereogenic centers in the reacting substrates has been studied extensively, and the outcome of the reaction is now well predictable.

Mukai and Hanaoka applied this approach to the synthesis of numerous natural products in optically pure form. They prepared numerous 'chirons' from the abundant natural chiral pool, such as dimethyl L-tartrate or L-ascorbic acid, and employed them in the PKR. One example is the previously reported synthesis of the bicyclo[4.3.0] ring with high diastereoselectivity as given in equation 42.[102a] Two more examples will be discussed in Section 5.24.6.1.



Condition	139-a:139-b	Yield
R, R = TBDMS	1. 100:0	99%
R, R = H	2. 1:99	94%
R, R = $OC(CH_3)_2O$	3. 0:100	56%

Condition: 1. 70–75 °C in MeCN 2. NMO in CH_2Cl_2

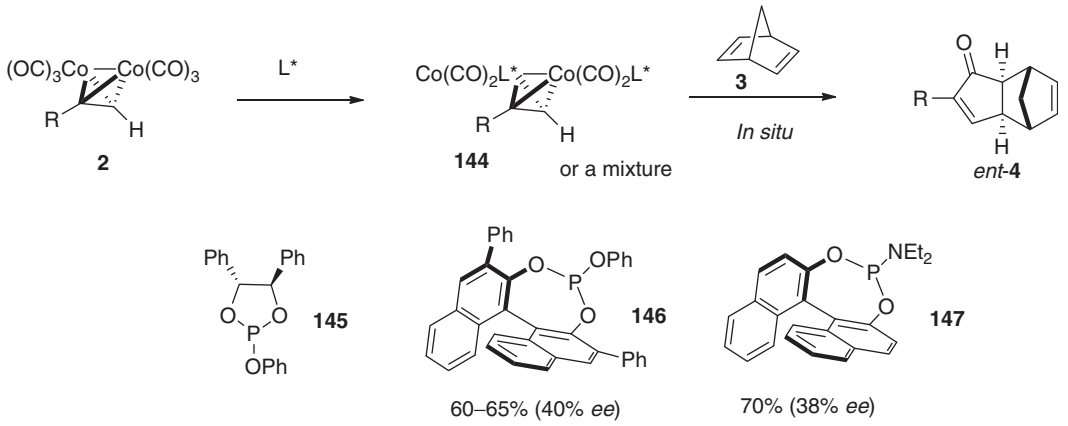


(42)

Brummond's example of successful chirality transfer from a chiral allene **140** in the PKR is also noteworthy (equation 43).[103]

(43)

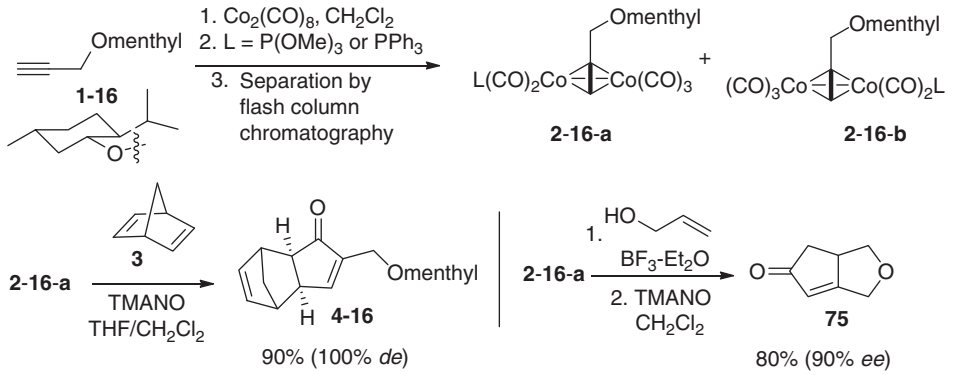
Hiroi et al. employed the alkynamide **142** derived from (*S*)-methionine to obtain **143** in a regio- and stereoselective manner (equation 44).[104,99]



(44)

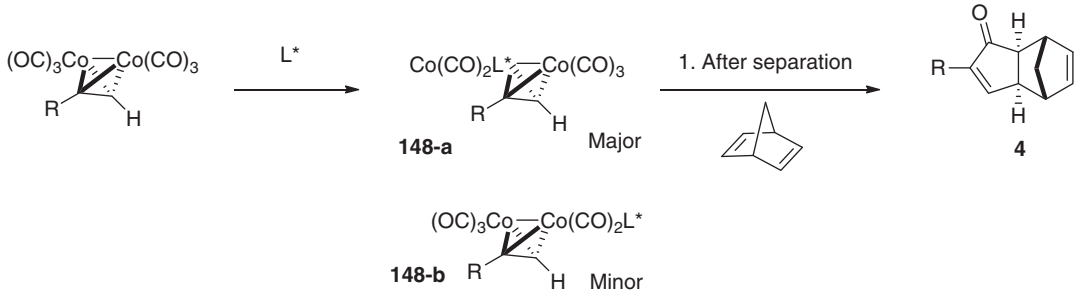
5.24.4.2 Reagent-Controlled Asymmetric PKR

5.24.4.2.1 Based on cobalt



One of the simplest approaches is the modification of the environment around the metal. This can be divided into two categories: (1) the use of a chirally modified alkyne–metal complex formed *in situ* and (2) the use of preformed chiral alkyne–metal complexes.

The first approach is carried out by simply mixing the alkyne-dicobalt hexacarbonyl complexes (**2**) with a chiral phosphorous ligand and, then, the presumed chiral intermediate is subjected to the PKR. It was assumed that two CO, one from each $Co(CO)_3$ moiety, were replaced to form the intermediate **144**. The PKR induced either by thermal conditions or by promoter-assisted conditions would allow the optically enriched product **4** to be obtained. The chiral phosphites, **145** or **146**, were used first.[97] Subsequently, Monophos **147**, a commercially available BINOL-derived monodentate phosphoramidite, was also used for the intermolecular PKR. However, the enantioselectivity was not satisfactory in any of the cases (equation 45).[105]



The second approach uses preformed chiral alkyne-cobalt carbonyl complexes. A mixture of diastereomeric metal-alkyne complexes was usually obtained and each diastereomer was separated by column chromatography or other means. Then, the isolated optically pure diastereomer was subjected to the PKR either under thermal or promoter-assisted conditions. When an enantiomerically pure substrate was employed, the PKR was highly stereoselective.

One of the first approaches employed a propargyl alcohol having a menthyl group, **1-16**. The replacement of only one CO afforded a 1:1 mixture of diastereomers, **2-16-a** and **2-16-b**, which were separated by column chromatography. Each diastereomer was employed in the intermolecular PKR reaction with norbornadiene to give the PK product **4-16**, or subjected to the Nicholas reaction with the allyl alcohol followed by the PKR to afford **75** in optically pure form (Scheme 13).[106]

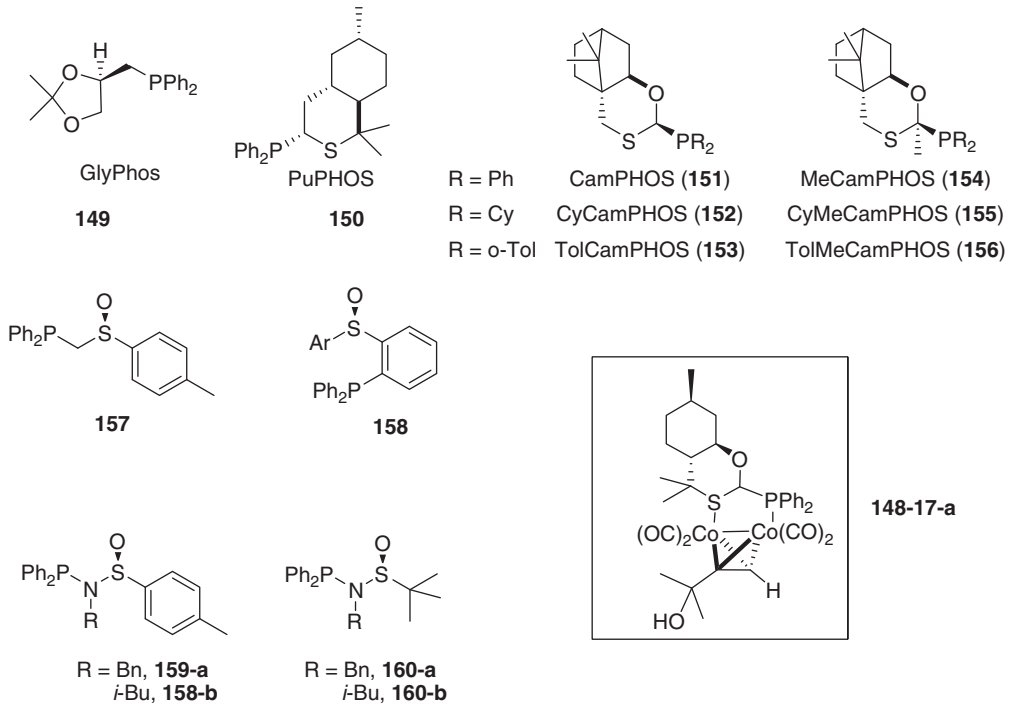
Scheme 13

The next approach is to treat the prochiral alkyne–dicobalt hexacarbonyl complex **2** with chiral ligands. Again, a mixture of diastereomers was obtained, which were separated and then used for the PKR (Scheme 14; for the conditions, see Figure 18 and Table 7).

Scheme 14

All of the ligands used in this category are summarized in Figure 18 and some representative results are listed in Table 7.

Glyphosphate was employed for the first time by Pauson and coworkers. The replacement of only one CO would lead to a 1:1 mixture of diasteromers. Each diastereomer was separated by chromatography and then subjected to the PKR.[107,108]



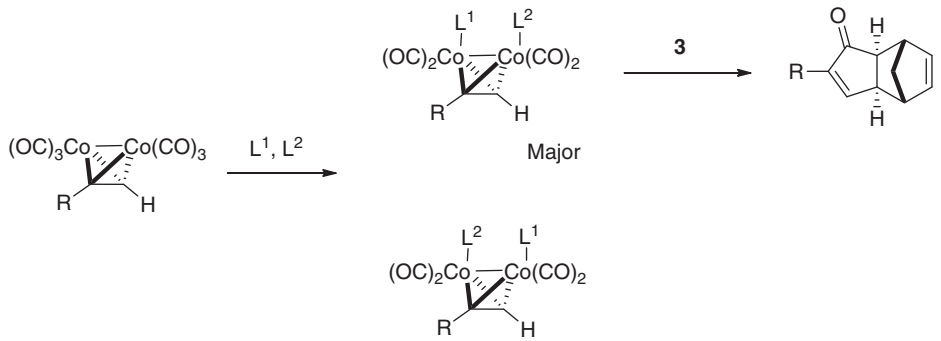


Figure 18 Representative chiral ligands been used for the preparation of optically pure diastereomeric alkyne-metal complexes.

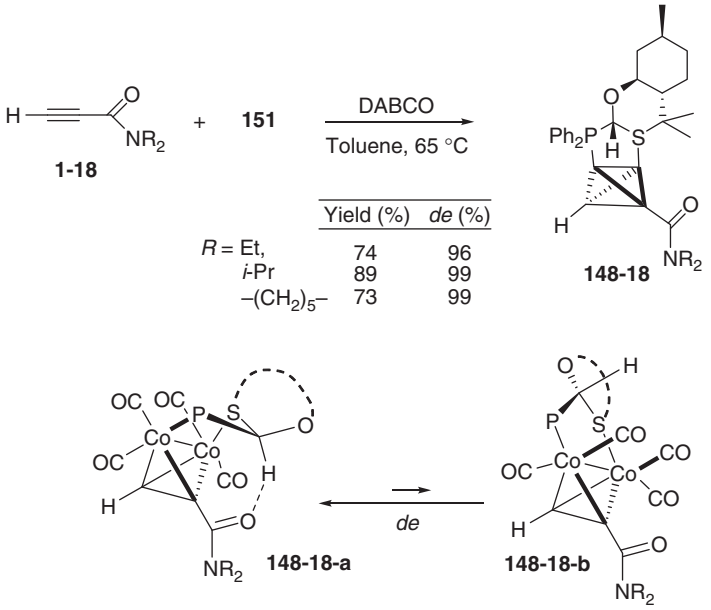
[a]Disubstituted alkyne.

Many years later, Greene, Pericas, and Moyano prepared a series of complexes between the cobalt–alkyne and hemi labile P,S ligands with a chiral backbone[109] such as PuPHOS (**39**) and various CamPHOS derivatives (**151-153**), which were readily obtained from (+)-pulegone or camphor, respectively.

The diastereomers derived from **1-17**, obtained in a 4.5:1 ratio when PuPHOS (**150**) was used, were separated. Then the major diastereomer (**148-17-a**) reacted with norbornadiene by the assistance of NMO as promoter to give the PKR product (**4**) in excellent yield as well as enantioselectivity.[109a]

Subsequently, Verdaguer et al. introduced new auxiliaries for the asymmetric PKR bearing chirality on the sulfoxide, for example, P-C-SulfOxide (PCSO) ligands such as **157** and **158** and P-N-SulfOxide (PNSO) ligands such as **159–160**.[109e]

Among the examples in Table 7, entry 4 is noteworthy. For the alkyne substrate **1-18** with an amide substituent, which can participate in the formation of an internal nonclassical hydrogen bond found in **148-18-a** to rigidify the conformation, the diastereoselectivity was dramatically improved by this secondary effect (Figure 19).[109c]



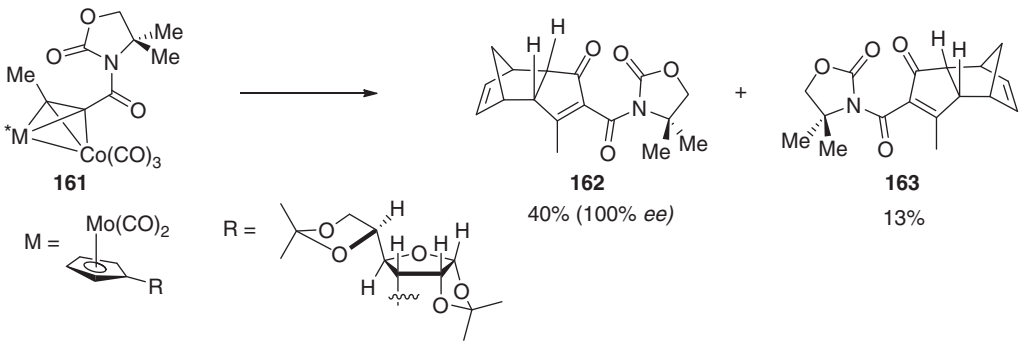


Figure 19 Internal nonclassical hydrogen bonding guided stereoselective intermolecular PKR.

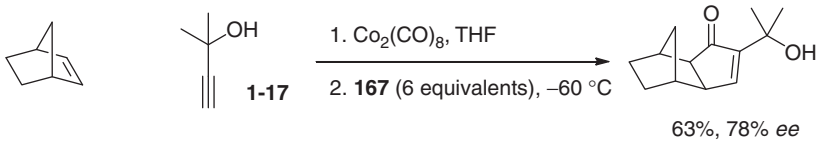


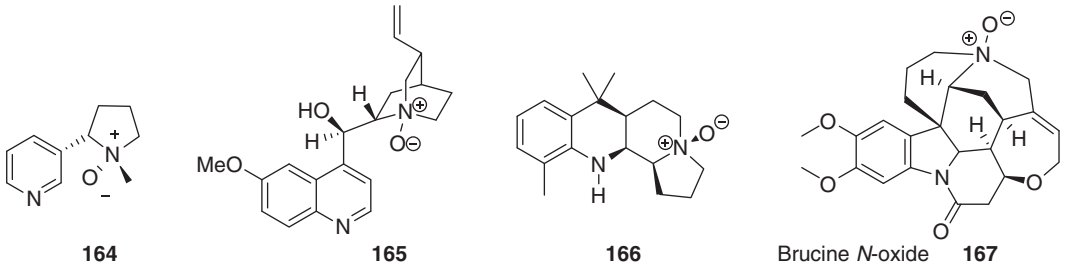
Pericas and Moyano reported an interesting observation that a heterobimetallic (Mo–Co) complex provided the intermolecular PKR products in favor of the *endo*-isomer (equation 46).[110]

(46)

5.24.4.2.1.1 Use of chiral promoters

The use of chiral promoters is an obviously straightforward entry into the enantioselective PKR. The chiral promoter may approach one of the two equivalents cobalts and effect the oxidation of a specific CO group preferentially. However, early attempts to make a vacant coordination site stereoselectively were not encouraging (Figure 20). After much effort, enhanced enantioselectivity at a practical level was obtained by using brucine *N*-oxide (**167**), a bulky amine *N*-oxide, under carefully controlled conditions (− 60 °C) (equation 47).[111]

(47)



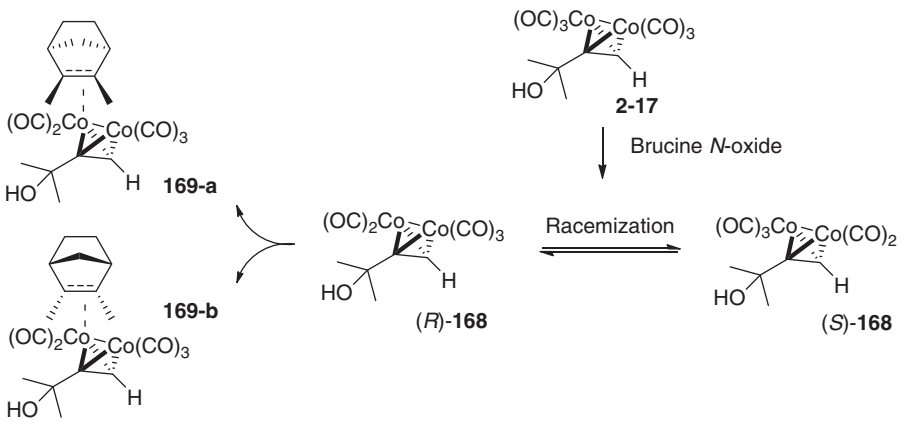


Figure 20 Representative chiral amine *N*-oxide promoters.

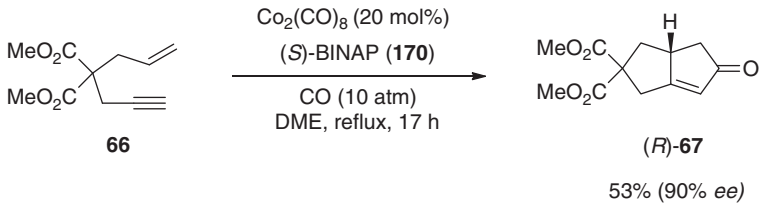
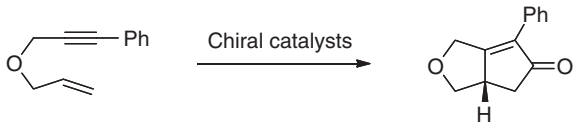
A computational study revealed that the partial racemization at the intermediate **168** can hardly be avoided and, thus, the enantioselectivity is noticeably lowered. This racemization can be reduced by elevating the energy barrier between the two intermediates. If the substrate bore an alcohol functionality in it, the barrier was raised through an intramolecular hydrogen bond. Under these circumstances, a significantly higher ee was obtained (Scheme 15).[111e]



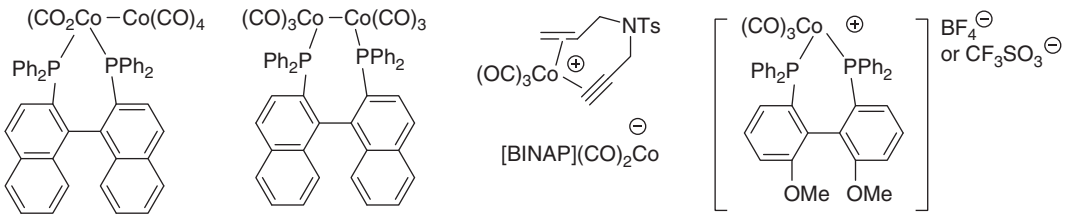
Scheme 15

5.24.4.2.1.2 The use of chiral catalysts



Despite the impressive advances in the catalytic PKR, the development of a catalytic enantioselective version has not kept pace with the other successes (Table 8). Naturally, the use of a cobalt catalyst bearing an external ligand was extended to the use of chiral phosphane or phosphite ligands, but the success of this approach has been extremely limited.

The asymmetric PKR using cobalt modified by the chiral phosphane (*S*)-BINAP (**170**) was reported by Hiroi et al. for the first time (equation 48).[112] However, the narrow scope of the substrates and high catalyst loading seemed to be a major shortcoming. Such a drawback can be explained by the fact that the chemical constitution of the real catalyst was ill-defined. To overcome this problem, Gibson et al. purified complex **171** before the reaction and characterized its structure. Utilizing this compound as a catalyst, a highly enantioselective PKR was realized.[113] Extensive studies to understand the further behavior of **171** to give putative $[Co_2(substrate)(BINAP)(CO)_4]$ complexes followed. Monitoring of the reaction pathway with ^{31}P NMR strongly suggested the occurrence of intermediate **173** in which the Co–Co bond was cleaved by the presence of the pendent alkene during the intramolecular reaction. However, the correlation between this mono cobalt-intermediate and the PK reactivity remained unclear (Figure 21).



(48)

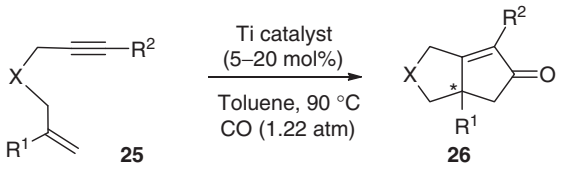
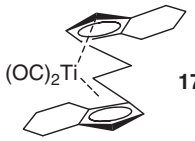
Figure 21 Chiral cobalt carbonyl catalysts modified with bisphosphane ligands.

In the meantime, the cationic chiral monocobalt catalyst [Co(*R*)-MeO-Biphep)$(CO)_3$]X (X = BF_4 or OTf) (**174**) was also reported, although it was found to be slightly less efficient.[114]

Buchwald and Sturla introduced a cobalt-catalyst carrying chiral phosphites (Figure 22).[115] Only modest *ee* values (64%–75%) were reported, however.

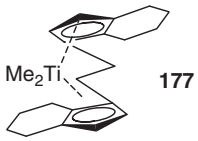




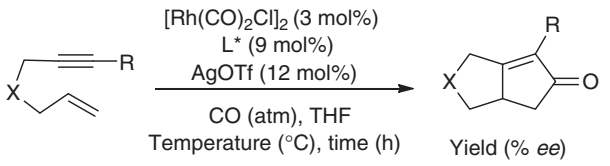
175

Figure 22 Chiral phosphite used for the preparation of a chiral cobalt carbonyl catalyst.

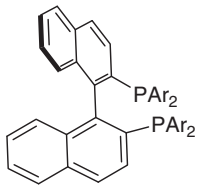
5.24.4.2.2 Based on metals other than cobalt



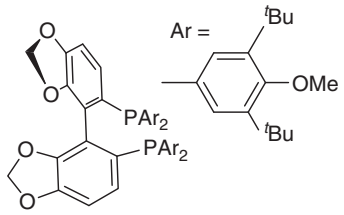
Buchwald and Hicks reported the first asymmetric PKR utilizing a catalytic amount of a chiral titanocene complex. The titanium catalyst (*S*,*S*)-(EBTHI)Ti(CO)$_2$ (**176**) obtained *in situ* from (*S*,*S*)-(EBTHI)TiMe$_2$ (**177**) and CO was efficient for the enantioselective PKR.[116] Not only the *N*-tethered enyne but also *C*- and *O*-tethered substrates provided the corresponding cyclopentenones **26** in excellent yield and enantioselectivity (equation 49).



(49)



X	R^1	R^2	Yield (%)	*ee* (%)
O	H	Ph	96	85
CH_2	H	Ph	87	70
$C(CO_2Et)_2$	H	Ph	94	92
$C(CO_2Et)_2$	Me	Me	72	90



Following the successful application of a rhodium(I) catalyst bearing tunable bidentate phosphine ligands such as dppp, Jeong et al. performed the first rhodium-based enantioselective PK reaction.[117a] Initial results were somewhat unsatisfactory because a high *ee* was obtained only in the case of *O*-tethered substrates. Furthermore, such high *ee* values were often obtained at the expense of the chemical yield.[117b]

Extensive optimization was subsequently performed along with the elucidation of the reaction mechanism for the purpose of clarifying some of the fundamental features. For example, the CO concentration must be kept as low as possible in order for the transformation to be efficient.[117c] The higher enantioselectivity obtained for *O*-tethered substrates than for other congeners is explained by the prechelation by the oxygen atom in the substrate to rhodium in the transition state (**Scheme 16**).[117d] In subsequent years, two notable optimizations were reported. First, the reaction induced by the catalyst obtained from 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP) bearing bulky phosphorus substituents, especially 3,5-*xylyl*-BINAP (**178**),

Ar = Ph **(170)**

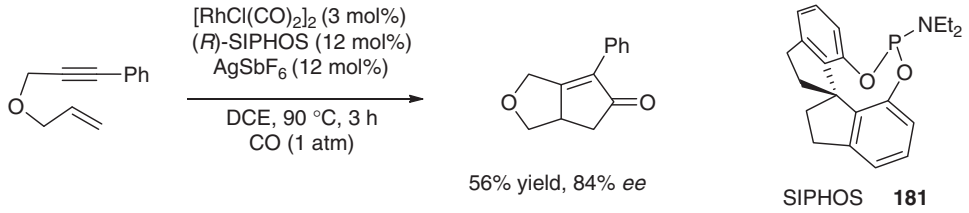
Scheme 16

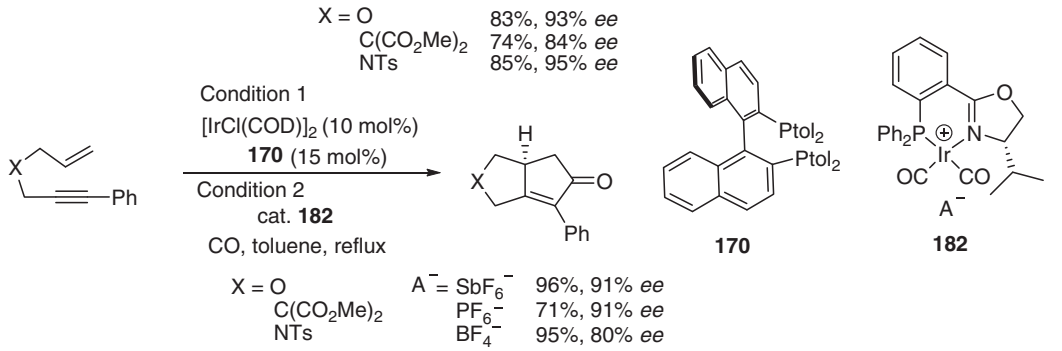
proceeded at ambient temperature, affording much improved enantioselectivities under reduced CO pressure (10% CO in argon at atmospheric pressure).[117c] However, there is still a trade-off between the chemical yield and stereoselectivity for some substrates.



Second, the reaction by catalysts bearing a highly sterically demanding ligand, DTBM–MeO–BIPHEP (**179**), under reduced pressure of CO, but at high temperature, provided the PKR products in higher yields as well as enantioselectivity for a wide range of substrates. Pleasantly, the side product formation is significantly suppressed under this condition.[117f]

Many modifications of the original protocol appeared in the literature in the following years. A molecular sieve CO reservoir was also used as a CO source in place of a CO balloon. With this modification, the reaction temperature was lowered significantly to 0 °C. However, a low concentration of CO often led to a low chemical yield of the PKR product, even after the complete conversion of the starting materials (equation 50).[118]

(50)

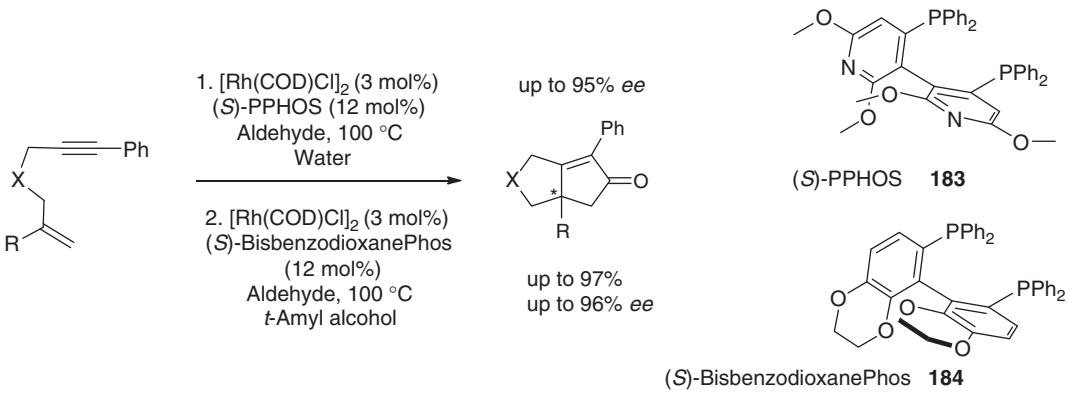


The monodentate phosphoramidite SIPHOS ligand (**181**) was employed to afford the PKR product in dichloromethane with a decent chemical yield and good enantioselectivity (equation 51).[119]

(51)

Following the success with cobalt and rhodium, Ir(I)-based enantioselective catalytic PKRs were attempted. Right after the observation of the catalytic activity of $[IrCl(cod)]_2$ in the PKR in the presence of phosphane ligands, Shibata moved directly to the use of chiral tol-BINAP and examined the enantioselectivity.[120a] The TON and TOF of the reaction were low and the number of examples was limited; however, a high efficiency was observed in terms of the enantioselectivity. Moreover, this catalytic system provided the first asymmetric intermolecular reaction as well.

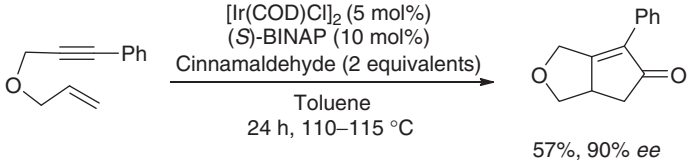
Subsequently, Pfaltz and coworkers utilized the catalyst **182**. Excellent *ee*'s for a wide range of substrates were realized, especially in the case of oxygen and malonate tethered 1,6-enynes (equation 52).[120b]



(52)

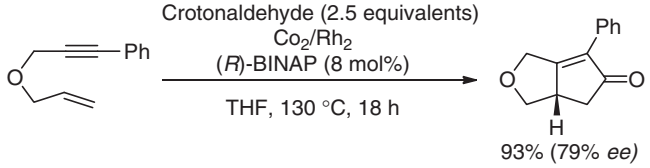
Asymmetric catalytic versions with Rh(I) using other CO sources have also been reported. Kakiuchi, Morimoto, and Shibata used a neutral rhodium(I) complex bearing chiral ligands together with aldehydes as the CO source. These reactions were comparable to the conventional PKR carried out with cationic Rh(I) under CO pressure in terms of their enantioselectivities and chemical yields.[121] Since this condition used a neutral Rh(I) catalyst, it proved useful in reactions of acid-sensitive substrates (e.g., the acetal-carrying alkyne **193** shown later in equation 58).[122]

Polar protic solvents such as water and alcohols can also be used for these reactions if a solubilizing additive is present. Kakiuchi developed the asymmetric PKR in water using formaldehyde as a water soluble CO source and BINAP-based chiral ligands, after solubilizing them using a surfactant. They were able to obtain evenly high enantioselectivities over a broad range of substrates.[89b]



The use of a surfactant can be omitted if the solubility of the ligands in a polar protic solvent is guaranteed. This is the case for catalysts obtained using PPhos and its analogs. Neutral Rh(I) catalysts coupled with PPhos (**183**) or bisbenzodioxane-Phos (**184**)

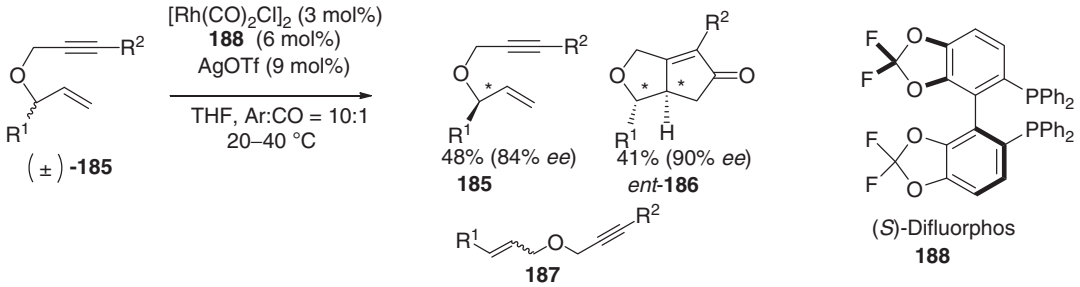
turned out to be efficient catalysts in water and *t*-amyl alcohol, respectively (equation 53). Reactions with the latter are further expedited by microwave radiation.[123]



(53)

The iridium catalyst obtained from $[Ir(COD)Cl]_2$ and (*S*)-BINAP (**170**) is also useful for the enantioselective PKR with aldehydes as the CO source, providing a modest yield (57%) but excellent enantioselectivity (90% *ee*) (equation 54). A linear correlation between the *ee* of the ligand and that of the product was confirmed in this specific reaction.[124]

(54)

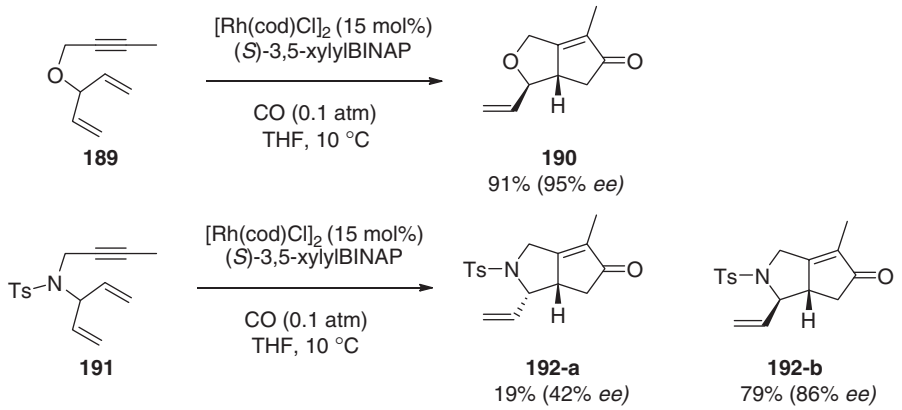


An interesting catalyst, obtained by the adsorption of the chiral ligand BINAP (**170**) on heterogeneous Co_2/Rh_2 particles, is also effective for the enantioselective PKR in the presence of crotonaldehyde (equation 55).[125]

(55)

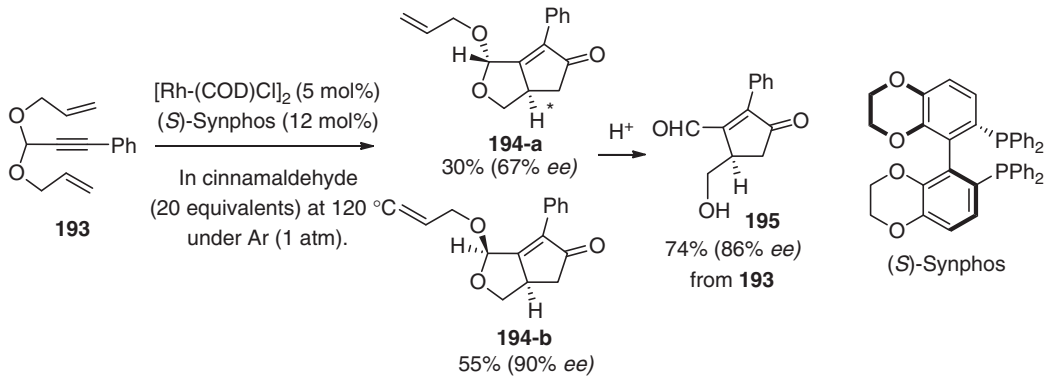
5.24.4.2.2.1 Application of enantioselective PKR

The kinetic resolution of **185** was realized, although its successful application is limited to R^2 = aryl. It is important to identify the right ligand to suppress the transition metal mediated allylic rearrangement. In this regard, ligand **188**, whose dihedral angle in the corresponding metal complex is smaller than that of BINAP derivatives and for which phosphorus is significantly deshielded, provides a good compromise in terms of the chemical yield and enantioselectivity at ambient temperature (equation 56).[126]



(56)

The desymmetrization of prochiral compounds is more attractive than a kinetic resolution because of the intrinsic problem of the latter that the maximum yield is 50%.

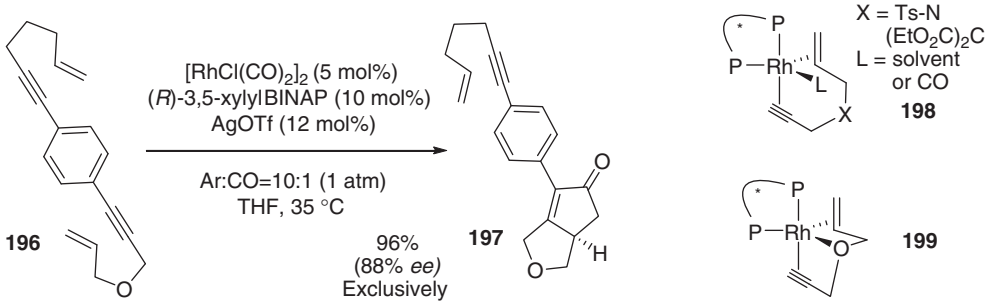


In the desymmetrization of the dienynes **189** and **191** by the asymmetric Rh(I)-based PK-type reaction, the corresponding vinyl-substituted bicyclo[3.3.0]octenones **190** and **192** were obtained with high diastereoselectivity and enantioselectivity,

respectively (equation 57).[117e,127] The interesting observation of the reversal of the diastereoselectivity, depending on the nature of the tether, is rationalized by the precoordination by the heteroatom.[117d]

(57)

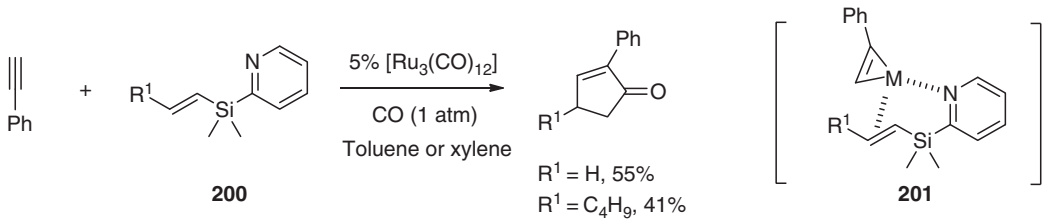
The desymmetrization of bisallyl propargyl acetals **193** was accomplished by using a neutral Rh(I) catalyst together with cinnamaldehyde as the CO source. The use of a cationic Rh(I) catalyst was detrimental to this acid-sensitive substrate (equation 58).[122]



(58)

5.24.4.2.2.2 Chelation-guided reaction

When Rh(I) cationic catalysts are used, the reaction efficiency is significantly dependent on the nature of the tether. Substrates bearing an *O*-tether were superior to their congeners in terms of the reaction rate, chemical yield, and stereoselectivity when subjected to the asymmetric PKR utilizing a cationic rhodium catalyst. This special effect is accounted for by the prechelation of the oxygen atom to the metal center. The chelated precursor **199** allows the facile assembly of each reaction component and has a rigid conformation that results in high enantioselectivity.

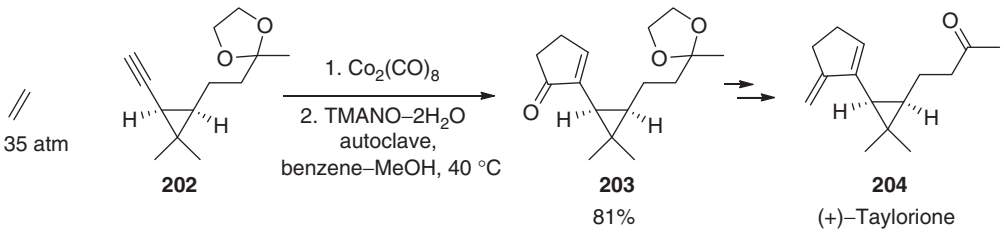


As shown in the competition experiment with **196**, only the *O*-tethered side chain reacted to give product **197** exclusively (equation 59).[117d]

(59)

The importance of chelation during the PKR was demonstrated by the case given in equation 60. Itami and Yoshida reported an elegant surrogate for terminal olefins, dimethyl(2′pyridyl)-vinylsilane (**200**) (equation 60). Since the reaction proceeds through the precomplexation of Ru with the pyridine moiety, the outcome is regioselective to provide the products with the R_1

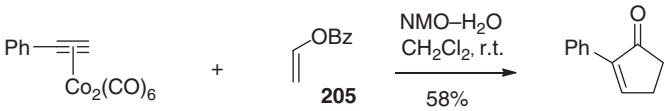
located at the β-position from the carbonyl. This approach allows the products to be obtained from any terminal olefins with well-defined regiochemistry.[128]



(60)

5.24.5 Some Special Features

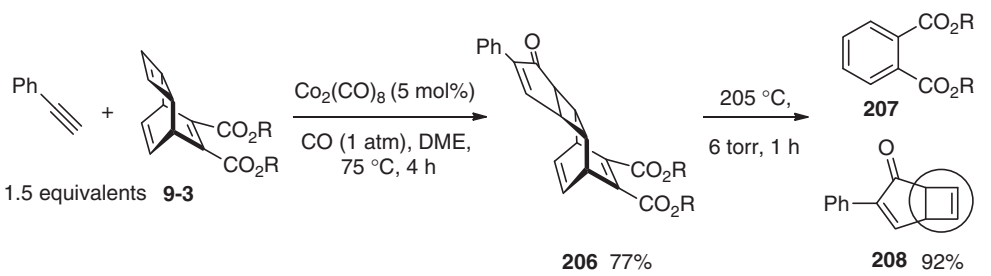
5.24.5.1 Substrate Scope



5.24.5.1.1 Ethylene

As we already discussed in Section 5.24.1.1, ethylene is generally a poor substrate for the PKR. Some special treatments are required to utilize ethylene efficiently, as described earlier. For some more examples, Kerr enforced the reaction of **202** by using more of TMANO hydrate in the presence of ethylene under pressure (35 atm) to give **203**, which served as an intermediate for the synthesis of (+) – taylorione **204** (equation 61).[129]

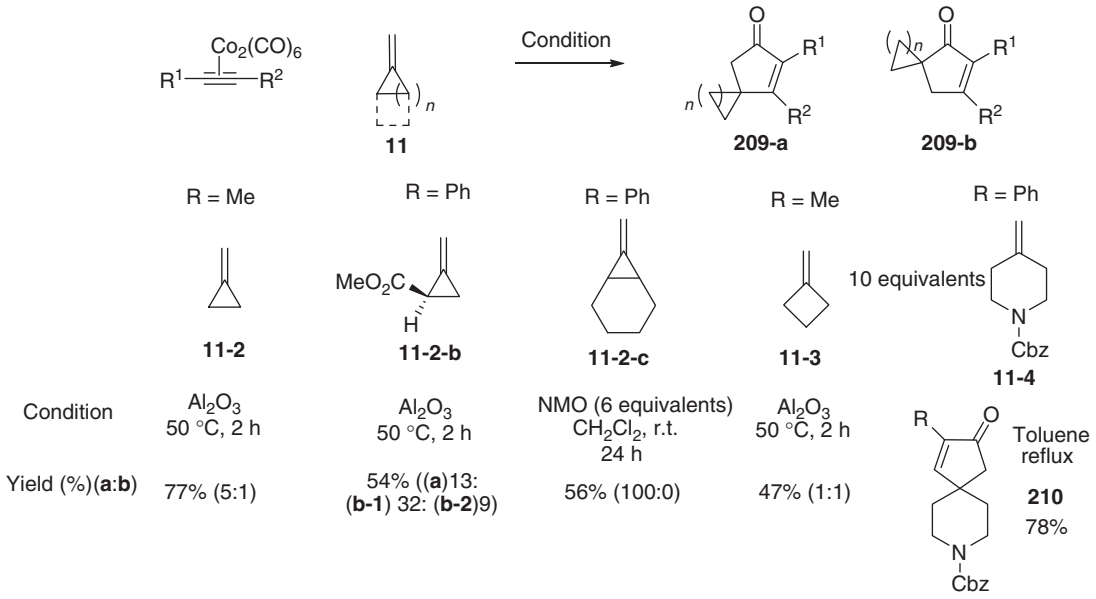
(61)



In addition, a couple of ethylene surrogates were reported. Dimethyl(2′-pyridyl)-vinylsilane (**200**) mentioned above is one of them, and the vinyl ester **205** is another. Kerr and Pauson successfully employed **205** as an ethylene substitute, and its reaction with the alkyne–dicobalt carbonyl complex (**2**) gave the desired product at ambient pressure and temperature (equation 62).[130]

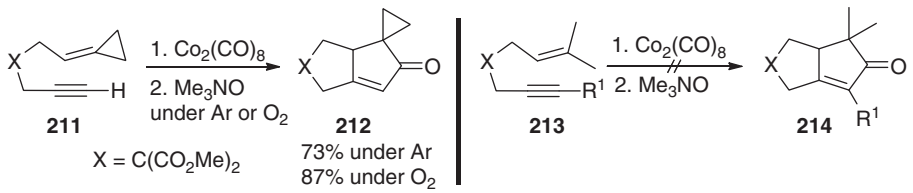
(62)

5.24.5.1.2 Cyclobutadiene



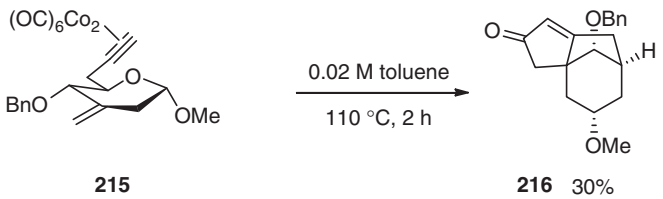
Gibson et al. introduced a well-designed latent cyclobutadiene moiety **9-3**, which reacted with a phenylethyne–cobalt complex (**2-1**) to yield **206**. The PKR took place at the sterically less hindered site to give **206** as a single stereoisomer (equation 63). This product was further subjected to a retro-Diels–Alder reaction at 205 °C under 6 Torr to give **208**.[10]

(63)



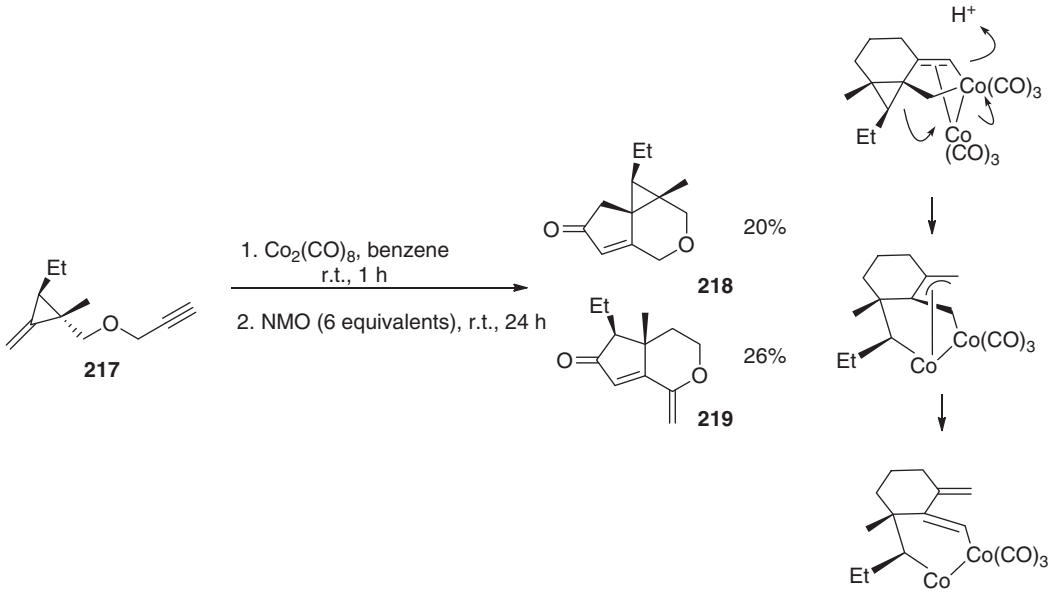
5.24.5.1.3 Exocyclic olefins

When we discussed the substrate scope of the PKR, the reactions of exocyclic olefins, especially those with a small size ring were considered, illustrating the excellent reactivity of highly strained olefins (Section 5.24.1.1). Following the first example of the intermolecular PKR with *exo*-methylenecyclopropane **11-2** reported by Smit with the aid of a solid support,[13] several more examples were reported in the literature (Scheme 17). Summarizing them roughly, usually greater than **11** was reacted with dicobalthexacarbonyl–alkyne complexes (**2**) adsorbed on silica to provide the corresponding PKR products **209** in fair to good yields. The regioselectivity of this reaction was found to be dependent on the nature of the alkynes. With terminal alkyne **1**, the methylenecyclopropanes **11-2** and **11-2-c** provided the corresponding compounds **209-a** as major products, whereas the cyclopropane substrates **11-2-b** bearing carboxylates afforded an isomeric cyclopentenone **209-b** as the major product.[131] Methylenecyclobutane (**11-3**) gave rise to a nearly 1:1 mixture of **209**.[13]



Scheme 17

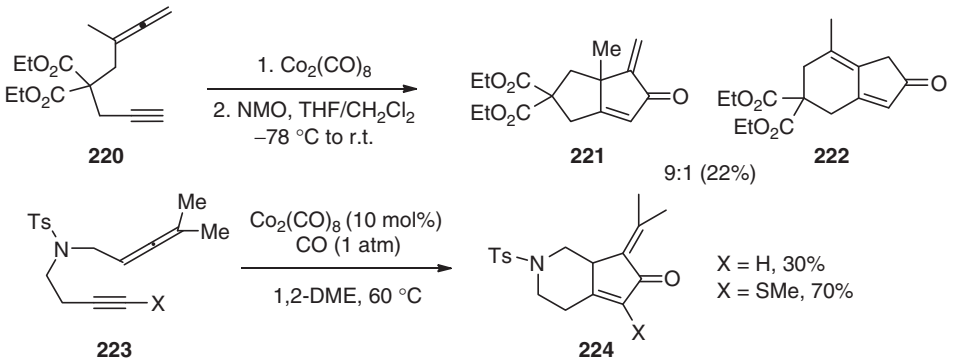
The intramolecular PKRs of substrates bearing an alkylidenecyclopropane moiety were reported as well. The strain on the olefin is critical to their success. Thus, substrates **211** bearing a cyclopropyl ring on the alkenyl group (tri- and even tetra-substituted) reacted smoothly, affording the corresponding PKR products **212** in moderate to high yield.[132] However, the non-strained olefin **213** bearing a 1,1-dimethylolefin unit did not undergo the cyclization under the same reaction conditions (equation 64).[132]



(64)

In analogy to the exocyclic olefin **11-4** with a six-membered ring, where the PKR took place smoothly, substrate **215** underwent the PKR nicely to yield the bicyclic[4.1.0] compound **216**, although the chemical yield was low (equation 65).[132]

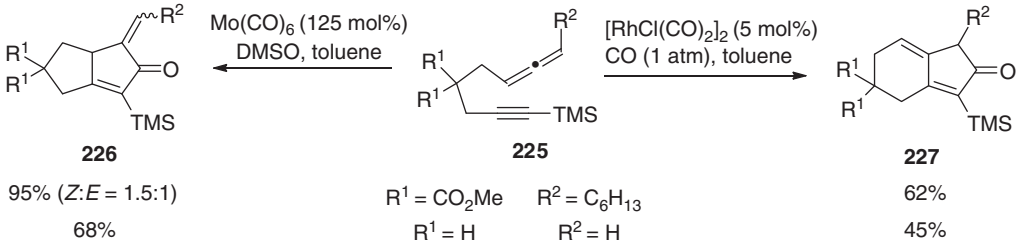
(65)



An unusual rearrangement accompanying the intramolecular PKR of substrate **217** was reported by Motherwell. When the reaction was carried out at room temperature, an unusual product **219**, in which none of the carbon atoms of the alkyne were incorporated in the cyclopentenone ring, was obtained as the major product through rearrangement, together with a small amount of the expected PKR product **218** (equation 66).[133]

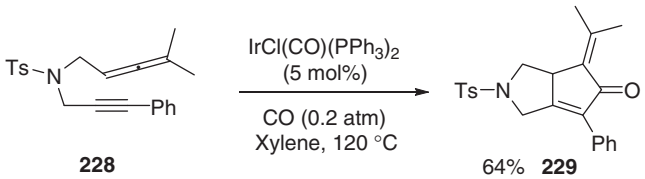
(66)

5.24.5.1.4 Allenic substrates



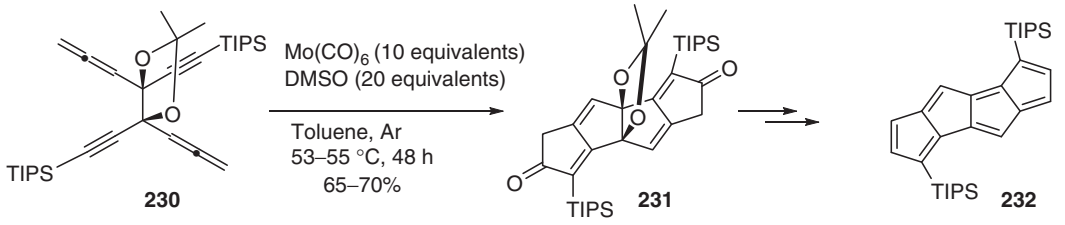
The PKR with some allenes have already been discussed. Benchmark substrates were used to demonstrate the unique features of the newly introduced reagents or catalysts. More examples are summarized here. Some earlier trials employing cobalt metal turned out to be frustrating and gave only limited success (equation 67).[134]

(67)



As previously mentioned, molybdenum carbonyl with DMSO[50] and rhodium complexes[79,80] were identified as excellent catalysts for the PKR of allenic substrates, which are complementary in terms of their regioselectivity.

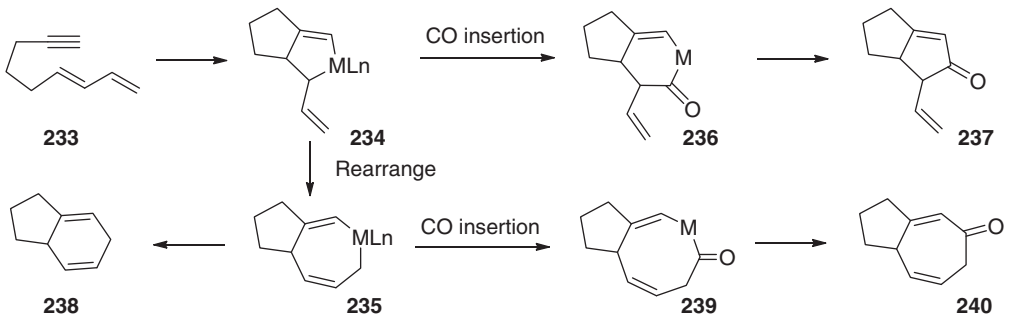
The molybdenum catalyst favored the formation of **226** from **225**, whereas rhodium gave product **227** (equation 68).[122] Although the internal olefin in the allene takes part in the reaction with molybdenum, as previously mentioned, the terminal olefin in the allene reacts with the rhodium catalyst to give a larger ring.[134]



(68)

Iridium was also found to catalyze the PKR through the same reaction, and behaved more like molybdenum in terms of the regioselectivity (equation 69).[135]

228 64% 229 (69)

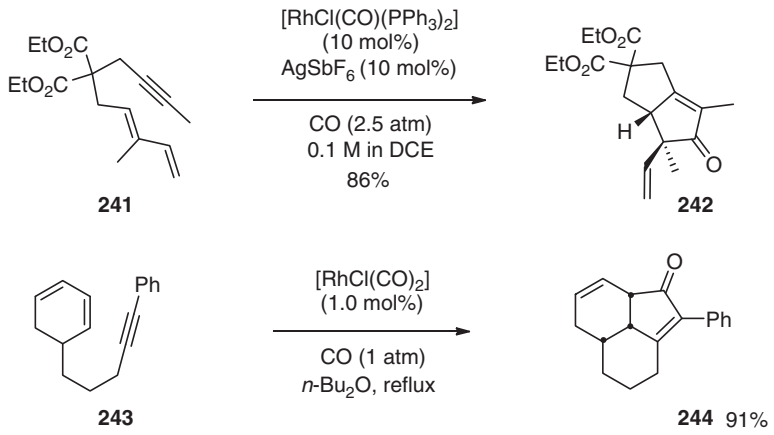


Cook and coworker took advantage of the molybdenum-based methodology and reported one of the most graceful applications of the allenic PKR. They intended to use the PKR reaction to synthesize a theoretically interesting tertracyclic compound **232**, which has 14 π-electrons and is expected to be aromatic in principle. To this end, they applied the PK reaction to various alkynyl allenes and finally employed the diyn-diallene substrate **230** successfully. The double PKR employing molybdenum hexacarbonyl and DMSO more afforded the requisite intermediate **231** in high yield (equation 70).[136]

230 231 232 (70)

5.24.5.1.5 1,3-Dienes and ene-vinylcyclopropane

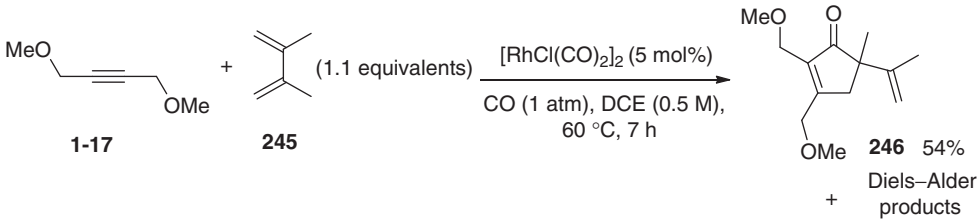
The PK reaction with 1,3-dienes **233** has many interesting features. First, there must be pathways that compete with the formation of the PK product **237**, leading to the Diels–Alder product **238** and to the homologous PKR product bicyclo[5.3.0]-decadienone **240** (Scheme 18).



233 234 236 237 238 235 239 240

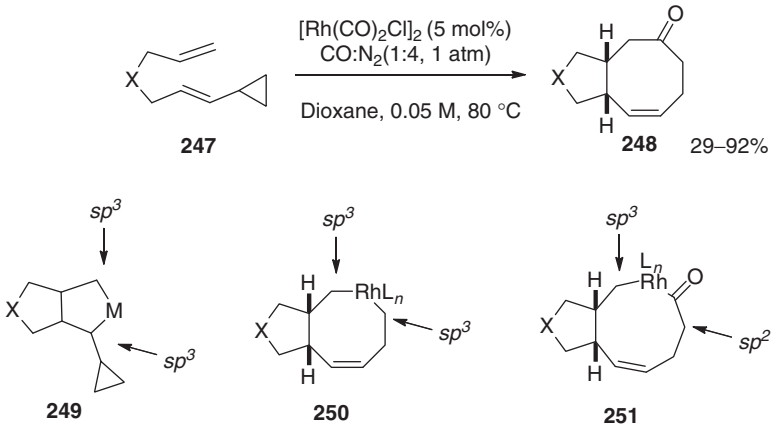
Scheme 18

In most studies with a sufficient amount of CO, the PKR product **237** was obtained as a major product with the bicyclo[5.3.0]-decadienone **240** as minor product. Because the insertion of CO into **234**, followed by the reductive elimination of the sp^2-hybridized C-atoms of the olefin and carbonyl in **236**, is much more facile than the rearrangement of **234**-**235**, the reaction provided **237** predominantly.



Wender et al. focused their attention on the selectivity of the reaction with the dienynes related to **233** using rhodium catalysts. Disubstituted alkynes gave excellent yields of the PK products, whereas terminal alkynes react less efficiently. Substituents at the 2- and 3-positions of the diene moiety did not slow down the reaction. The stereochemistry of the alkenes are well transferred during the transformation (equation 71).[137]

Yeh et al. employed the conformationally rigid dienes **243** and successfully obtained the PKR products in high yields.[138]

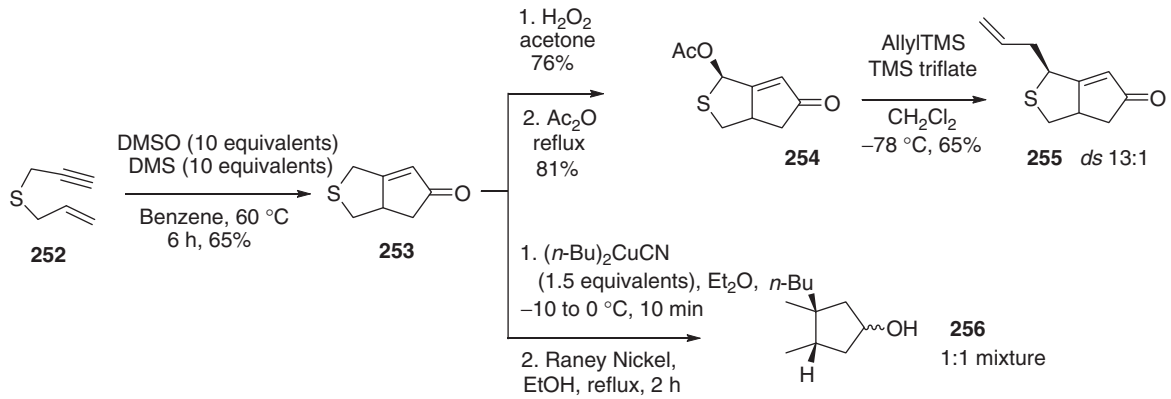


(71)

Later, Wender et al. showed that an intermolecular reaction with the disubstituted alkynes **1-17** and 2,3-dimethylbutadiene (**245**) provided the PKR products in high yields under similar conditions (equation 72).[139]

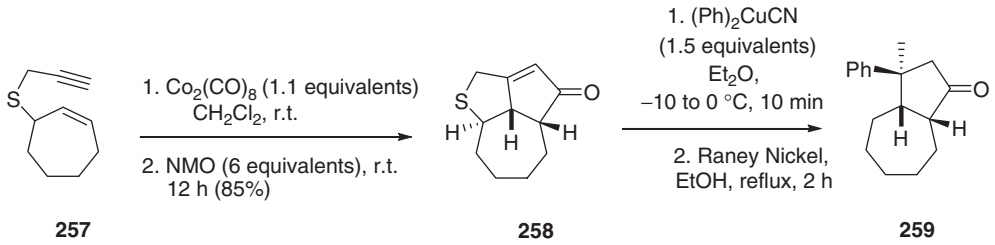
(72)

Controlling the rate of reductive elimination by changing the hybridization of the carbon atom and introducing strain into the ring allowed bicyclo[6.3.0]-nonadecadienones to be obtained. The product **248** was formed from **247** under similar conditions.[140] Since the reductive elimination of sp^3C-sp^3 C-atoms is much slower, in contrast to the case of **236**, **249** underwent the rearrangement to give **250** with the release of the strain of the cyclopropyl group. Even though **250** was formed, the reductive elimination between the two sp^3C-sp^3 centers is still slow and, thus, the intermediate **250** was intercepted by CO insertion to form **251**. Once **251** was formed, the faster reductive elimination between the sp^3C and sp^2-hybridized C-atoms occurred (equation 73).[140]



(73)

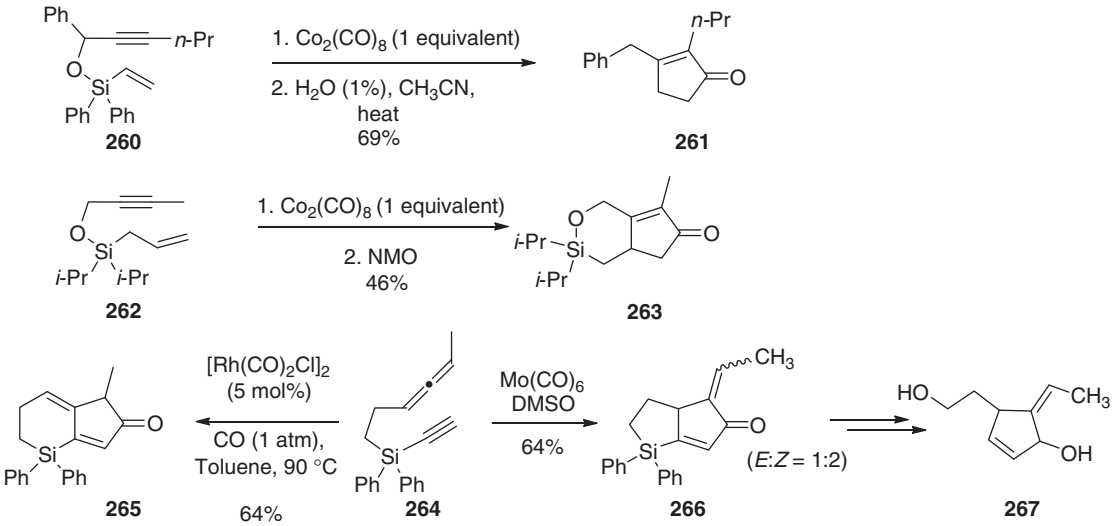
5.24.5.1.6 Substrates having removable tethers



The application of the intermolecular PKR is still largely restricted because of its lack of regioselectivity, especially in the preparation of monocyclic compounds. A detour to make such monocyclic products in high yield with high regioselectivity is necessary, using substrates bearing a removable functional group to take advantage of the regiocontrol of the intramolecular reaction.

Pericas and Jeong independently demonstrated that the sulfur-tethered substrate **252**, when subjected to PKR conditions, afforded the bicyclic product **253**. Then the sulfur tether is removed cleanly by desulfurization with Raney nickel in the presence of hydrogen after all the necessary transformations. Another example uses the Pummerer reaction after the oxidation of sulfur to

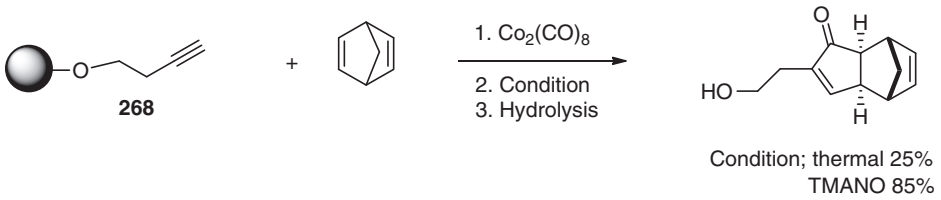
sulfoxide to give **254**, which was further subjected to Lewis acid catalysed allylation to furnish **255**. Alternatively, the 1,4-addition to either **253** or **258** with dialkyl-cuprate followed by hydrogenolysis gave rise to **256** or **259**, respectively. It is worth mentioning that the regioselectivity regarding the acetylene part is opposite to that of the intermolecular version (equation 74).[141]



(74)

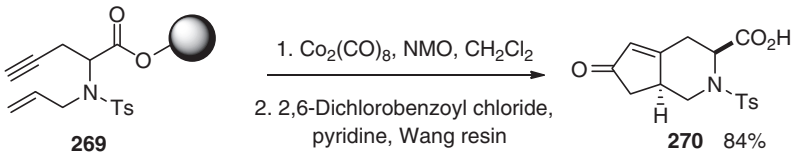
The use of a silicon atom as a removable tether was envisioned earlier. Since the projected silicon-containing PK products could be functionalized in various ways, such as protodesilylation and Tamao–Fleming oxidation, much effort has been directed to perform the PKR of silicon-tethered substrates (equation 75). However, the outcome in the beginning was far from expected.[142]

Upon optimization of this particular PKR, propargyl vinylsilyl ether **260** always afforded the monocyclic products **261** after the loss of a silicon atom. The yield was moderate, possibly due to the formation of a presumed hydridocobalt species. However, Pagenkopf intensively optimized this transformation and found that a small amount of water substantially improved the yield.[142b,c] Subsequently, the PKR product was obtained when iPr groups were present on the Si atom. However, this reaction is still erratic and gives a very low yield for a limited number of substrates.[142d]



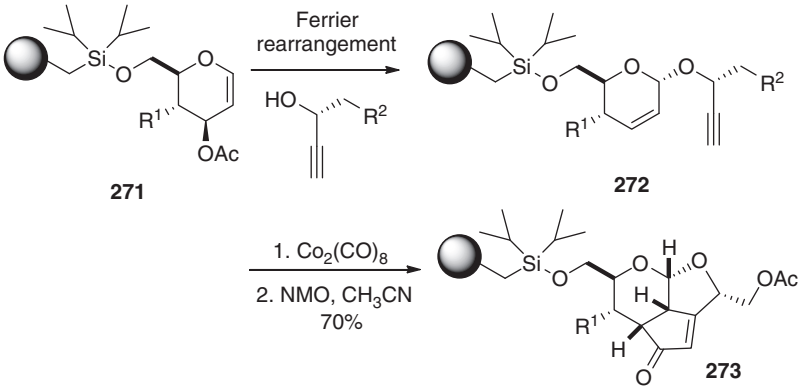
Brummond reported that the silicon-bound products **265** could be obtained from the (allenylethyl)alkynylsilane **264**. Either molybdenum/DMSO or rhodium(I) catalysts afforded the desired products, but the regioselectivity was dependent on the catalyst used. This trend is in line with the dependence of the regioselectivity on the chosen catalysts mentioned previously.[143]

(75)



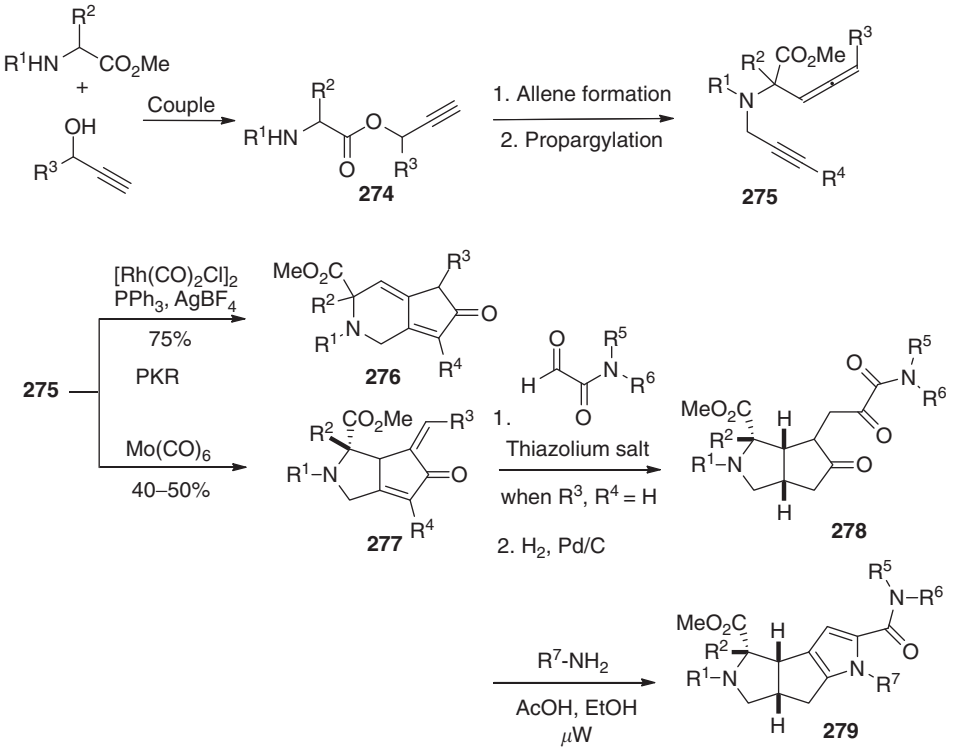
5.24.5.1.7 Substrates on solid support and chemical libraries

The PK reaction with substrates attached to a solid support was first reported by Schore and Kurth to improve the chemical yield of an intermolecular reaction with low-molecular weight alkynol and norbornadienes. An alkynol anchored on silica gel was reacted with norbornadiene and high chemical yield of the PK product was obtained after cleavage from the solid support (equation 76).[144]



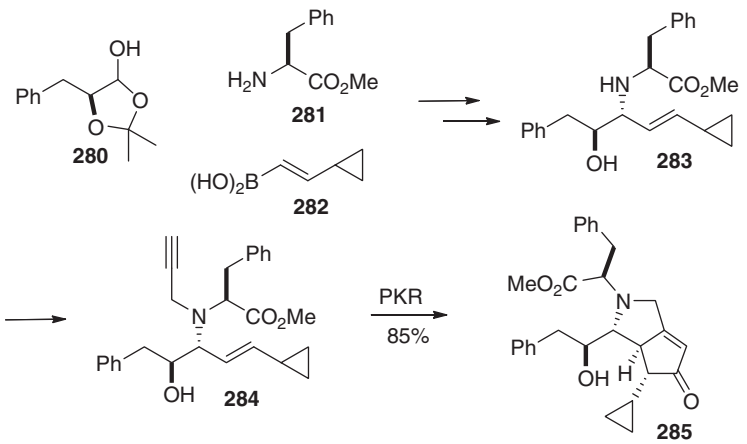
(76)

Later, Bolton extended this approach to an intramolecular reaction to form the bicyclic α-amino acids **270** (equation 77).[145]



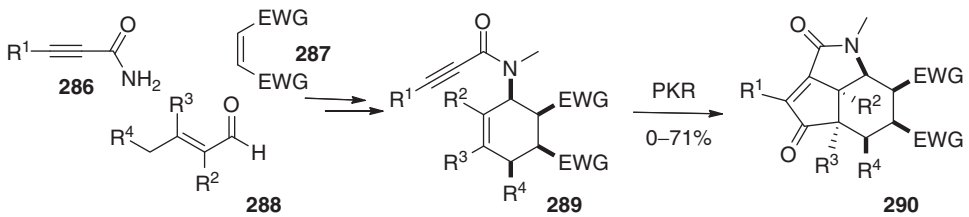
(77)

This approach paved the way to the synthesis of chemical libraries.[146] Schreiber and coworkers showed that this approach is useful for the preparation of compound libraries. One of their examples is the diversity-oriented synthesis of polycyclic scaffolds **273** from a glycal template **271** on solid support by the Ferrier reaction followed by the PKR (equation 78).[147]



(78)

The solution-phase synthesis of discovery libraries was also reported. Brummond prepared a library consisting of tricyclic pyrrole-2-carboxamides (**279**) by applying the PKR, Stetter, and Paal–Knorr reactions sequentially (equation 79).[148]

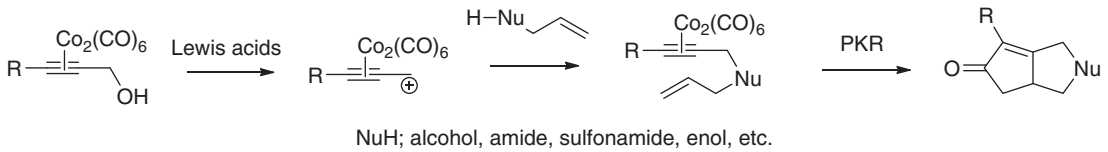


(79)

The Petatis condensation of three components, namely, boronic acids, lactol, and ester-protected amino acids, yielded new *β*-amino alcohols, some of which were subjected to the PKR after propargylation at the *N* atom (equation 80).[149]

(80)

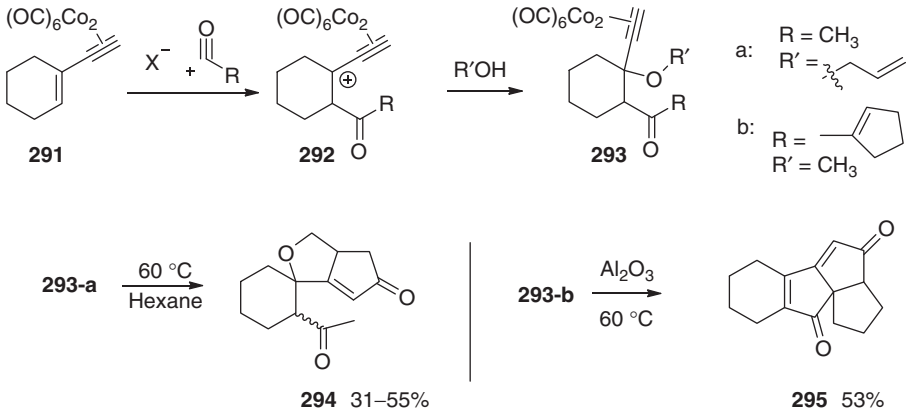
Beller and coworkers used the multicomponent coupling of the aldehyde **288**, amide **286**, and dienophile **287**;[150] the resultant enynes **289** were subjected to the PKR. Some other examples have already been reviewed (equation 81).[147]



(81)

5.24.5.2 Tandem Approaches Coupled with Other Reactions

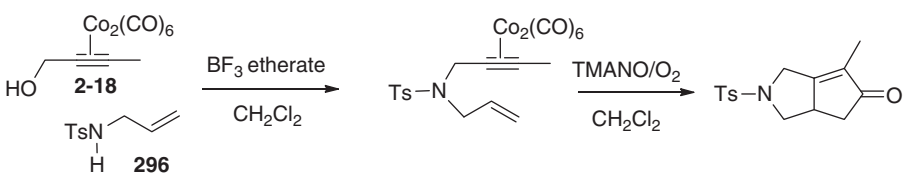
Tandem reactions have attracted much interest in recent years, because they allow multiple transformations to be performed in one operation. All of the reports can be classified into two categories: sequential reactions, in which the additional reagents are added or changes of the conditions are required, and single operations with all ingredients in one pot to effect at least more than two transformations.



5.24.5.2.1 PKR coupled with the Nicholas reaction

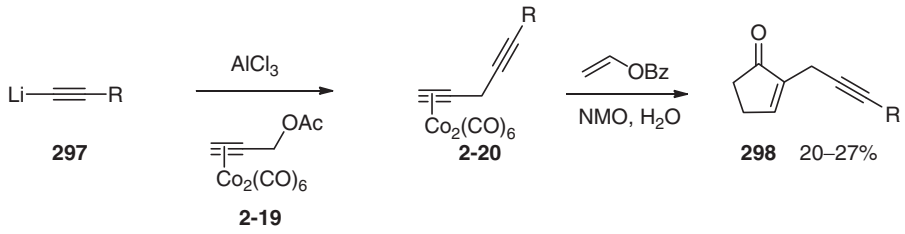
The most popular approach is a combination of the Nicholas reaction and the PKR.[151] Properly functionalized 1,6- or 1,7-enynes for the PKR are readily obtained from propargyl alcohol–dicobalt hexacarbonyl complexes and an allylic and/or homoallylic nucleophile in the presence of a Lewis acid. The resultant enynes are usually subjected to the promoter-assisted PKR without purification to afford the desired PKR products (Scheme 19).[140]

Scheme 19



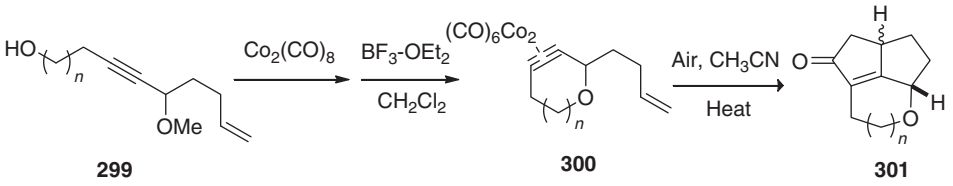
Smit prepared the Nicholas reaction precursor **292-a** by treating a conjugated enyne-dicobalt hexacarbonyl complex **291** with an acylium species. The resultant propargylic cation intermediate was then trapped with an allylic alcohol to give the enyne **293-a**. The PKR of **293-a** gave rise to the PK product **294** (Scheme 20).[29b,152]

Scheme 20



Subsequently, the same group used an olefin-conjugated acylium species to yield **292-b**, and the Nicholas precursor was trapped with methanol. Compound **293-b** was subjected to the PK condition to yield the tetracyclic compound **294-b**.

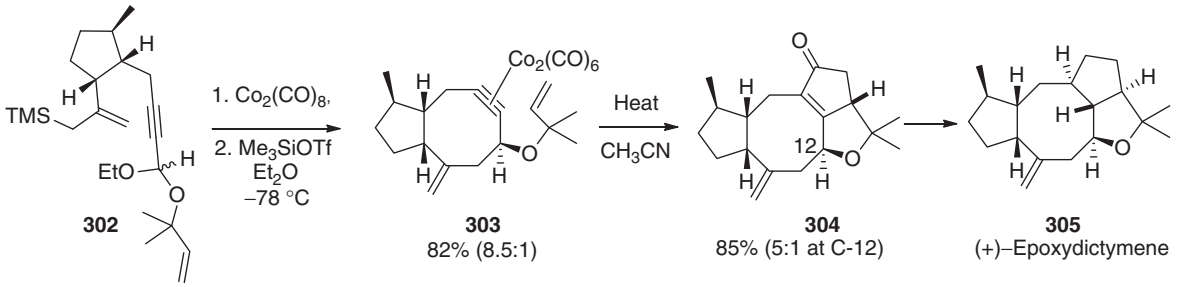
Cobalt carbonyl–propargyl alcohol derivatives are more popular precursors for the Nicholas reaction. In their first report, Jeong et al. reported that compound **2-18** was subjected to the Nicholas reaction by a Lewis acid in the presence of an allylamide nucleophile **296**. The resultant *N*-tosyl allyl propyne was transformed into the PK product without purification with the aid of an amine *N*-oxide promoter (equation 82).[153a]



(82)

The regioselectively metal-coordinated dialkyne complex **2-20** was obtained by taking advantage of the Nicholas reaction and used for the intermolecular PKR to obtain **298** (equation 83).[154]

(83)

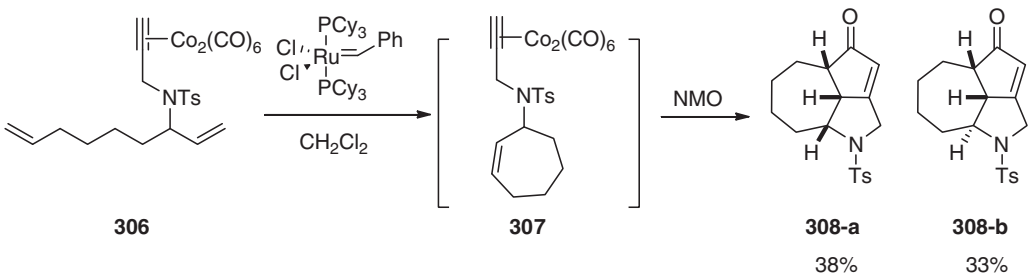


The intramolecular Nicholas reaction followed by the PKR exhibited its synthetic utility as well. Shea and coworkers prepared complex **300** from substrate **299** in the presence of boron trifluoride, which was further subjected to the PKR condition without purification. The tricyclic compound **301** was obtained in high yield (equation 84).[155]

(84)

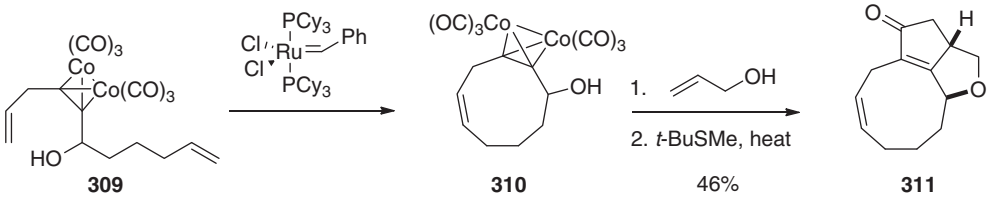
n = 1, 3% (from **299**), *cis*:*trans* = 66:34
n = 2, 63%, *cis*:*trans* = 37:63
n = 3, 86%, *cis*:*trans* = 55:45

Schreiber and coworkers provide one of the most stylish examples of this approach. The successful synthesis of (+) – epoxydictymene (**305**) relied on the selective activation of an ethyloxy group in the mixed acetal **302** by the Nicholas reaction (selectivity 8:1) followed by a stereoselective PKR (equation 85).[156]



(85)

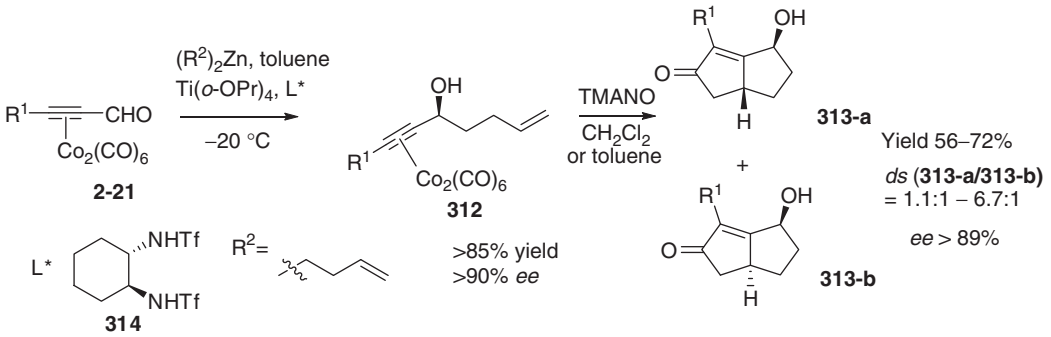
More examples in this line can be found in the reports of Carbery et al.[157]



5.24.5.2.2 PKR coupled with RCM

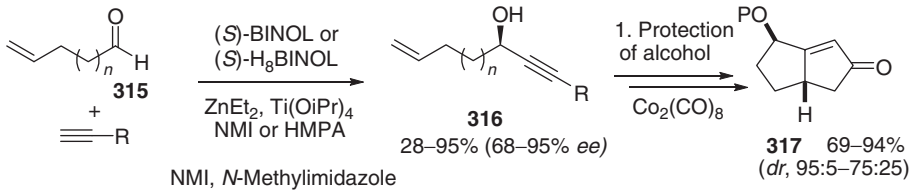
There are several examples utilizing a combination of ring-closing metathesis (RCM) and the PKR. Perez-Castells and coworkers combined RCM and the PKR for the synthesis of tricyclic compounds in one batch. In this approach, the Grubbs catalyst first mediated the RCM of **306**, bearing an alkyne–cobalt carbonyl complexed side chain as an alkyne protecting group for the metathesis stage to give the cobalt complex **307**, which was used directly as a PKR precursor in the next stage, affording **308** (equation 86).[158]

(86)



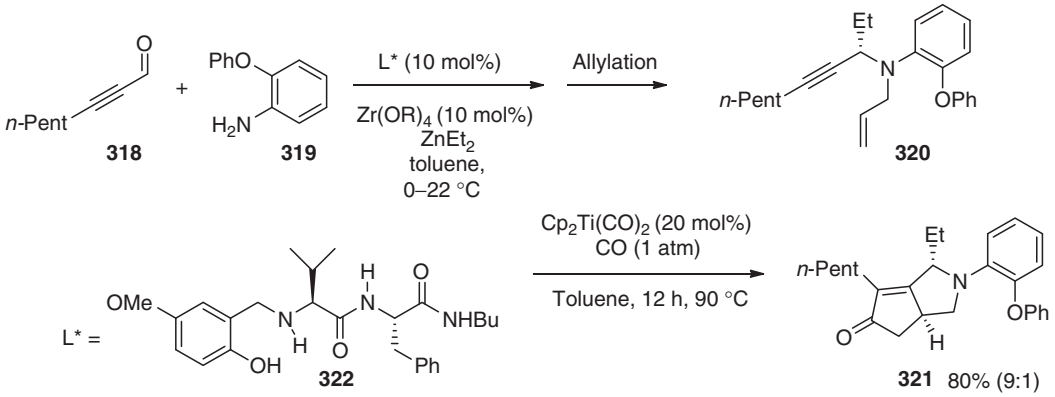
A sequence consisting of a combination of RCM and the Nicholas reaction followed by the PKR was successfully employed by Young et al. to form compound **311** (equation 87).[159]

(87)



5.24.5.2.3 PKR coupled with carbonyl addition of one component of the resultant enynes

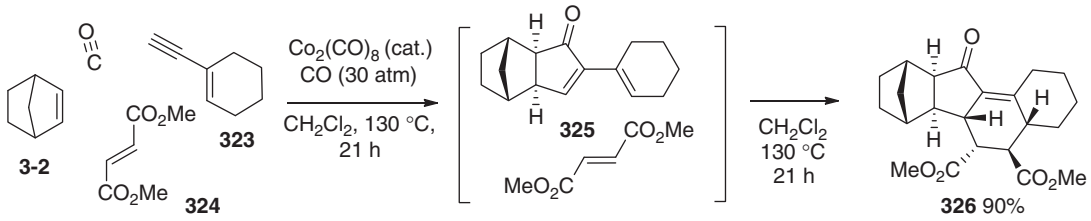
Jeong et al. utilized a cobalt–alkyne complex **2-21** to increase the enantioselectivity of the addition of bis(homoallyl)zinc to propargyl aldehydes by enhancing the steric environment. The reaction provided the optically enriched propargyl alcohol **312** in the presence of a chiral ligand and titanium tetra(isopropoxide) more. The adduct **312** was subjected to the PKR to yield the optically enriched bicyclic compounds **313** (equation 88).[160]



(88)

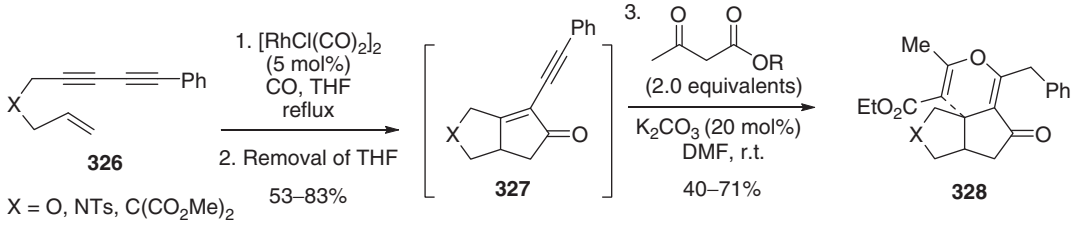
In contrast, the strategy utilizing the enantioselective addition of a terminal alkyne to the carbonyl **315** followed by the PKR was also reported (equation 89).[161] This example and the following one cannot be classified as a tandem reaction in one pot, but it is worthwhile discussing them also in this section.

(89)



An imine can be used as a substitute for the carbonyl group. The enantioselective addition of diethyl zinc to the imine species in the presence of the chiral ligand **322**, formed from the propynal **318** and aniline **319**, provided the amine compound **320** in high enantioselectivity, which was subjected to the PKR in the presence of a Ti(II) catalyst to give product **321** in high diastereoselectivity (equation 90).[162]

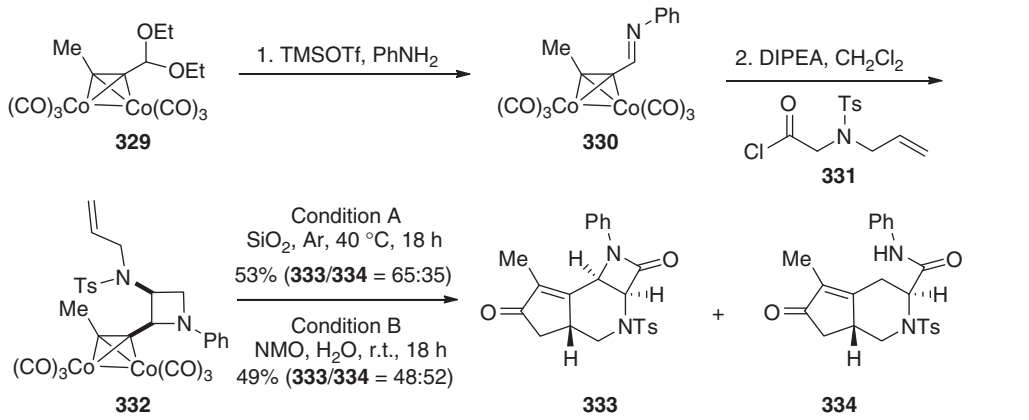
(90)



5.24.5.2.4 PKR coupled with post modifications

The PKR between compounds **3-2** and **323** proceeded to yield the diene intermediate **325**, which underwent the Diels–Alder reaction with the fumarate **324** to afford the tetracyclic compound **326** (equation 91).[163] To this end, a mixture of all components was heated in the presence of a catalytic amount of dicobalt octacarbonyl under a high pressure of CO.

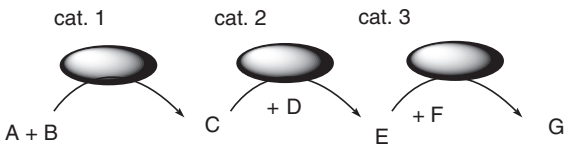
(91)



The PKR of substrate **326** catalyzed by a rhodium complex yielded the α-alkynyl enone **327**, which underwent a Michael addition of β-ketoesters to give product **328** (equation 92).[164]

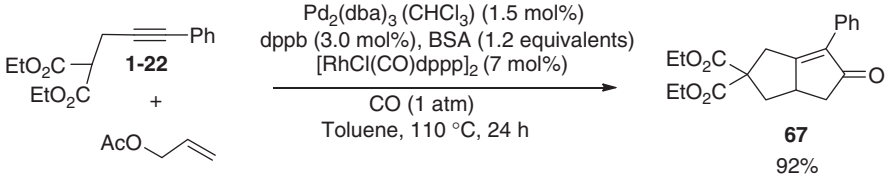
(92)

5.24.5.2.5 PKR coupled with a Staudinger reaction



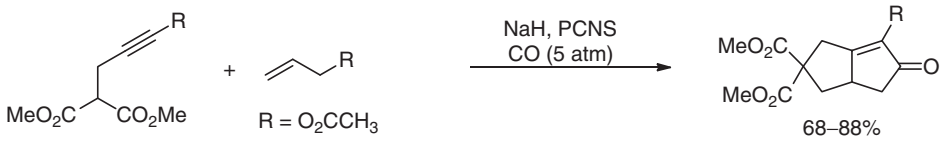
Dicobalt hexacarbonyl complexes of alkynyl imines, which were obtained *in situ* from the corresponding acetal and amines in the presence of a Lewis acid, underwent the Staudinger reaction with the ketene derived from **331**, providing the intermediate **332**. Then the PKR of **332** was performed without purification to afford the tricyclic compound **333** as the major product together with the bicyclic product **334** (equation 93).[165]

(93)



5.24.5.2.6 Mimic of multi enzymatic systems

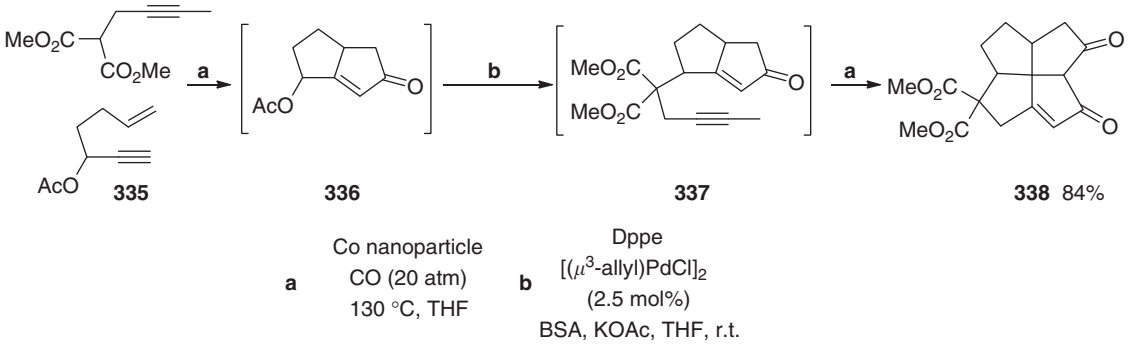
The most desirable tandem process is a mimic of the multi-enzymatic process in a cell, in which most of the metabolites are synthesized by a programmed sequence of enzymes with high specificity for the substrates, although many other potential intermediates are around the reacting enzymes (Scheme 21).[166]



Scheme 21

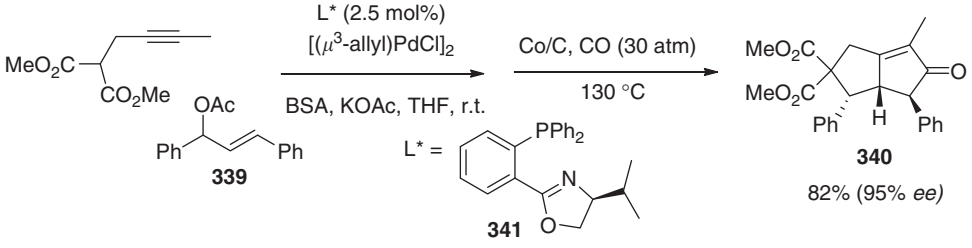
In particular, Jeong was the first to demonstrate that this concept was feasible with the combination of π-allylic substitution by a palladium catalyst and the PKR by a rhodium catalyst. This two-step transformation is achieved by mixing all of the ingredients and heating the mixture in toluene at 110 °C (equation 94).[167]

(94)



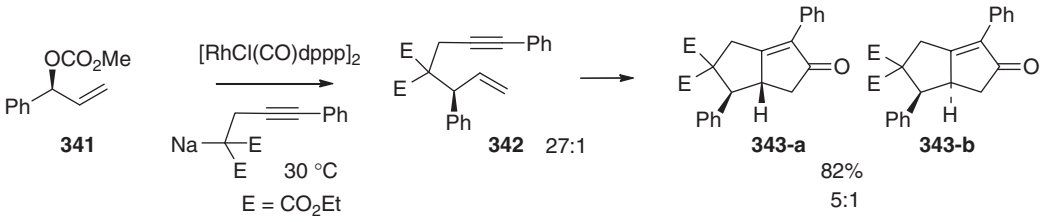
Subsequently, Chung and coworkers extended this concept further. Especially, this group emphasized the use of heterogeneous PKR catalysts for the tandem reaction. By differentiating the catalyst phases, they were able to avoid cross-poisoning between the catalysts (equation 95).[168]

(95)



PCNS, palladium and cobalt nanoparticles immobilized on silica

The treatment of enyne **335** with propargyl malonate in the presence of cobalt nanoparticles and an allyl–Pd(II) complex led to the formation of the fenestranes **338** in high yield (84%).[169] π-Allylic substitution took place at the initially formed PK product **336**, before a second PKR afforded the tetracyclic compound **338** (equation 96).

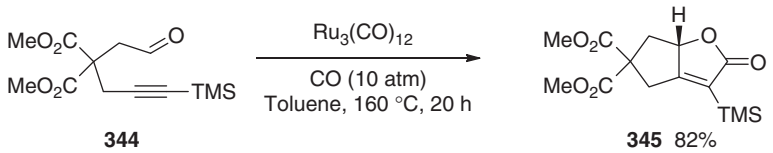


(96)

An optically enriched enyne was obtained from **339** by taking advantage of enantioselective allylation by a chiral palladium catalyst (obtained by mixing a Pd precursor and ligand **341**) and subjected to the PKR employing cobalt on charcoal to give rise to product **340** (equation 97).[170]

(97)

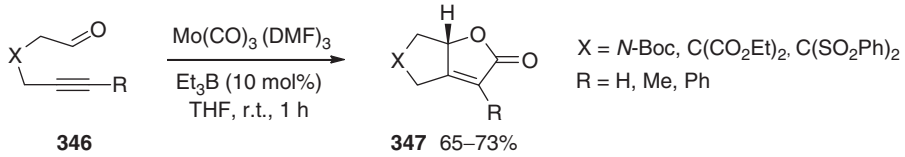
The regio- and diastereoselective rhodium-catalyzed tandem allylic alkylation of **341** with stabilized carbon and heteroatom nucleophiles followed by the Pauson–Khand annulation by the same catalyst was described by Evans and coworkers. The alkylation of an optically active allylic alcohol carbonate **341** proceeded in a regio- and stereospecific manner at 30 °C with π-acidic Rh(I) catalysts. The resultant product **342** then underwent the PKR with the aid of the preexisting catalyst under CO pressure at elevated temperature (equation 98).[17] The moderate diastereoselectivity that is common with the PKR was substantially increased by the introduction of bulkier substituents.



(98)

5.24.5.3 Variations of the PKR

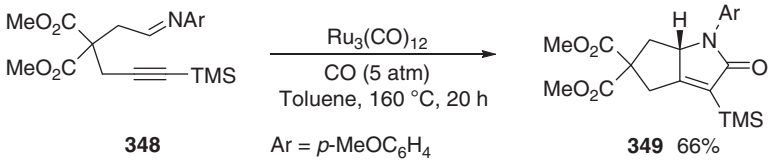
Some notable variations utilizing multiple bonded substitutes for alkynes and alkenes are summarized in this section.



5.24.5.3.1 Carbonyl groups as a substitute for the alkene

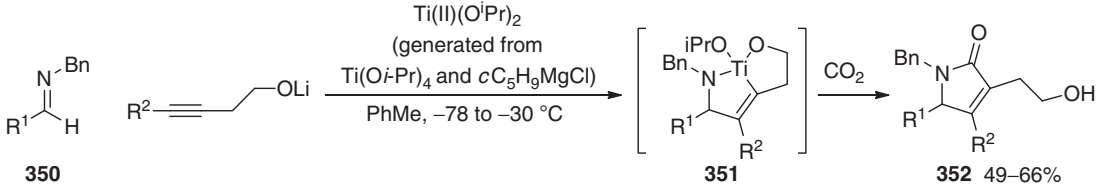
Carbonyls can replace alkenes to yield lactones. Because of the higher oxophilicity of ruthenium, Murai and Chatani first discovered that $Ru_3(CO)_{12}$ can catalyze the reaction to provide the lactones **345** (equation 99).[171]

(99)



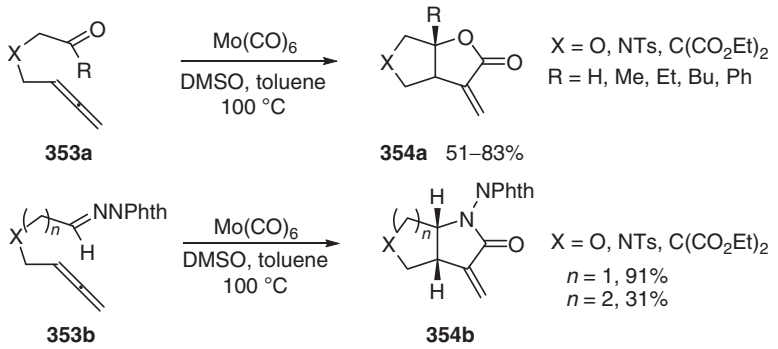
A stoichiomatric amount of the preactivated molybdenum catalyst, $Mo(CO)_3(DMF)_3$ or $Mo(CO)_6$, coupled with DMSO is also active for this transformation (equation 100).[172]

(100)



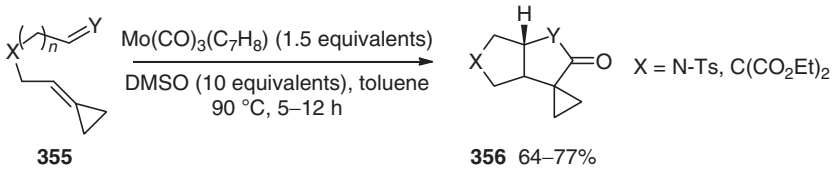
Rhodium was an efficient catalyst too. Moreover, the reaction was completed even under 1 atm of CO with this catalyst, although the substrate scope is severely limited.[173]

The same ruthenium catalytic systems are known to catalyze the reaction with the imines **348** to give the lactams **349** (equation 101).[173]



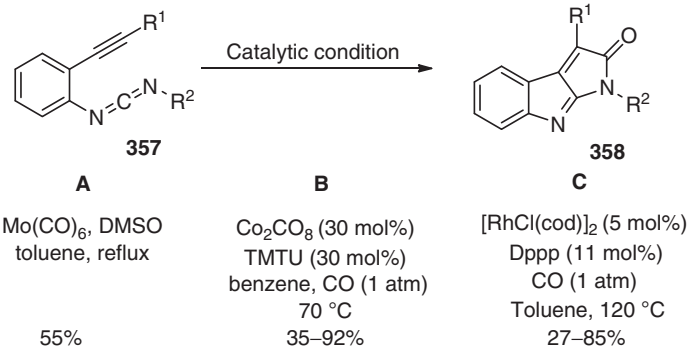
(101)

In addition, the imines **350** could couple with alkynes with the aid of a Ti(II) catalyst to provide γ-lactams of type **352** in decent yield (equation 102).[174]



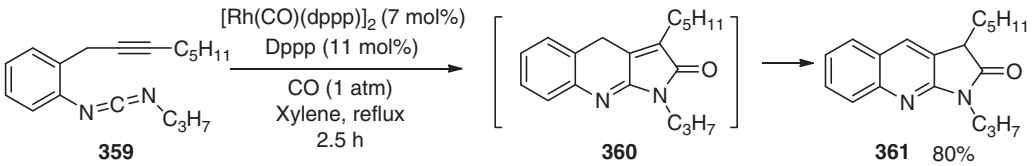
(102)

Furthermore, the double switching of the alkyne to an allene, and of the alkene to a carbonyl or hydrazone allowed α-methylene lactones **354-a** and lactams **354-b,** respectively, to be formed as described in equation 103.[175,176]



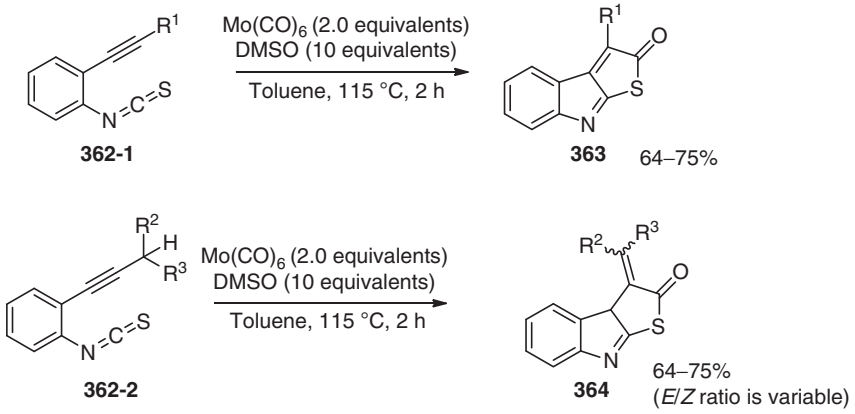
(103)

Replacing the allene by a vinylcyclopropane allowed the α-cyclopropyl-lactone **356** to be obtained under similar conditions (equation 104).[177]



(104)

The carbodiimide **357** successfully replaced the alkenes to afford the pyrrolo[2,3–b]indol-2-one ring system **358** in reasonable yield (**Scheme 22**). Cobalt, molybdenum, and rhodium catalysts are effective for this transformation, which was utilized for the synthesis of various indole alkaloids (see equation 108).[178]



Scheme 22

The quinolines **361** were obtained from the homologous substrate **359** after the cyclization followed by the rearrangement of the olefin in the resultant intermediate **360** under the reaction conditions (equation 105).[179]

(105)

The 2-alkynylphenyl isocyanates **362** were used to afford the 3-substitruted-2*H*-thieno[2,3–b]indol-2-ones **363** and **364**. A stoichiometric amount of $Mo(CO)_6$ or $Co_2(CO)_8$ was effective. A catalytic amount of Rh could also be used but provided another regioisomer as the major product (equation 106).[180]

(106)

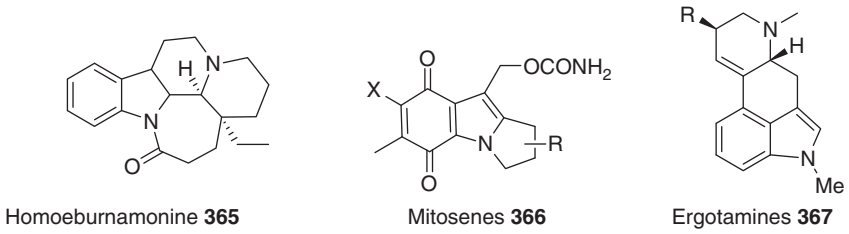
5.24.6 Application to Synthesis

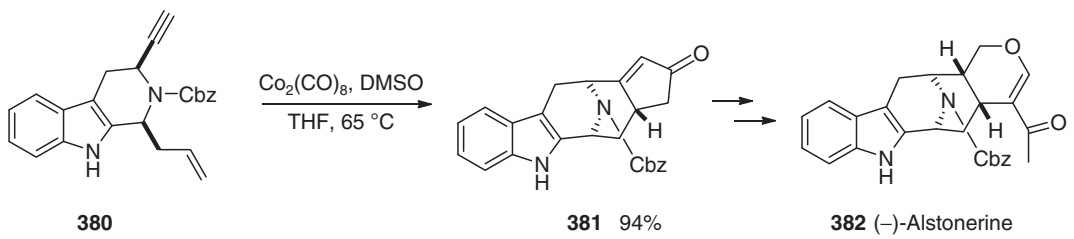
5.24.6.1 Natural Products Synthesis

One of the most prominent features of the PKR is that it provides quick access to relatively complex polycyclic compounds. Specially, the intramolecular PKR with properly functionalized precursors allows for the preparation of highly functionalized cyclic intermediates with complete control of the regioselectivity as well as the stereoselectivity.

5.24.6.1.1 Synthesis of alkaloid natural products

Model studies utilizing the PKR for the synthesis of the basic skeleton found in the various alkaloids shown in Figure 23 are summarized in Scheme 23.[181] Various skeletons are easily accessed by the PKR protocol from the substrates based on the indole skeleton having properly located appendages.[182]





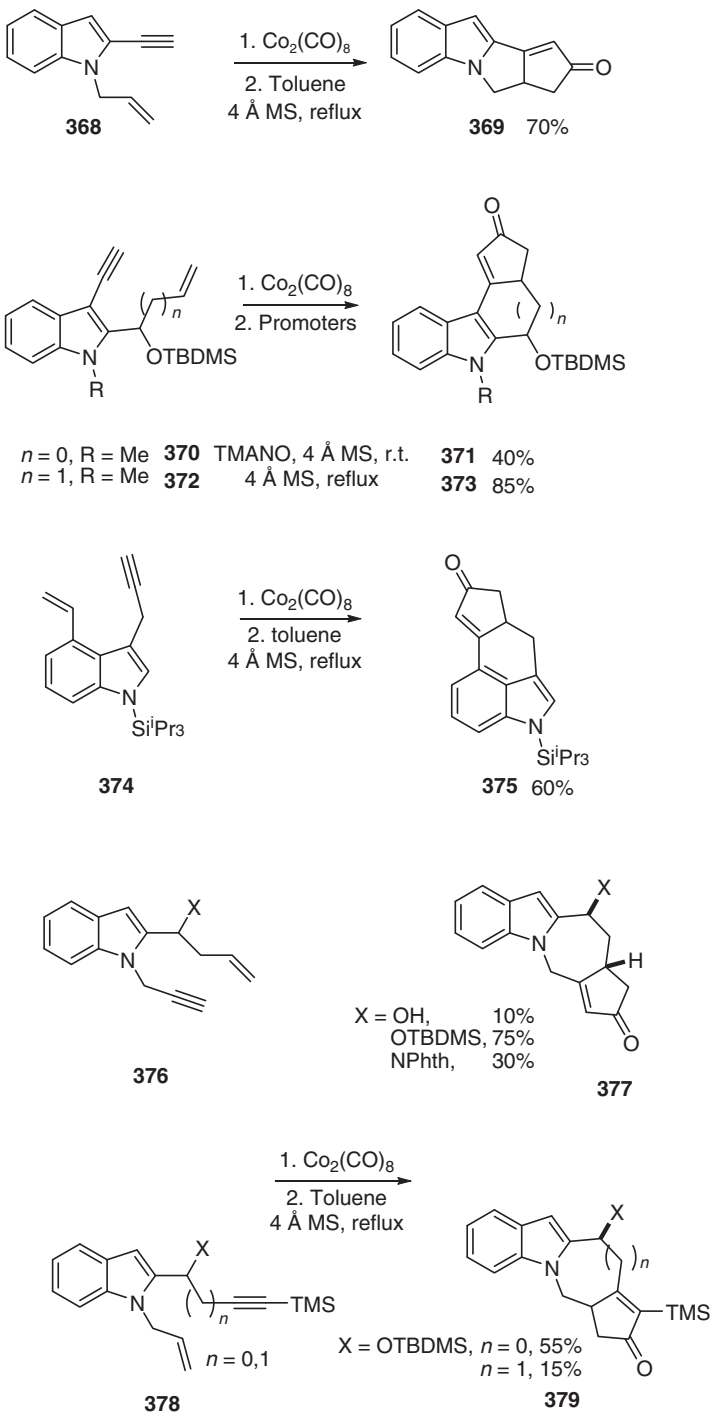


Figure 23 Representative alkaloids natural products being targeted by PKR.

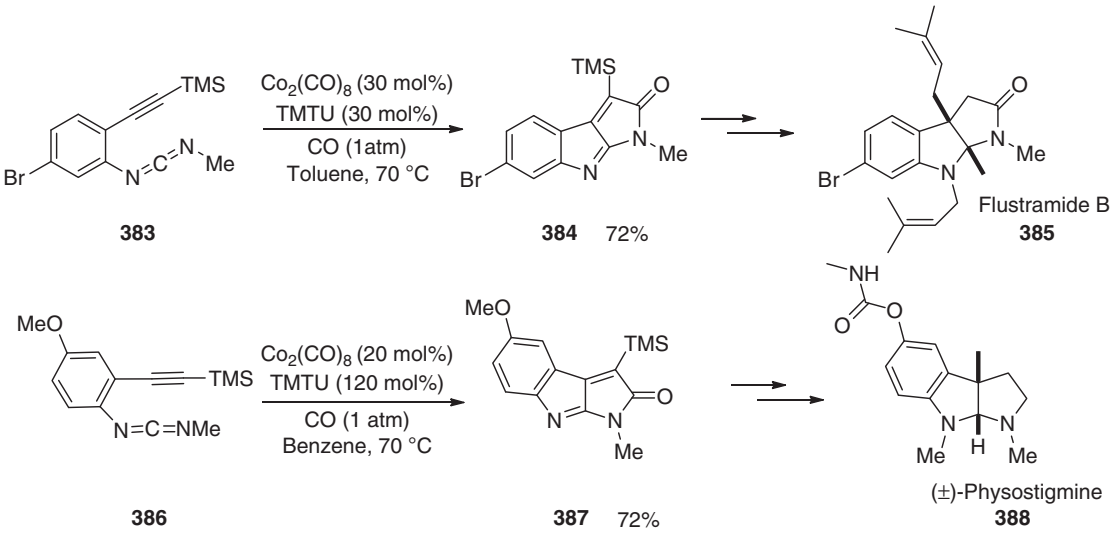
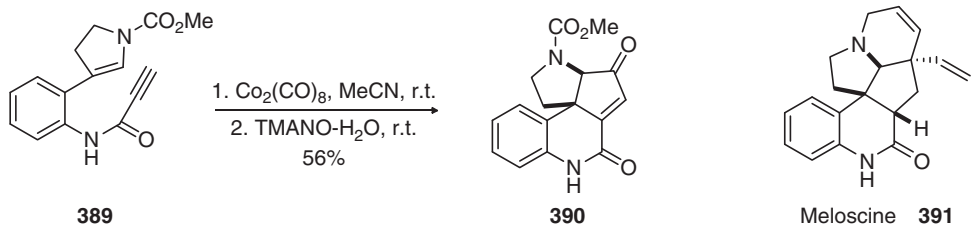
A bridged azabicyclic [3.3.1] skeleton found in the macroline/sarpagine class of indole-based alkaloids such as (–)-alstonerine (**382**) was efficiently assembled by utilizing a stoichiometric PKR with cobalt carbonyl in combination with DMSO. The substrate **380** derived from L-trytophan provided the pentacyclic intermediate **381** in 94% yield (equation 107).[183]

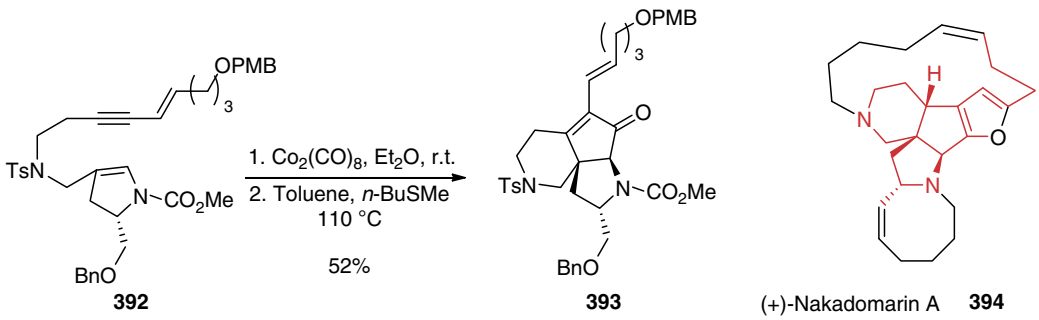


(107)



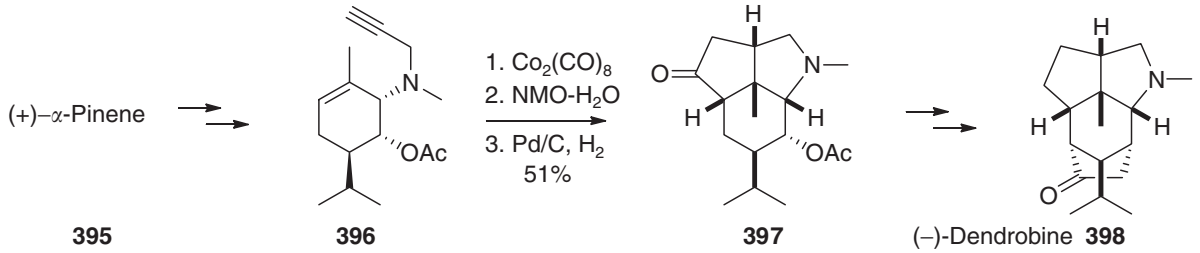
Scheme 23

Other indole alkaloids such as (±)–flustramide B (**385**) and (±)–physostigmine (**388**) were efficiently synthesized by employing the aza-PKR. The carbodiimides **383** and **386** provided **384** and **387** which were then used for the synthesis of **385** and **388**, respectively (equation 108).[178b,c]



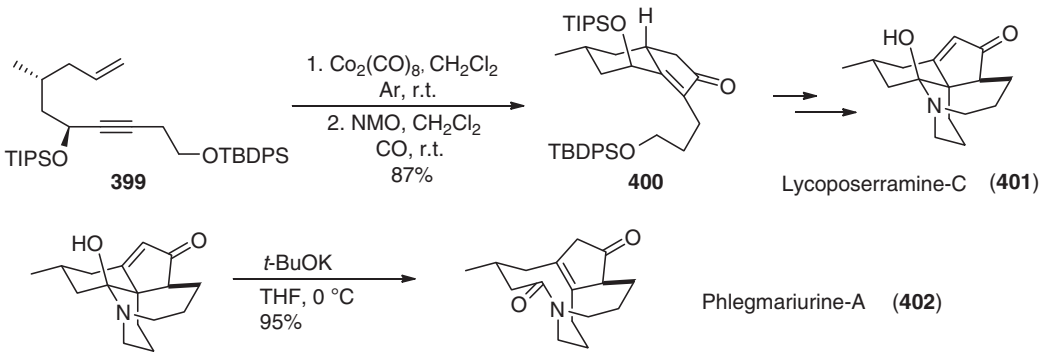
(108)

Meloscine (**391**) is representative of the Melodinus alkaloids, also known as meloquinolins, and has a unique pentacyclic carbon skeleton, which can be synthesized by using the PKR from substrates having enamines. The amine *N*-oxide promoted PKR worked nicely even with the electron-deficient alkyne of compound **389**, resulting in the desired tetracyclic compound **390** in 56% yield (equation 109).[184]



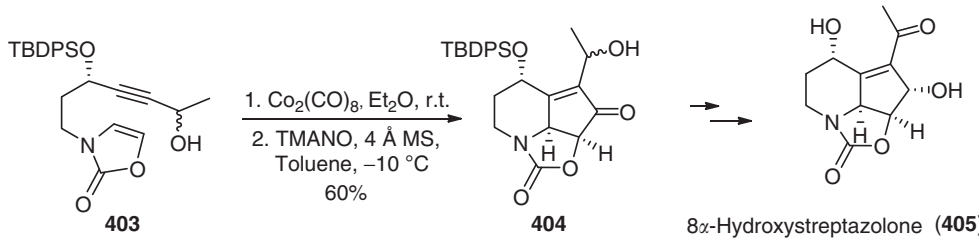
(109)

The same strategy involving the PKR was employed again for the formal synthesis of (+)-nakadomarin[185] and manzamine,[185b] representative manzamine-related alkaloids, starting from substrate **392**. This highlighted the stereoselective formation of the diazatricyclic[6.4.0.0]dodecene skeleton (equation 110).[185]



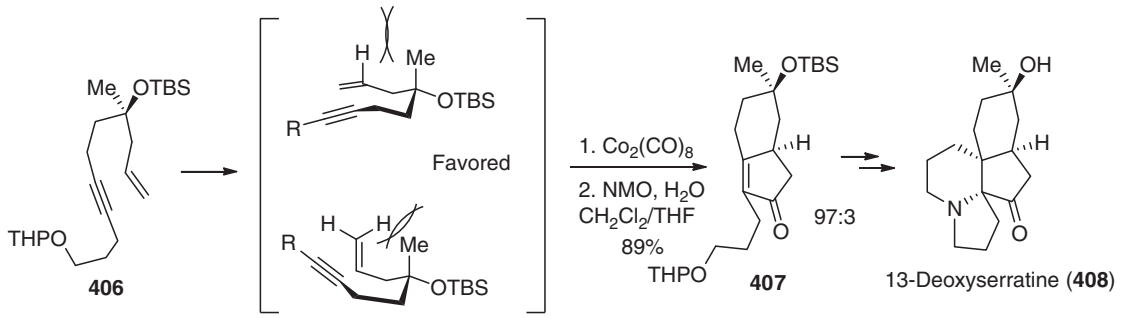
(110)

The formation of the quaternary carbon present in dendrobin (**398**) was readily achieved by the PKR. Takano[186a] and Zard[186b] independently employed the PKR for the synthesis of optically pure (–)-dendrobin (equation 111).



(111)

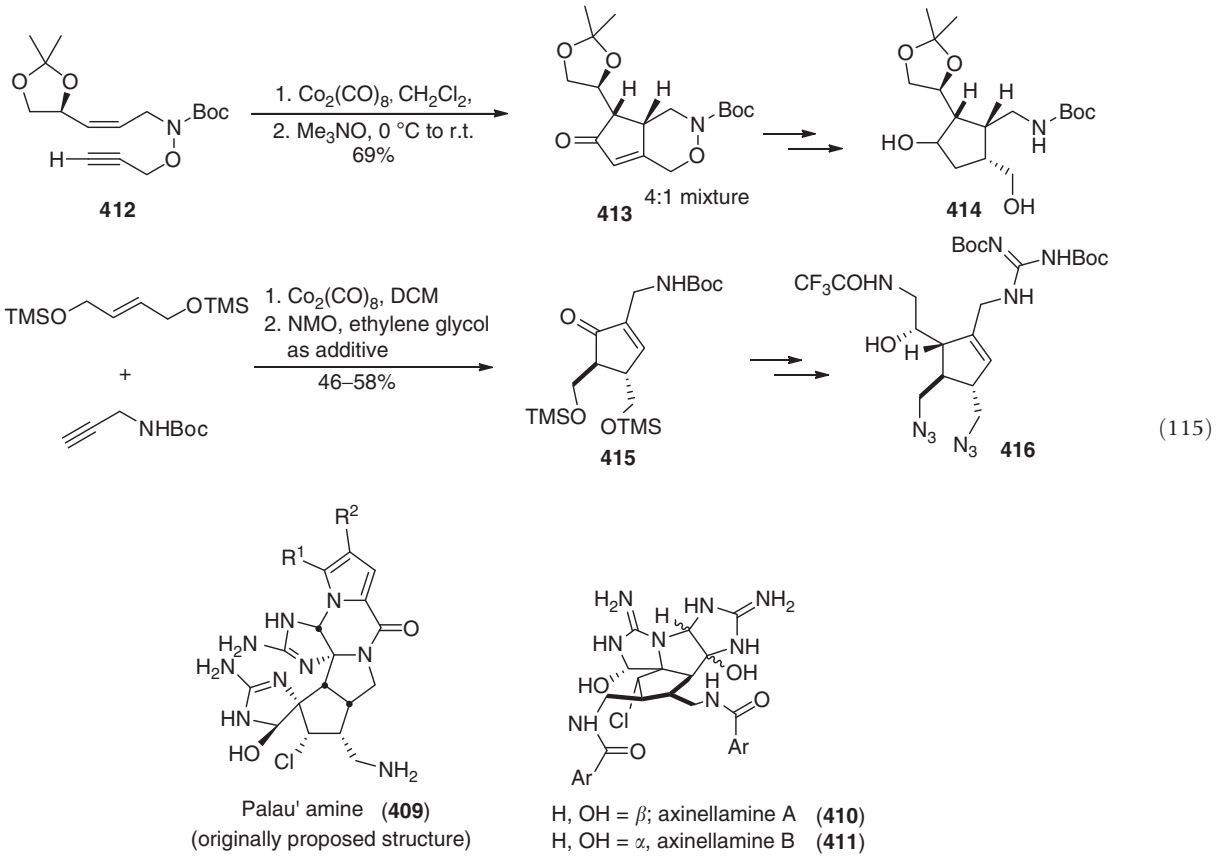
A key intermediate **400** of the newly identified fawcettimine-type lycopodium alkaloid lycoposerramine-C (**401**) was also synthesized by using the PKR as a key step. A related alkaloid phlegmariurine-A (**402**) was obtained from lycoposerramine-C afterwards (equation 112).[187]



(112)

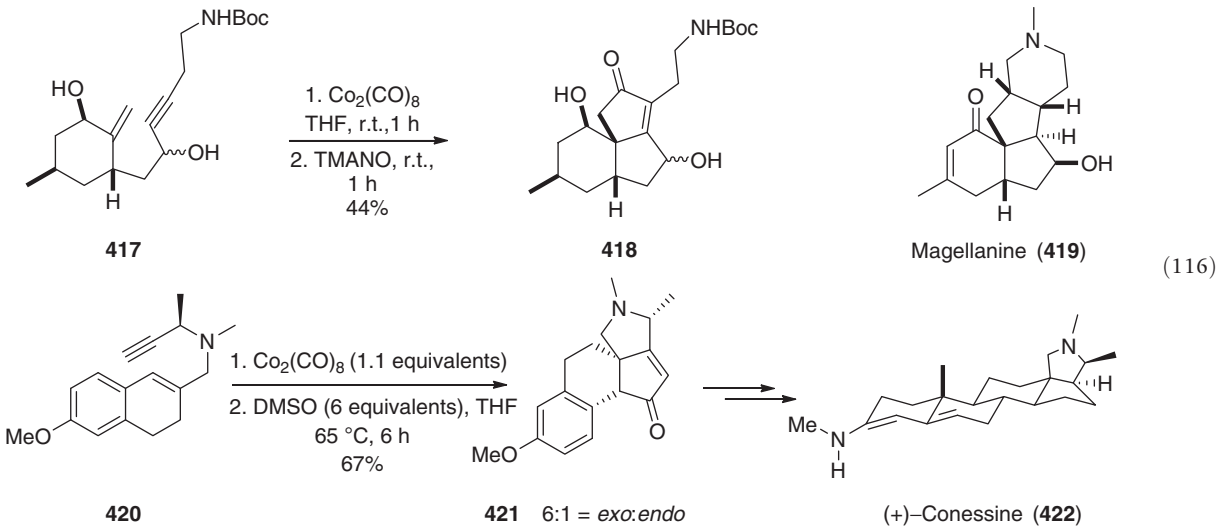
Mukai's synthesis of 8α-hydroxystreptazolone (**405**) and streptazoline represents an example of the use of an oxazolone derivative in the PKR (equation 113).[188]

(113)



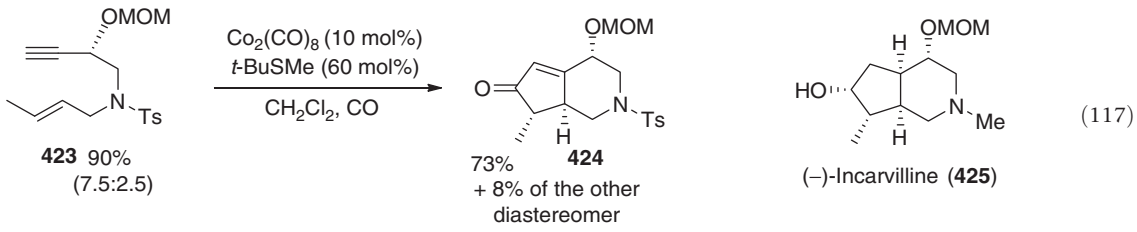
Zard and coworkers recently reported the synthesis of 13-deoxyserratine (**408**). This synthesis includes a highly diastereoselective PKR (equation 114).[189]

(114)



The family of pyrrole–imidazole marine alkaloids (PIA) consists of the Palau'amine (**409**), axinellamines (**410**), and massadines (**411**). They seem to be formidable targets, due to their highly decorated guanidine moieties. Koenig employed the *N–O* linked substrates **412** in the PKR to synthesize the fully functionalized bottom core of Palau'amine **414** and styloguanidine (equation 115).[190a,b]

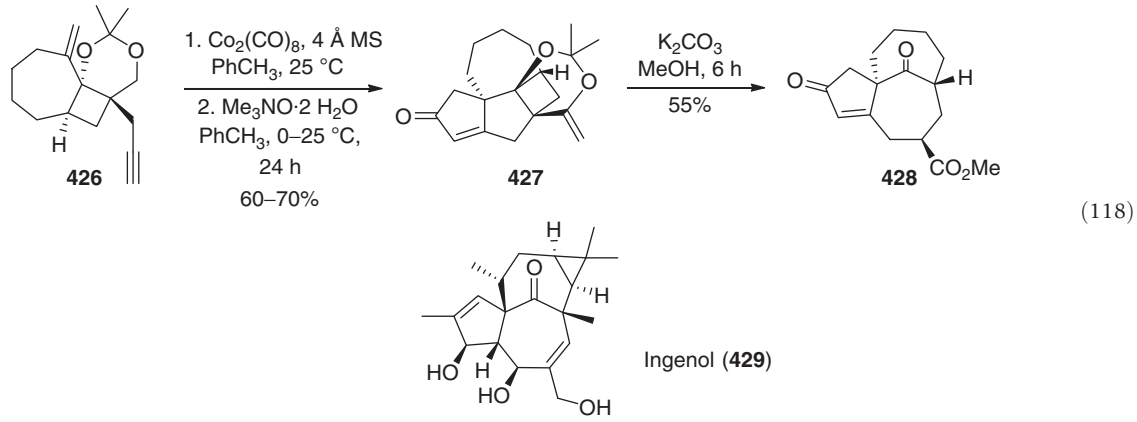
More recently, the complete synthesis of the axinellamines A (**410**) and B (**411**) was accomplished by Baran and coworkers. The key carbocyclic portion **416** of the target compound was obtained by utilizing the PKR.[190c]



(115)

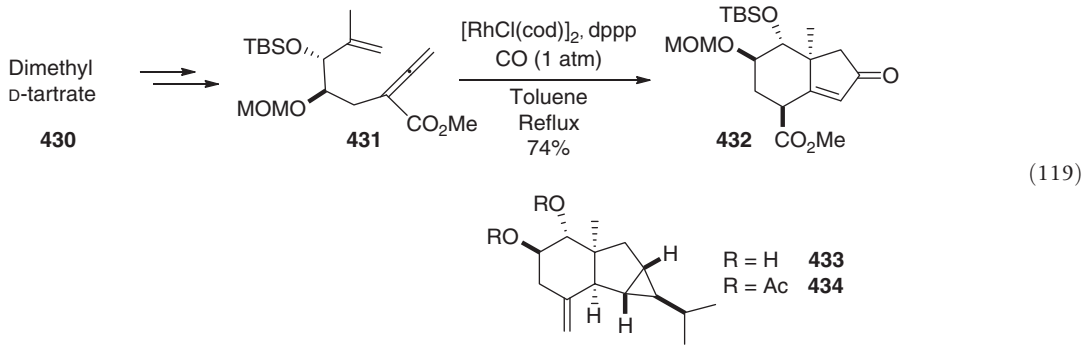
The efforts made toward the synthesis of portions of (±)–magellanine (**419**)[191a] and (+)–conessine (**422**)[191b] are noteworthy. The exocyclic olefin **417** was successfully employed in the key reaction for the synthesis of **419**, and the vinyl group conjugated to the phenyl ring in **420** served nicely as a PKR substrate for the synthesis of (+)–conessine with good diastereoselectivity (equation 116).

(116)



In this line, the homologous substrate **423** was also used to form a bicyclo[4.3.0] skeleton, which would be eventually transformed into a monoterpene alkaloid, (–)-incarvilline, which is a component of incarvillateine (equation 117).[192]

(117)



5.24.6.1.2 Synthesis of terpenoid natural products

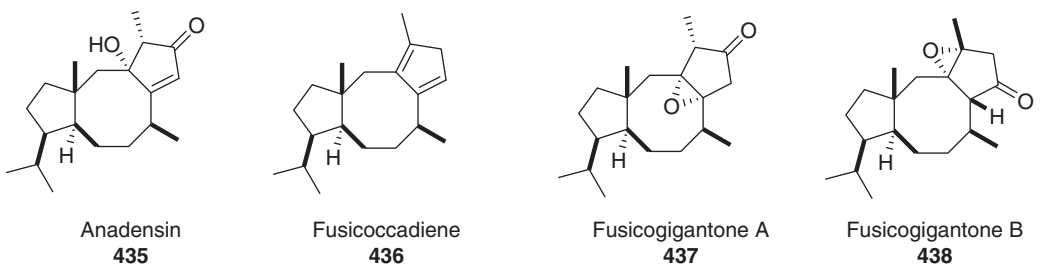
Winkler's first synthesis of the highly oxygenated diterpenoid ingenol (**429**) in racemic form required 42 synthetic steps from commercially available materials. Subsequently, the authors devised a new synthetic pathway to obtain the key intermediate **428** based on the PKR as a key reaction. The substrate **426** having an exocyclic double bond underwent the PKR smoothly to yield **427** in 60–70% yield (equation 118).[193]

(118)

Two uncommon tricyclic sesquiterpenes **433** and **434** were synthesized for the first time.The key bicyclic [4.3.0]nonenone **432** was synthesized by a variant of PKR from the optically pure precursor **431** derived from dimethyl tartrate. Afterwards, the highly stereoselective construction of the isopropylcyclopropane ring was nicely achieved (equation 119).[194]

(119)

The fusicoccain family of diterpenes is characterized by a fused 5-8-5 carbotricyclic skeleton (Figure 24).



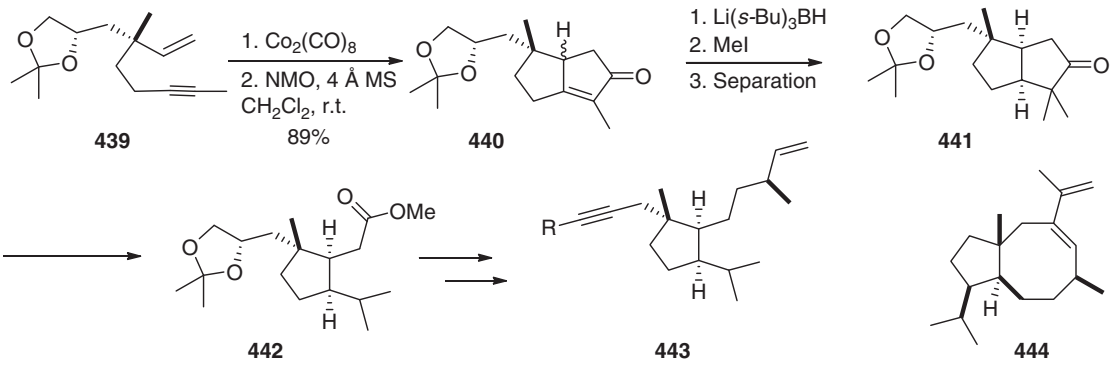


Figure 24 Representative fusicoccain diterpenoids.

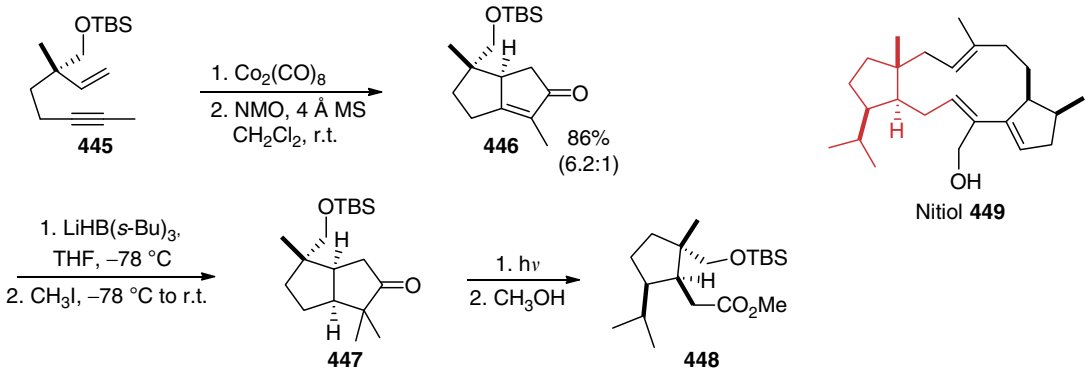
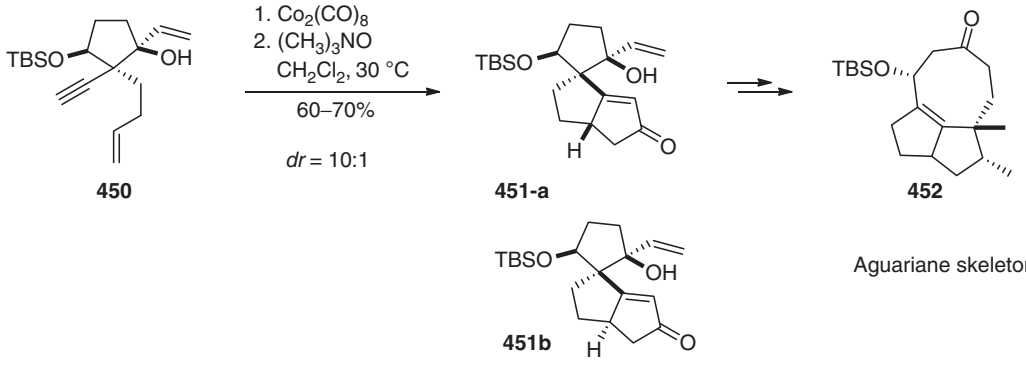


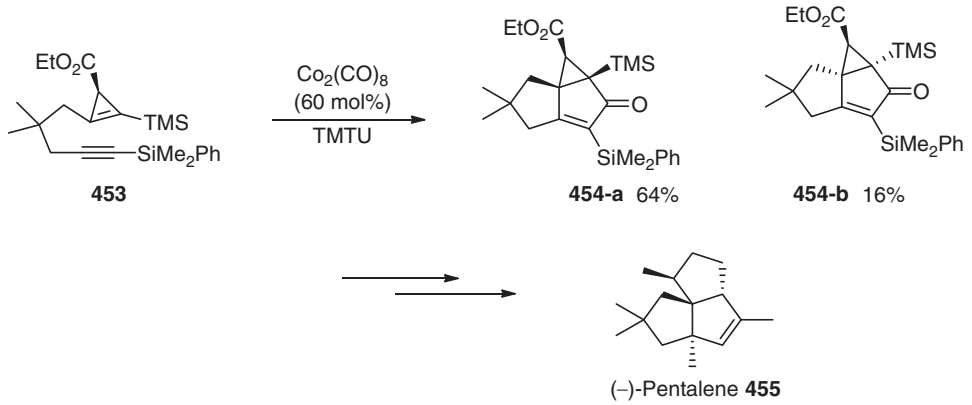
It was proposed that the key bicyclic[6.3.0]ring skeleton in **444**, where the third ring would be introduced, could be formulated from the monocyclic intermediate **443** by enyne metathesis. The key intermediate **443** would be obtained from compound **442** which derives from a Norrish type I fragmentation of the bicyclic precursor **441**.[195]

The introduction of a methyl group on the α-position of the enone was achieved by selective 1,4-hydride addition to the PKR product **440** by L-selectride, followed by trapping of the resultant enolate with the methyl group. The resultant product **441** was subjected to the Norrish Type I fragmentation under UV light (190 nm) to afford the isopropyl-substituted five-membered ring product **442** (equation 120).[195a]



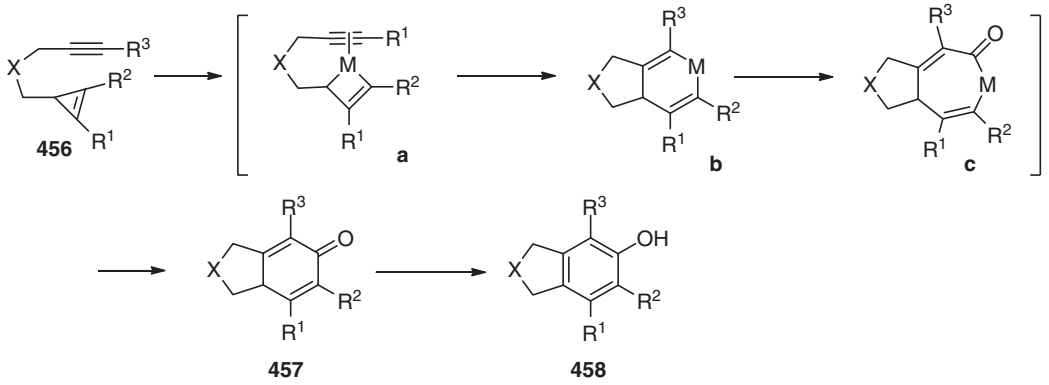
439 **440** **441** **442** **443** **444** (120)

Nitiol (**449**) is characterized by two five-membered rings fused to a central 12-membered macrocycle. Its left five-membered ring was synthesized earlier by utilizing the same strategy (equation 121).[195b]



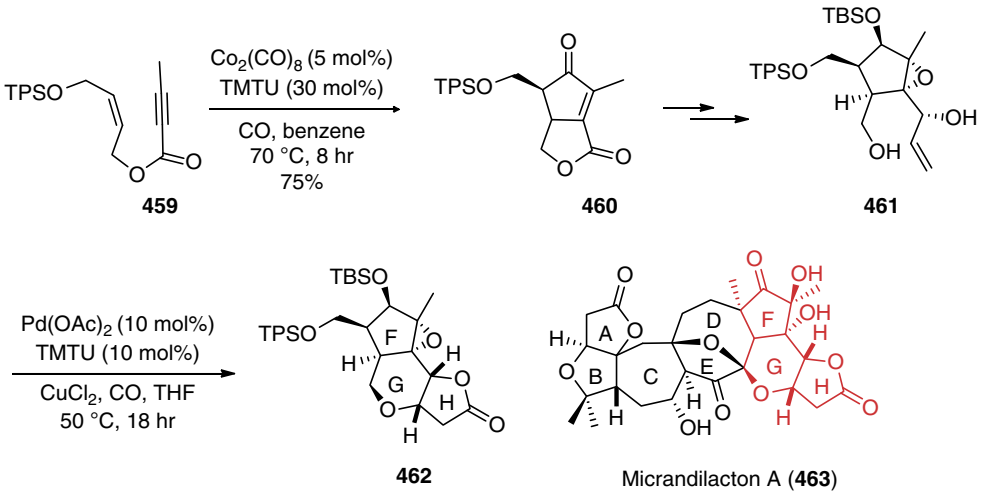
445 **446** **447** **448** Nitiol **449** (121)

Aquariolides are cyclic diterpenes, in which a nine-membered ring is fused to two five-membered rings. The PKR was used to set the stage by affording the intermediate **451** which served in a ring-expanding Cope rearrangement to form the nine-membered ring **452** in a highly diastereoselective manner (equation 122).[196]



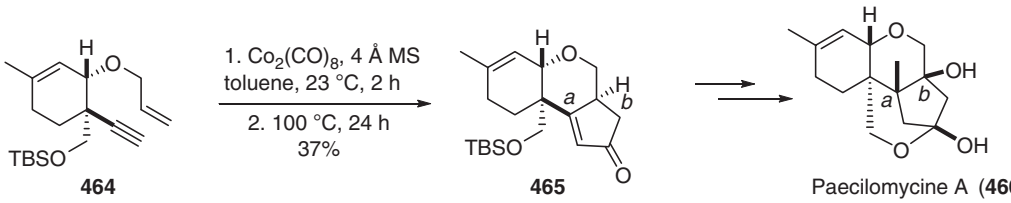
450 **451-a** **451b** **452** (122)

The tricyclic compound **454**, which could be transformed into (–)-pentalene **455**, was formed from substrate **453** by the TMTU-assisted cobalt catalyzed PKR (equation 123).[197]



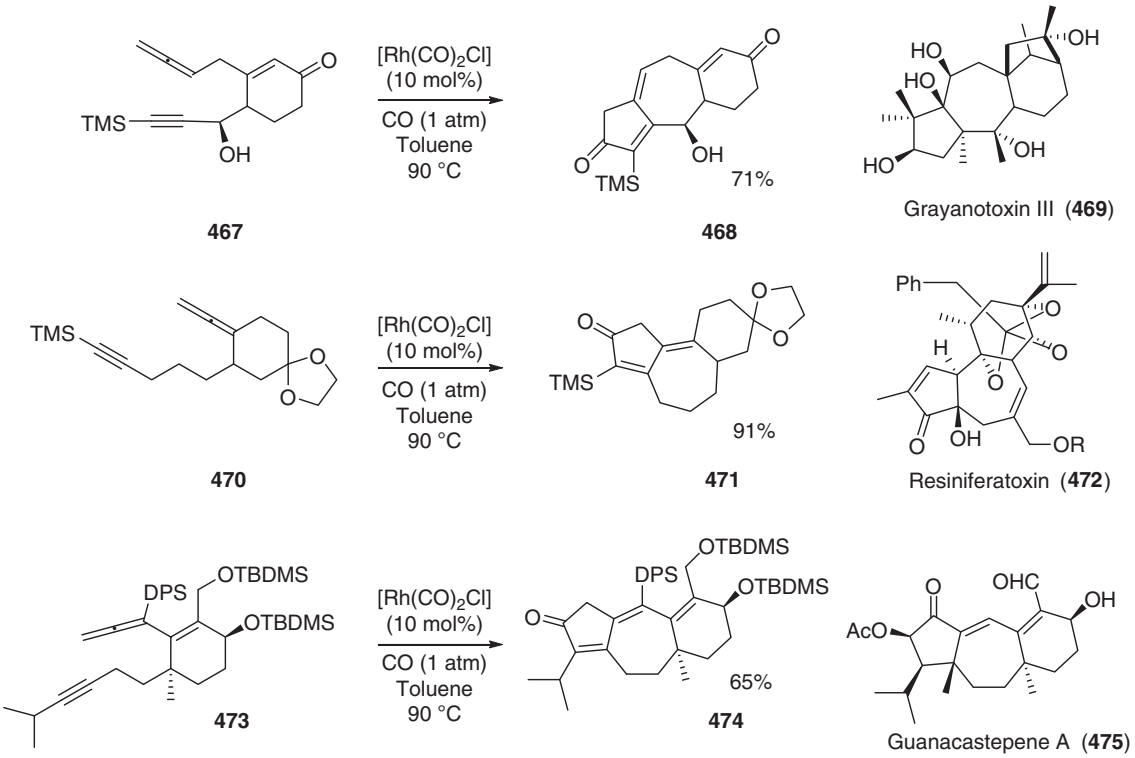
(123)

In conjunction with this, it is worth mentioning about the related [3 + 2 + 1] cycloaddition at this point. Compound **456**, a regioisomer of **453**, in which the olefin in the cyclopropene is distant from the reaction site, underwent a metal insertion into a C–C single bond of the cyclopropene followed by the formation of metallacyclopentane intermediate **b**; a subsequent CO insertion and the reductive elimination afforded a cyclohexadienone **457**, which was tautomerized to the phenolic compound **458** (equation 124).



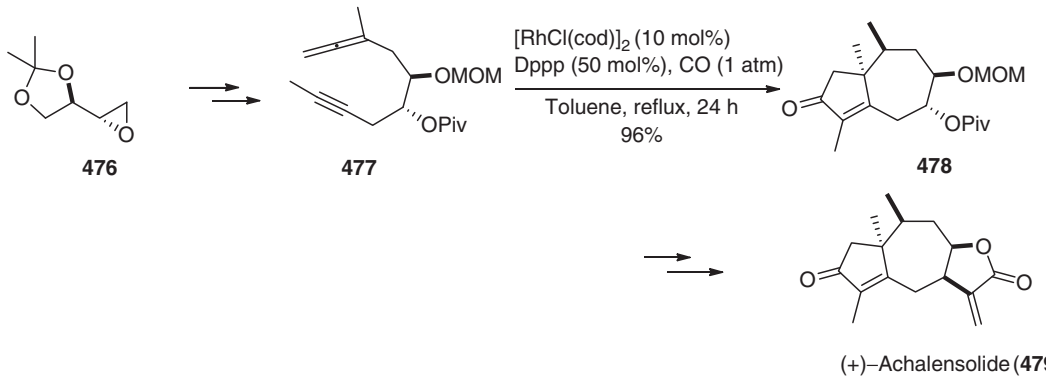
(124)

The critical portion of micrandilacton A (**463**) (FGH ring as assigned in equation 125) was synthesized by a couple of reactions catalyzed by a transition metal. First, the F ring having side chains for the synthesis of the G ring at a later stage was prepared by the PKR. The substrate **459** was subjected to the catalytic reaction employing $Co_2(CO)_8$ and TMTU to form **460**. After proper functionalization, the substrate **461** was set up for the synthesis of **462** in next key step by a palladium catalyzed carbonylative annulation in the presence of TMTU (equation 125).[198]



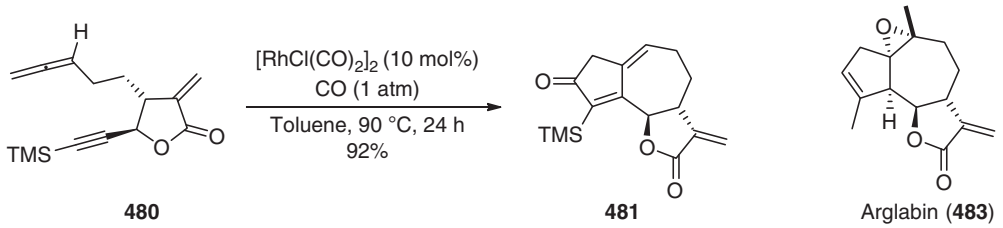
(125)

The key tricyclic skeleton **465** of paecilomycine A (**466**), one of several terpenoids derived from *Paecilomyces tenuipes*, was synthesized by Danishefsky and coworkers from substrate **464** by the thermal PKR using a cobalt reagent (equation 126).[199]



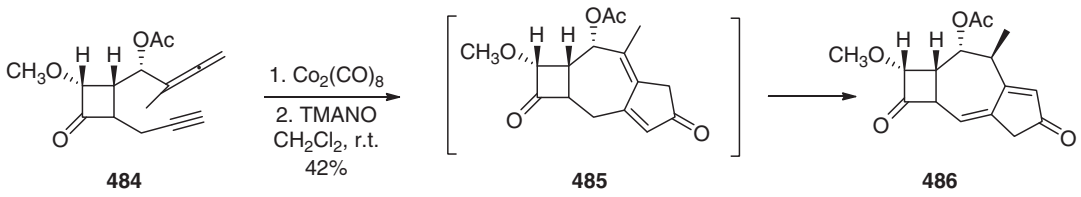
(126)

Guaianolides are a notable class of sesquiterpene lactones, which possess a 5-7-6 ring system. Such polycyclic systems are found in grayanotoxin (**469**), resiniferatoxin (**472**), and guanacastepene A (**475**) and have been shown to be formidable targets for conventional PK reactions. As mentioned earlier, Rh(I) could catalyze the PKR of 1,7 alkynyl allenes to afford such a skeleton, especially the 5-7 ring system. Taking advantage of this result, compound **469** was obtained from **467** via **468**, **472** from **470** via **471**, and **475** from **473** via **474**. All of the resultant PKR products have been further elaborated to the corresponding natural products (Scheme 24).[200]

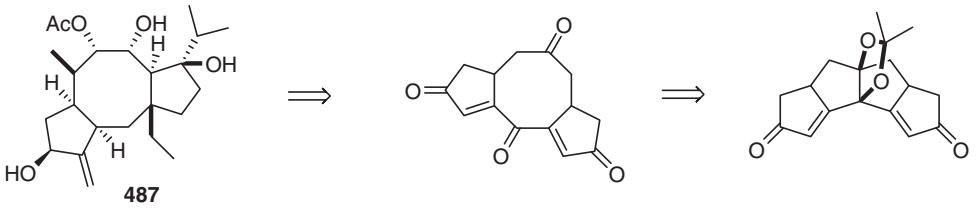


Scheme 24

In addition, guaianolides such as **479** or **483** having an α-methylene butyrolactone were also synthesized. Mukai prepared the requisite bicyclo[5.3.0] ring system **478** first from **477** by the PKR and then introduced the α-methylene lactone ring later in their synthesis of (+) – achalensolide (**479**) (equation 127).[201a] Direct access to the 5-7-5 ring skeleton bearing the α-methylene lactone appendage **481** was realized starting from **480** by Brummond under nearly identical reaction conditions (equation 128).[201b]

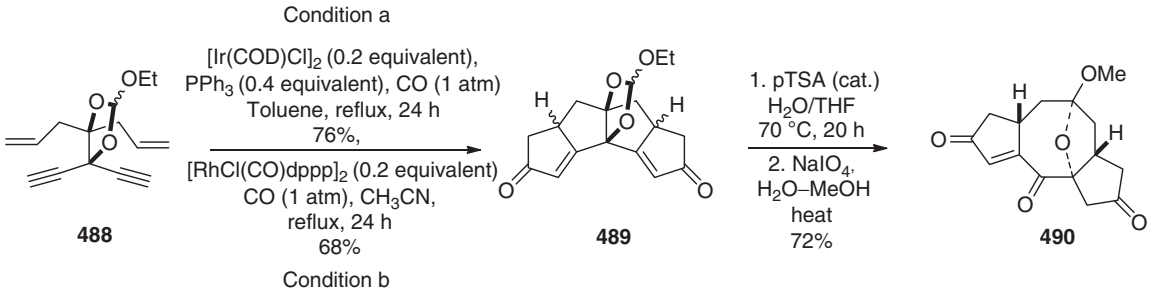


(127)



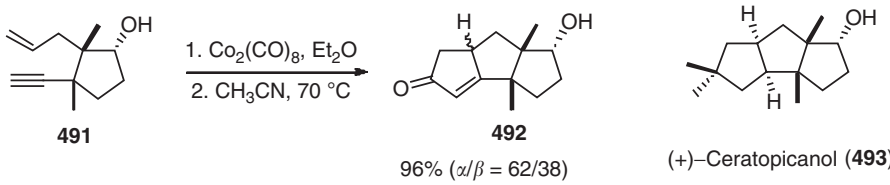
(128)

The extension of this strategy to substrate **484** allowed the 4-7-5 ring system of **486** to be obtained (equation 129).[202]

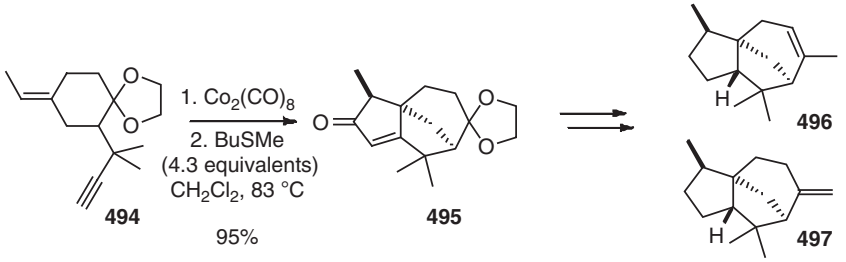


(129)

Access to a 5-8-5 ring system was realized by ring expansion through the double PKR of **488** (Scheme 25, equation 130). The two five-membered rings at the center of the tetracyclic product **489** were transformed into the eight-membered ring of **490** by treatment with an acid and periodate cleavage of the resulting diol.[203]

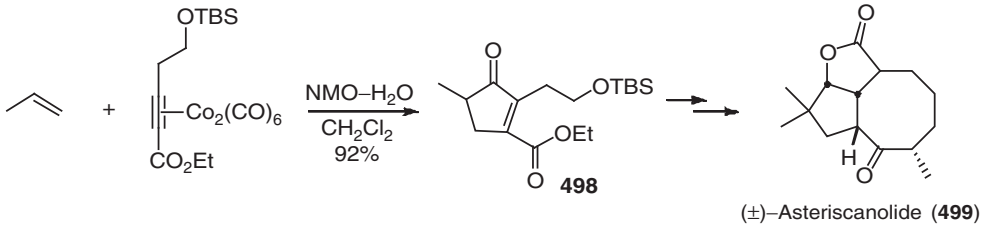


Scheme 25



(130)

Persistent synthetic efforts toward the triquinane skeleton by the intramolecular PKR, triggered by a seminal synthesis of *dl*-coriolin by Magnus,[204] have appeared in the literature. These include the synthesis of (+) – ceratopicanol (**493**) by Mukai,[205] the synthesis of the tricyclic moiety of kalmanol by Paquette,[206] and the asymmetric synthesis of 15-nor-pentalene by Pericas and Moyano.[96] The synthesis of (+) – ceratopicanol is illustrated in equation 131. In related work, the synthesis of the D/E ring of the pentacyclic steroid xestoergosterol was described by Krafft.[207]



(131)

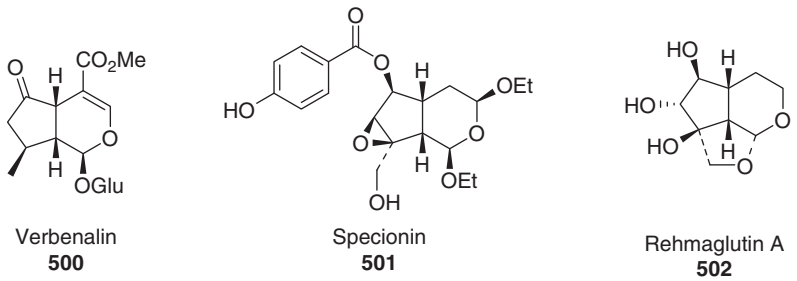
A number of examples for the formation of quaternary carbon centers by PKR were reported, including the synthesis of α-cedrene and β-cedrene by Kerr an Pauson (equation 132),[208a] and of the core of (–)-tricycloillicinone.[208b]

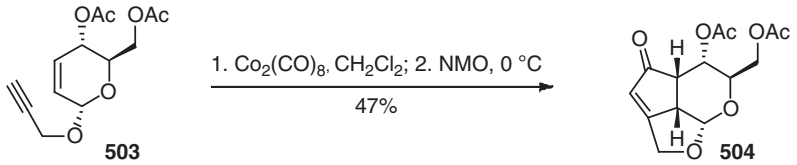
(132)

In spite of the complication in terms of the regiochemistry, the intermolecular PKR has been used for the synthesis of some natural products. Taking advantage of the regiochemical control based on the electronic nature of the substituent, in which the more electron-withdrawing group on the alkyne goes to the β-position of the enone, a couple of examples were reported. Krafft reported the synthesis of the key skeleton of (±)-asteriscanolide (**499**). The desired regioisomer **498** was formed exclusively by the intermolecular PKR (equation 133).[209a]

(133)

One of the distinctive virtues of the cobalt-mediated PKR is its acceptance to various functional groups, especially oxygen substituents. Iridoids are monoterpenes which often serve as intermediates in the biosynthesis of alkaloids. Chemically, iridoids usually consist of a cyclopentane ring fused to a six-membered oxygen heterocycle. They are among the most challenging synthetic targets, because of their plethora of oxygen functionalities present in a relatively small backbone (**Figure 25**). Utilizing the precursor **503** derived from carbohydrates, this class of target has been efficiently synthesized (equation 134).[210]





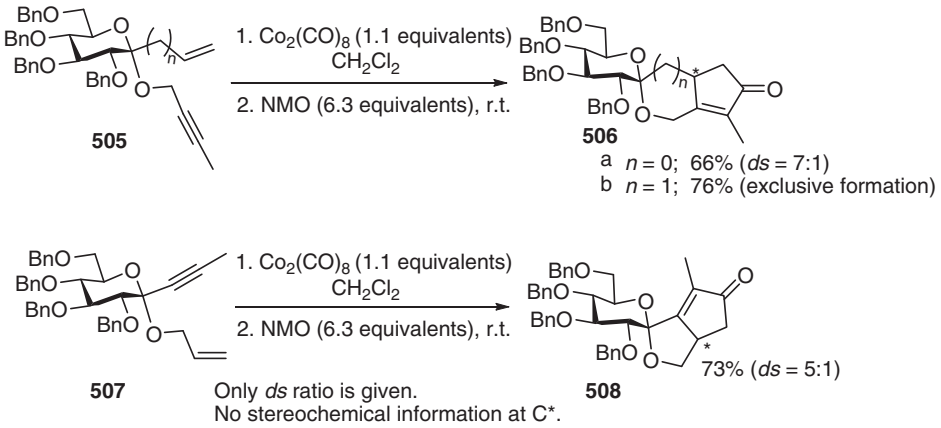


Figure 25 Representative iridoid monoterpenoids.

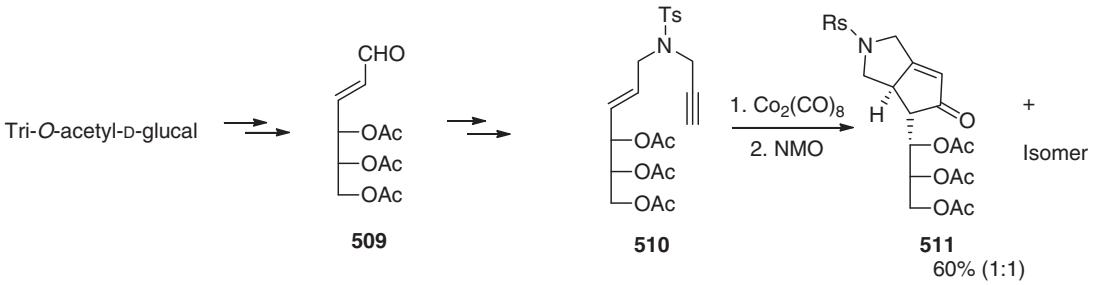
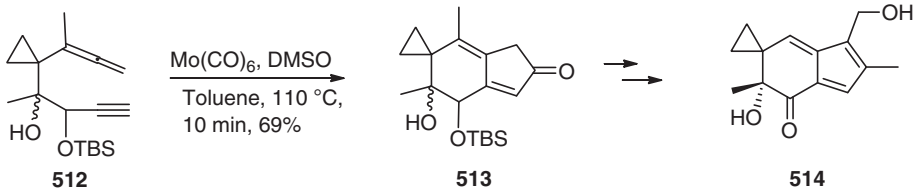


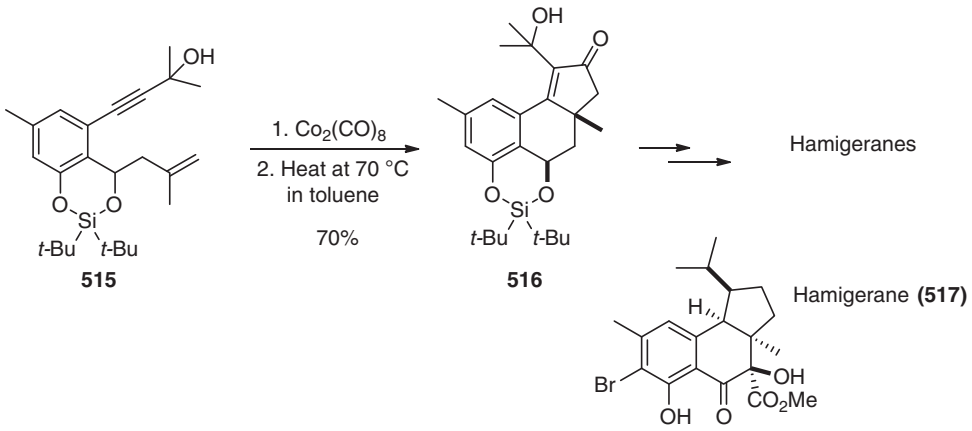
(134)

Along similar lines, the enynes **505** and **507**, having a sugar appendage derived from D-glucose, were utilized for the intramolecular reaction to give products **506** and **508** with good to excellent diastereoselectivity, respectively (equation 135).[211]



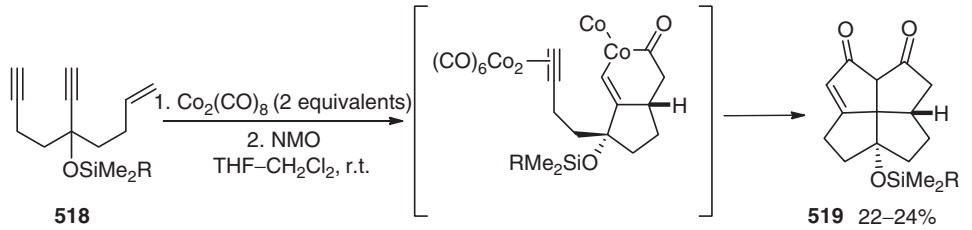
(135)

The *N*-tosyl tethered enyne **510** bearing a sugar side chain was also used to yield the bicyclic compound **511** (equation 136).[212]



(136)

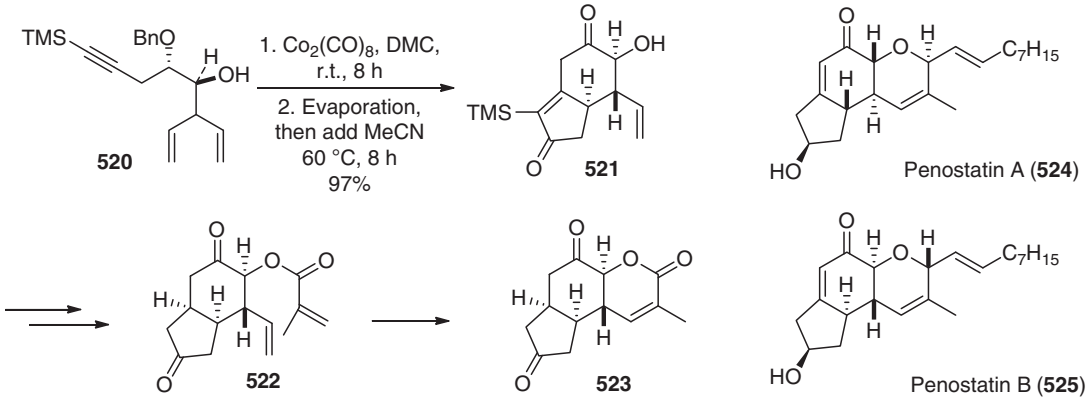
As seen in Section 5.24.6.1.1, the PKR of the allene-ynes opens up a new type of application. One of the rewards of this approach is the synthesis of highly functionalized compact bicyclic compounds, such as the illudins. Brummond et al. performed the PKR with the properly functionalized allenyne **512** to afford compound **513**, which is transformed into hydroxymethylacylfulvene (HMAF) (**514**) (equation 137).[213]



(137)

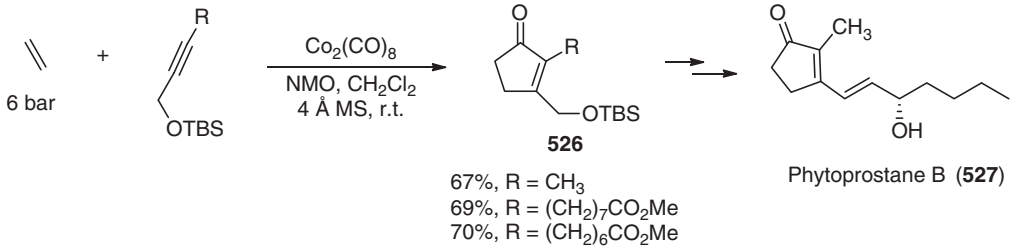
The core structure of the hamigerane terpenes was constructed by the use of the PKR. Enyne **515**, renderd rigid by silicon-protection, was subjected to thermal PKR to afford product **516** efficiently (equation 138).[214a]

(138)



Keese's elegant synthesis of the farnestane [5.5.5.5] ring system through the PKR is particularly attractive (equation 139). Chung and coworkers upgraded this synthesis with the assistance of the improved tandem protocols mentioned in equation 96.[215]

(139)



5.24.6.1.3 Synthesis of polyketide natural products

The penostatins A (**524**) and B (**525**) constitute a family of polyketide natural products, whose structure is highlighted by a densely functionalized hexahydrocyclopenta[f]-chromenone skeleton. Among this family, penostatin B (**525**) was synthesized in the natural form for the first time by employing a highly diastereoselective PKR for the construction of the tetrahydroindenone segment. A promoter-assisted PKR was applied to substrate **520** and furnished compound **521** with high diastereoselectivity (>20:1) in 97% yield.[214] The subsequent esterification of **521** with acrylic acid followed by ring-closing metathesis with the Grubbs–Hoveyda catalyst yielded the desired skeleton **523** (equation 140).[216]

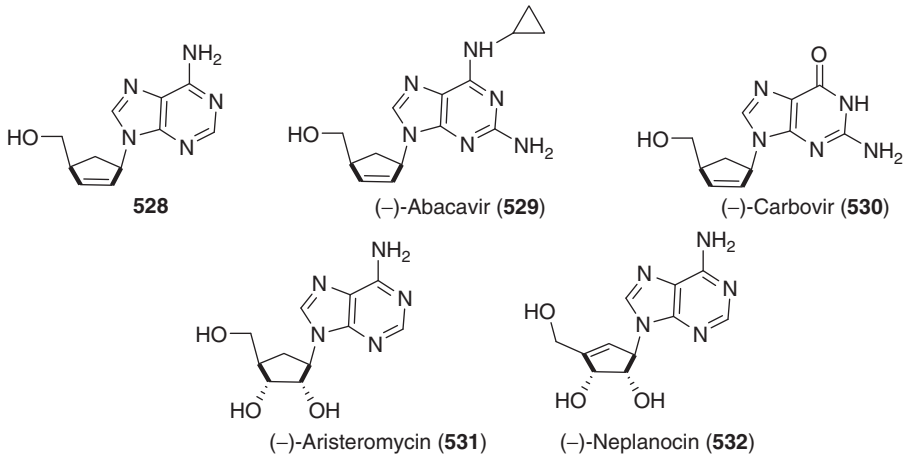
(140)

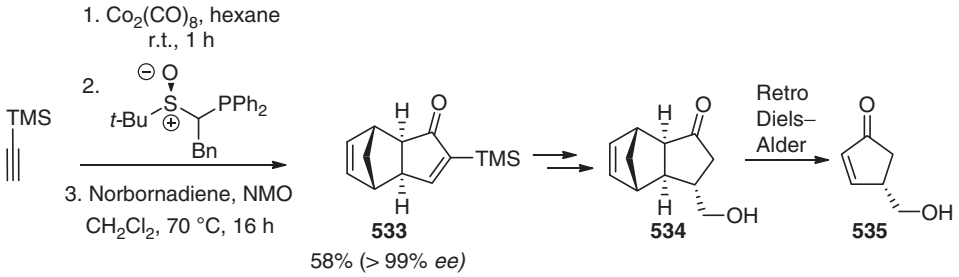
The synthesis of phytoprostane B (**527**) is another example of an intermolecular reaction, in which again the more electron-withdrawing group is placed in the β-position of the PKR product **526** (equation 141).[217]

(141)

5.24.6.1.4 Carbanucleosides

The identification of the carbanucleosides such as (–)-aristeromycin (**531**) and (–)-neplanocin (**532**) as antitumor and antiviral agents has attracted a great deal of interest from the medicinal chemistry community (Figure 26). A couple of synthetic approaches based on the PKR were reported. First, the optically pure cyclopentenone **535** was utilized, which was obtained by the enantioselective catalytic PKR mediated by $Co_2(CO)_8$ and a chiral S-P ligand. The resultant PKR product **533** in optically pure form was transformed into compound **534** in a series of reactions. **535** was then obtained by the retro Diels–Alder reaction of **534** promoted by the Lewis acid $MeAlCl_2$ (equation 142).[218]





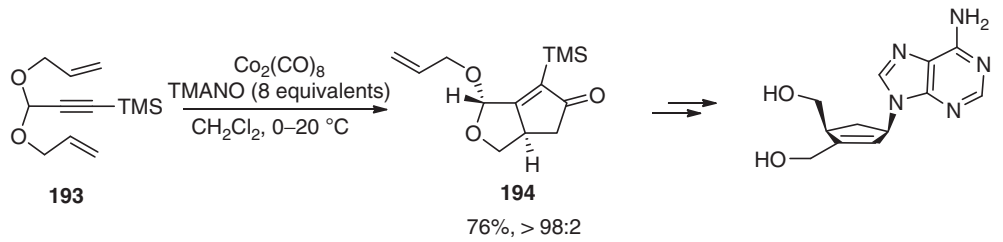


Figure 26 Representative carbanucleotides.

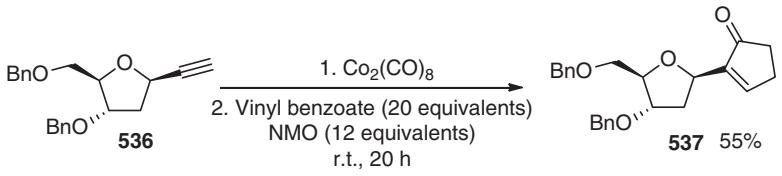
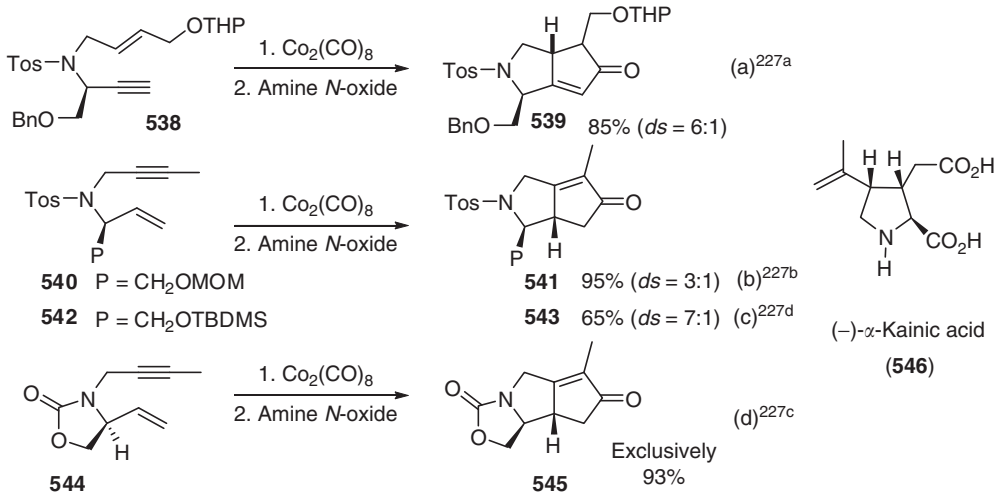


(142)

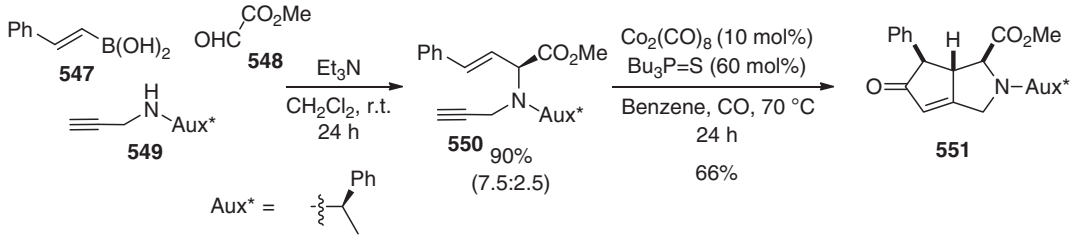
In conjunction with this, Jeong reported the cycloadditions of the bis(allyl) and bis(homoallyl) acetals of alkynals leading to bicyclic lactols.[219a] Schmalz and coworkers extended their utility to the synthesis of carbocyclic nucleosides via nucleophilic substitution of a π-allylic palladium complex (equation 143).[219b]

(143)



The PKR with the 1-alkynyl-2-deoxy-D-ribose derivative **536** constitutes an example for the use of highly oxygenated sugar-based substrates (equation 144).[220]

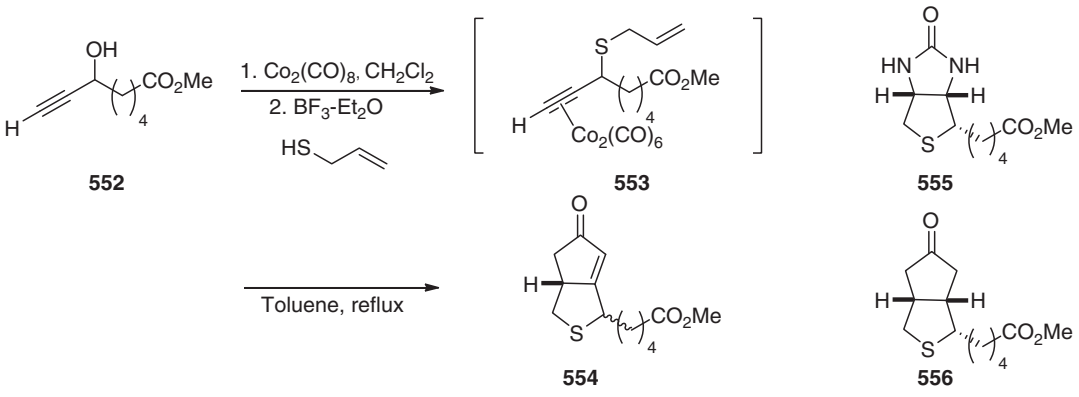
(144)



5.24.6.1.5 Amino acid derivatives

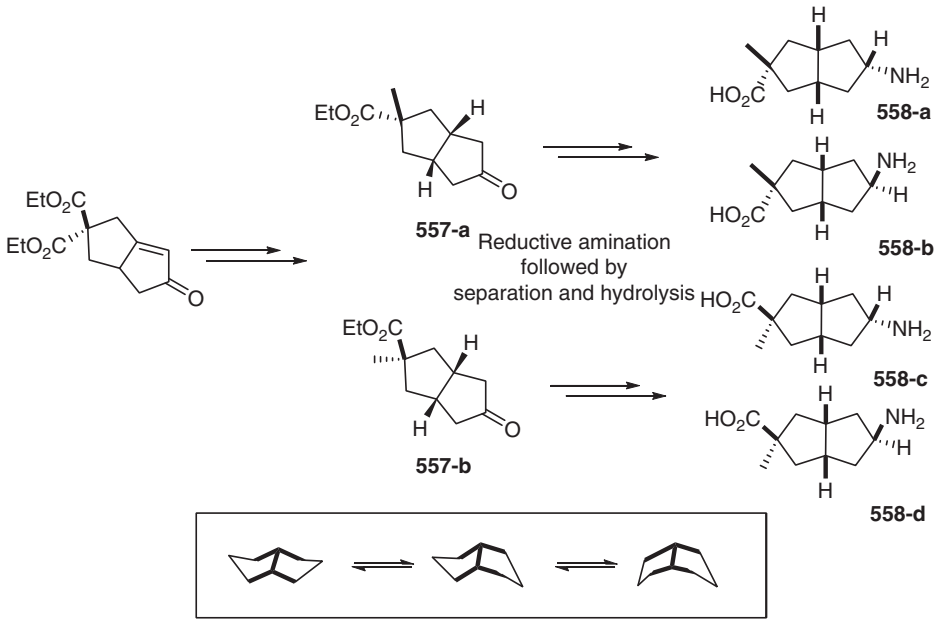
An excitatory neurotransmitter, (–)-α-kainic acid (**546**), has frequently served as synthetic target in approaches based on the PKR as a key reaction. Various precursors, such as **538**, **540**, **542**, and **544**, were tested to enhance the diastereoselectivity. Modest to excellent diastereoselectivities were observed with the first three acyclic precursors,[221a,b,d] but perfect stereoselectivity was obtained when the rigid cyclic precursor **544** was used (equation 145).[221c]

(145)



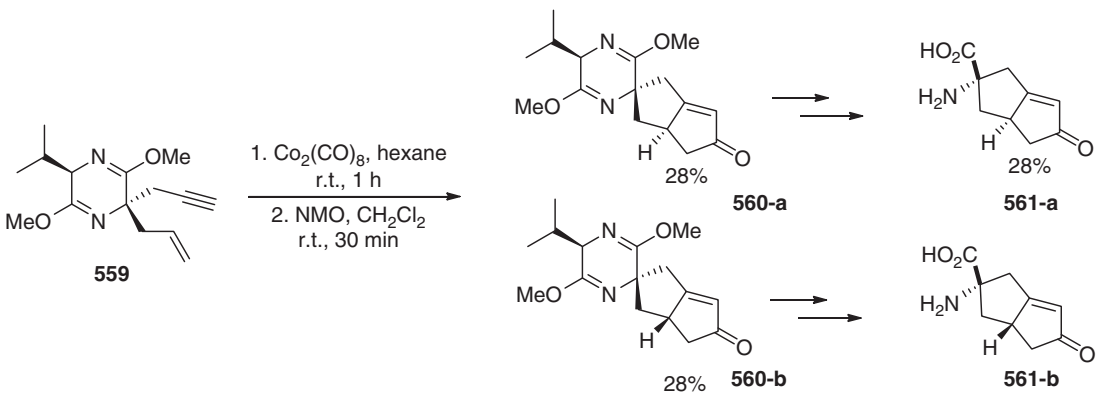
In conjunction with this study, it is noteworthy that a bicyclic proline derivative was obtained in a highly diastereoselective manner. The starting material, **550**, an optically pure enyne amino acid derivative, was prepared by trapping the imine intermediates formed *in situ* by mixing propargyl amine **549** and glyoxylic acid **548** with an alkenyl boronic acid **547**. At this point, the diastereoselectivity is not high and, thus, it is necessary to separate each diastereomer by chromatography. Once the optically pure starting material was subjected to the catalytic PKR condition, the single stereoisomer **551** was obtained (equation 146).[222]

(146)



5.24.6.1.6 Unnatural but biorelevent products

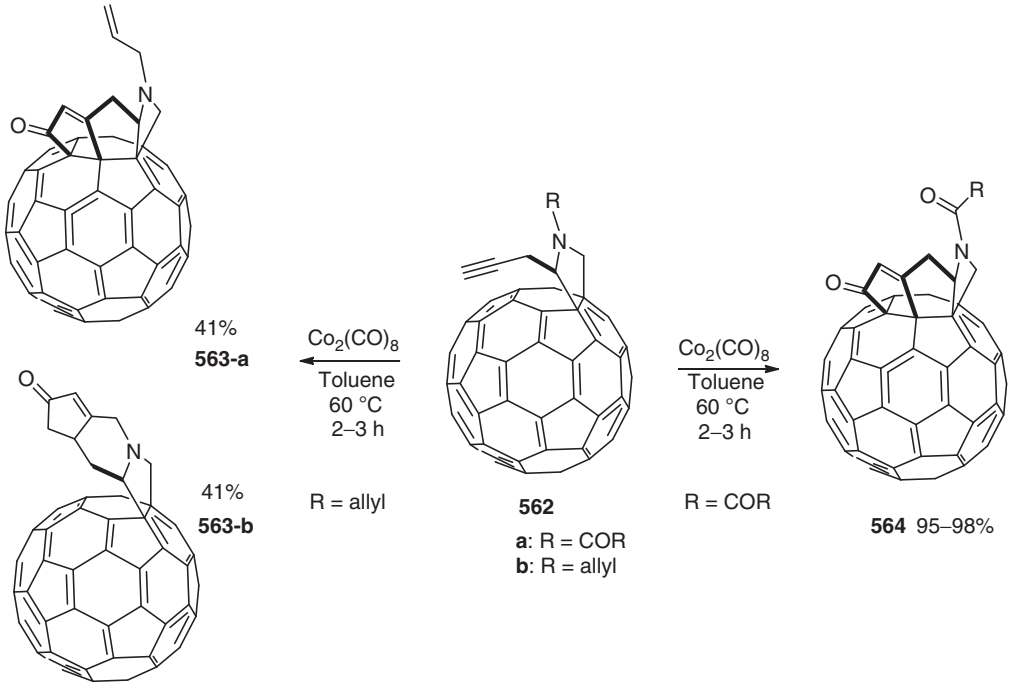
Compound **556**, an analog of biotin (**555**), in which the urea moiety of the natural product is replaced by a ketone, was obtained starting from the substrate **552** (equation 147).[223]



(147)

The ε-amino acid **558** was synthesized from the PKR product **557**, which has a rigid backbone together with flexible ends, and used as a probe for protein folding (equation 148).[224]

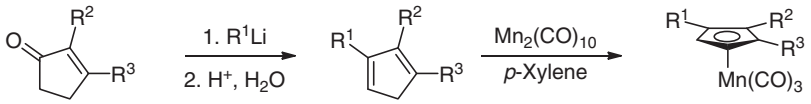
(148)



Numerous unnatural cyclic amino acids were synthesized in optically pure form by the transition metal mediated reaction from enyne substrates carrying the Schoellkopf bislactam ether auxiliary. The promoter-assisted PKR of substrate **559** provided a diastereomeric mixture (1:1) of the bicyclic compound **560**, which were separated easily by flash chromatography and then transformed into the corresponding amino acids **561** (equation 149).[225]

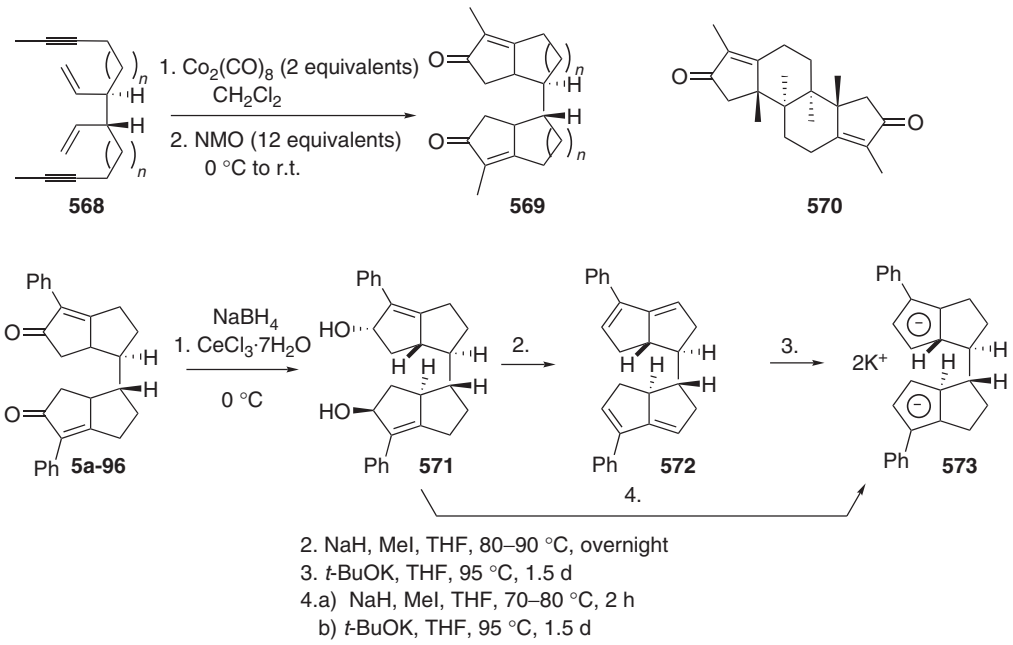
(149)

5.24.6.2 Miscellaneous



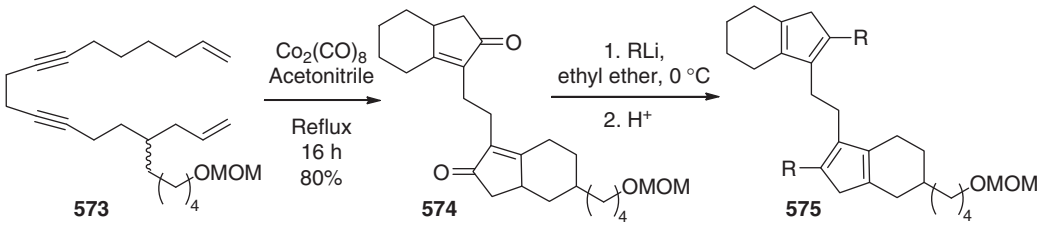
When the fullerene derivative **562-a** was subjected to the PKR, the reaction was forced to take place on C_{60}. However, there are two options when **562-b** is employed, but no significant preference was observed, yielding a 1:1 mixture of **563,** which means that the reactivity of the olefin within C_{60} is comparable to that of the allyl group (equation 150).[226]

(150)



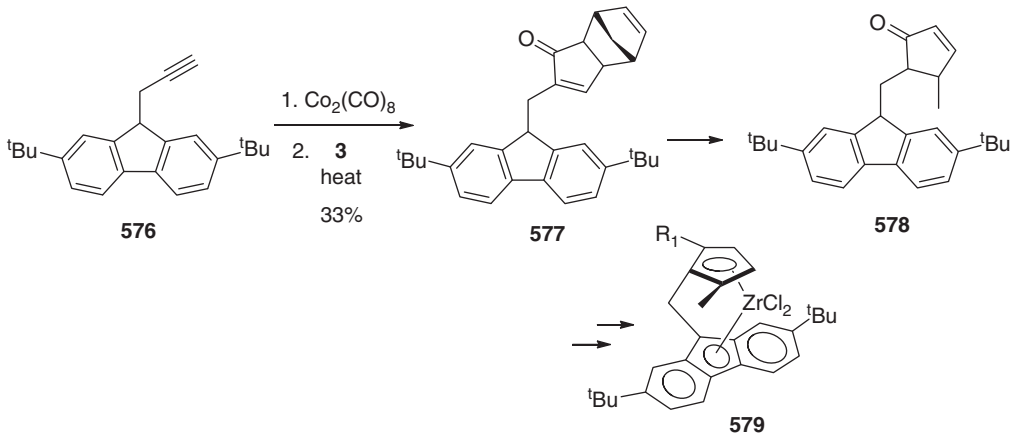
5.24.6.2.1 Cyclopentadienes

Cyclopentenones obtained by the PKR can be used as precursors for Cp-type ligands. These efforts are summarized thoroughly elsewhere. Chung and Jeong demonstrated the efficient transformation of the PKR product into the Cp ligand. Subsequently, many applications followed. A given cyclopentenone was treated with an alkyl lithium reagent, followed by dehydration by an acid to give a mixture of regioisomers of cyclopentadienes **565** (equation 151).[227]



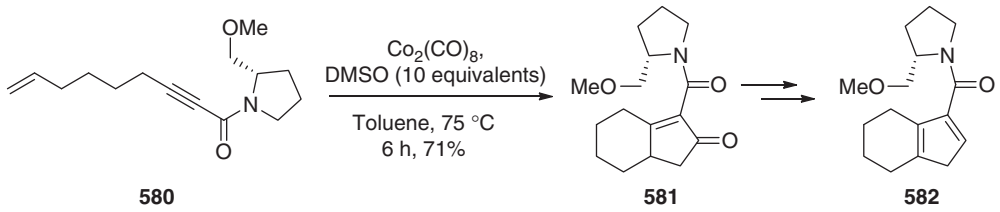
(151)

It is interesting to notice that the double PKR of substrate **567** gave rise to product **568** instead of **569**. This can be accounted for by the fact that the two bicyclic[3.3.0] rings are more favorably formed than the fused [4.3.0] ring, when $n=1$. **568-a** was further modified to give the bis Cp-ligand **572** (equation 152).[228]



(152)

The same strategy was applied to the synthesis of **575**. The appendage on **575** can be used for the immobilization of this ligand on a solid support (equation 153).[229]



(153)

The derivatives **579**, which were obtained from **578**, were used as catalysts in combination with methylaluminoxane (MAO) for ethylene–norbornene copolymerization and their activity is comparable to that of isopropylene[9-fluorenylcyclopentadienyl]zirconium dichloride under identical conditions.[79a] **578** was derived from **577**, a PKR product of **576**, by a series of reactions including the 1,4-addition of a methyl group and a retro-Diels–Alder reaction (equation 154).[230]

(154)

Moyano and Pericas prepared the cyclopentadiene **582** having a chiral appendage (equation 155; see equation 44).[231]

(155)

5.24.7 Conclusions

The Pauson–Khand reaction is a truly remarkable synthetic method in several respects. It creates much molecular complexity in one-step while retaining the original functionality in the substrate. Every carbon on the pentagon corner can be further functionalized to lead to the desired target products decorated with various functional groups.

The drawbacks imposed on the early version of this transformation, such as the limited substrate scope, low efficiency, and problems associated with regio- and stereoselectivity, have been overcome and/or eliminated by the extensive efforts over the past four decades. Thus, the horizon of the reaction has been greatly widened. More specifically, the finding of promoters for the stoichiometric cobalt-mediated reaction, and the development of catalytic versions, including heterogeneous as well as enantioselective ones, clearly demonstrate that its application to synthetic chemistry in academia and even in industry is more tangible. We have also witnessed the rapid expansion of the substrate scope and are expecting further applications of this method to be developed. With the deepening understanding of the reaction mechanism and accumulated knowledge of its regio- and stereoselectivities, this reaction has become an indispensable tool in organic synthesis.

Glossary

Benzannulation Construction of a benzene ring from a nonbenzene precursor.

Carbene complex A compound that contains a double bond between a carbon and a metal, or the metal complex of a stable carbene species.

Cyclization Construction of a new ring system in a process that creates one bond of the newly formed ring system.

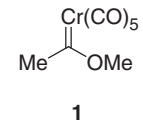
Cycloaddition Construction of a new ring system in a process that creates two or more bonds of the newly formed ring system.

Cyclohexadienone annulations The Dötz benzannulation reaction applied to a β-disubstituted-α,β-unsaturated carbene complex, resulting in a cyclohexadienone system since aromatic ring formation is blocked.

Cyclopentannulation Construction of a five-membered carbocyclic ring system from a precursor that does not already contain the five-membered ring system.

Cyclopropanation Creation of a cyclopropane ring via the coupling of an alkene and a carbene or carbene complex.

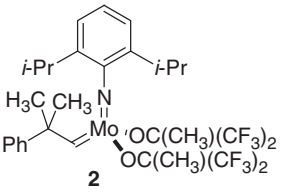
Dötz benzannulation reaction The construction of a phenol through reaction of an α,β-unsaturated carbene complex and an alkyne; formally a $[3+2+1]$-cycloaddition incorporating the carbene carbon and unsaturated group, the alkyne, and CO.



Enynylcarbene complex A carbene complex that contains an alkyne group at the carbene compound, featuring an alkene group attached to the other side of the alkyne.

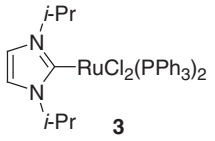
Olefin metathesis Exchange of the alkene carbons of two or more alkenes, often catalyzed by transition metal carbene complexes.

Tandem reaction A reaction where the initial product is designed to undergo an additional reaction process without isolation of the initial product.



5.25.1 Introduction

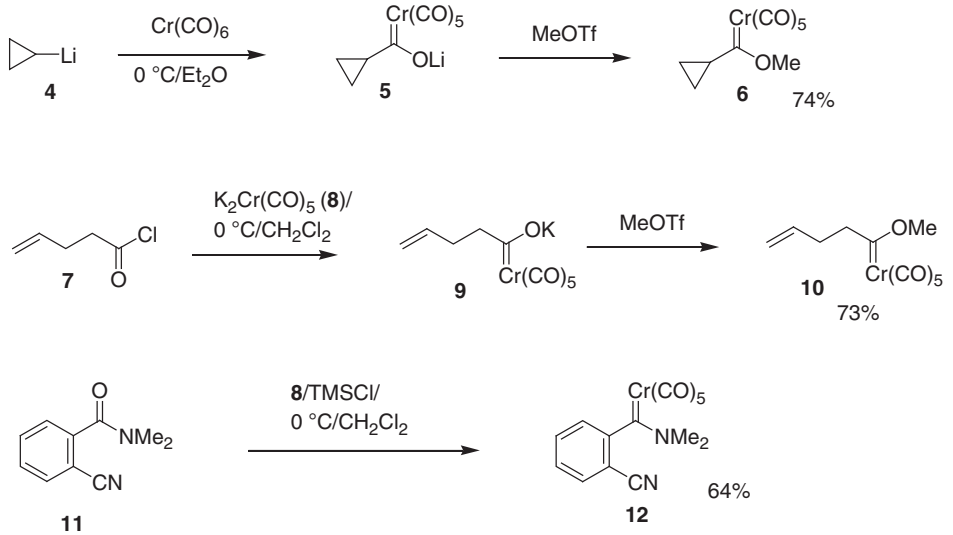
This chapter is an update to a chapter by the same title published in the first edition of Comprehensive Organic Synthesis.[1] The literature of carbene complexes in the intervening years has been vast. Emphasis in this chapter is the reactions where new ring systems are formed as a result of the reaction with a carbene complex and emphasizes the period of 1990–2010. This has been divided into two sections, involving reactions at the carbene ligand followed by reactions that initially occur at the metal center. The review has primarily been restricted to reaction processes that lead to an organic structure and is also primarily restricted to reaction processes that involve a stable carbene or isolable carbene complex as one of the reactants. In most cases, only processes that have been demonstrated by a significant number of examples have been presented. There are three general classes of carbene complexes, Fischer carbene complexes, Schrock carbene complexes, and Arduengo carbene complexes. Fischer carbene complexes feature electrophilic carbene carbons and relatively low oxidation state metals. Schrock carbene complexes feature nucleophilic carbene carbons and relatively high oxidation state metals. Arduengo carbene complexes, often referred to as *N*-heterocyclic carbene (NHC) complexes, feature carbene ligands that are moderately stable as free carbenes and display minimal C–M double bond character. Emphasis in this chapter is on Fischer-type carbene complexes, which are electrophilic at the carbene carbon. Schrock carbene complexes are reviewed elsewhere. Arduengo carbene complexes typically undergo no change in their chemical structure in most reactions. The vast majority of the carbene complexes depicted in this review involve the Group 6 metals. The chapter is intended to give an overview and present as many examples as is possible, which demonstrate the synthetic utility of individual processes, and is thus not comprehensive. Major comprehensive review works in this area have been authored by the Barluenga,[2,3] Dötz,[4] and Wulff[5] groups. Many other subject-specific reviews have appeared and are noted; their areas of relevance are discussed. A comprehensive survey of all carbon–metal doubly bonded systems appears annually.[6] The chapter headings employed in the Wulff chapter in Comprehensive Organic Synthesis, 1st edition, have been largely retained in this chapter; however, the proliferation of tandem reaction processes incorporating multiple reaction types has made it difficult to uniquely classify many of the reaction processes.



1

A Fischer carbene complex

2

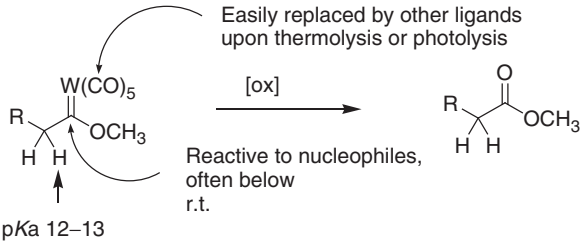


A Schrock carbene complex

3

An Arduengo (or NHC) carbene complex

Carbene complexes employed in these investigations are prepared using primarily two basic methods, depicted in **Scheme 1**. Synthesis of carbene complexes from organolithium reagents (**4**) is known as the Fischer synthesis. The Fischer synthesis is the most commonly employed method for carbene complex preparation. In this conversion, the organolithium reagent is treated with a metal carbonyl derivative, and the resulting acylate complex is treated with a highly reactive alkylating agent. Recent improvements in Fischer synthesis include several papers reporting the use of less expensive iodides in the final alkylation step.[7,8]

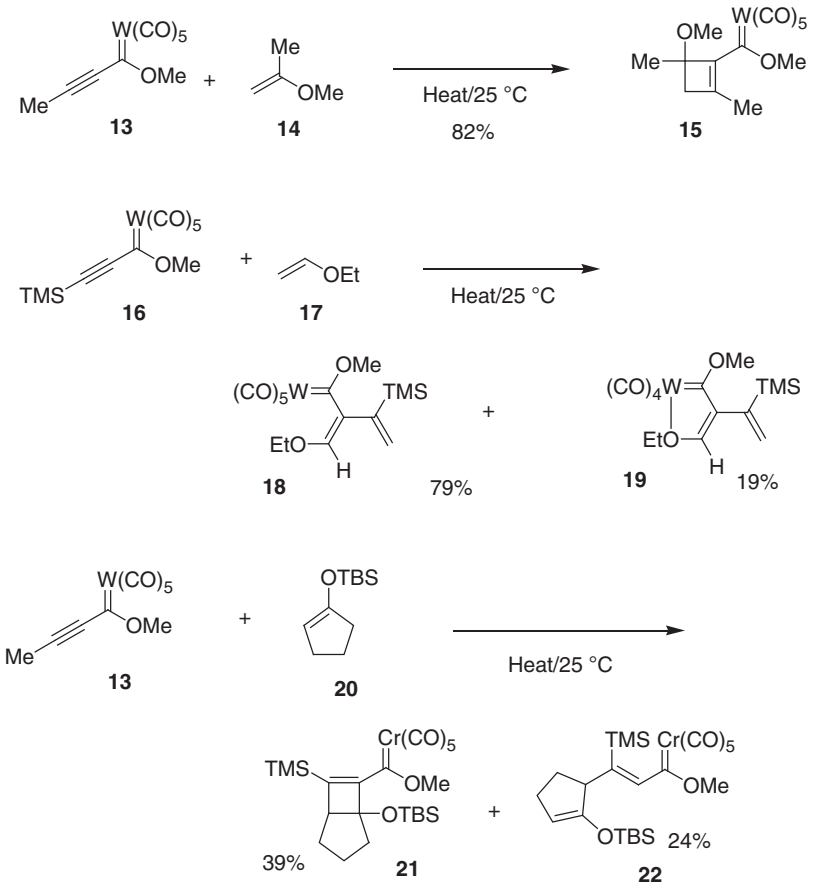


Scheme 1

Most of the carbene complexes depicted in this chapter are synthesized according to this method. The most commonly used alternative method involves the use of acid chlorides (**7**) or amides (**8**) and is known as the Hegedus/Semmelhack synthesis. Alkoxycarbene complexes are prepared from the reaction of acid chlorides with metal carbonyl dianions (**8**), which are then treated with highly reactive alkylating agents as in the Fischer synthesis. Aminocarbene complexes are obtained from the reaction of tertiary amides with metal carbonyl dianions in the presence of silyl chlorides, resulting in the direct formation of the aminocarbene complex. Other lesser employed methods have been documented, including preparation from terminal alkynes via vinylidene complexes and preparation from diazo compounds.

5.25.2 Reactions on the Carbene Ligand: The Metal as Reactivity and Selectivity Auxiliary

The representative reactivity profile for Fischer carbene complexes is depicted in Scheme 2. In several cases, the carbene complex functionality serves as a surrogate for an activated ester or amide. The carbene complex group functions as a strongly electron-withdrawing group and leads to a substantial increase in the acidity of protons at the alpha position. The p*K*a value for protons in simple alkyl complexes is approximately 12–13 for alkoxycarbene complexes[9] and 25–30 for aminocarbene complexes (in acetonitrile).[10] The carbene complex functionality also electronically activates conjugated alkene and alkyne groups for nucleophilic addition processes and other cycloaddition processes commonly associated with α,β-unsaturated carbonyl compounds. The carbene complex functionality is easily transformed into the corresponding carbonyl group through reaction with a variety of mild oxidizing agents. The carbene complex functionality also undergoes nucleophilic acyl substitution-like processes than can transform alkoxycarbene complexes to aminocarbene or thiocarbene complexes. Finally, the carbene complex undergoes numerous reactions at the metal atom.



Scheme 2

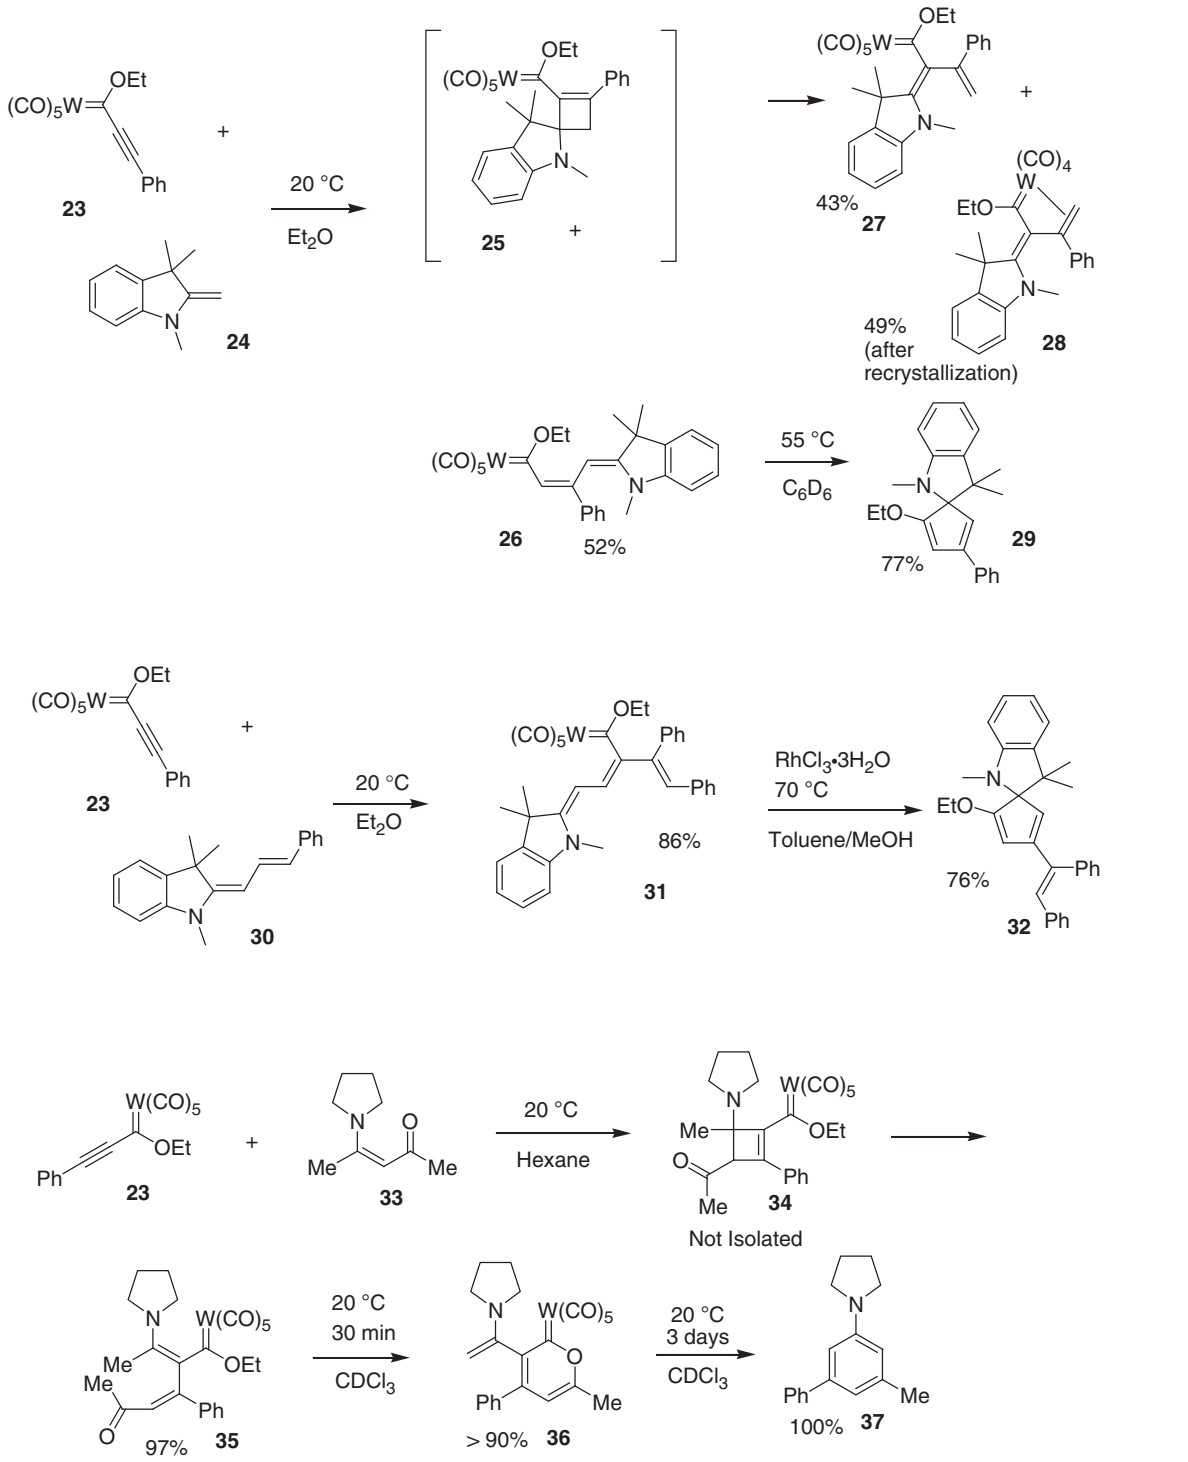
5.25.2.1 2 + 2 Cycloaddition

As noted in the previous edition of Comprehensive Organic Synthesis, several examples of this process involving primarily the reaction of alkynylcarbene complexes of Group 6 metals and highly electron-rich alkenes, in most cases enol ethers or enamines, had been reported. The reaction occurs under milder conditions than analogous ester systems (typically room temperature). The reaction typically proceeds with retention of configuration and is frequently accompanied by subsequent ring-opening reactions of the initially formed cyclobutenes. Representative examples reported since the previous edition of Comprehensive Organic Synthesis are depicted in Scheme 3. The carbene complexes are easily transformed to the analogous esters through reaction with various oxidants (e.g., DMSO). Most of the examples demonstrated to date involve alkynylcarbene complexes. In numerous cases, addition to the alkyne group of alkynylcarbene complexes is employed for the primary purpose of setting up an electrocyclization process. Examples of this will be presented in a future section. An extensive compilation of [2 + 2]-cycloadditions and ene reactions for alkynylcarbene complexes and either enol ethers or ketene acetals has been reported.[11] These studies demonstrate a competition between ene reaction (product **22**) and [2 + 2] cycloaddition (product **21**). The ene reaction was favored for trimethylsilylalkynylcarbene complexes reacting with acyclic enol ethers and cyclic enol ethers featuring an exocyclic oxygen. In many cases, the products undergo cyclobutene ring opening to afford dienylcarbene complexes. The [2 + 2]-cycloaddition reaction can be accelerated through high-pressure conditions.[12] Coupling of enol ethers with *exo*-methylene cyclic carbene–chromium and –tungsten complexes resulted in a completely diastereoselective [2 + 2]-cycloaddition process.[13]

In most cases, the [2 + 2]-cycloaddition of alkynylcarbene complexes and enamines results in the direct preparation of ring-opened products. The initial coupling of alkynylcarbene complexes (e.g., **23**) and enamines proceeded via dual-reaction pathways (formation of **25** vs. **26**, Scheme 4): (1) [2 + 2]-cycloaddition followed by ring opening of the resulting cyclobutene to afford dienylcarbene complexes (e.g., **27** and **28**) or (2) Michael addition followed by cyclization to afford a cyclopentadiene derivative (e.g., **29**).[14,15] The reactions using dienamines (e.g., **30**) led to dienylcarbene complexes (e.g., **31**) through [2 + 2]-cycloaddition and ring opening, which also transformed to the corresponding cyclopentadienes (e.g., **32**).[16] Conversion of the dienylcarbene complex to the cyclopentadiene (**32**) could be accelerated by transforming the tungsten–carbene complex to a rhodium–carbene complex, which underwent a more rapid cyclization reaction. The reaction using β-aminoketones (e.g., **33**) leads to

Scheme 3

aminobenzene derivatives (e.g., **37**).[17] In this case, the initially formed [2 + 2]-cycloadduct opens to form the enamine **35**, which undergoes an internal condensation process to afford the pyridine derivative.



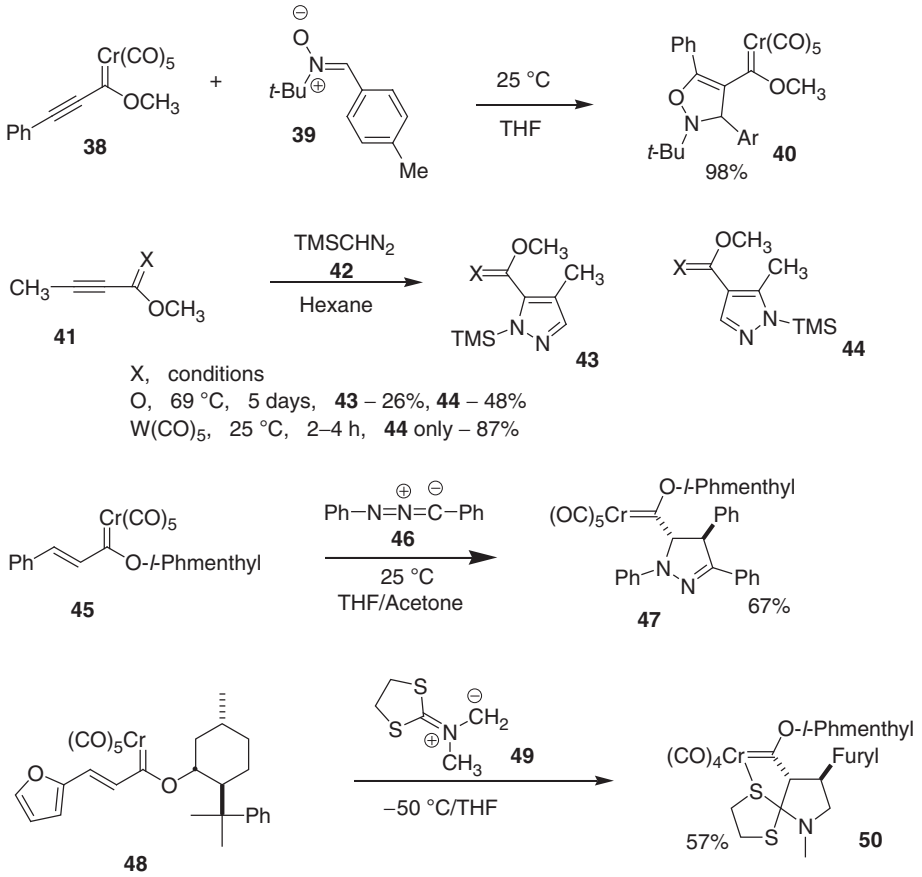
5.25.2.2 3 + 2 Cycloaddition

Several examples of the 1,3-dipolar cycloaddition reaction of alkenyl and alkynylcarbene complexes with various dipoles have been demonstrated. These reaction processes proceed under milder conditions and with higher regioselectivity than reactions employing analogous ester derivatives. The resulting products are easily transformed to esters through oxidation reactions. Some examples of this reaction were reported in the previous edition of Comprehensive Organic Synthesis; however, the range of dipole types has expanded tremendously since that publication.

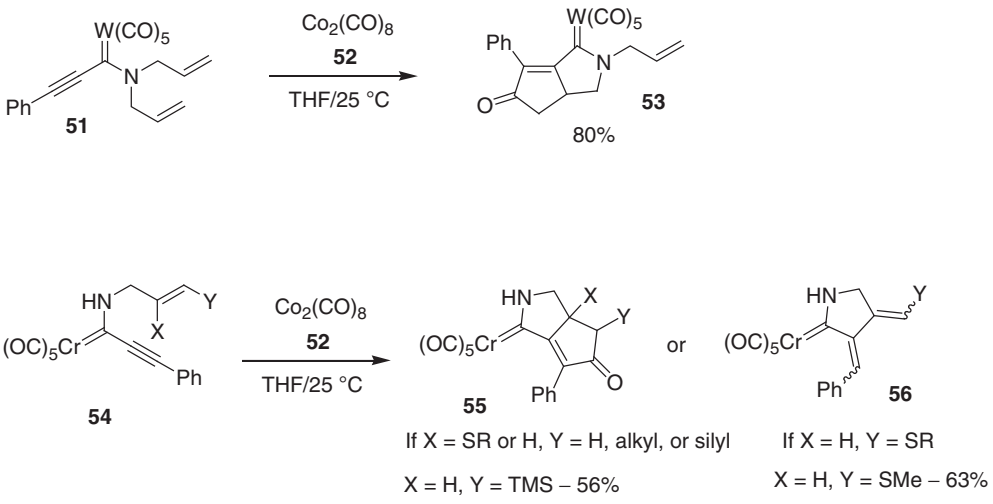
Examples of 1,3-dipoles that have been reported are depicted in Scheme 5 and include nitrones (e.g., **39**),[18–20] diazo compounds (e.g., **42**),[21,22] diazo ylides,[18] nitrilimines (e.g., **46**),[23] azomethine ylides (e.g., **49**),[24] and azides.[25,26] In most cases, the reaction proceeds with a very high degree of relative asymmetric induction when carbene complexes featuring chiral oxygen or nitrogen carbene substituents were employed. The azomethine ylide cycloaddition process was used as a key step in the enantioselective synthesis of rolipram. A theoretical study of 1,3-dipolar cycloaddition reactions of alkynyl Fischer carbene complexes suggests that the origin of the superior reactivity and regioselectivity arises from a transition state that is more asynchronous than that for esters.[27] Nonconcerted cycloaddition reactions were observed using alkylideneimidazole derivatives.[28]

5.25.2.3 2 + 2 + 1 Cycloaddition

Several examples that employ carbene complexes as reactive auxiliaries in the Pauson–Khand reaction have been reported (Scheme 6). These Pauson–Khand reactions occur at much milder temperatures than typical intramolecular Pauson–Khand reactions. Most of the successful examples involve an alkynylcarbene complex featuring an allylamino group (e.g., **51**).[29,30] The Pauson–Khand reaction involving allylamino(alkynyl)carbene complexes was studied, with emphasis on heteroatom-substituted alkene derivatives.[31] Alkene–carbene complexes (**54**) where X is a thio group and Y is a nonheteroatom afforded mostly Pauson–Khand products (**55**), whereas derivatives of **54** where Y is a heteroatom afforded mostly diene derivative (**56**). The



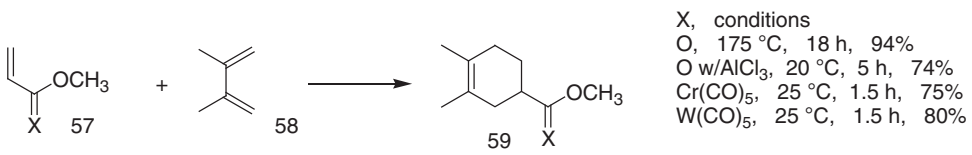
Scheme 4



reactivity of alkynylcarbene complexes in the Pauson–Khand reaction was accelerated by fluoride ion.[32] The use of carbene complexes where the alkyne is not conjugated in intermolecular Pauson–Khand reactions has also been reported.[33]

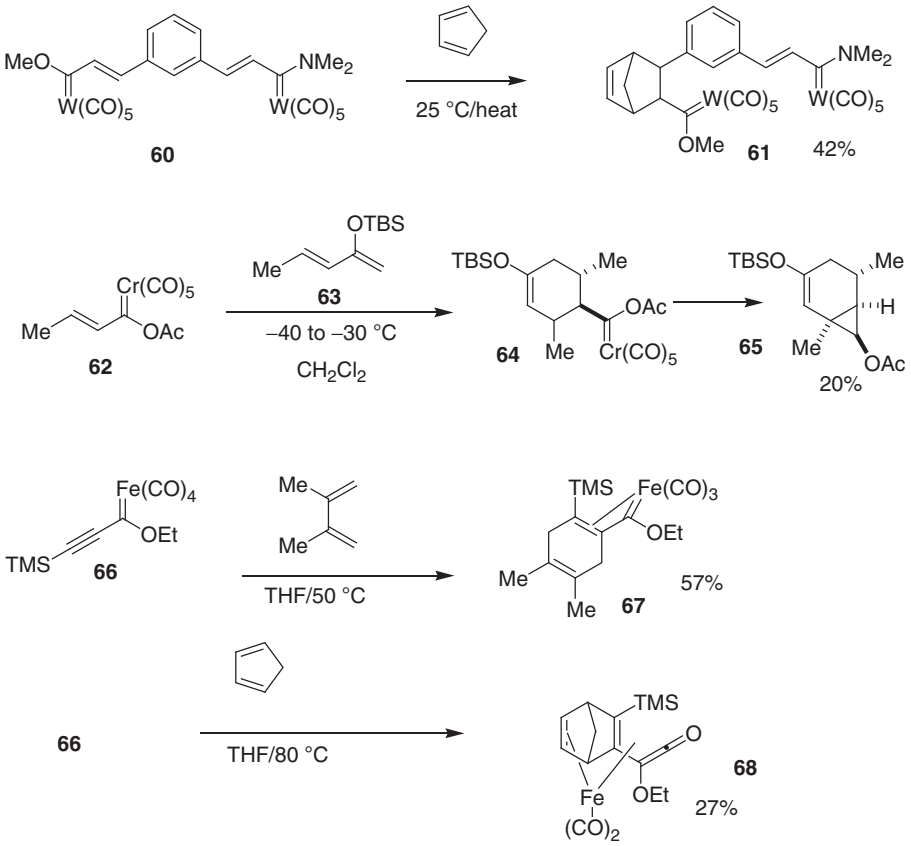
5.25.2.4 4 + 2 Cycloaddition

One of the major synthetic uses of carbene complexes is the Diels–Alder reaction of α,β-unsaturated carbene complexes and dienes[34] (Scheme 7). These complexes are extremely reactive dienophiles. Their reactivity resembles that of α,β-unsaturated esters

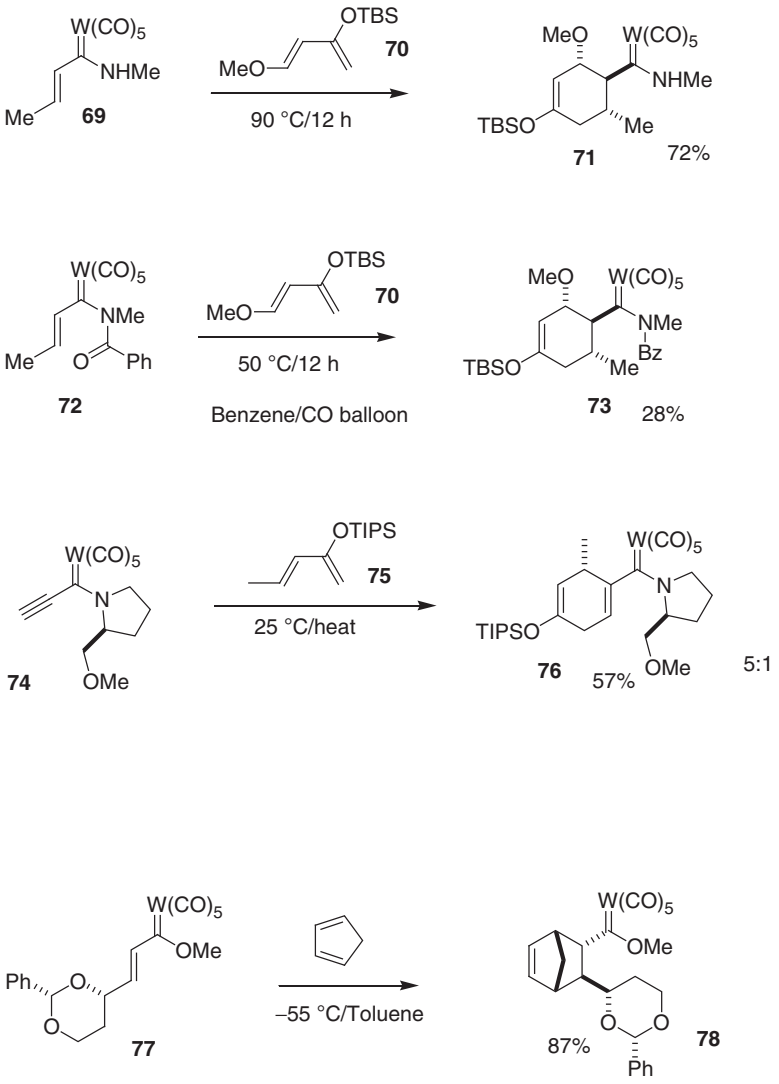


Scheme 5

Scheme 6



in the presence of Lewis acids, and they offer superior regio- and stereoselectivity in reactions with unsymmetrical dienes relative to α,β-unsaturated esters. Diels–Alder reactions involving α,β-unsaturated carbene complex dienophiles often proceed at room temperature. Oxidation of the carbene complex adducts to the corresponding esters or amides can be accomplished with a variety of reagents under very mild conditions. Numerous synthetic transformations have been demonstrated for the carbene complex functionality. Specific cases that demonstrate these and several other features are discussed in the following paragraphs. A variety of diene types have successfully been employed in this process, including several examples of 2-amino-1,3-dienes[35–37] and

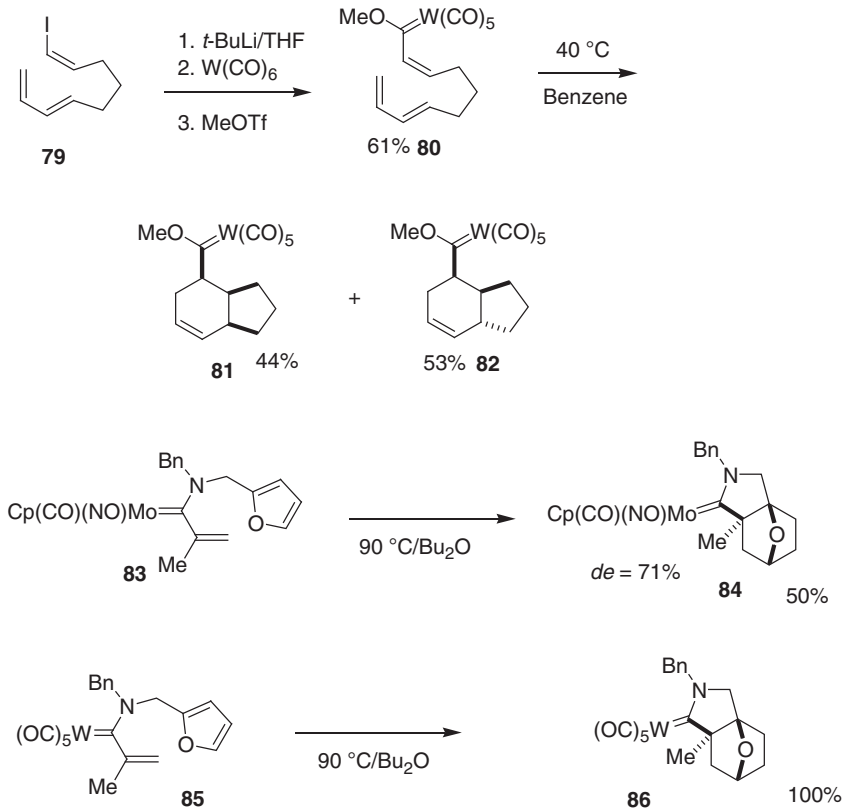


Scheme 7

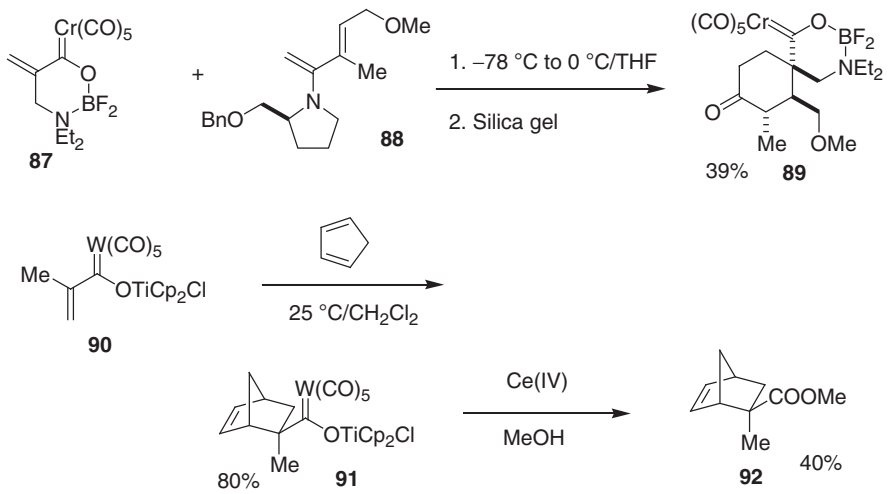
imino-dienes, which result in pyrimidine derivatives.[38,39] Alkoxycarbene complexes, aminocarbene complexes, and acyloxycarbene complexes have all been successfully demonstrated. Alkoxycarbene complexes are generally more reactive, as noted in the reaction of bis(carbene complex) **60** with cyclopentadiene (Scheme 8).[40] The acyl analogs of both aminocarbene complexes and alkoxycarbene complexes are more activated for the Diels–Alder reactions. The reaction of acetoxycarbene **62** and 2-silyloxydienes afforded bicyclo[4.1.0]heptane derivatives (e.g., **65**) in a process involving Diels–Alder reaction followed by intramolecular C–H insertion, which occurs in competition with direct cyclopropanation.[41] Diverse functionality has been demonstrated for the carbene ligand, including α-alkoxyethenylcarbene complexes.[42] Use of the parent ethynylcarbene complex in the Diels–Alder reaction with cyclopentadiene has also been demonstrated.[43] Although most of the examples employ chromium and tungsten carbene complexes, examples using iron–carbene complexes (e.g., **66**) have also been demonstrated.[44] In some cases, the product vinylcarbene complexes directly afford the ketene complexes (e.g., **68**). In many cases, an initial Diels–Alder reaction is followed up by another process employing the carbene complex functionality; examples of these processes are depicted in a future section.

A diverse array of stereoselective Diels–Alder reactions have been demonstrated for carbene complexes. The use of chiral auxiliaries to effect relative asymmetric induction in Fischer carbene complex reactions has been reviewed.[45] A variety of *exo*-selective Diels–Alder reactions of aminocarbene–tungsten complexes were demonstrated (Scheme 9).[46,47] The *exo*-selectivity derives from steric inhibitions in the approach of the diene from the endo direction. The simple aminocarbene complexes (e.g., **69**) were reactive only with the most reactive dienes, and only the E rotamer was reactive. The *N*-acyl complexes (e.g., **72**) were far more reactive. This reaction can also be conducted asymmetrically if a chiral auxiliary is present on the heteroatom substituent. Moderately diastereoselective Diels–Alder reactions were observed using chiral alkynylcarbene complexes (e.g., **74**).[48] Diastereoselective Diels–Alder reactions were also reported for chiral α,β-unsaturated carbene complex **77**.[49] Stereoselective Diels–Alder reactions were reported for cyclic carbene complexes featuring an *exo*-methylene group and a carbohydrate substituent.[50]

Scheme 8



Scheme 9

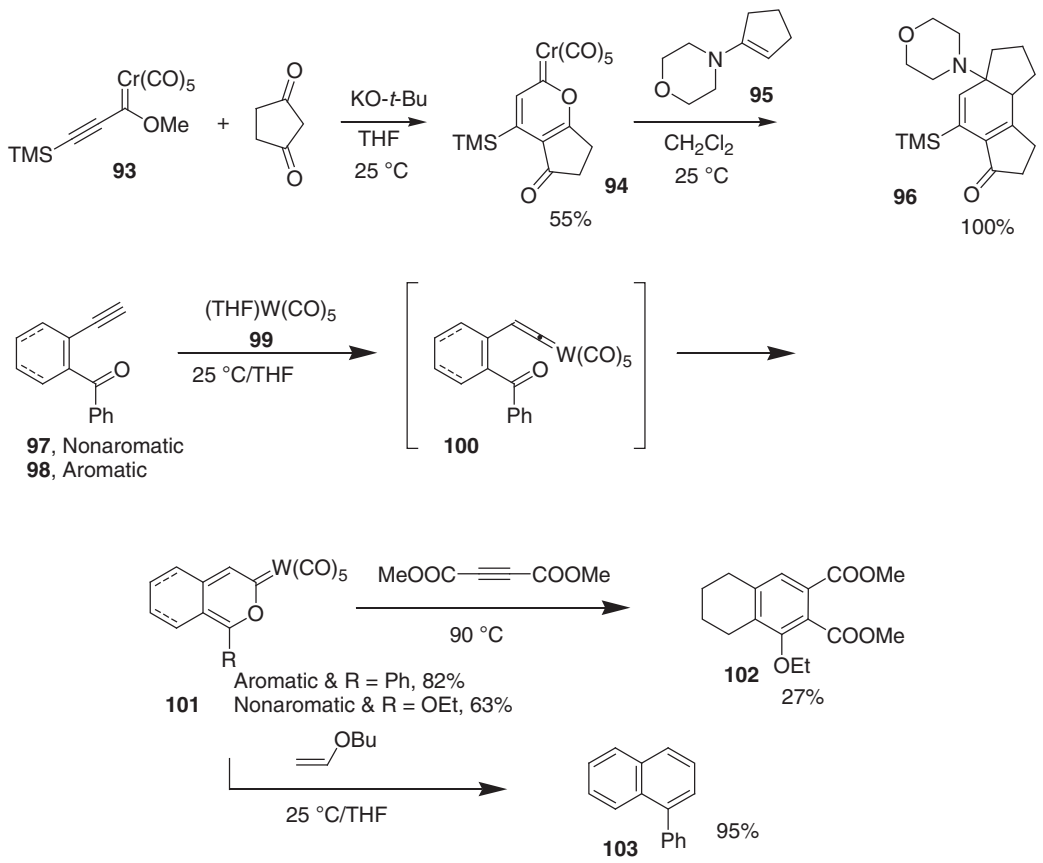


Several examples of intramolecular Diels–Alder reactions involving carbene complexes were also demonstrated (Scheme 10).[51] Carbene complexes containing triene functionality (e.g., **80**) were prepared using the Fischer route and cyclized on mild thermolysis to afford a mixture of *exo* (**82**) and *endo* (**81**) isomers. Chiral-at-molybdenum α,β-unsaturated carbene complexes (e.g., **83**) were prepared and their intramolecular Diels–Alder reactions with appended furan rings examined.[52] A comparison with analogous achiral tungsten– and manganese–carbene complexes and simple ester analogs was also conducted. The diastereoselectivity in the Diels–Alder step was moderate; however, it was better than that observed for achiral-at-metal carbene complexes featuring chiral nitrogen substituents. The molybdenum complexes were less reactive than the $(CO)_5$W- and $Cp(CO)_2$Mn-complexes and provided the lowest yields of Diels–Alder products.

Several examples that involve bimetallic carbene complexes have also been reported (Scheme 11). Use of these complexes is advantageous in that the alkylation step of carbene complex synthesis can be avoided. The reaction of cyclic boryloxycarbene complexes (e.g., **87**) with various dienes afforded the Diels–Alder products under very mild conditions.[53] Use of chiral dienes led to the cycloadducts with a high degree of enantioselectivity. The reaction of titanium acylate α,β-unsaturated carbene complexes (e.g., **90**) and dienes was also *exo*-selective.[54]

Several examples of inverse electron-demand Diels–Alder reactions using dienylcarbene complexes were reported (Scheme 12). A net [3 + 3]-cycloaddition of alkynylcarbene complex **93** and 1,3-diketones led to pyranylidene complexes (**94**), which then undergo Diels–Alder reaction with electron-rich alkenes.[55] Several pyranylidene complexes (**101**) were prepared through the reaction of enyne-carbonyl derivatives (e.g., **97** and **98**) with Group 6 metal pentacarbonyl sources. The intermediate pyranylidene complexes undergo reaction with both electron-rich and electron-deficient dienophiles.[56] Diels–Alder reaction of **101** with electron-deficient acetylenes followed by loss of tungsten hexacarbonyl afforded highly substituted aromatic rings

Scheme 10

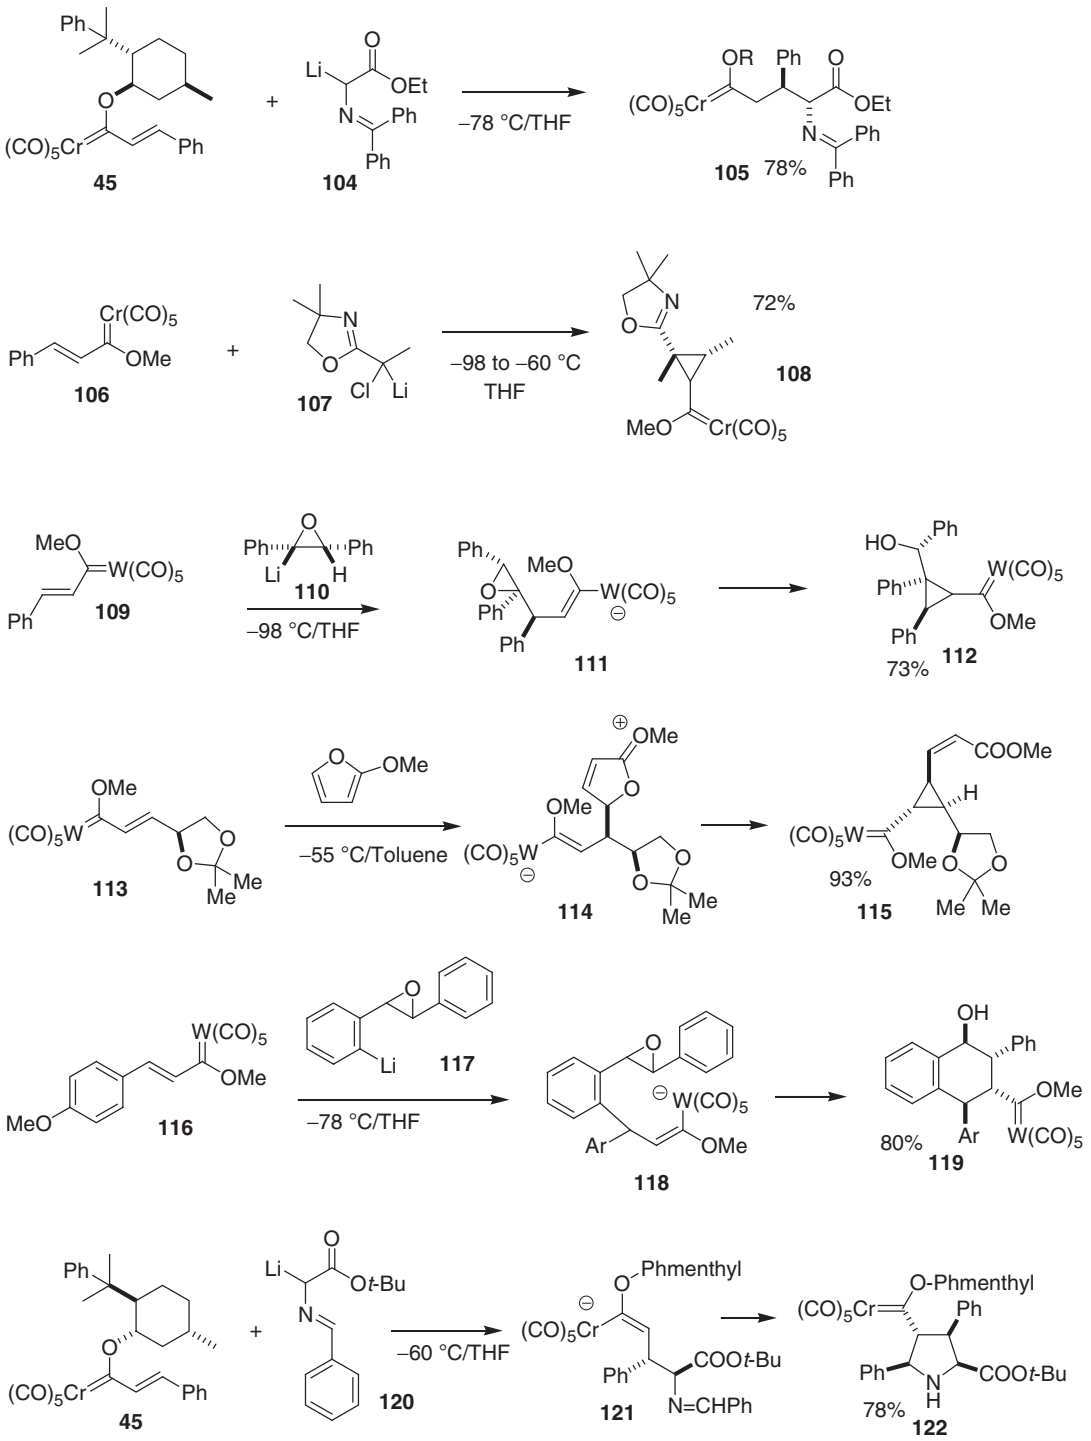


Scheme 11

(e.g., **102**). An analogous reaction process was reported for *o*-ethynylbenzoates and phenylketone analogs.[57] The resulting *o*-quinoidal systems underwent Diels–Alder reactions with enamines and enol ethers to afford naphthalene ring systems.

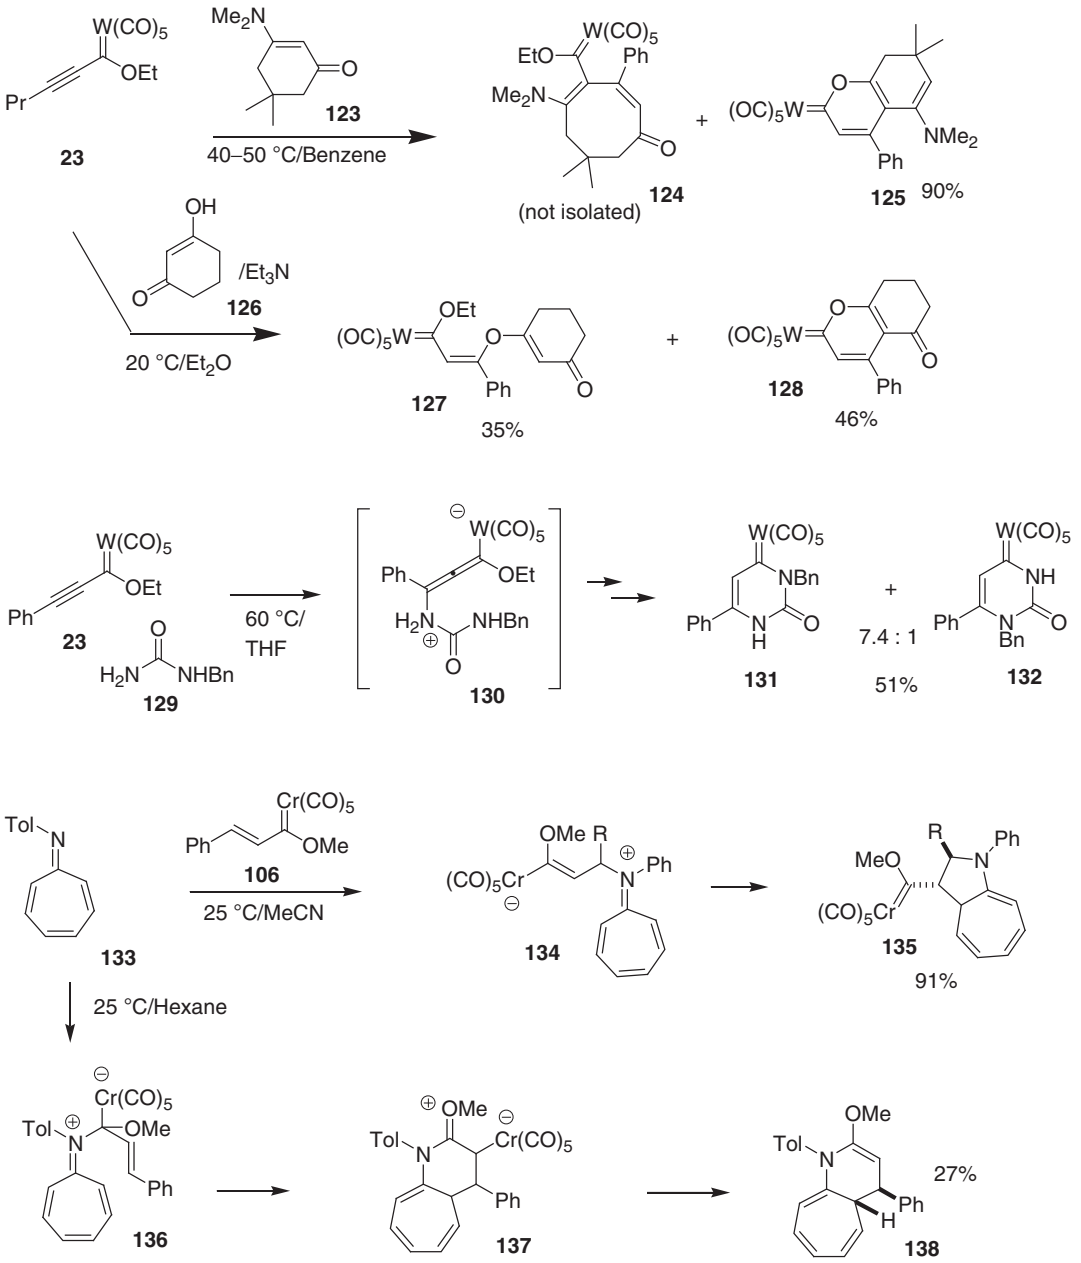
5.25.2.5 Michael Addition to α,β-Unsaturated Carbene Complexes

Many examples of simple and complex reaction processes initiated by nucleophilic addition to an α,β-unsaturated carbene complex have been documented. Due to the superior electron-withdrawing ability of a carbene complex functionality, this process typically proceeds under milder conditions than analogous Michael additions to purely organic carbonyl compounds. As in the case with purely organic compounds, Michael addition occurs in competition with direct nucleophilic addition to the carbene



Scheme 12

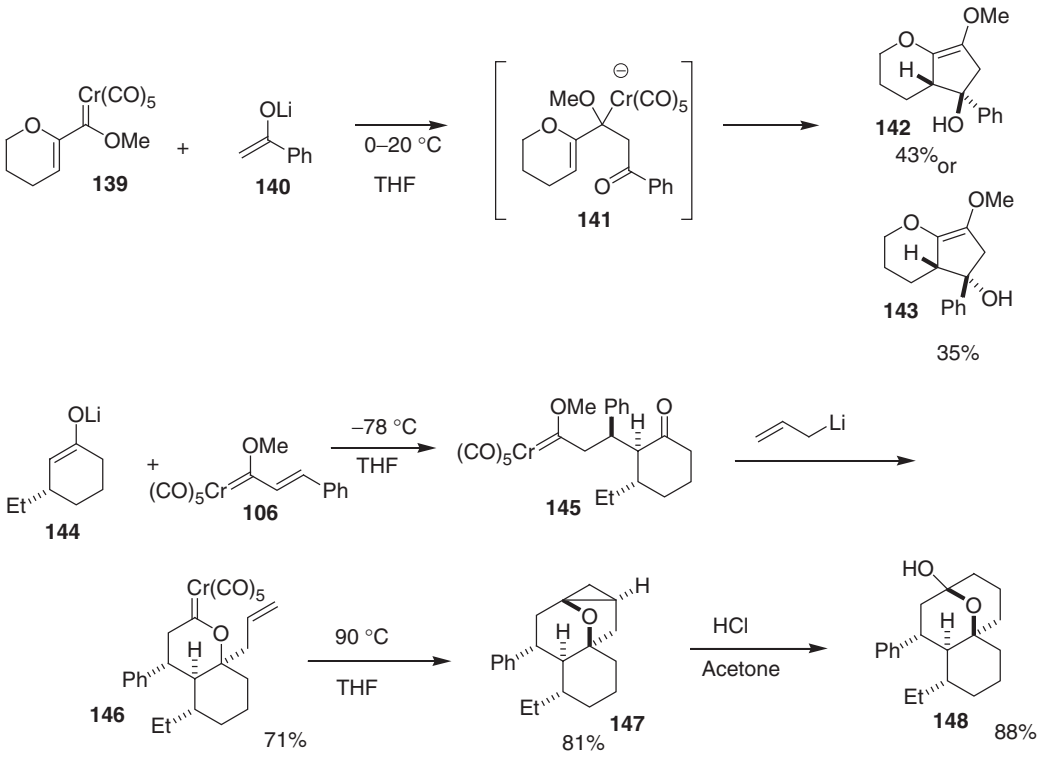
carbon of these complexes. Many of the reported studies involve both types of processes. Many of the Michael additions to alkynylcarbene complexes are merely the first step in a tandem process involving the resulting alkenylcarbene complex. Examples of these processes will be discussed in a subsequent section.



Several examples of simple Michael addition followed by electrophilic quench, resulting in more complex carbene complexes, have been documented. The Michael addition of glycine-derived carbanions (e.g., **104** and Scheme 13) to homochiral α,β-unsaturated alkoxycarbene complexes featuring a chiral alkoxy substituent (e.g., **45**) led to carbene complexes having multiple stereocenters (e.g., **105**) with a very high degree of stereoselectivity.[58] Reactions involving diphenylmethylidene-protected amines were highly selective for formation of the antidiastereomer, whereas reactions involving dibenzyl-protected or disilyl-protected nitrogens were selective for formation of the *syn* diastereomer. In all cases involving the 8-phenylmenthyl chiral auxiliary, the addition was completely face selective. The reaction of organolithium reagents to furyl menthyloxycarbene complexes afforded Michael addition products with a moderate degree of diastereoselectivity.[59] Cyclopropylcarbene–chromium complexes (e.g., **108**) are produced from the coupling of α,β-unsaturated chromium carbene complexes (e.g., **106**) and lithiated α-chloroiminoesters (e.g., **107**).[60] The reaction involves the Michael addition to the carbene complex followed by intramolecular S_N2 reaction. Cyclopropylcarbene tungsten complexes were prepared by Michael addition of lithiated epoxides (e.g., **110**)[61] or epoxide-imin-others to α,β-unsaturated tungsten complexes.[62] Synthesis of chiral cyclopropylcarbene complexes through Michael addition of iodomethyllithium to chiral and enantiomerically pure α,β-unsaturated carbene complexes has also been demonstrated.[63] A novel cyclopropanation reaction was observed in the coupling of chiral α,β-unsaturated tungsten carbene complexes (e.g., **113**) with methoxyfuran, leading to alkenylcyclopropylcarbene complexes (e.g., **115**).[64] A mechanism involving Michael addition to afford a zwitterionic intermediate (**114**) followed by intramolecular S_N2 reaction on the oxonium ion intermediate was proposed. The overall process was highly stereoselective. A net [4 + 2]-cycloaddition reaction was observed in the coupling of *o*-lithiated stilbene oxides (e.g., **117**) with α,β-unsaturated carbene complexes (e.g., **116**).[65] A mechanism involving Michael addition to form intermediate **118**, followed by intramolecular S_N2 reaction at the epoxide in a 6-*endo* fashion was proposed. Pyrrolidine derivatives (e.g., **122**) were prepared through the coupling of chiral and optically pure α,β-unsaturated carbene complexes (e.g., **45**) with imido-enolate derivatives (e.g., **120**).[66] A mechanism involving stereocontrolled Michael addition followed by addition of the resulting anion to the imine was proposed.

Several examples of net [3 + 3]-cycloaddition processes have been reported for alkynylcarbene complexes (Scheme 14). In general, these reactions proceed through Michael addition followed by proton transfer followed by an intramolecular addition to the carbene carbon. The coupling of alkynylcarbene complexes (e.g., **23**) with enaminones (e.g., **123**) led to either ring expanded

Scheme 13



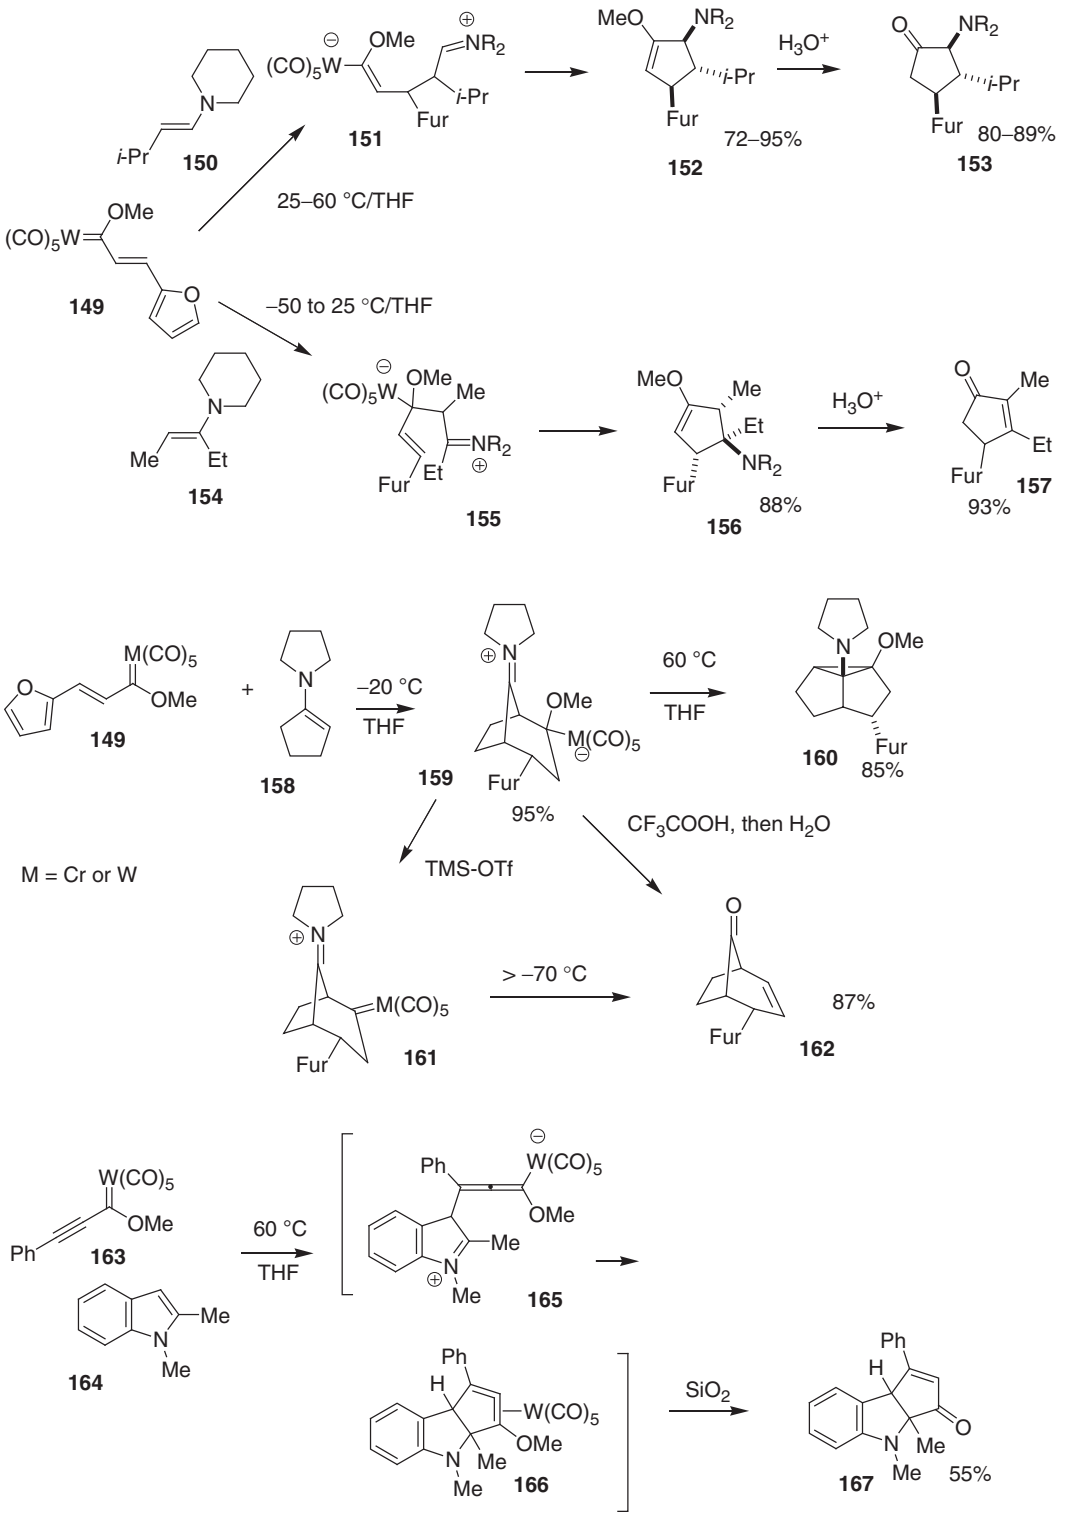
products (e.g., **124**) or cycloaddition products (e.g., **125**).[67] A mechanism involving [2 + 2]-cycloaddition followed by ring expansion was proposed for the formation of cyclooctadienone product **124**. For formation of [3 + 3]-cycloadduct **125**, Michael addition, followed by proton transfer, followed by intramolecular displacement of the ethoxy group was proposed. The analogous reaction with 1,3-diketone enolate led to either products resulting from Michael addition at O (e.g., **127**) or to C-addition products, which later cyclized to carbene complexes of general structure **128**. Several examples of the net cycloaddition of urea derivatives to alkylcarbene complexes leading to uracil-like systems, which form via Michael addition followed by intramolecular heteroatom exchange at the carbene carbon, have been demonstrated.[68,69] Net competitive [8 + 3]- and [8 + 2]-cycloaddition processes were observed in the coupling of alkynylcarbene complexes and aza-heptafulvenes (e.g., **133**).[70,71] Carbene complexes

Scheme 14

that feature a five-membered heterocyclic or an alkene group in the β-position afforded exclusively [8 + 3]-cycloadducts regardless of the solvent employed. The proposed mechanism for the [8 + 2]-cycloaddition involves Michael addition followed by ring closure of the zwitterion (**134**). In the case of [8 + 3]-cycloaddition, direct addition to the carbene carbon followed by intramolecular attack on the ring by the allylchromium intermediate establishes the ring system (**137**), and subsequent loss of chromium affords the final product (**138**). Both processes were highly stereoselective. A variety of carbene complex demetallation reactions were demonstrated for the [8 + 2]-cycloadducts. The reaction of various primary diamines with alkynylcarbene tungsten and chromium complexes leads to cyclic products from Michael addition and carbene carbon addition.[72]

In several cases, addition of an enolate in a Michael fashion or directly to the carbene carbon initiates a cascade process that results in cyclic products (Scheme 15). Cyclopentenols (e.g., **143**) arise through the coupling of α,β-unsaturated carbene complexes (e.g., **139**) with enolates (e.g., **140**).[73] A mechanism involving 1,2-addition followed by nucleophilic addition to the carbonyl group with allylic rearrangement was proposed. The stereochemistry of the reaction was controlled by choice of solvent (ether vs. THF vs. coordinating additives). A novel eight-membered ring synthesis (e.g., formation of **148** from carbene complex **106**) results from the one-pot sequential coupling of a lithium enolate, α,β-unsaturated carbene complex, and an allylic Grignard reagent.[74] This reaction sequence proceeds through Michael addition of a silyl enol ether to the carbene complex, followed by

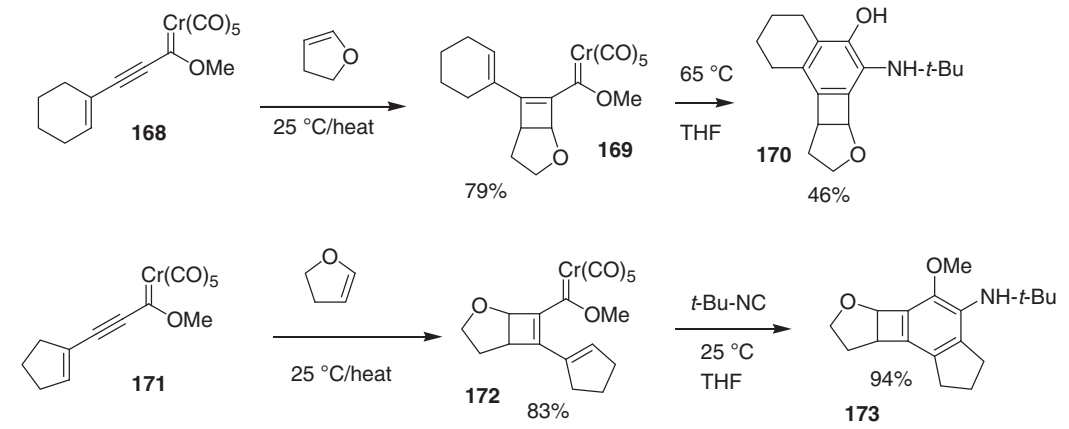
Scheme 15



allylation of the ketone group in Michael adduct **145** to form **146** after alkoxide metathesis, followed by intramolecular cyclopropanation and ring opening.

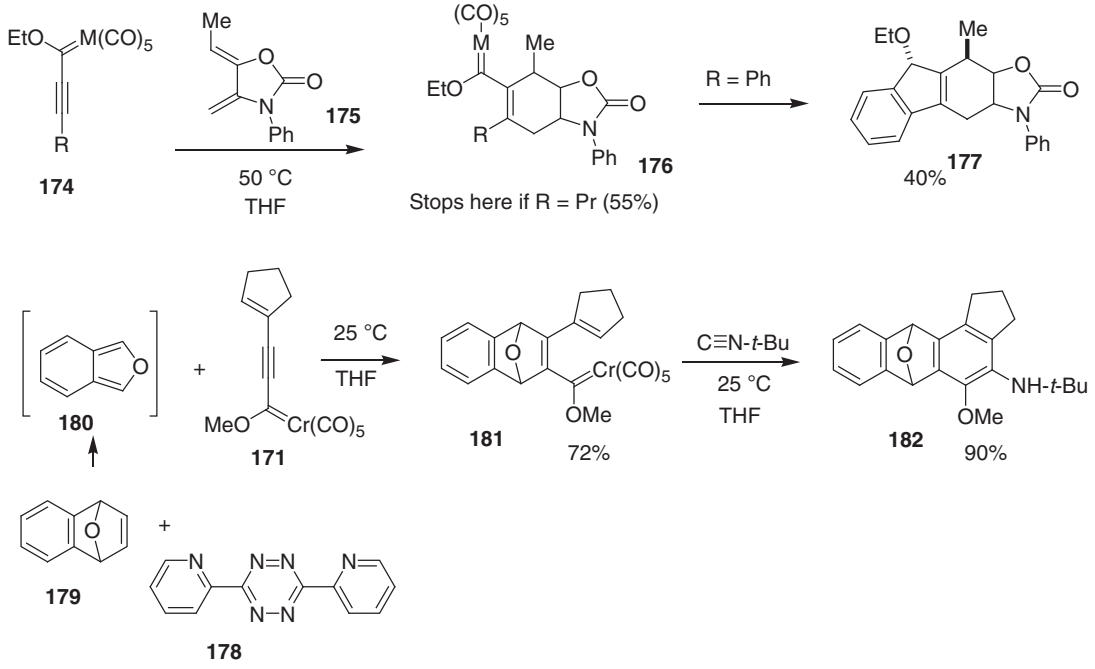
Several cascade processes were initiated through the Michael addition of enamines to α,β-unsaturated carbene complexes (Scheme 16). Cyclopentannulation reactions were reported for the coupling of alkenylcarbene complexes (e.g., **149**) with enamines.[75] Different types of cyclopentenones were obtained, depending on whether the imine is derived from an aldehyde (e.g., **150**) or a ketone (e.g., **154**). Aldehyde-derived imine **150** led to cyclopentenone **153** through Michael addition of the imine followed by attack of the vinyl anionic equivalent **151** at the iminium salt followed by hydrolysis. Ketone-derived imine **154** afforded cyclopentenone **157** through reaction of the imine at the carbene carbon followed by intramolecular addition of the resulting allyl-tungsten species (**156**) to the iminium salt, followed by hydrolysis. Both processes occurred with a high degree of diastereoselectivity, and homochiral products were produced if chiral enamines were employed. Coupling of α,β-unsaturated carbene complexes with cyclic enamines (e.g., **158**) led to bicyclic structures (e.g., **161** and **162**).[76,77] Initially, zwitterionic compound **159** forms through Michael addition, followed by proton transfer to afford an enamine–carbene complex, followed by 1,2-addition. Thermolysis of **159** leads to tricyclic compound **160**, whereas reaction with trifluoroacetic acid leads to bicyclic compound **162**. Alkynylcarbene complexes (e.g., **163**) are highly useful reagents for the annulation of three carbons onto an enamine or an indole ring (e.g., **164**).[78] The mechanism involves Michael addition followed by ring closure to a cyclic allene complex (**165**), which affords the final product (**167**) after protonation/hydrolysis on silica gel. Enantiomerically pure products were obtained if the carbene complex contains a chiral alkoxide group. Michael addition of enamine species to alkynylcarbene complexes was also a key event in a novel synthesis of dihydropyridine derivatives.[79]

5.25.2.6 Addition to Alkynylcarbene Complexes Followed by Electrocyclization



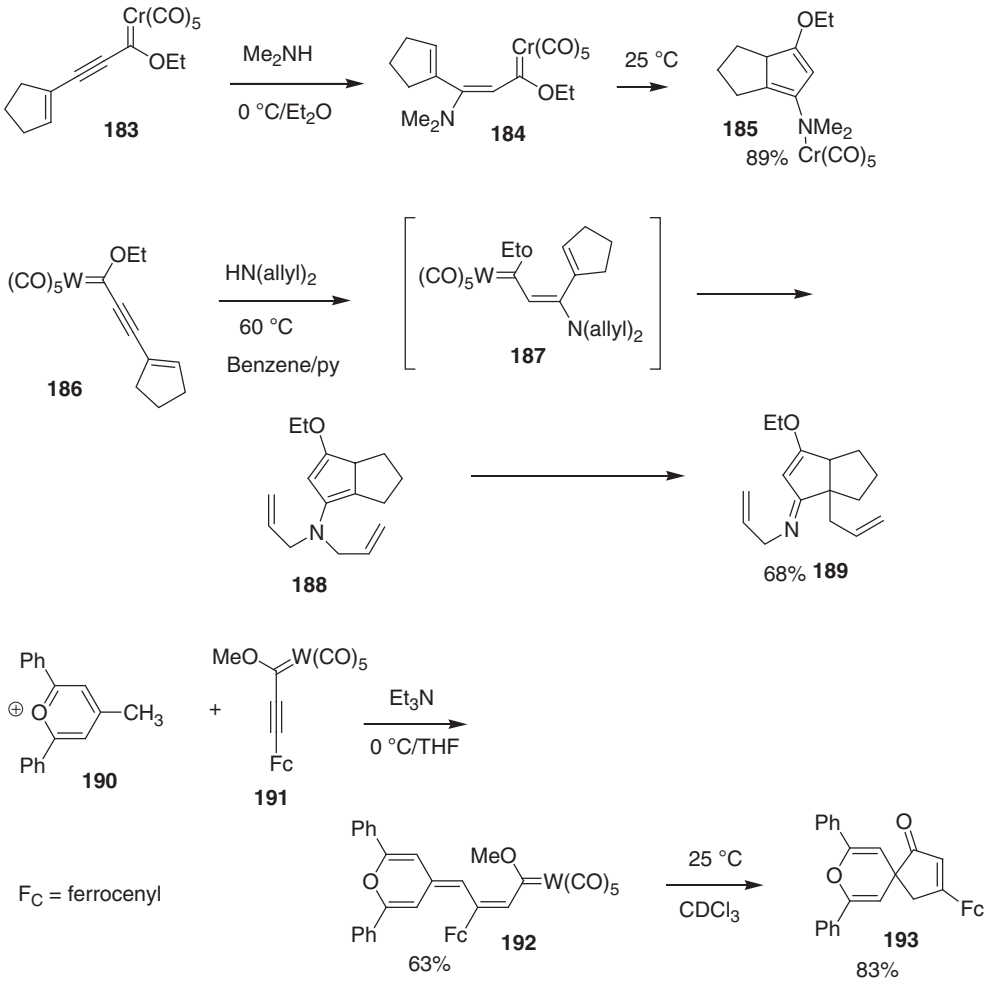
A major application of alkynylcarbene complex involves their conversion to an alkenylcarbene complex through cycloaddition or Michael addition followed by electrocyclization with or without CO or isonitrile insertion. All of the previously mentioned reactions in this section have been utilized in this manner. This research area has been reviewed.[80]

Many examples of [2 + 2]-cycloaddition involving an alkynylcarbene complex and an electron-rich alkene followed by cyclization of the resulting alkenylcarbene complex have been documented (Scheme 17). The coupling of cyclic enol ethers with enynylcarbene complexes (e.g., **168**) afforded cyclobutenylcarbene complexes (e.g., **169**), which underwent cyclization in refluxing THF to afford the corresponding benzocyclobutane derivatives (e.g., **170**).[81] Treatment of the cyclobutylcarbene complexes with isocyanides led to aniline derivatives (e.g., **173**) in a process involving formation of the conjugated ketenimines followed by electrocyclization.



Scheme 16

In several cases, the initial Diels–Alder adducts undergo secondary cyclization processes initiated by the carbene complex functionality (Scheme 18). The reaction of alkynylcarbene complexes of general structure **174** with dienes (e.g., **175**) proceeds through an initial Diels–Alder reaction to afford an alkenylcarbene complex (e.g., **176**).[82] In the case of arylethynylcarbene complexes, tetracyclic compounds (e.g., **177**) were produced in a process involving tandem Diels–Alder reaction followed by cyclization of the alkenylphenylcarbene complex. Diels–Alder reactions were reported for enynylcarbene complexes (e.g., **171**)

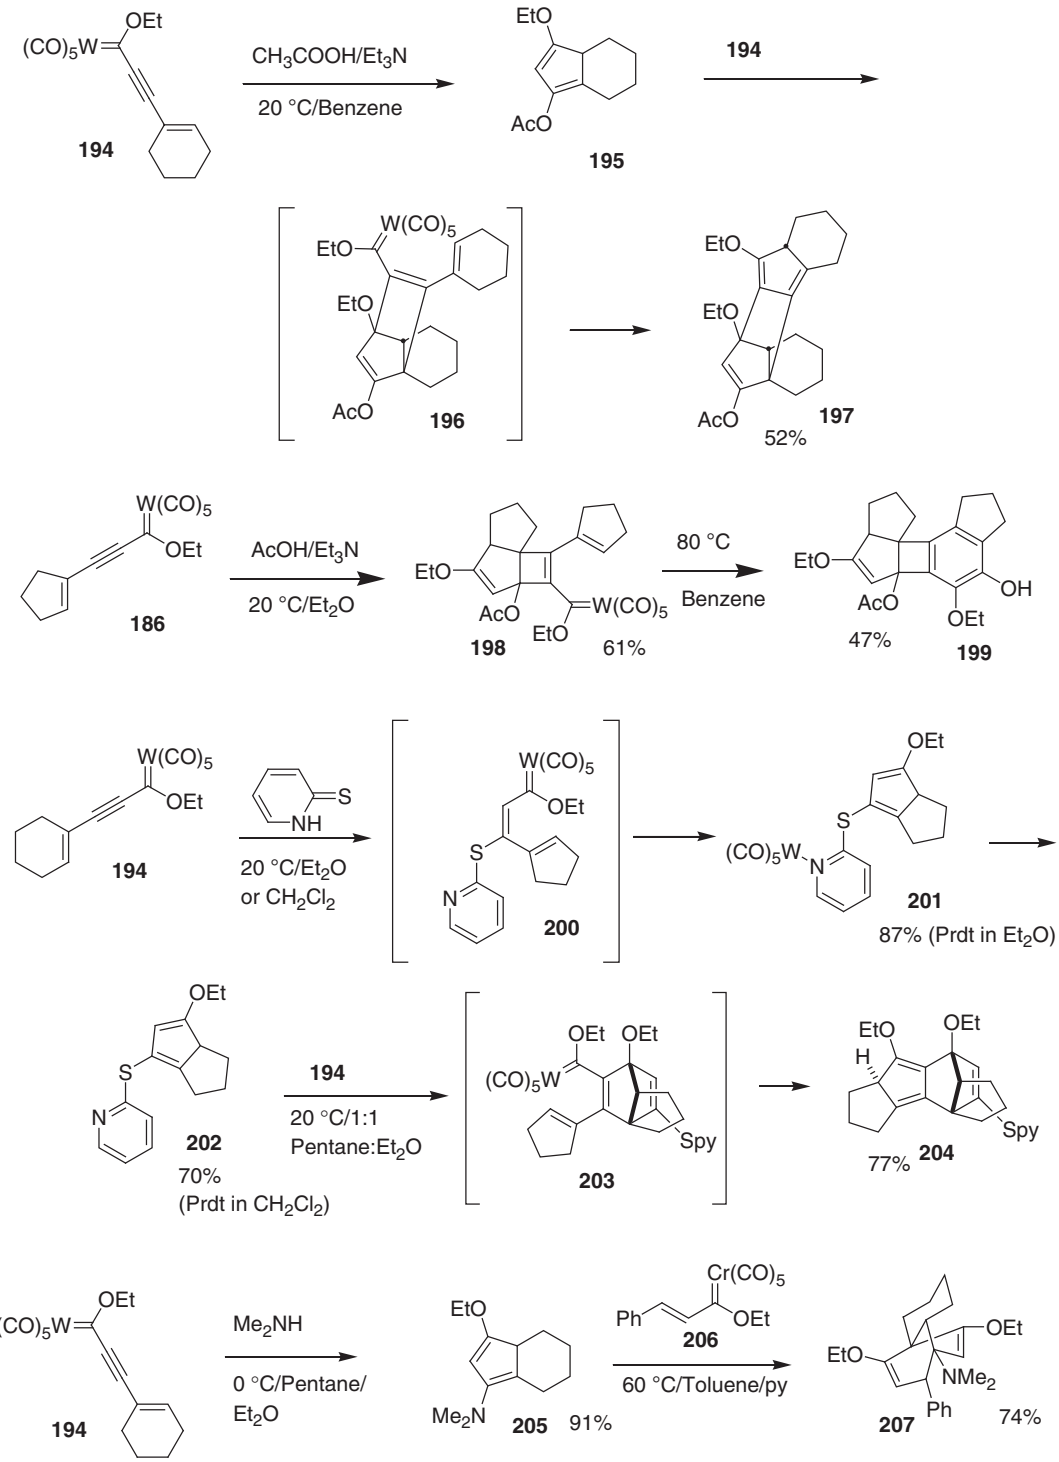


Scheme 17

Scheme 18

and *in situ*-generated isobenzofuran derivatives (e.g., **180**).[83] The reaction of adducts (**181**) with isocyanides or photolysis in the presence of CO leads to the formation of oxygen-bridged anthracene derivatives (e.g., **182**). Tandem Diels–Alder-cyclopentannulation reactions were reported in the coupling of phenylethynylcarbene complexes with *o*-quinonedimethane precursors.[84] The Diels–Alder adducts of pentamethylcyclopentadiene and alkynylcarbene complexes undergo a secondary benzannulation reaction which was observed when the reaction was conducted at 50 °C.[85]

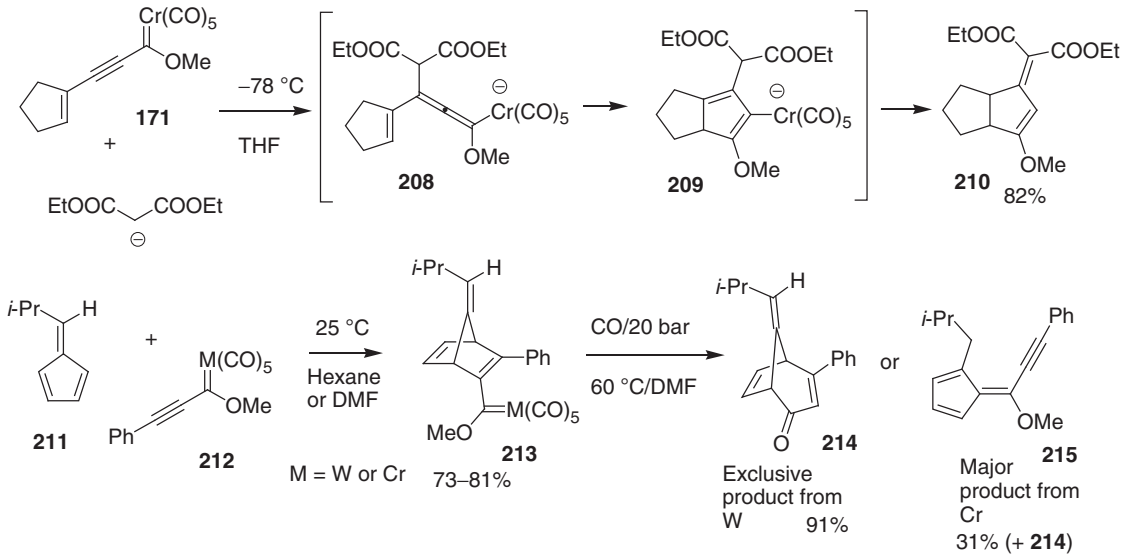
Several examples of the preparation of cyclopentene derivatives through Michael addition of various nucleophiles to enynylcarbene complexes have been reported (Scheme 19). In this reaction, the Michael addition process leads to a dienylcarbene complex system that subsequently undergoes a cyclization process to afford the alkoxycyclopentadiene, which affords the cyclopentone derivatives after hydrolysis. Michael addition of amines to enynylcarbene complexes (e.g., **183**) afforded dienylcarbene complexes (e.g., **184**), which cyclized at room temperature without CO insertion to provide cyclopentadiene derivatives (e.g., **185**).[86] Cyclopentannulation reactions were reported for the coupling of enynylcarbene complexes (e.g., **186**) with allylamines.[87] In these cases, after cyclopentannulation (forming **188**), an amino-Claisen rearrangement occurs to give the C-allylated products (e.g., **189**). Reaction of enynylcarbene complexes with β-aminoenones also proceeded via Michael addition followed by cyclization to the expected cyclopentadiene derivatives.[88] Similar cyclopentannulation reactions were reported in the coupling of enynylcarbene complexes with sulfur nucleophiles.[89] A net cycloaddition process leading to spirocyclic cyclopentenones (e.g., **193**) was observed in the base-catalyzed reaction of methylpyrilium salts (e.g., **190**) and ferrocenyalkynylcarbene



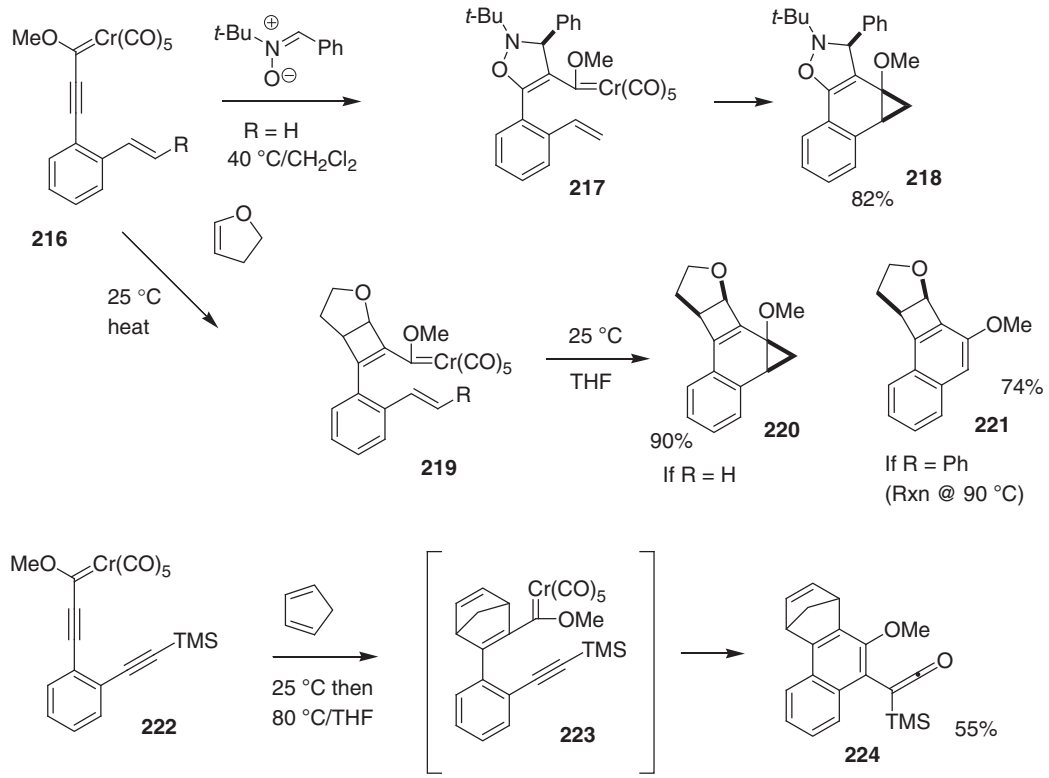
Scheme 19

complexes (e.g., **191**).[90] A mechanism that involves Michael addition to afford dienylcarbene complex **192** followed by cyclization was proposed. The dienylcarbene complex could be observed at low temperature. In some cases, a secondary cleavage of the heterocyclic ring occurred under the reaction conditions.

Many examples that involve the incorporation of one or more carbene units or diene units that result in the rapid construction of complex architectures were also reported (Scheme 20). Addition of carboxylate anions to enynylcarbene complexes led to the expected cyclopentadiene derivatives (e.g., **195**); however, these very rapidly underwent a Diels–Alder reaction with the starting carbene complex to afford complex cyclopentadienes (e.g., **197**) after secondary cyclization.[91] The resulting complexes can undergo additional iterations of this reaction to form rather complex structures. A net dimerization product (**199**) was formed in the coupling of enynylcarbene complex **186** with acetate ion.[92] Michael addition followed by cyclization affords a cyclopentadiene (**198**), which subsequently undergoes a [2 + 2]-cycloaddition with a second mole of carbene. Cyclization of cyclobutene derivative **198** then leads to the observed benzannulation product **199**. Nucleophilic addition of thioamides to enynylcarbene complexes (e.g., **186**) led to the $\alpha,\beta,\gamma,\delta$-unsaturated carbene complex (e.g., **200**), which rapidly cyclized to a cyclopentadiene derivative (e.g., **201**).[93] After decomplexation of tungsten to afford **202**, an additional mole of enynylcarbene complex could be incorporated through Diels–Alder reaction followed by cyclization to afford a complex ring system exhibited by **204**. Capture by alkenylcarbene complex dienophiles also has precedent. Michael addition and thermolysis of enynylcarbene complexes (e.g., **194**) also afforded cyclopentannulation products, which underwent Diels–Alder reactions when thermolysis was performed in the presence of a variety of dienophiles.[94,95] Use of alkenylcarbene complex **206** led to net [4 + 3]-cycloaddition products (e.g., **207**).



The products from addition to the triple bond of alkynylcarbene complexes were successfully captured by other methods. The addition of stabilized carbanions (e.g., malonate anion) to enynylcarbene–chromium complexes (e.g., **171**; Scheme 21) led to cyclized compounds (e.g., **210**).[96] A mechanism involving Michael addition followed by cyclization with chromium migration, followed by protonolysis of the C–Cr bond was proposed. Diels–Alder reactions were reported for alkynylcarbene complexes (e.g., **212**) and fulvene derivatives (e.g., **211**).[97] The Diels–Alder adducts (**213**) are produced at room temperature; however, heating transforms the Diels–Alder adducts into either of the compounds **214** or **215**. The distribution of the products was highly

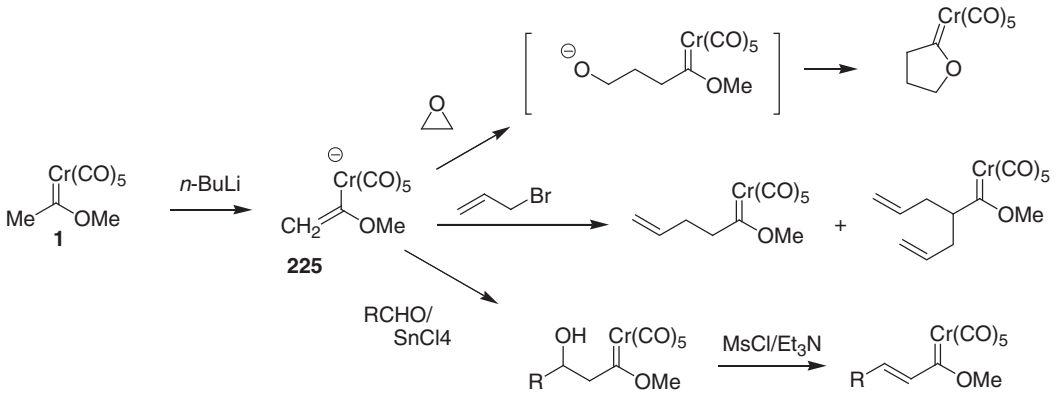


Scheme 20

dependent on the metal. The cyclopentadienes (**215**) were formed only when chromium was employed, although tungsten carbene complexes led exclusively to bicyclo[3.2.1]octadienone systems (**214**).

Alkynylcarbene complexes that feature additional conjugating substituents also undergo additions to the triple bond followed by capture of the resulting alkenylcarbene complex (Scheme 22). Reaction of *o*-styrylalkynylcarbene complexes (e.g., **216**) with various species that add to alkynylcarbene complexes (e.g., nitrones, enol ethers, or dienes) was reported.[98] The intermediate highly conjugated carbene complex (e.g., **217** and **219**) was successfully captured through cyclopropanation (e.g., formation of **212** and **214**) and olefin metathesis (e.g., formation of **221**). A tandem cycloaddition-alkyne insertion sequence was also

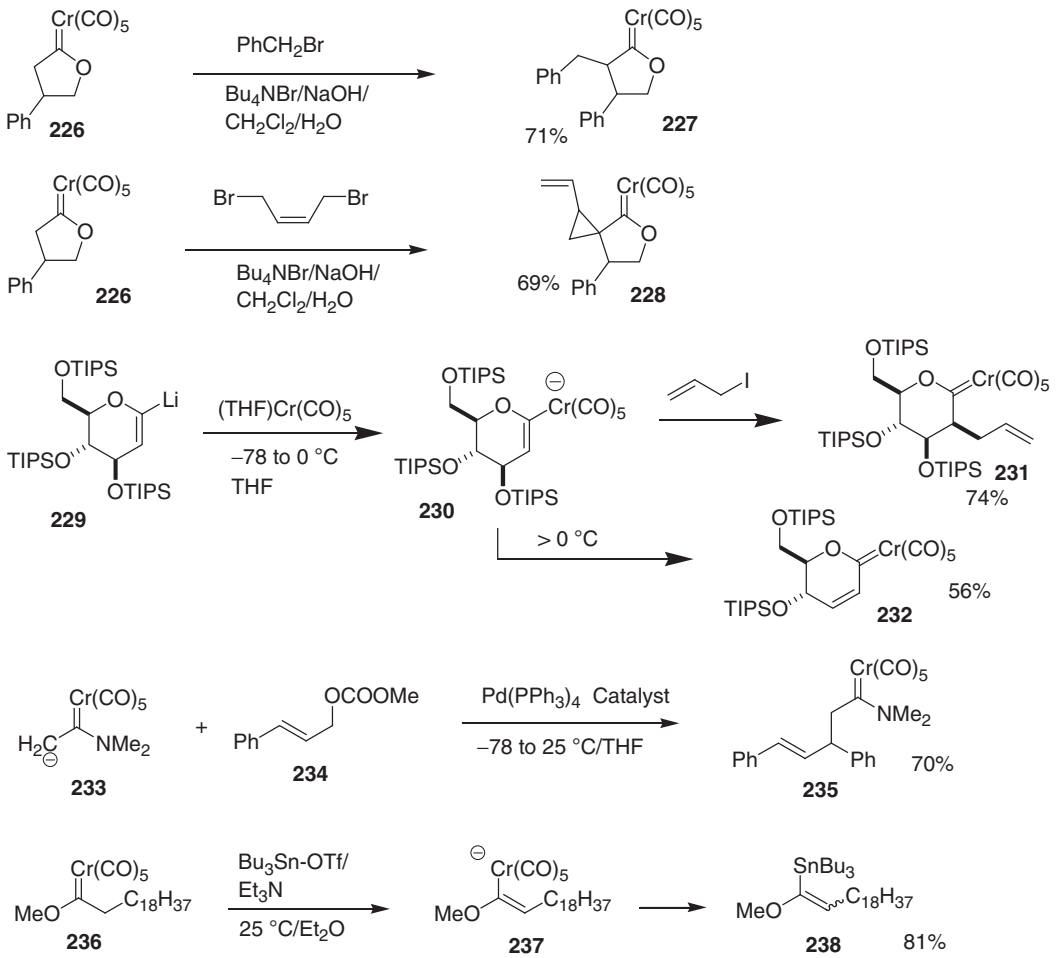
Scheme 21



Scheme 22

demonstrated.[99] In this case, a conjugated enediyne–carbene complex (e.g., **222**) undergoes cycloaddition to afford an alkenyl-carbene complex (e.g., **223**), which subsequently undergoes intramolecular alkyne–carbene insertion reaction. In cases of trimethylsilylalkynes, a stable ketene (e.g., **224**) could be isolated. In other cases, ketene trapping products were obtained.

5.25.2.7 Anions of the Carbene Ligand – Reaction with C–X Sigma Bonds

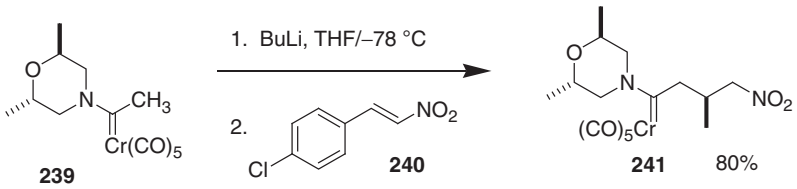


Fischer carbene complexes substantially increase the acidity of α-hydrogens. As such, the compounds are easily deprotonated relative to analogous esters and amides; however, the resulting anions tend to be comparatively unreactive except to the most reactive of electrophiles.

Several examples of deprotonation followed by alkylation with alkyl halides were reported in the previous edition of Comprehensive Organic Synthesis. The coupling of allylic, benzylic, and α-carbonyl halides[100] with the pentacarbonyl derivatives is well-documented; however, dialkylation is sometimes a problem in these reactions. Representative classical transformations of carbene complex-derived anions (e.g., **225**) are depicted in Scheme 23.

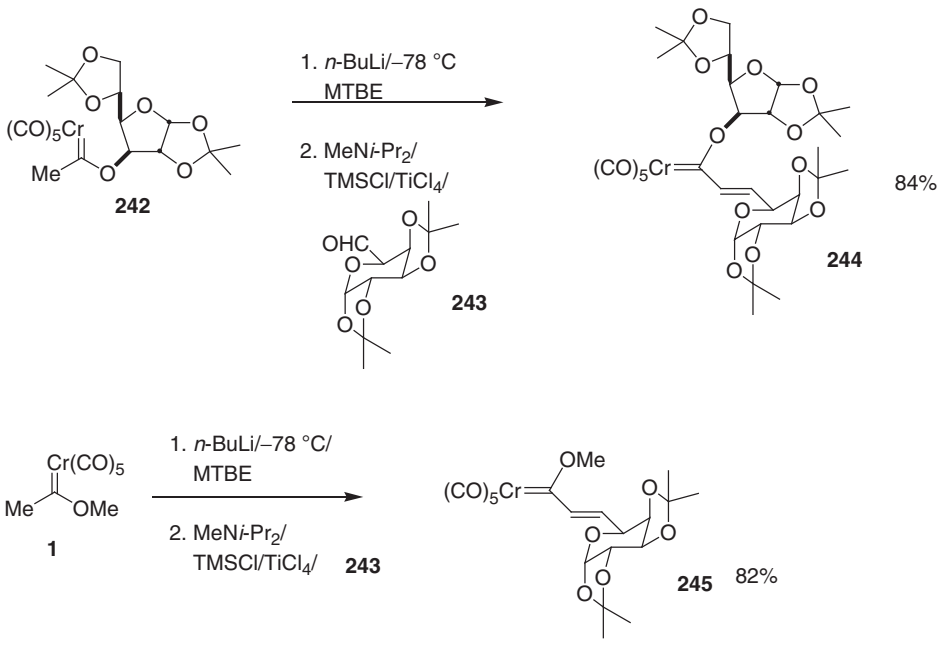
Scheme 23

Several examples have been reported where carbene complexes react with carbon atom and heteroatom electrophiles to afford substituted carbene complexes (Scheme 24). Biphasic alkylation in the presence of phase transfer catalysts often leads to alkylated



Scheme 24

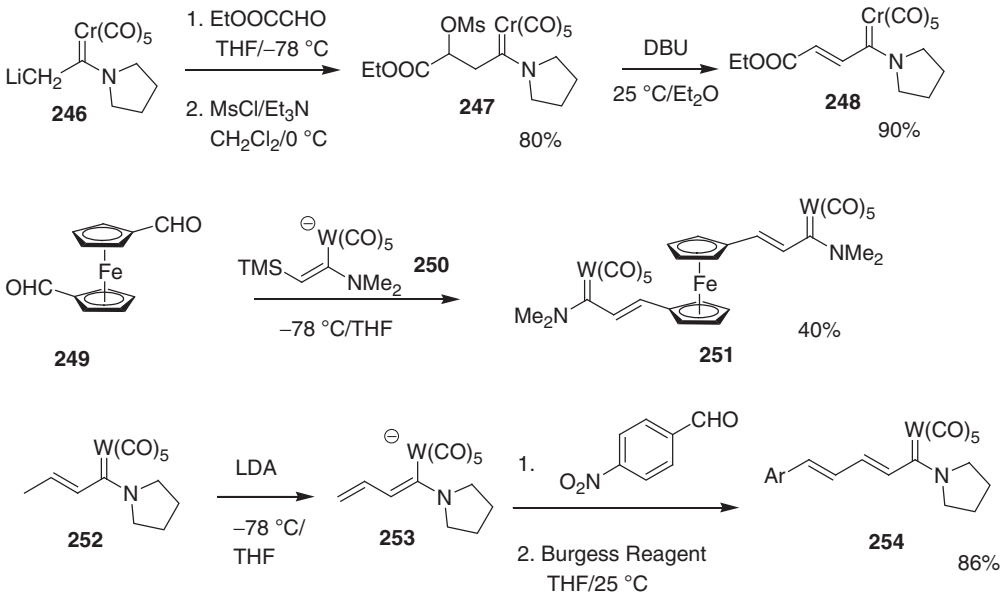
carbene complexes in higher yields than conventional monophasic alkylation procedures. The reaction of carbene complexes that contain α-hydrogens with allylic halides under phase transfer conditions led to alkylated carbene complexes (e.g., **227**).[101,102] The reaction employing 1,4-dibromo-2-alkenes led to cyclopropylcarbene complexes (e.g., **228**) in a double alkylation process. The alkylation reactions of hydrazinocarbene complexes were also explored and offer advantages for multiple alkylation reactions.[103] Carbene complex-stabilized anions (e.g., **230**) can be alternatively formed from the reaction of alkenyllithium reagents (e.g., **229**) with Group 6 metal pentacarbonyl sources.[104] Anions generated from glycals in this way were allylated with a high degree of diastereoselectivity in favor of the axial diastereomer (e.g., **231**). A β-elimination process resulting in unsaturated carbene complexes (e.g., **232**) was observed if anion **230** was allowed to warm above 0 °C. Successful palladium-catalyzed allylic alkylation was reported for carbanions derived from aminocarbene complexes (e.g., **233**).[105] Other electrophiles that have been successfully coupled to these types of carbanions include (1) polyene–metal complexes,[106] (2) phosphorus electrophiles,[107] and (3) sulfenylating agents.[108] Vinylstannanes (e.g., **238**) were prepared through deprotonation of alkoxycarbene complexes followed by quenching with tributyltin triflate.[109] In addition to the studies with alkoxy pentacarbonyl complexes, a variety of studies employing other types of carbene complexes have been documented. Treatment of carbene complex anions with iodinating agents leads to mixtures of alkenyl iodides and CO-inserted products.[110]



5.25.2.8 Anions of the Carbene Ligand – Reaction with C–X pi Bonds

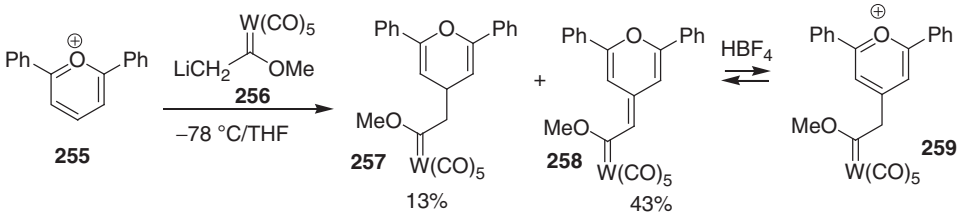
Several examples of asymmetric Michael addition to nitro styrene derivatives were reported (Scheme 25). Reaction of chiral carbene complex-derived carbanions (e.g., anion from aminocarbene complex **239**) with nitro alkenes led to Michael addition products (e.g., **241**).[111] The addition proceeded with a moderate degree of diastereoselectivity, and was higher for nitrostyrene derivatives featuring an electron-withdrawing group and for Z nitrostyrenes. Diastereoselective Michael addition of a homochiral aminocarbene complex **239** with nitrostyrene derivative **240** was a key step in the asymmetric total synthesis of baclofen.[112]

Scheme 25



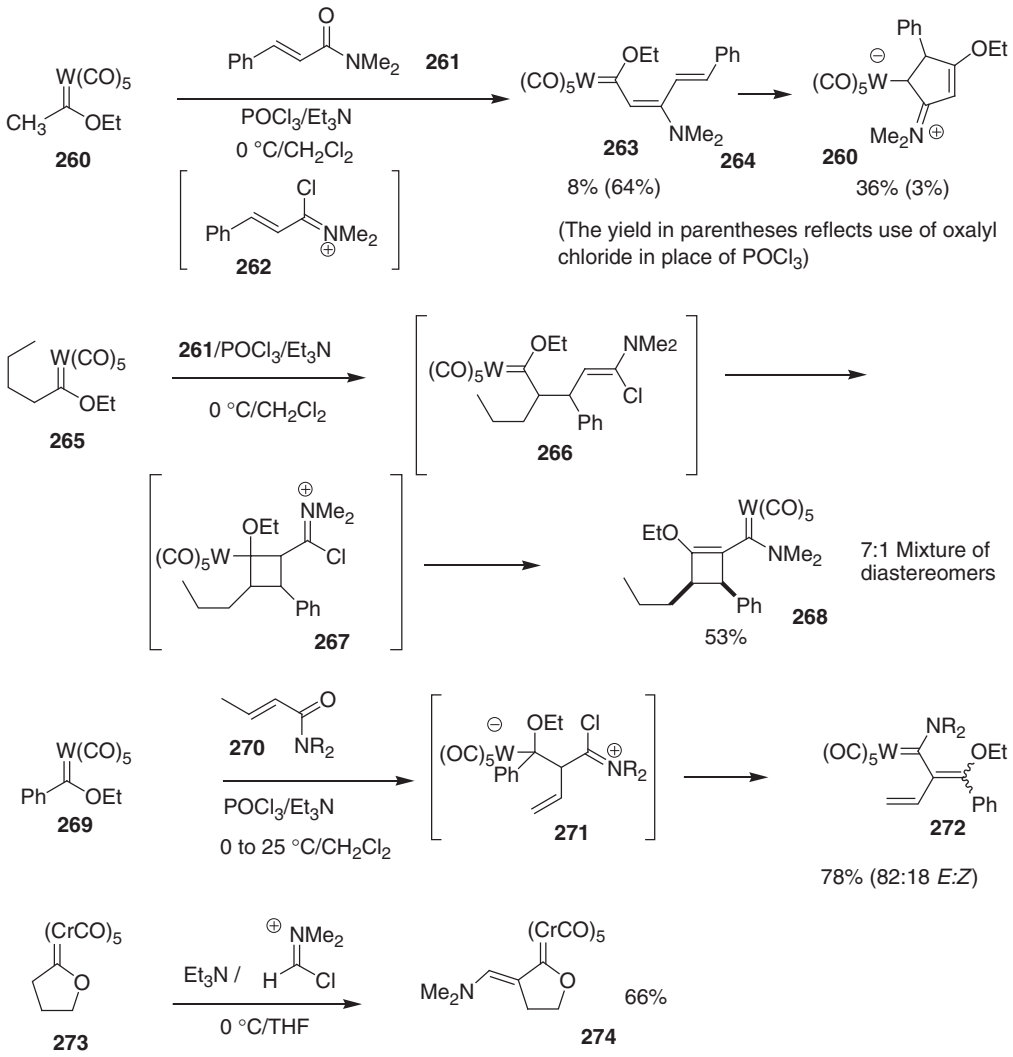
Numerous examples of the aldol condensation employing carbanions derived from alkoxycarbene complexes have been reported since the previous edition (Scheme 26). Since the carbene complex-stabilized anion is of limited reactivity, most of the

Scheme 26



examples employ Lewis acid activators.[113,114] Carbene complex-linked carbohydrate derivatives (e.g., **244**) were prepared through the coupling of carbanions derived from carbohydrate-containing carbene complexes (e.g., **242**) with carbohydrate–aldehydes (e.g., **243**).[115] Related couplings using pyran-containing aldehydes and simple methylcarbene complexes led to aldol-like products (i.e., α,β-unsaturated carbene complexes).[116] Aldol-type reactions were also reported for simple methylcarbene complex **1** with various carbohydrate aldehydes[117] and other chiral aldehydes.[118]

Several examples of aldol reactions that involve aminocarbenes have been documented (Scheme 27). The reaction of aminocarbene–chromium complex-derived carbanion **246** and glyoxal ester, followed by methanesulfonyl chloride afforded the anticipated alkylated carbene complex **247**, which afforded the γ-oxo-α,β-unsaturated carbene complex **248** on base-induced elimination.[119] This aminocarbene complex underwent efficient benzannulation at 60 °C with a variety of alkynes. Hydrocarbon- and ferrocene-bridged carbene complexes (e.g., **251**) were prepared using the Peterson olefination involving dialdehydes (e.g., **249**) and anions derived from α-silylcarbene–tungsten complexes (**250**).[120] A carbene–aldol strategy was also employed for the synthesis of ϕ-ferrocenylhexatrienylcarbene–tungsten complexes from 5-ferrocenyl-2,4-pentadienal.[121] The coupling of hydrazinocarbene complex-stabilized anions with α,β-unsaturated carbonyl compounds and simple carbonyl compounds resulted in dienylcarbene complexes.[122] Dienylcarbene complexes (e.g., **254**) were prepared by γ-deprotonation of α,β-unsaturated carbene complexes (e.g., **252**), followed by treatment with an aromatic aldehyde and dehydration.[123]

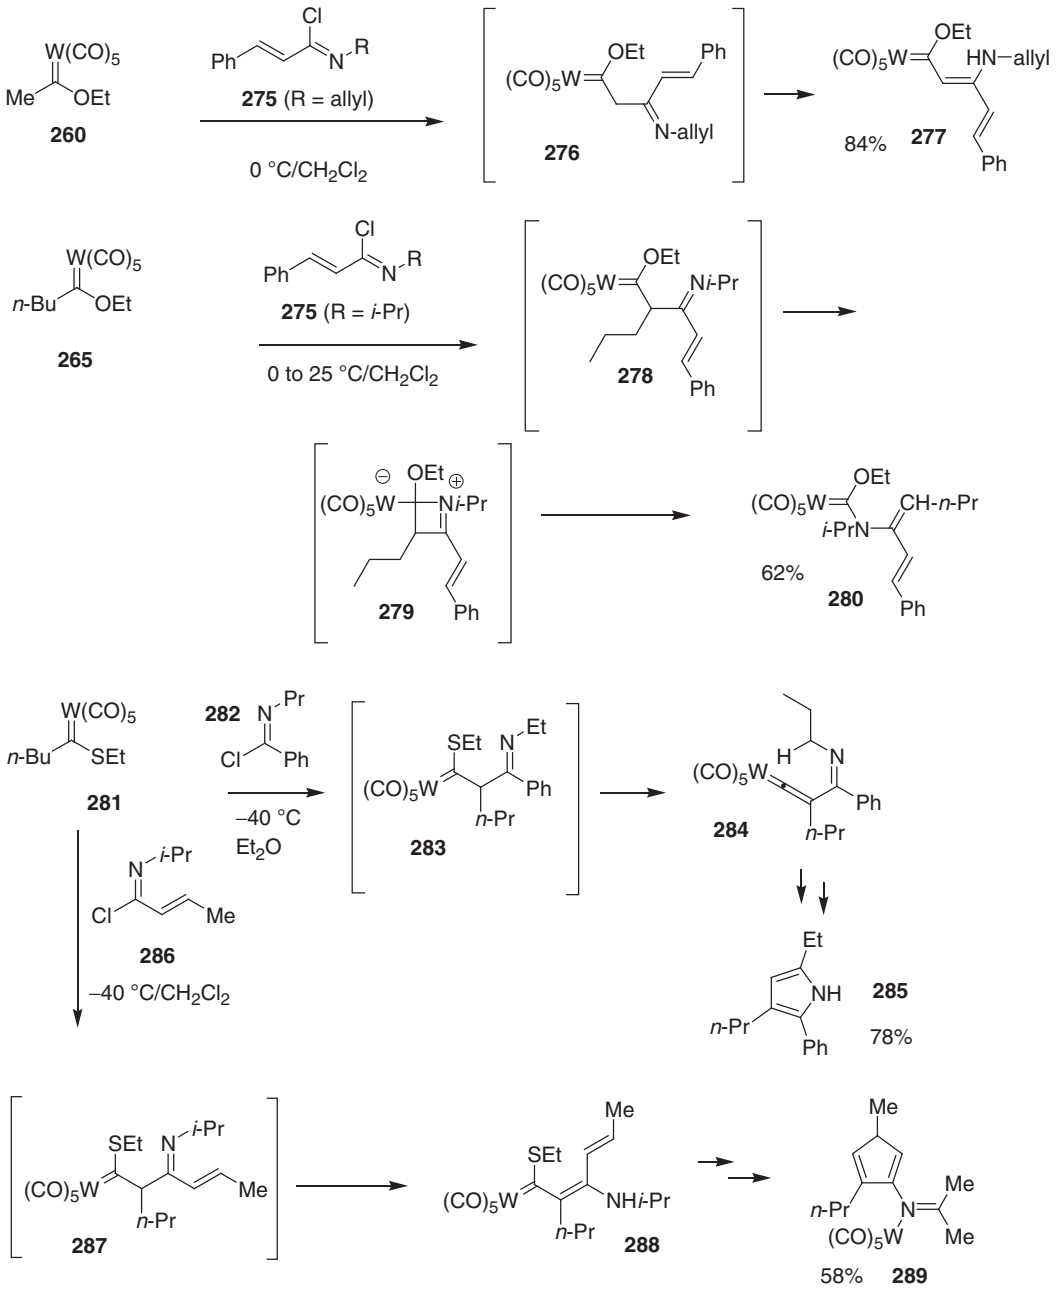


Scheme 27

A large number of reported aldol-type reactions feature pyrilium salts and result in the preparation of donor–acceptor molecules (Scheme 28). The coupling of carbene complex-derived carbanions (e.g., **256**) with pyrilium salts (e.g., **255**) afforded pyran derivatives (e.g., **257** and **258**) featuring a carbene complex-containing substituent in the 4-position.[124] The oxidation of the 4-alkylpyrone to the 4-alkylidenepyrone was induced by the pyrilium salt. Protonation of carbene complex **258** regenerated a pyrilium salt (**259**). Reactions using aminocarbene complexes generally led to compounds analogous to **258**. Additional examples that vary in metal, heteroatom, and length of conjugation spacers were also reported.[125–127]

Scheme 28

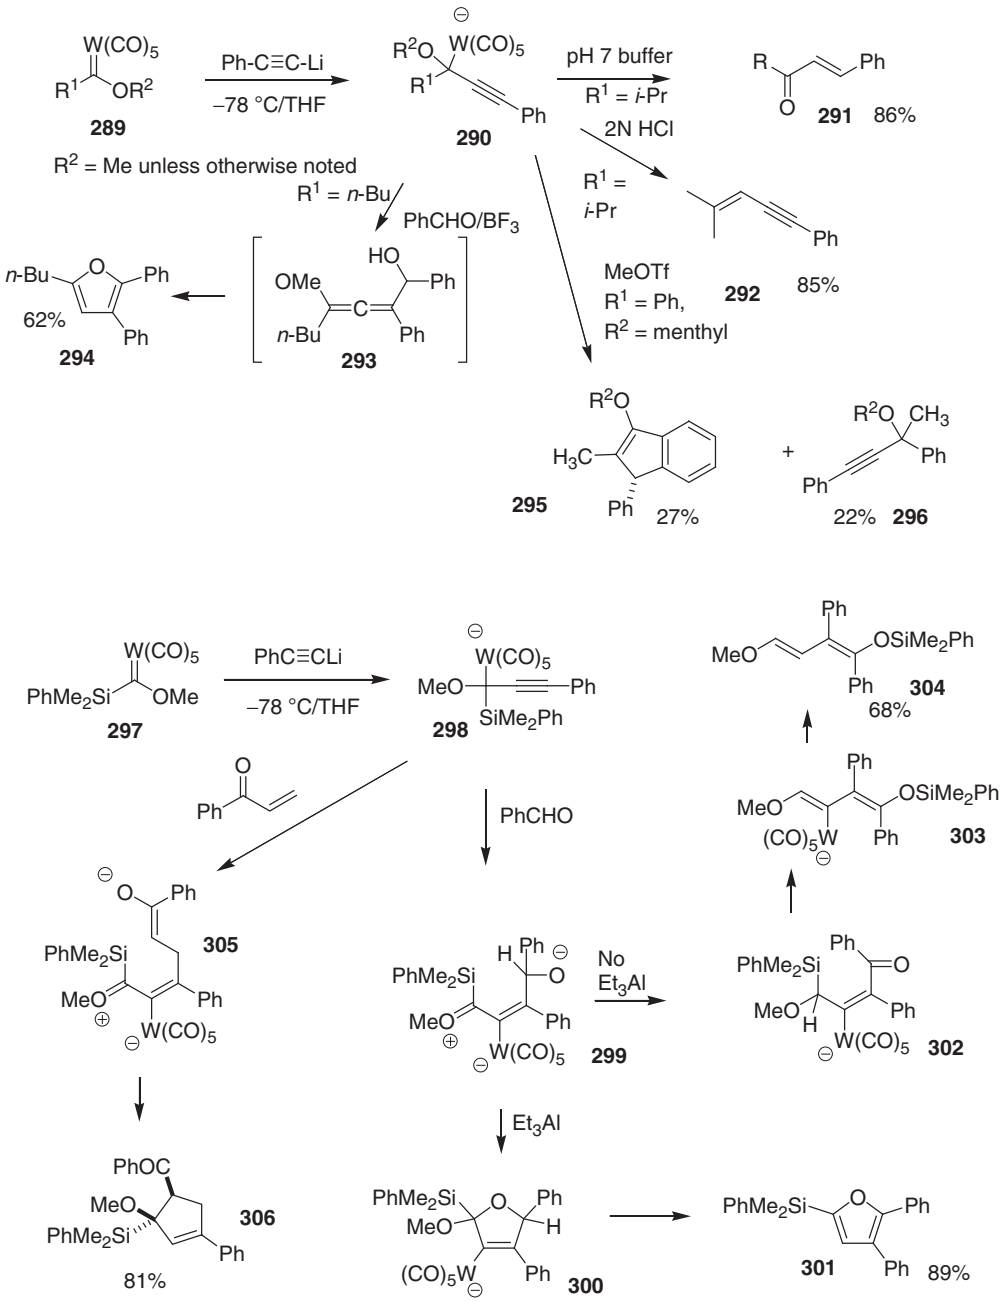
Several examples of the coupling of carbene complexes with amide-derived electrophiles have been reported (Scheme 29). The observed reaction pathway depends on the substitution pattern of the chloroiminium salt, and this coupling provides a variety of



Scheme 29

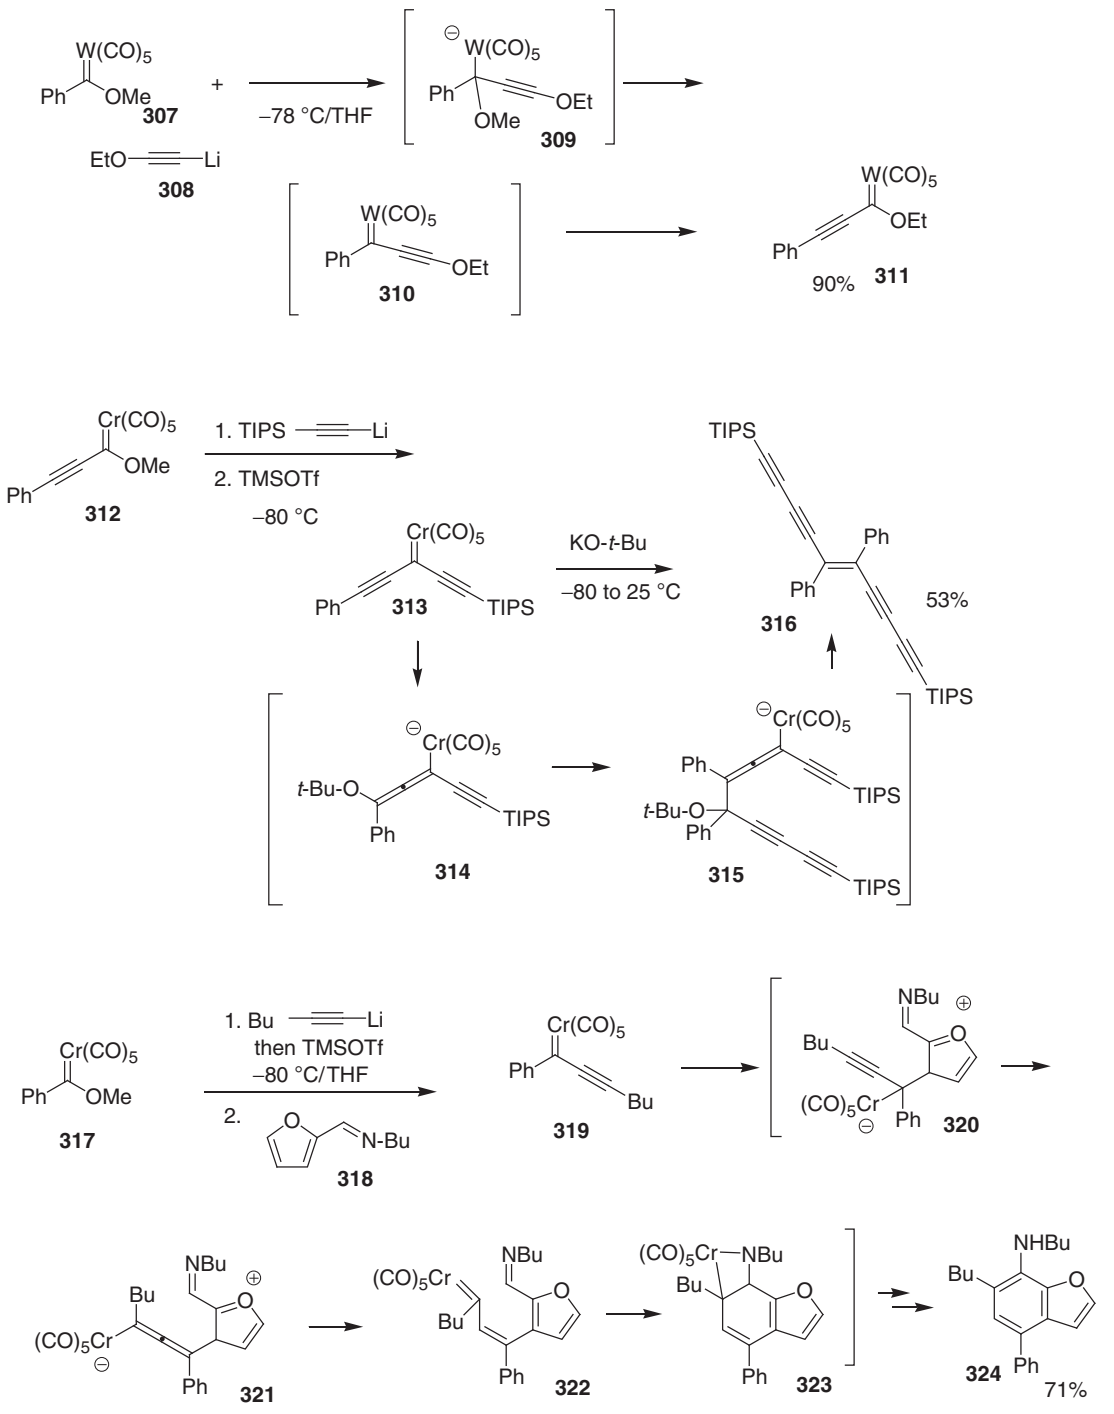
different product types. Reaction of carbene complex-derived anions with *in situ*-generated chloroiminium salt derivatives initially affords mainly the β-aminocarbene complex (e.g., **263**) via 1,2-addition to the chloroiminium carbon.[128] The β-aminocarbene complex decomposes at room temperature to afford five-membered ring species (e.g., **264**). Higher homologs (e.g., butylcarbene complex **265**) afforded a four-membered ring derivative (e.g., **268**) in a process involving Michael addition followed by intramolecular reaction of the resulting enamine (**266**) with the carbene complex. The coupling of carbene complexes with α,β-unsaturated amides that feature an acidic γ-hydrogen (i.e., **270**) in the presence of $POCl_3$ led to dienylcarbene complexes (e.g., **272**) accompanied by the enol ether hydrolysis products.[129] The reaction of cyclic carbene complexes (e.g., **273**) with Villsmeyer reagents afforded the alkenylcarbene complex (e.g., **274**).[130] Condensation with β-aminoacrolein derivatives afforded dienylcarbene complexes. Analogs featuring additional conjugated alkenes were similarly prepared.

Analogous reaction of neutral iminoyl chlorides (e.g., **275**, Scheme 30) led to β-aminocarbene complexes (e.g., **277**) for the methylcarbene complexes and to dienylaminocarbene complexes (e.g., **280**) for higher homologs.[131] Formation of dienylaminocarbene complex **280** was proposed to occur through intramolecular nucleophilic addition of nitrogen to the carbene carbon followed by electrocyclic ring opening. Thiocarbene complexes (e.g., **281**) led to pyrroles (e.g., **285**) through formation of a vinylidene intermediate (**284**) followed by intramolecular hydrogen transfer and cyclization.[132] Related coupling with α,β-unsaturated iminoyl chlorides (e.g., **286**) afforded predominately the cyclopentadienimine (e.g., **289**) (and isomeric cyclopentadienes) after cyclization of the initially formed dienylcarbene complex (e.g., **288**).[133]



5.25.2.9 Nucleophilic Substitution at and Cleavage of Carbene Ligands

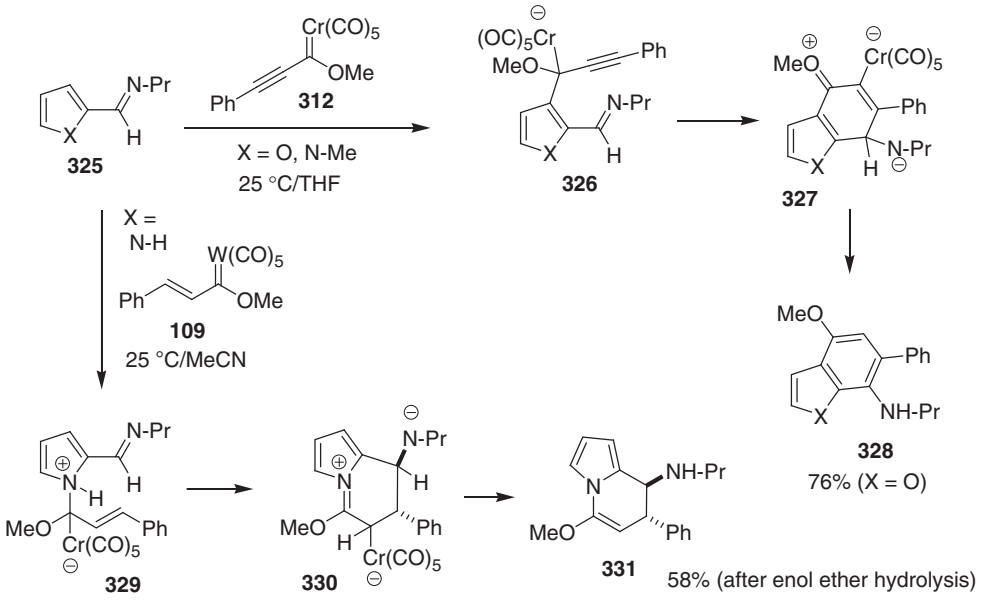
Several new reaction processes were reported for anionic propargyl–tungsten complexes (e.g., **290**, Scheme 31), which were derived from addition of alkynyl anions to Fischer carbene complexes.[134,135] If the complex was simply allowed to warm to 25 °C,



Scheme 30

the α,β-unsaturated ketone **291** was obtained via an allene intermediate. Treatment of propargyl compound **290** with 2M HCl afforded the enyne derivative **292**. Reaction with aldehydes and Lewis acids afforded furan derivatives (e.g., **294**). A mechanism involving electrophilic attack at the γ-position, forming allene **293** followed by acid-catalyzed ring-closure was proposed for furan formation. This methodology was used as the cornerstone for the total synthesis of the antibiotic PI-091.[136] Similar processes were demonstrated for anionic propargyl–tungsten complexes derived from addition of alkynyl anions to arylcarbene complexes.[137] Treatment of this complex with methyl triflate resulted in indene (e.g., **295**) formation, which proceeds via a 1,3-shift of tungsten before alkylation, followed by cyclization. The coupling of silylcarbene complexes (e.g., **297**) with alkynyl anions initially afforded the anionic complex (**298**).[138] The reaction with simple aldehydes afforded either dienes (**304**) or furans (**301**), depending on the presence or absence of triethylaluminum. The proposed mechanism involves attack at the γ-carbon to afford intermediate zwitterion **299**, which undergoes a hydride shift to afford the ketone (**302**), which affords the product (**304**) after 1,5-silicon shift and demetallation. Nucleophilic addition of oxygen to afford the dihydrofuran (**300**) followed by methanol elimination leads to the furan (**301**) in the presence of triethylaluminum. Reaction with α,β-unsaturated ketones led to cyclopentenols (e.g., **306**) in a mechanism involving Michael addition at the γ-position of the enone followed by cyclization.

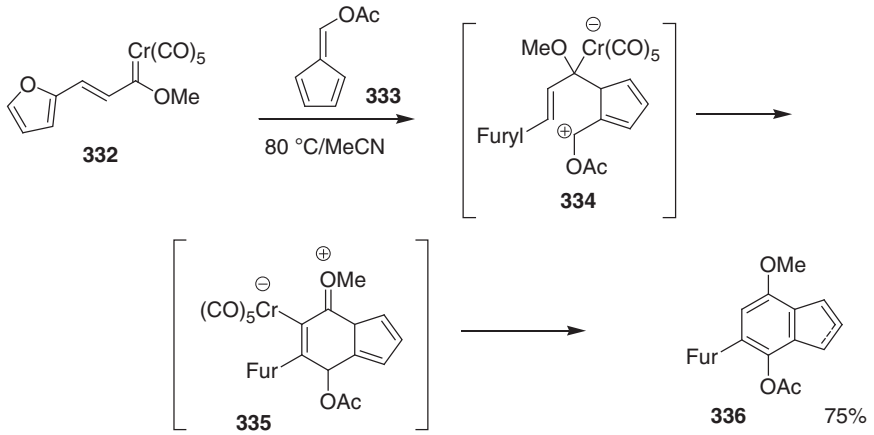
Scheme 31



In several examples, the addition of alkynyl anions to carbene complexes leads to formation of alkynylcarbene complexes devoid of heteroatom substitution, which are stable at low temperatures (Scheme 32). A new synthetic route to alkynylcarbene complexes (e.g., **311**) was developed that employs the reaction of carbene complexes with alkoxyacetylide anions (e.g., **308**).[139] Nucleophilic addition to the carbene carbon, followed by loss of methoxide and 1,3-rearrangement yields the alkynylcarbene complexes. The addition of alkynyllithium reagents to carbene complexes devoid of α-hydrogens (e.g., **312**) followed by reaction with trimethylsilyl triflate led to alkynylcarbene complexes devoid of heteroatom stabilization (e.g., **313**).[140] These carbene complexes are stable only at low temperature and form dimers (e.g., **316**) when warmed to room temperature in the presence of potassium *t*-butoxide. Head-to-head as well as head-to-tail dimers were produced, depending on the structure of the carbene complex. A mechanism was proposed that involves Michael addition of *t*-butoxide ion followed by propargylation of a virgin carbene complex resulting in a dimeric anionic complex (**315**), followed by demetallation/alkoxide elimination. Coupling of carbene complexes (e.g., **317**) with alkynyllithiums followed by reaction with furfural imines (e.g., **318**) led to substituted benzofurans (e.g., **324**).[141] Subsequent treatment of the intermediate alkynylcarbene complex with furfural imine proceeds via

Scheme 32

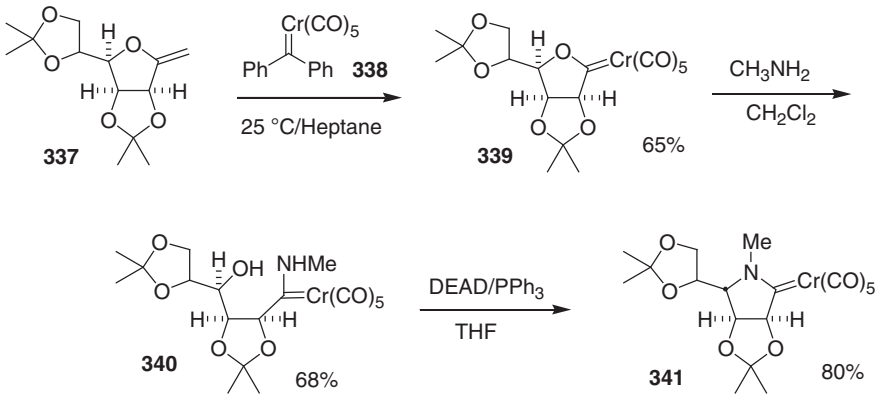
Michael addition of the furan ring to the alkynylcarbene complex (**319**) followed by proton transfer to afford a carbene complex-imine (**322**), followed by [2 + 2]-cycloaddition and β-hydride elimination.



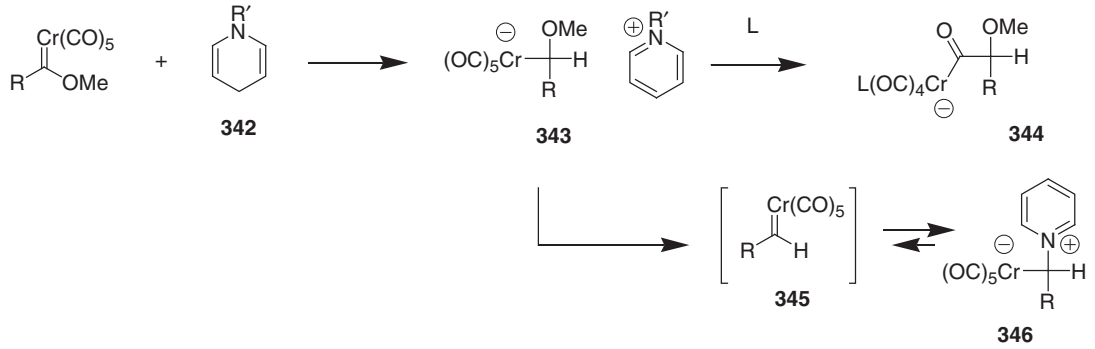
A novel benzannulation process was reported for the coupling of alkynylcarbene complexes (e.g., **312**, Scheme 33) with heteroaromatic aldehyde-derived imines (e.g., **325**).[142] Furan, benzofuran, and *N*-substituted indole derivatives led to the carbocyclic benzannulation products (e.g., **328**) via a mechanism involving nucleophilic addition to the carbene carbon at the 3-position of the heterocyclic ring, followed by simultaneous 1,2-shift of the metal and attack on the imine. A heterocyclic benzannulation product (e.g., **331**) was formed from the coupling of N–H pyrrole and indole-starting materials. A similar mechanism was proposed except that the initial attack occurs at the heterocyclic N atom. Coupling of N–H pyrroles and indoles

Scheme 33

with alkynylcarbene complexes afforded seven-membered ring annulation products which result from initial Michael addition of the imine N atom to the alkyne carbon followed by a 1,3-shift of the metal.



A net [6 + 3]-cycloaddition process was observed in the coupling of α,β-unsaturated chromium carbene complexes (e.g., **332**, Scheme 34) with electron-rich fulvenes (e.g., **333**).[143] The proposed mechanism involves electrophilic attack on the carbene complex at the 2-carbon of the fulvene, affording intermediate **334**, followed by simultaneous 1,3-shift of chromium and nucleophilic attack at the exocyclic carbon of the delocalized cation to afford cyclized intermediate **335**. Subsequent aromatization leads to the cycloaddition product **336**. Compound **336** was obtained as a mixture of alkene regioisomers.

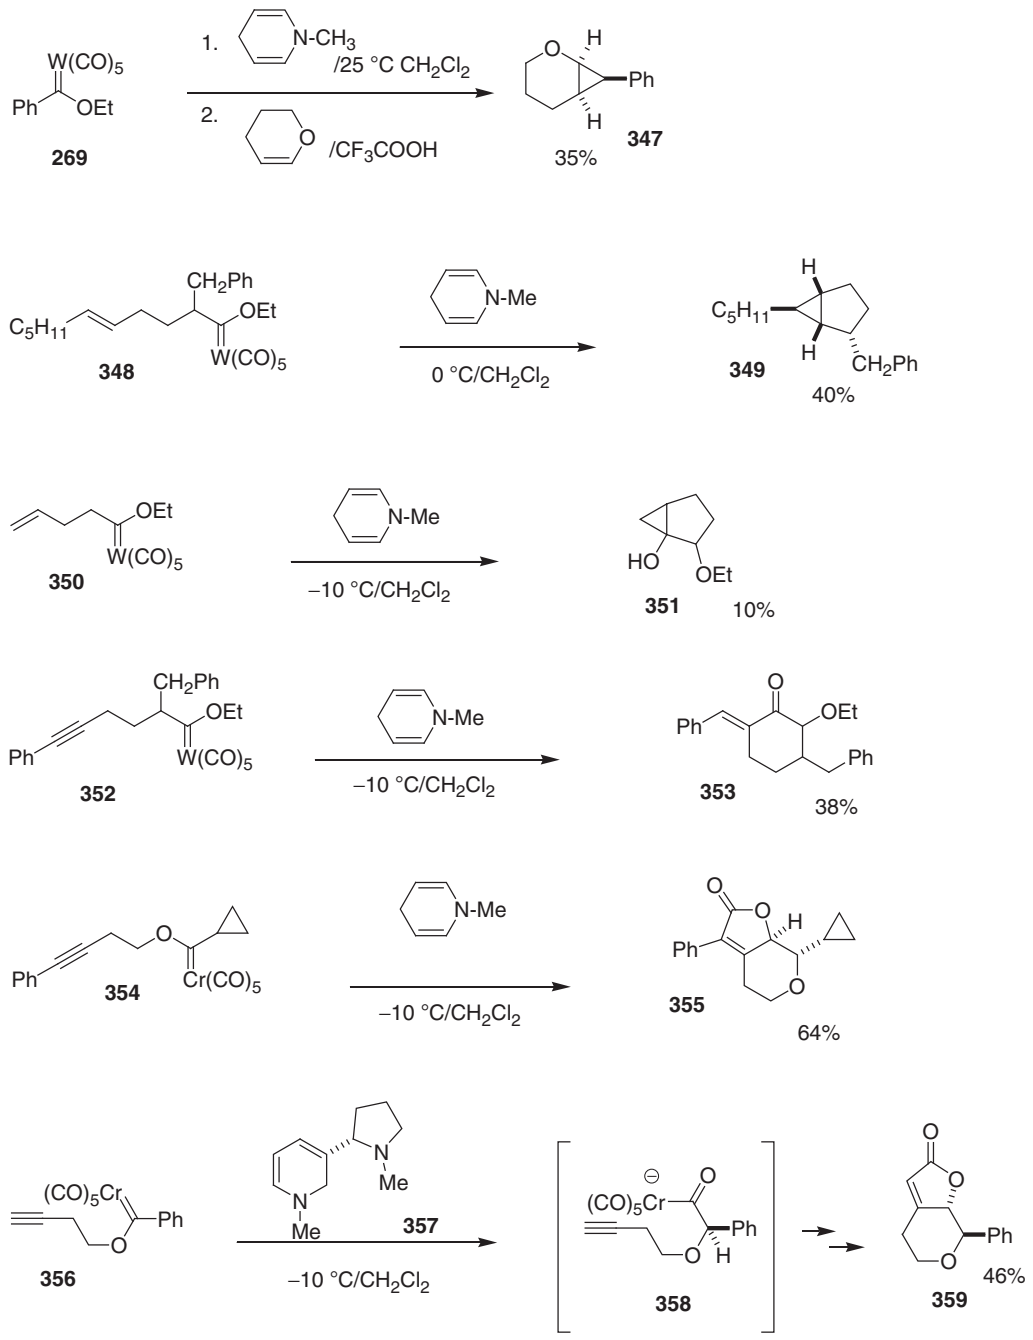


Scheme 34

Synthesis and aminolysis of a variety of carbohydrate-derived carbene complexes have been demonstrated (Scheme 35). Carbene complex **339** was prepared from methylenetetrahydrofuran **337** by an olefin metathesis route.[144] A net conversion of the oxygen heterocycle **339** to the nitrogen heterocycle **341** was effected by the sequence of aminolysis-ring opening followed by a Mitsunobu-type ring closure process. Other examples utilizing carbene complexes for carbohydrate synthesis have been documented, including a three-carbon chain extension process based on the conversion of homopropargyl alcohols to cyclic carbene complexes,[145] and preparation and aminolysis of iron-, chromium-, molybdenum-, and tungsten-alkoxycarbene complexes derived from aldonic acid chloride derivatives and the corresponding metal carbonyl dianions.[146]

Several examples employ the use of dihydropyridines or dihydroquinolines to form ylide complexes, which serve as synthetic equivalents to hydrido-Fischer carbene complexes (Scheme 36).[147–151] Common reaction pathways observed in these systems include initial formation of a stable tetrahedral complex (e.g., **343**) as a pyridinium salt followed by either *in situ* generation of the nonheteroatom-stabilized carbene complex (e.g., **345**), which is in equilibrium with a stable pyridinium ylide complex (e.g., **346**),

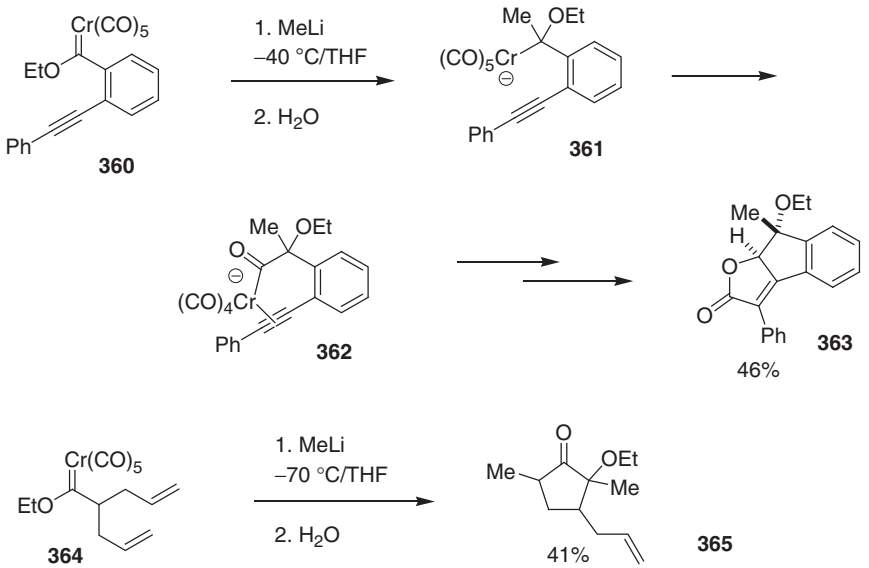
Scheme 35



Scheme 36

or CO insertion to generate the acylate complex (e.g., **344**). Specific examples are depicted in Scheme 37. Reaction of the pyridinium salt complexes with electron-rich alkenes led to cyclopropanation products (e.g., **347**) with a high degree of stereoselectivity for the depicted isomer. Direct intramolecular cyclopropanation without isolation of the ylide complexes was observed in the reaction of δ,ω-unsaturated carbene complexes (e.g., **349**) with dihydropyridine derivatives; formation of cyclopropane derivative **349** proceeded with a high degree of stereoselectivity. Alkene complexes which feature a shorter tether (e.g., **350**) afforded hydroxycyclopropanes (e.g., **351**) on treatment with *N*-methyldihydropyridine via a CO-insertion process. Reaction of alkyne–carbene tungsten complexes (e.g., **352**) with *N*-methyldihydropyridine led to CO insertion-cyclization products (e.g., **353**), although chromium analogs (e.g., **354**) afforded multiple CO-insertion products (e.g., **355**).[152] A key step in the formation of compounds **353** and **355** is intramolecular alkyne-insertion reaction of a chromium acylate (analogous to **344**, Scheme 36). Treatment of alkyne–carbene complexes (e.g., **356**) with dihydronicotine (**357**) led to the bicyclic derivatives (e.g., **358**) with a moderate degree of enantioselectivity.[153]

Several examples of related cascade cyclization processes initiated by the addition of nucleophiles to the carbene carbon have been reported (Scheme 38). The coupling of alkynylphenylcarbene–chromium complexes (e.g., **360**) with dihydropyridine derivatives and with carbon nucleophiles (e.g., MeLi) led to indane-fused furanone derivatives (e.g., **363**) through a process involving nucleophilic addition to the carbene carbon, followed by CO insertion and alkyne insertion.[154,155] The process uses three of the CO ligands in the original chromium hexacarbonyl starting material. Related nucleophilic additions to γ,δ-unsaturated carbene complexes (e.g., **364**) led to cyclopentenones (e.g., **365**) through a related mechanistic process involving CO insertion and alkene insertion after the initial addition of carbanion to the carbene carbon.



Several examples, where nucleophilic addition of an enolate to a carbene complex carbon initiates a cascade process, have been documented (Scheme 39). The three-component coupling of carbene complexes (e.g., **317**), ketone or ester enolates (e.g., **366**, R = Me), and allylmagnesium bromide was reported.[156,157] Substituted enolates led to five-membered ring derivatives (e.g., **370**) in a reaction sequence involving addition of the enolate to the carbene carbon, followed by addition of allylmagnesium bromide to the ketone, followed by intramolecular alkene insertion and cyclopropanation. Enolates from methyl ketones (e.g., **366**, R = H) afforded six-membered rings (e.g., **372**) by a similar mechanism except that CO insertion occurs from intermediate **368**, which then undergoes a net oxidative addition into the alkene C–H bond to afford the six-membered ring product. In both cases, the reaction was highly stereoselective. New diastereoselective five- and seven-membered ring forming cycloaddition reactions that utilize the coupling of alkenylcarbene complexes (e.g., **109**) and enolates were reported.[158] The ultimate course of the reaction was highly dependent on the structure of the enolate. All of the products form via initial nucleophilic addition of the enolate to the

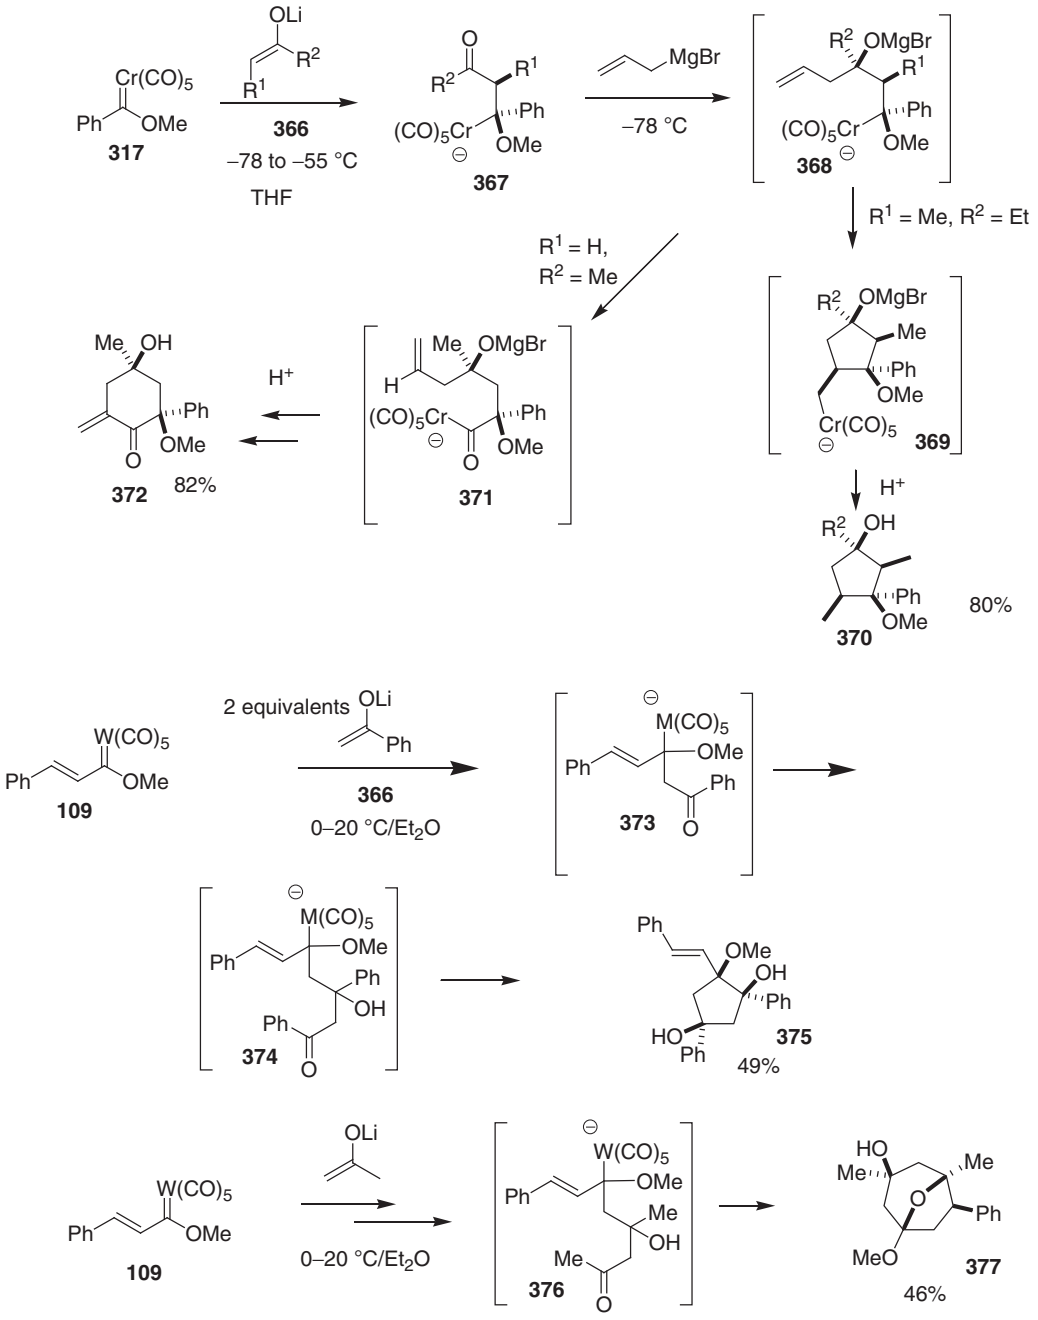
Scheme 37

carbene carbon to form a tetrahedral intermediate (**373** and **376**). Formation of five-membered rings (e.g., **375**) occurs through addition of a second mole of the enolate to the ketone to provide a pentanoyl–tungsten complex (**374**), which affords the five-membered ring through addition of the carbanion-like chromium-containing carbon to the carbonyl group. Formation of seven-membered rings (e.g., **377**) using the acetone-derived enolate occurs through a similar series of steps; however, the final ring-forming step occurs with allylic rearrangement.

A novel ring expansive cycloaddition of benzocyclobutenols (e.g., **378**, Scheme 40) and alkynylcarbene complexes (e.g., **194**) resulted in seven-membered rings (e.g., **379** and **380**).[159] A mechanism involving opening to the anionic *o*-quinonedimethane **381**, followed by nucleophilic addition to the carbene complex to afford aldehyde–alkynyltungsten complex **382**, followed by 1,2-shift of tungsten and attack at the aldehyde was proposed. The cyclized intermediate **383** either undergoes a hydride shift to produce **379** or attack of the alkoxide at the oxonium ion to afford **380**. Intermediates of nucleophilic addition of enolates to carbene complexes can also be intercepted through reaction with iodine[160] or methyl triflate, the latter process leading to

Scheme 38

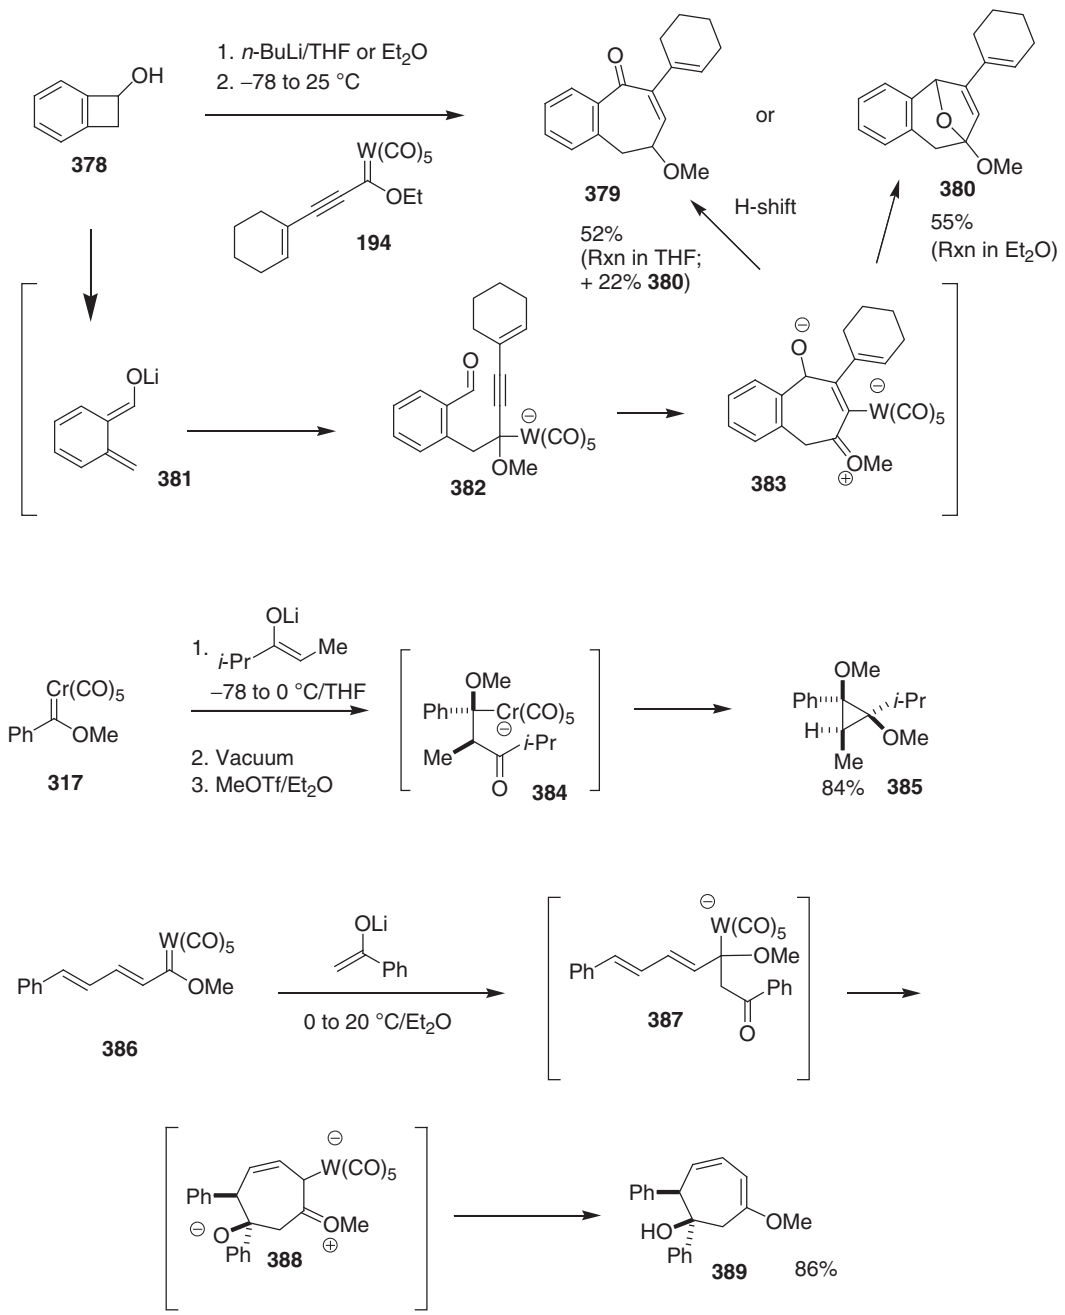
cyclopropanes (e.g., **385**).[161] Related processes were reported for amide enolates.[162] A new cycloheptadiene synthesis utilizes the coupling of dienylcarbene–tungsten complexes (e.g., **386**) and enolates.[163] A mechanism involving addition of the enolate to the carbene carbon followed by nucleophilic addition of the resulting pentadienoyl–tungsten complex to the carbonyl group was proposed.



Reaction of ketene acetals (e.g., **391**, Scheme 41) with carbene complexes (e.g., **390**) leads to either cyclopropanation products (e.g., **392**) or five-membered ring lactones (e.g., **393**).[164] All of the reaction products form from the zwitterion **394**, obtained through nucleophilic addition of the alkene carbon to the carbene carbon. The identity of the reaction product was dependent on the R group of the alkoxycarbene complex. Carbene complexes featuring hindered R groups led to cyclopropanone acetals. The methoxy complex led to γ-lactones through a mechanism involving formation of oxonium ion **397**, which then affords the lactone **393** in a sequence involving formation of unstabilized carbene complex **398**, C–H activation, alkyl shift, reductive elimination, and ortho ester hydrolysis. Additional reaction pathways were observed in many of the cases. Use of an α,β-unsaturated carbene complex led to the alkyne product **400** in addition to the expected lactone **399**.[165] Formation of the alkyne occurs through Michael addition followed by conversion of the resulting zwitterionic complex (**401**) to the vinylidene complex (**402**) followed by conversion to the alkyne and ortho ester hydrolysis. The reaction of Fischer carbene complexes and cyclic ketene acetals (e.g., **403**) led to cyclic products resulting from CO insertion (e.g., **406** and **407**).[166] The reaction proceeds via 1,2-addition to afford the zwitterionic complex **404**, which undergoes methoxy group transfer to afford the unstabilized carbene complex **405**, which then undergoes intramolecular C–H insertion. The reaction was employed in a relatively short total synthesis of edanolide.

5.25.3 Reaction at the Metal Center

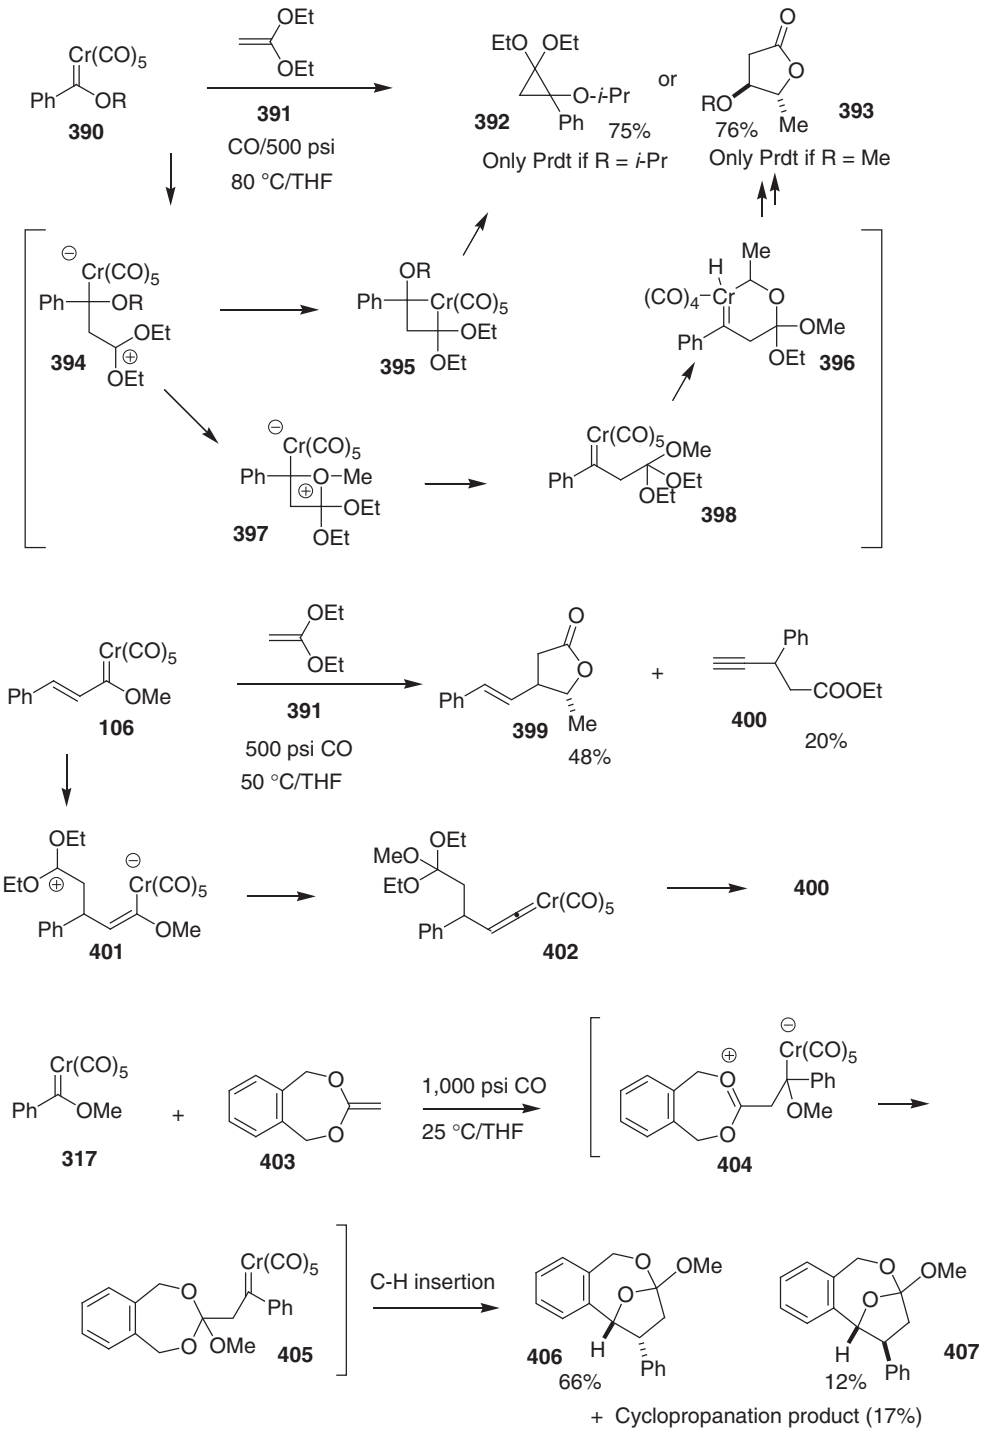
5.25.3.1 Coupling of the Carbene Ligand with Alkenes and 1,3-Dienes



5.25.3.1.1 Three-membered rings via 2 + 1 cycloaddition

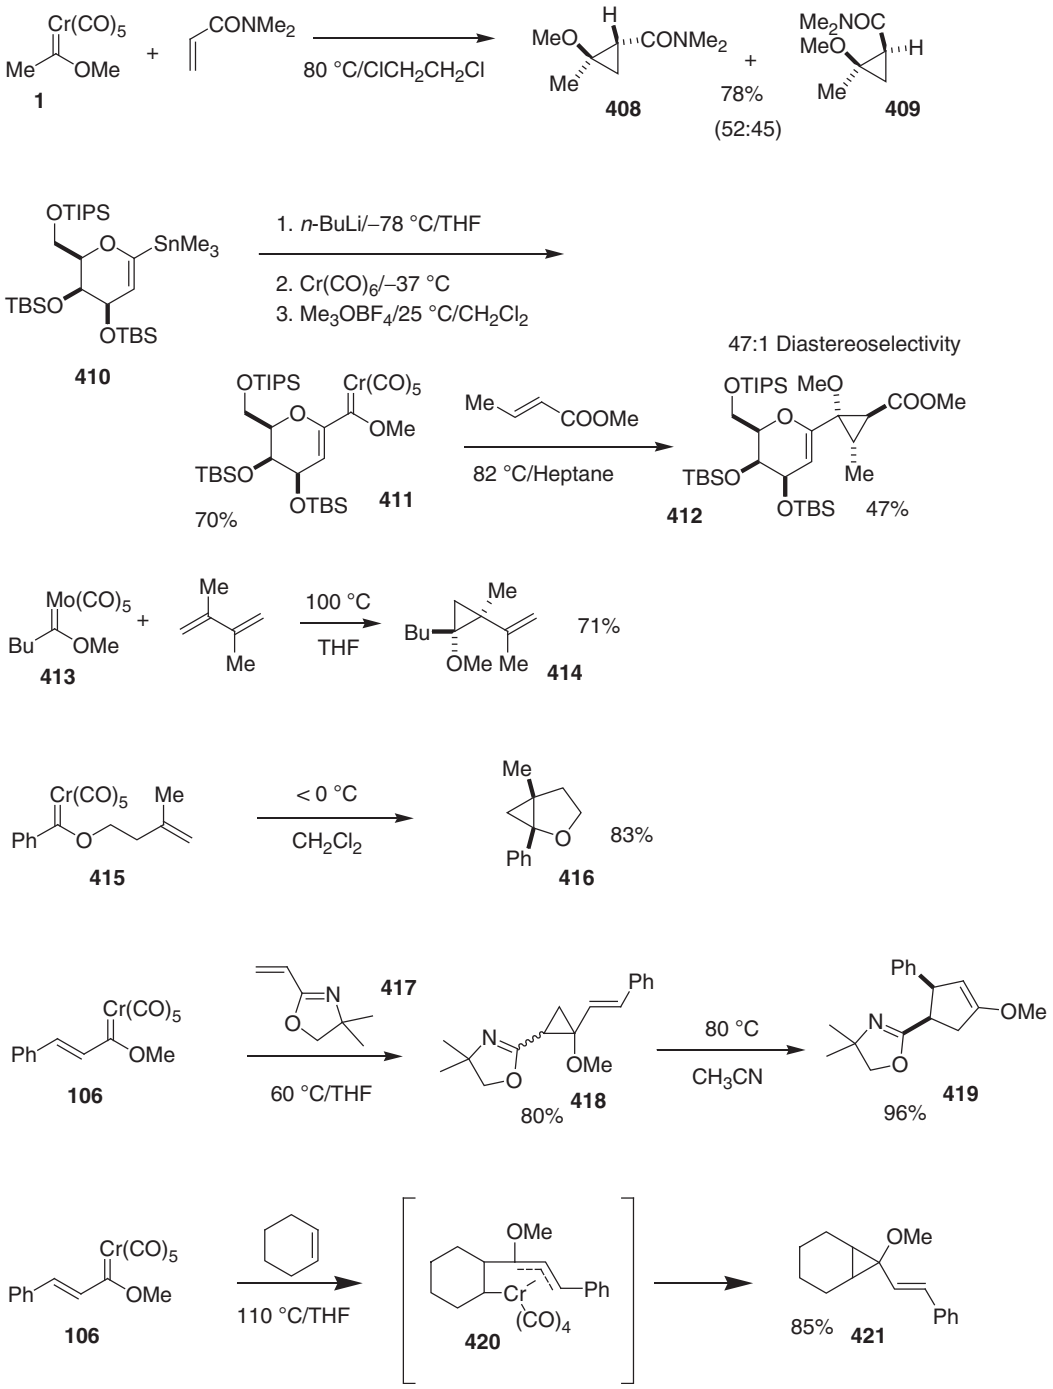
One of the early goals after the discovery of carbene complexes was to accomplish the most common transformation of carbenes, cyclopropanation.[167] In most of the early studies of Fischer-type carbene complexes, heteroatom-stabilized Fischer carbene complexes can only cyclopropanate electron-poor alkenes (e.g., **1** + *N*,*N*-dimethylacrylamide, Scheme 42),[168] or electron-rich alkenes under CO pressure. Numerous additional examples of these processes have been amassed since the first edition of Comprehensive Organic Synthesis, and new methods for the cyclopropanation of additional alkyne types have been developed. Cyclopropanation reactions involving glycal–carbene complexes (e.g., **411**) and various electron-deficient alkenes were reported.[169] Varying degrees of diastereoselectivity were observed depending on the aldohexose and the alcohol protecting groups. Cyclopropanation has been extended to conjugated diene substrates (e.g., complex **413** + 2,3-dimethylbutadiene).[170,171] These substrates are generally limited to diene systems that can attain the *s-cis* conformation. This limitation was attributed to required formation of a chelated π-allyl complex as a key intermediate. For the metals of Group 6, the molybdenum carbene complexes appear to be more reactive than the chromium carbene complexes; tungsten carbene complexes are not generally useful cyclopropanating agents except when lacking heteroatom substitution.[172] Cyclopropanation using alkynylcarbene–chromium complexes and electron-deficient alkenes was also reported.[173] Intramolecular cyclopropanation reactions (e.g., conversion of complex

Scheme 39



415 to **416**) appear to be more facile and proceed with unactivated alkene groups.[174] The cyclopropanation reaction has been successfully extended to alkenes conjugated to carbon–nitrogen double bonds. Reaction of α,β-unsaturated carbene complexes with 2-alkenyloxazoles (e.g., **417**) at 80 °C led to five-membered ring derivatives (e.g., **419**) after rearrangement of the initially formed cyclopropanes (e.g., **418**).[175] Cyclopropanation reactions of alkenyloximes were similarly reported.[176] Successful cyclopropanation of unactivated alkenes was achieved using α,β-unsaturated chromium carbene complexes (e.g., **106**) in refluxing DMF or THF at high temperature.[177] Only alkenylcarbene complexes and heteroarylcarbene complexes were successful in this reaction. The cyclopropanation of cyclohexene required a 20-fold molar excess of cyclohexene. In cases involving monosubstituted alkenes or *cis* 1,2-disubstituted alkenes, the cyclopropane stereoisomer where the methoxy group and the original alkene substituents are *cis* was produced with a high degree of stereoselectivity. A mechanism involving [2 + 2]-cycloaddition followed by conversion of the resulting σ-allyl/metallacyclobutane complex to a π-allyl complex (e.g., **420**) was proposed to account for the substrate limitations of this process. Solid phase reaction of carbene complexes with alkenes was also reported.[178]

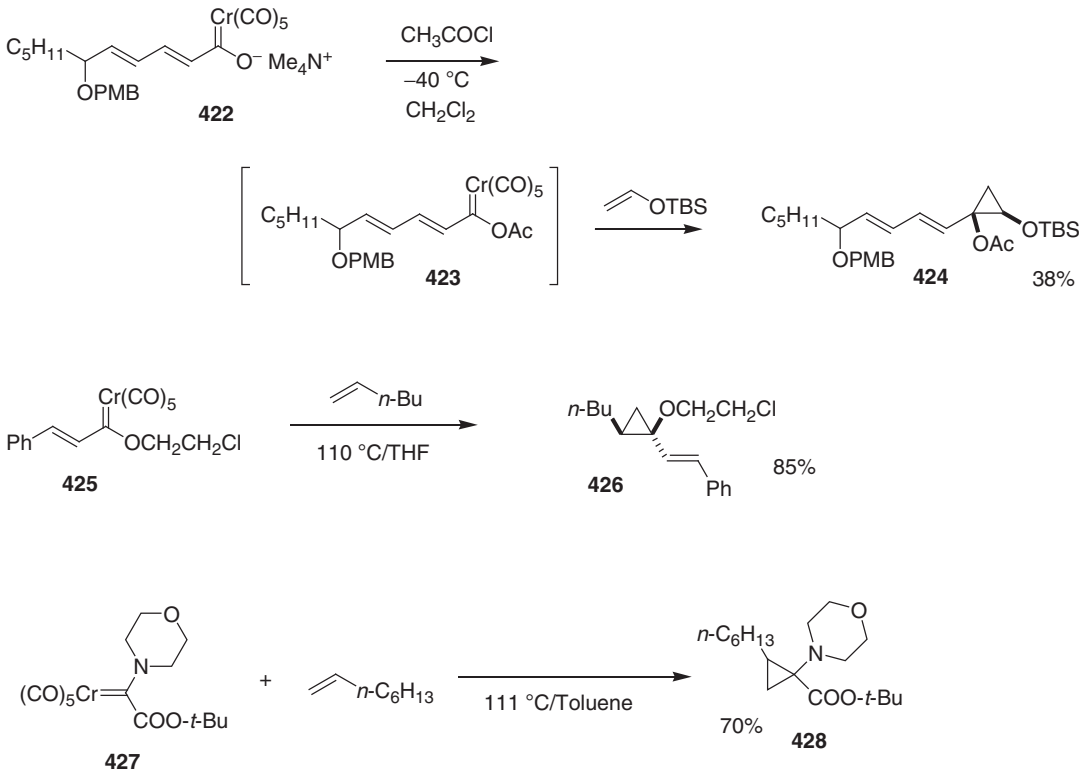
Scheme 40



Several successful attempts to activate the relatively unreactive Fischer carbene complex systems were reported (Scheme 43). Most employ the use of carbene complexes that have been deactivated by electron-withdrawing groups. Unstable acetoxycarbene analogs (e.g., **422**) appear to undergo cyclopropanation of electron-rich alkenes quite readily.[179] This reaction process is the cornerstone for the synthesis of prostaglandin derivatives. Chloroethylcarbene complex analogs (e.g., **425**) were noticeably more reactive and could successfully cyclopropanate norbornene, styrene, and 1-hexene.[180] Alkene cyclopropanation can be accomplished using aminocarbene complexes that feature an acyl group at the carbene carbon (e.g., **427**).[181]

Cationic iron carbene complexes undergo cyclopropanation reactions with electron-rich alkenes under very mild conditions (Scheme 44). These complexes are typically unstable but generated *in situ*, and appear to be excellent reagents for cyclopropanation of unactivated alkenes. These iron carbene complexes can be generated via a variety of methods, including protonation of vinyliron species (e.g., **429**), alkylation of thioalkyliron species, or protonation or silylation of alkoxyiron (or hydroxyiron) species (represented by general structure **431**). The thiomethyliron complexes appear to be the most convenient starting materials for carbene transfer.[182] Some degree of asymmetric induction has been observed in the reaction of chiral-at-iron

Scheme 41

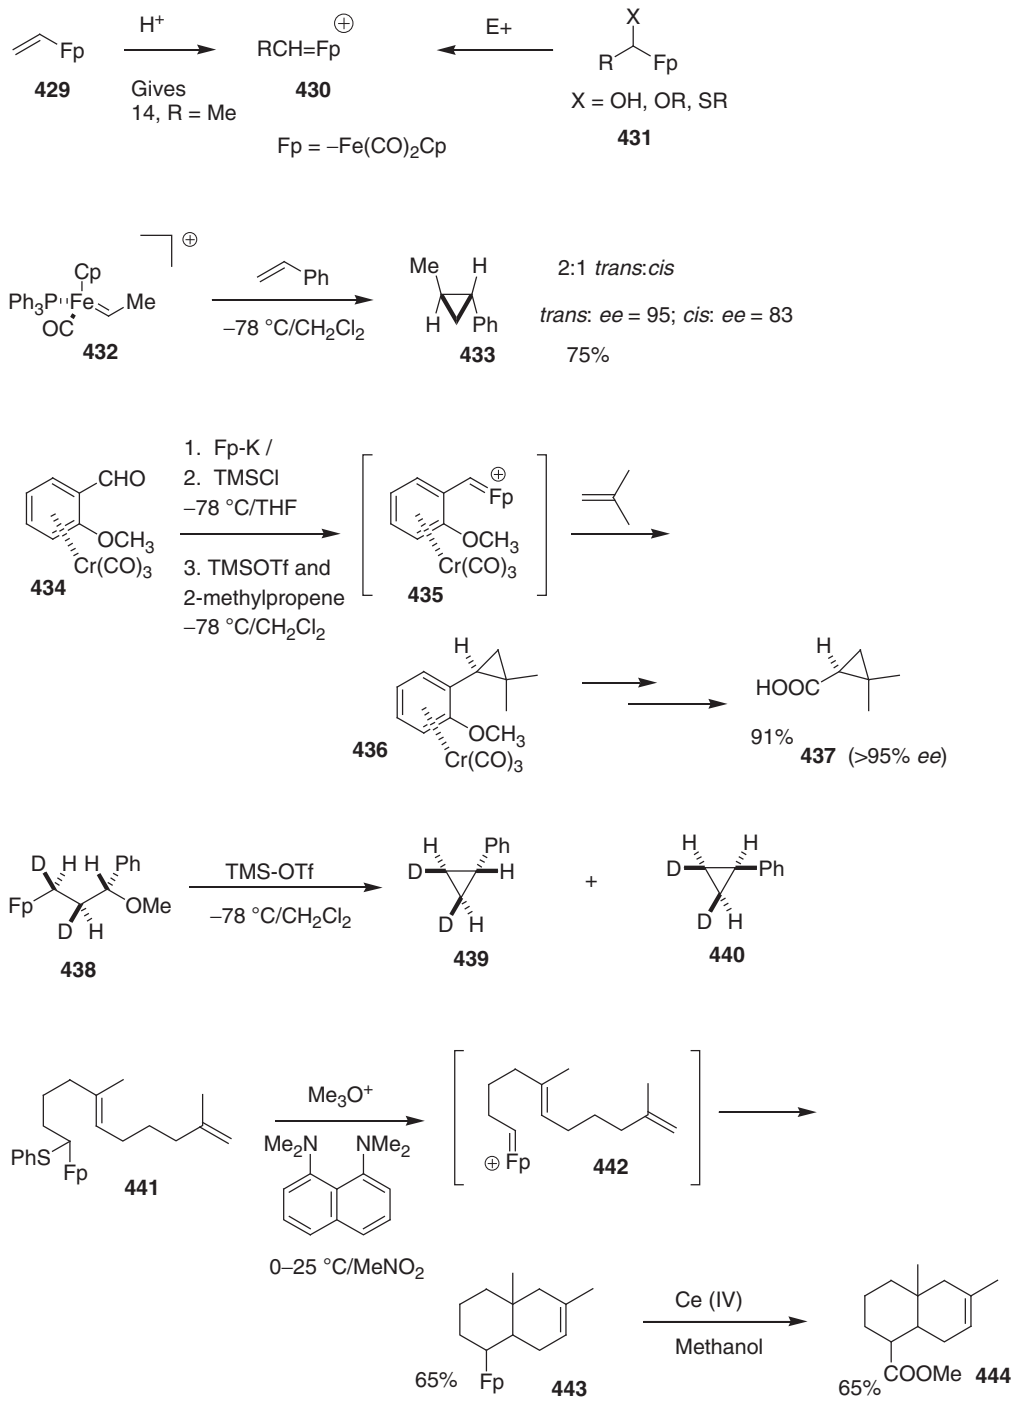


phosphine-substituted iron carbene complexes (e.g., **432**)[183,184] and for iron carbene complexes featuring the arene-chromium chiral auxiliary (e.g., **435**).[185] This method has been used as the cornerstone for a recent synthesis of optically pure cyclopropanecarboxylate derivatives (e.g., **437**). A mechanistic study of the reaction suggested that the reaction occurs via electrophilic attack at the alkene followed by ring closure that occurs with inversion at iron. The equivalent intermediate can be generated from stereo-labeled precursor **438**, which affords the cyclopropane product with clean inversion of the C–Fe bond on treatment with trimethylsilyl triflate.[186] Cation–olefin cascade cyclization processes can be initiated by the generation of iron carbene complexes in polyene systems (e.g., **442**).[187] In the reaction process depicted, the iron carbene complex functions as a carbocation equivalent.

Scheme 42

5.25.3.1.2 Five-membered and larger ring systems

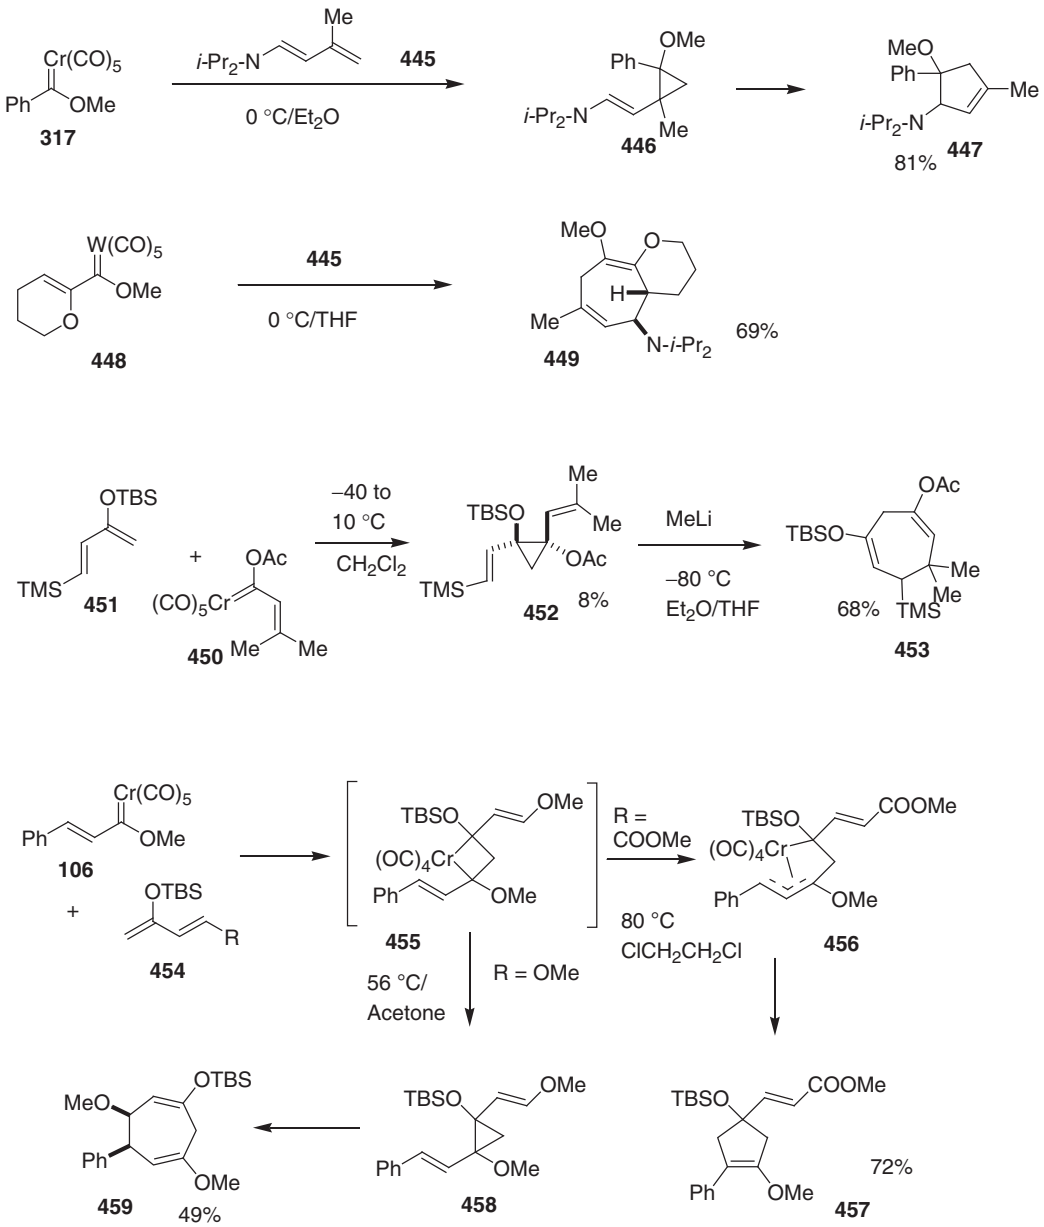
Diverse reaction modes leading to ring sizes other than three were observed in the reaction of carbene complexes with alkenes where either of the cycloaddition partners is carrying an extra alkene group (Scheme 45). Reaction of aminodiene **445** with arylcarbene–chromium complex **317** afforded cyclopentane derivatives (e.g., **447**) via a cyclopropanation–vinylcyclopropane rearrangement sequence.[188] Arylvinylcarbene–chromium complex **448** afforded seven-membered ring derivative **449** via a cyclopropanation–divinylcyclopropane rearrangement sequence on reaction with aminodiene **445**. Alkylvinylcarbene–chromium and tungsten carbene complexes afforded primarily Diels–Alder products. Other reactions involving the coupling of 1,3-dienes with α,β-unsaturated carbene complexes also feature competition between the Diels–Alder and carbene-addition pathways, including (1) the coupling of 2-azadienes with various types of α,β-unsaturated carbene complexes[189] and (2) the coupling of



Scheme 43

1-azadienes with alkynylcarbene–chromium complexes.[190] Cyclopropanation was observed in the coupling of electron-rich dienes (e.g., **451**) with (acetoxy)vinylcarbene–chromium complexes (e.g., **450**); the resulting divinylcyclopropanes (**452**) were transformed to cycloheptadiene derivatives (**453**) by treatment with methyllithium.[191] Intramolecular cyclopropanation was observed when chromium carbene acylates were treated with β,γ-unsaturated acid chlorides.[192] The coupling of α,β-unsaturated chromium carbene complexes (e.g., **106**) with silyloxydiene derivatives (e.g., **454**) afforded either five- or seven-membered ring products.[193] Competition between direct cyclopropanation followed by Cope rearrangement, resulting in the formation of cycloheptadiene (e.g., **459**), or direct five-membered ring formation resulting in the formation of cyclopentenes (e.g., **457**), was noted. In the reaction with complex **106**, electron-deficient silyloxydienes (e.g., **454**, R = COOMe) generally afforded five-membered rings, whereas other derivatives led to cycloheptadienones.

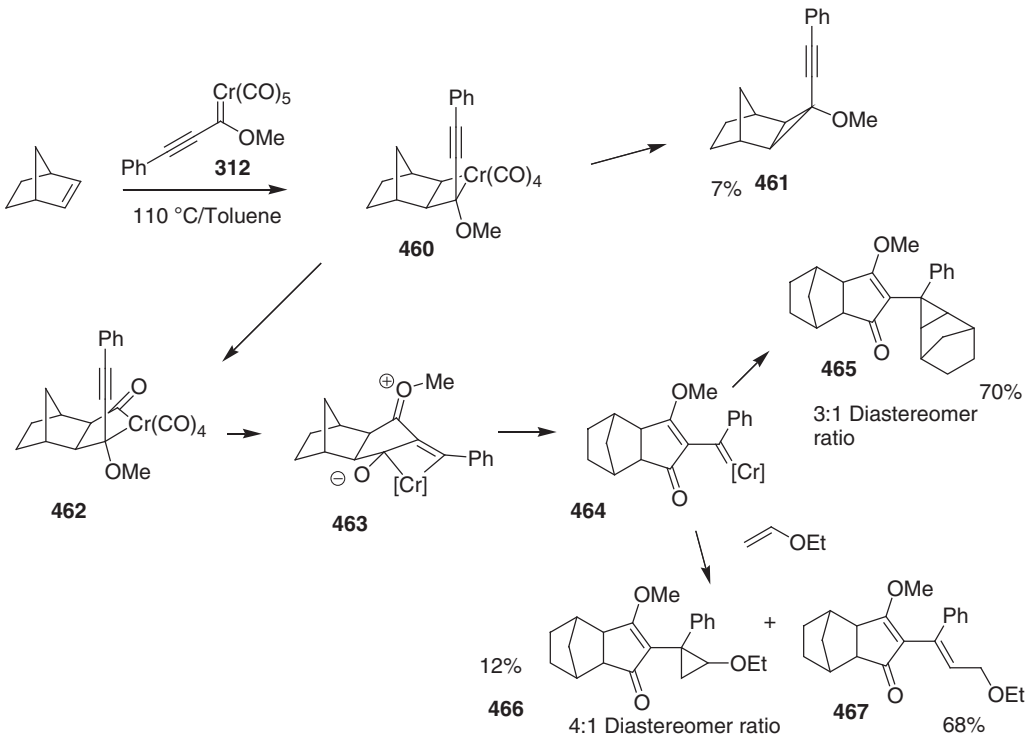
The coupling of alkynylcarbene complexes (e.g., **312**, Scheme 46) with strained rings (e.g., norbornene) afforded mixtures of the simple cyclopropanation product **461** and an adduct **465** incorporating CO and two moles of the norbornene.[194] A mechanism involving [2 + 2]-cycloaddition, CO insertion, and simultaneous 1,3 shift of chromium and carbonyl addition led to intermediate carbene complex **464**, which couples with the starting alkene to provide adduct **465**. This carbene complex intermediate can also couple with electron-rich alkenes to provide cyclopropane derivatives (e.g., **466**) accompanied by ring-opened products (e.g., **467**).



In several cases, the reaction of carbene complexes and alkenes where either partner has an extra alkene group leads to five-membered rings (Scheme 47). Cyclopentenones (e.g., **471**) were obtained from the coupling of α,β-unsaturated Fischer carbene complexes (e.g., **106**) and α,β-unsaturated *N,N*-dimethylhydrazones (e.g., **468**).[195] The pyrrole **474** was a minor product in the reaction. Moderate levels of ee were observed using the chiral alkoxycarbene complexes. Cyclopentenones were produced by nucleophilic addition of the β-carbon of the hydrazone at the carbene carbon followed by addition of the resulting allylmetal group of the initial adduct (**469**) to the vinyldiazonium group. The pyrrole was formed through nucleophilic attack of the imine nitrogen at the carbene carbon followed by intramolecular Michael addition of the organochromium group of **472** to the vinyliminium group. The coupling of alkenylcarbene complex **475** and electron-deficient alkenes affords either the expected vinylcyclopropanes (e.g., **476**) or a cyclopentene derivatives (e.g., **477**).[196] Coupling of α,β-unsaturated carbene–chromium complexes (e.g., **106**) with electroneutral 1,3-dienes (e.g., isoprene) leads to cyclopentane derivatives (e.g., **478** (a [4 + 1] adduct) and **479** (a [3 + 2] adduct)).[197] The distribution was solvent and temperature dependent and, however, exclusive formation of **478** was observed in THF at 120 °C, although **479** was the exclusive product from the reaction conducted at 90 °C in toluene. Exclusively the [3 + 2]-adduct was obtained from the analogous tungsten carbene complexes. The proposed mechanism for the formation of **478** and **479** both involve a metalla-Diels–Alder reaction followed by reductive elimination. The cycloaddition

Scheme 44

mode is determined by whether the metalla-Diels–Alder reaction utilizes the carbene complex as the 2π-component (affording intermediate **480**) or the 4π-component (affording intermediate **481**). The reaction of carbene complexes (e.g., **317**) with alkylidenecyclopropanes (e.g., **482**) also leads to cyclopentenones.[198] A mechanism involving [2 + 2]-cycloaddition to afford **484** followed by cyclopropylcarbinyl metal ring expansion to afford metallacyclopentane **485**, followed by CO insertion and reductive elimination was proposed.



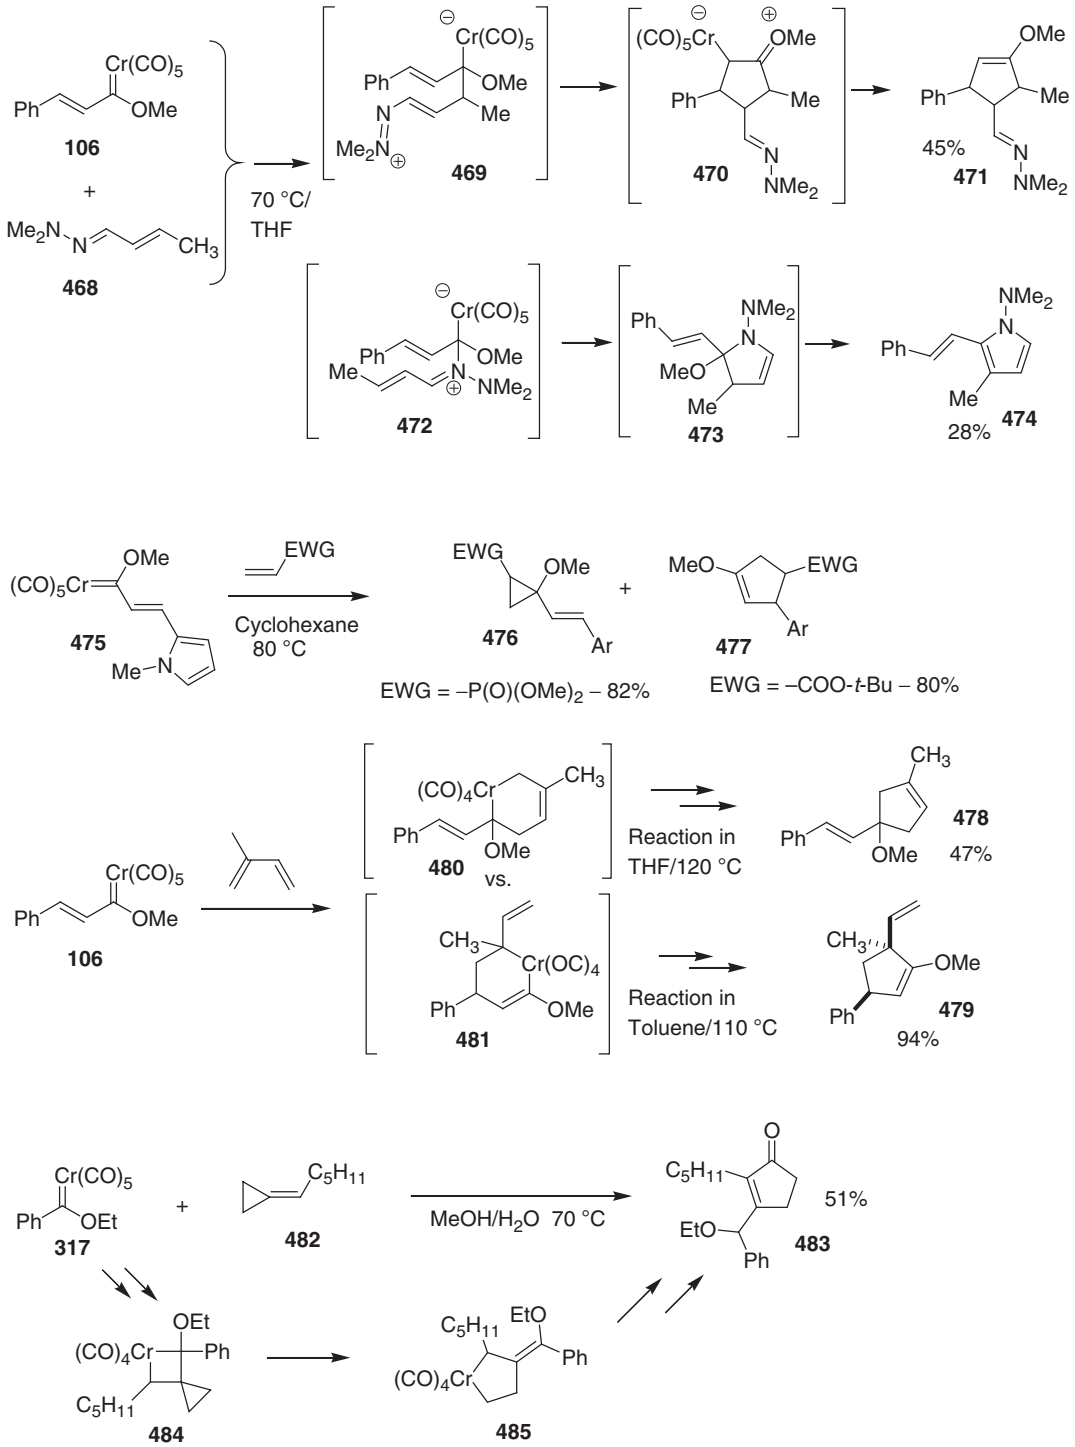
Several examples of the coupling of carbene complexes and alkenes leading to heterocyclic compounds have been reported (Scheme 48). Cyclopropanation or [4 + 1]-cycloaddition using alkenylcarbene–chromium complexes (e.g., **106**) and

Scheme 45

electron-deficient ketones leads to either the cyclopropanation product (e.g., **488**) or furan derivatives (e.g., **486** and **487**), depending on the substrate and reaction time.[199] In most cases, the cyclopropanation product rearranges to the [4 + 1]-cycloadduct on heating. Pyrroles (e.g., **494**) arise through the reaction of aminocarbene complexes (e.g., **490**) and α,β-unsaturated aldehydes.[200] A mechanism involving cyclopropanation to afford a donor–acceptor activated cyclopropane (**492**), followed by ring opening and aldehyde–enamine condensation was proposed.

Several examples of the photolytic coupling of iminocarbene Group 6 metal complexes (e.g., **495**, Scheme 49) and electron-deficient alkenes leading to five-membered ring nitrogen heterocycles (e.g., **498**) have been reported. The reaction pathway is highly dependent on the substitution pattern of the carbene substituents and that of the alkene or alkyne reactant. In the reaction of complex **495** with ethyl acrylate leading to pyrroline **498**, a mechanism involving photo-assisted CO dissociation, followed by complexation and cyclopropanation, followed by photochemically induced transformation of the *N*-cyclopropylimine (**497**) to the 1-pyrroline (**498**) was proposed.[201] The cyclopropylimine derivative **497** could be isolated from the reaction at short reaction times. Photolytic coupling of iminocarbene Group 6 metal complexes and various alkynes led to 1-pyrrolines (e.g., **500**).[202] The reaction with internal alkynes leads to acyclic 2-iminodiene derivatives.

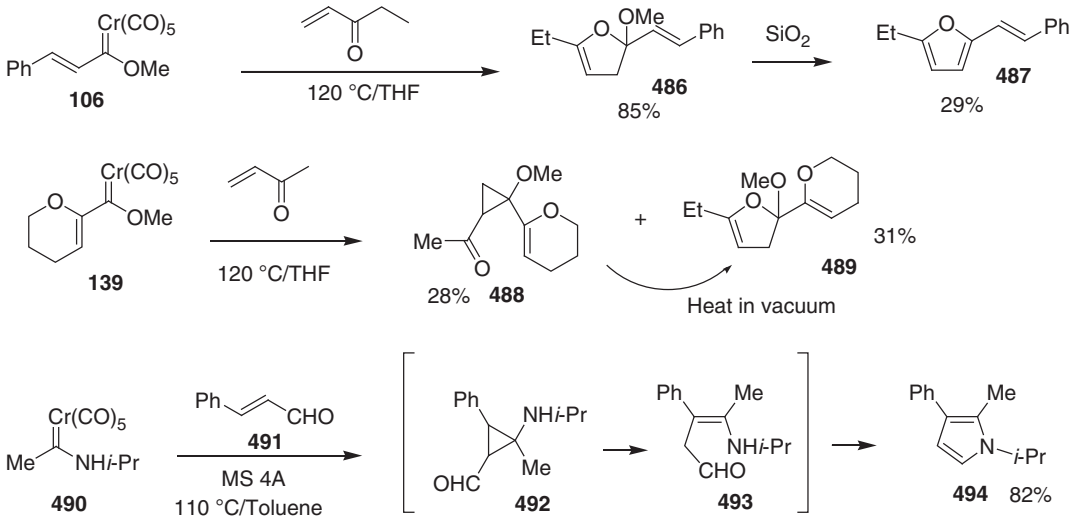
Scheme 46



5.25.3.2 Coupling of the Carbene Ligand with Alkynes

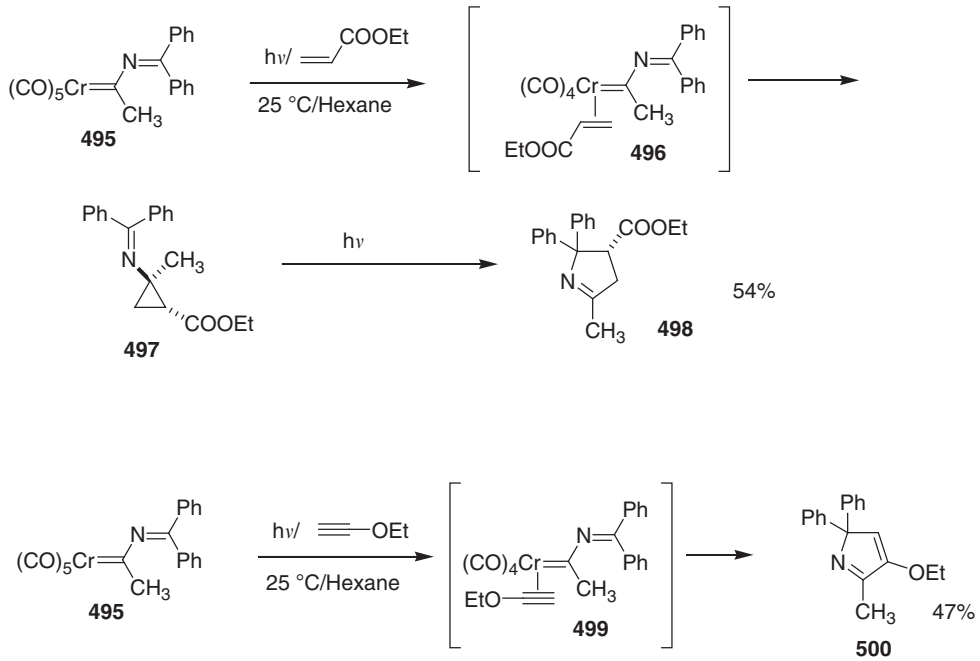
5.25.3.2.1 2 + 1 + 1 cycloadditions – cyclobutenones

Cyclobutenone formation is often a minor reaction pathway observed in the coupling of Fischer carbene complexes with alkynes; however, in a very limited number of cases cyclobutenone formation is the major pathway (Scheme 50). Coupling of ferrocenylcarbene complex **501** with alkynes led to predominantly cyclobutenones (e.g., **502**) and furans (e.g., **503**) and not benzannulation products.[203] The product distribution was highly dependent on the metal and on the number of equivalents of alkyne employed. The furan products were more prevalent when the reaction was conducted at high concentration. Alkynylboranes (e.g., **504**) were suitable substrates for benzannulation reactions, resulting in naphthylboronic esters (**505**);[204] however, sterically hindered alkynylboranes afforded predominantly cyclobutenones (**506**). The reactions provided products where the boron inserts β- to the carbene complex functionality; this regioselectivity preference was observed regardless of the steric bulk of the other alkyne substituent.



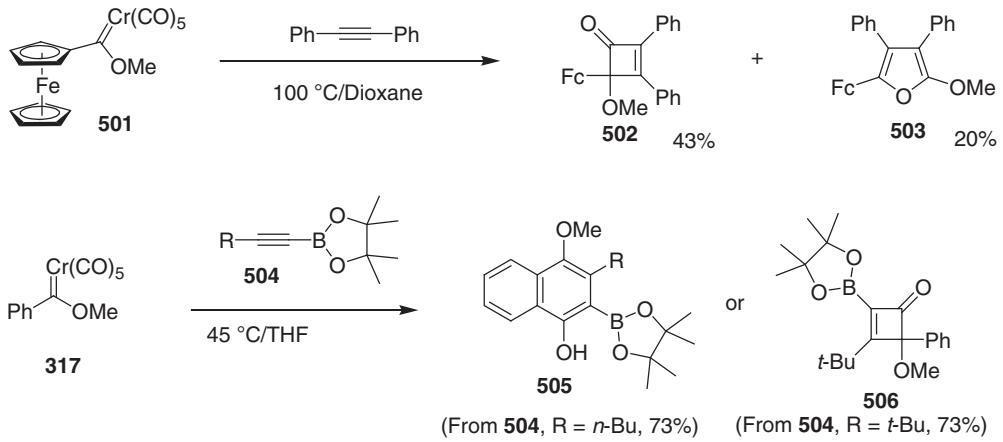
5.25.3.2.2 Five-membered rings[205]

Five-membered ring formation is often observed in the coupling of α,β-unsaturated carbene complexes with alkynes (Scheme 51). Often five- and six-membered ring formations are in competition. The ring formation is primarily determined by whether CO is incorporated, and in several cases conditions have been designed that maximize this five-membered ring-forming process. Certain substitution patterns are, however, far more likely to result in five-membered rings. Benzannulation (six-membered ring formation, see ahead) appears to be a general reaction process only for alkoxy-substituted chromium carbene complexes. Aryl aminocarbene complexes usually afford five-membered ring annulation products (e.g., **507**→**508**)[206] unless the nitrogen is acylated;[207] however, there are cases where benzannulation[119,208] and other ketene-derived products[209] are observed. Molybdenum– and tungsten–carbene complexes typically afford cyclopentannulation products also (e.g., **509**→**510**, **511**).[210,211] Iron carbene complexes afford pyrones (e.g., **512**→**513**/**514**)[212] or furans,[213,214] whereas cobalt carbene complexes afford furans (e.g., **515**→**516**).[215] Five-membered ring formation using alkoxycarbene-chromium complexes appears to be favored in polar coordinating solvents, and under high dilution conditions.[216] Electronic effects in the carbene complex and alkyne, as well as ring size effects for intramolecular reactions all play an important role in directing the course of the reaction. Additional examples of five-membered ring formation are depicted in Scheme 52 and include (1) the reaction of 1,6-methano[10]annulene-substituted tungsten carbene complexes (e.g., **520**) and alkynes leading to five-membered ring derivatives (e.g., **521**),[217] (2) thermolysis of aryl(amino)carbene complexes that feature remote alkyne groups (e.g., **523**) to afford five-membered rings fused to heterocyclic ring systems (e.g., **525**),[218] (3) cyclopentannulation reactions involving the coupling of alkynes and aminocarbene complexes fused to podocarpane rings (e.g., **526**),[219] and (4) coupling of 4-oxygenated-2,6-dimethylphenylcarbene–chromium complexes (e.g., **528**) and various alkynes to afford nonaromatic five- and six-membered ring annulation products (e.g., **529** and **530**).[220]

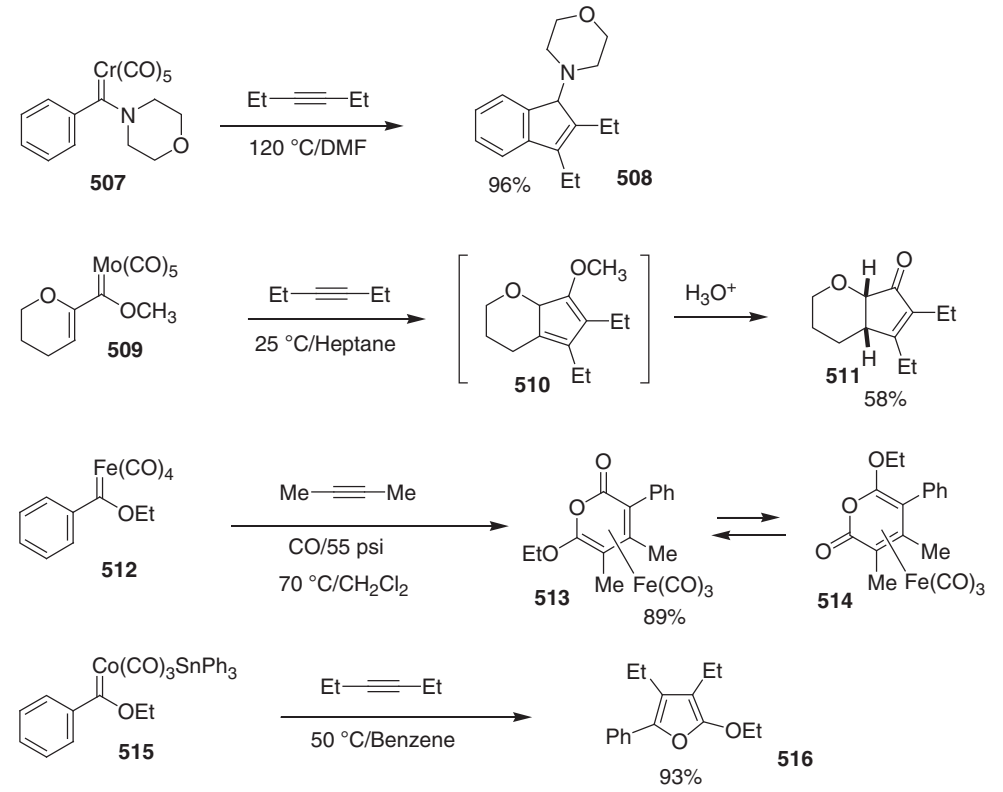


Scheme 47

Several examples of the intramolecular coupling of aminocarbene complex with alkynes leading to pyrrole and pyrrolidinone products have been reported.[221] The general reaction equation is depicted in Scheme 53 and involves alkyne insertion to afford a ketene (**533**) followed by formation of a nitrogen ylide (**534**), which then undergoes a Stevens-type rearrangement to afford the pyrrolidinones. The most thoroughly studied version of this reaction is the intramolecular coupling of aminocarbene–chromium complexes and alkynes (e.g., **538**→**541**, **542**). Thermolysis of **538** initially affords nitrogen ylide derivatives (**540**), which subsequently affords lactam derivatives **541**, **542**.[222] This reaction is also efficient for the formation of six-membered ring analogs.



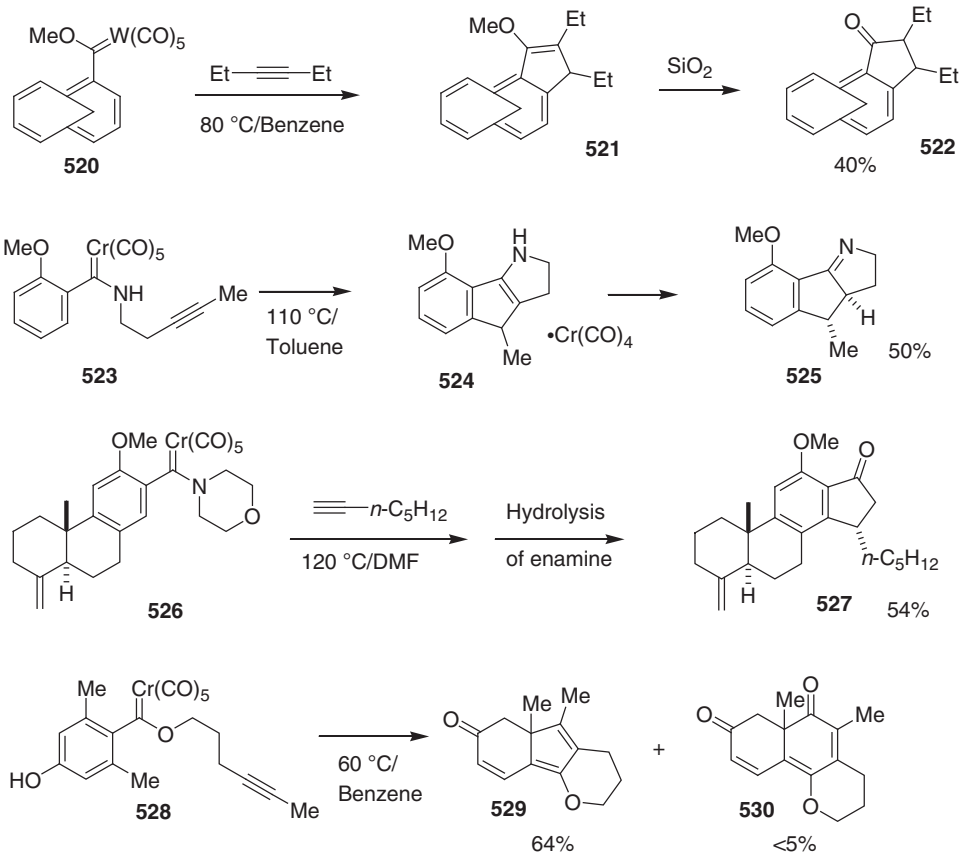
Scheme 48



Scheme 49

Several examples of this reaction type have been reported. Intermolecular variants of this process have also been reported (e.g., **543** → **545–548**).[223]

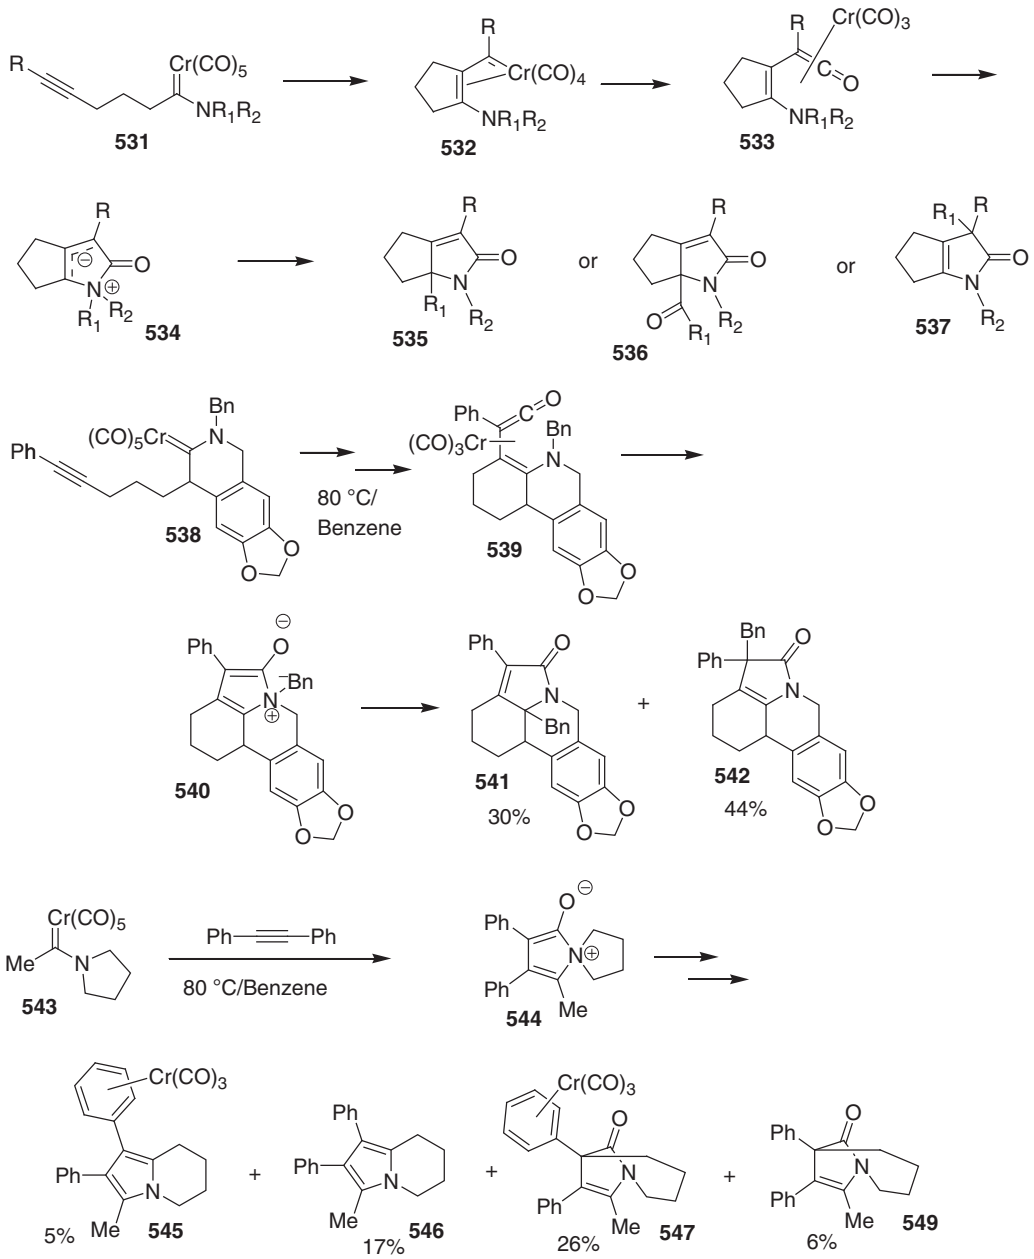
Numerous studies of the reaction of β-amino-α,β-unsaturated carbene complexes with alkynes to afford five-membered ring compounds have been documented (**Scheme 54**).[224,225] Cyclopentadienes (e.g., **552**) were produced from the reaction of alkynylcarbene complexes (e.g., **549**) with amines followed by reaction of the resulting alkenylcarbene complexes with alkynes.[226] This process involves first heating the alkenylcarbene complex to afford an amine-coordinated complex (**551**), which then reacts with an alkyne to afford the cyclopentadiene after cyclization. Hydrolysis affords the observed ketone product (**553**). In many cases the cyclopentadienes undergo Diels–Alder reactions with the alkynes to afford the ring-fused norbornadiene derivatives. The coupling of β-amino-α,β-unsaturated carbene complexes with cyclopropylacetylene derivatives (e.g., **554**) leads to alkylidenecyclopentane derivatives (e.g., **556**) via ring opening of cyclopentadiene derivative **555**.[227] Cyclopentannulation reactions of β-aminoalkenylcarbene–chromium complexes were employed as a key step for syntheses of angularly fused triquinanes.[228] In several examples, useful organic groups were incorporated for the deployment of tandem multiple ring-forming reactions. Reaction with bis(alkenyl)acetylenes (e.g., **558**) led to indanone derivatives (e.g., **561**) in a complex tandem process involving



Scheme 50

Scheme 51

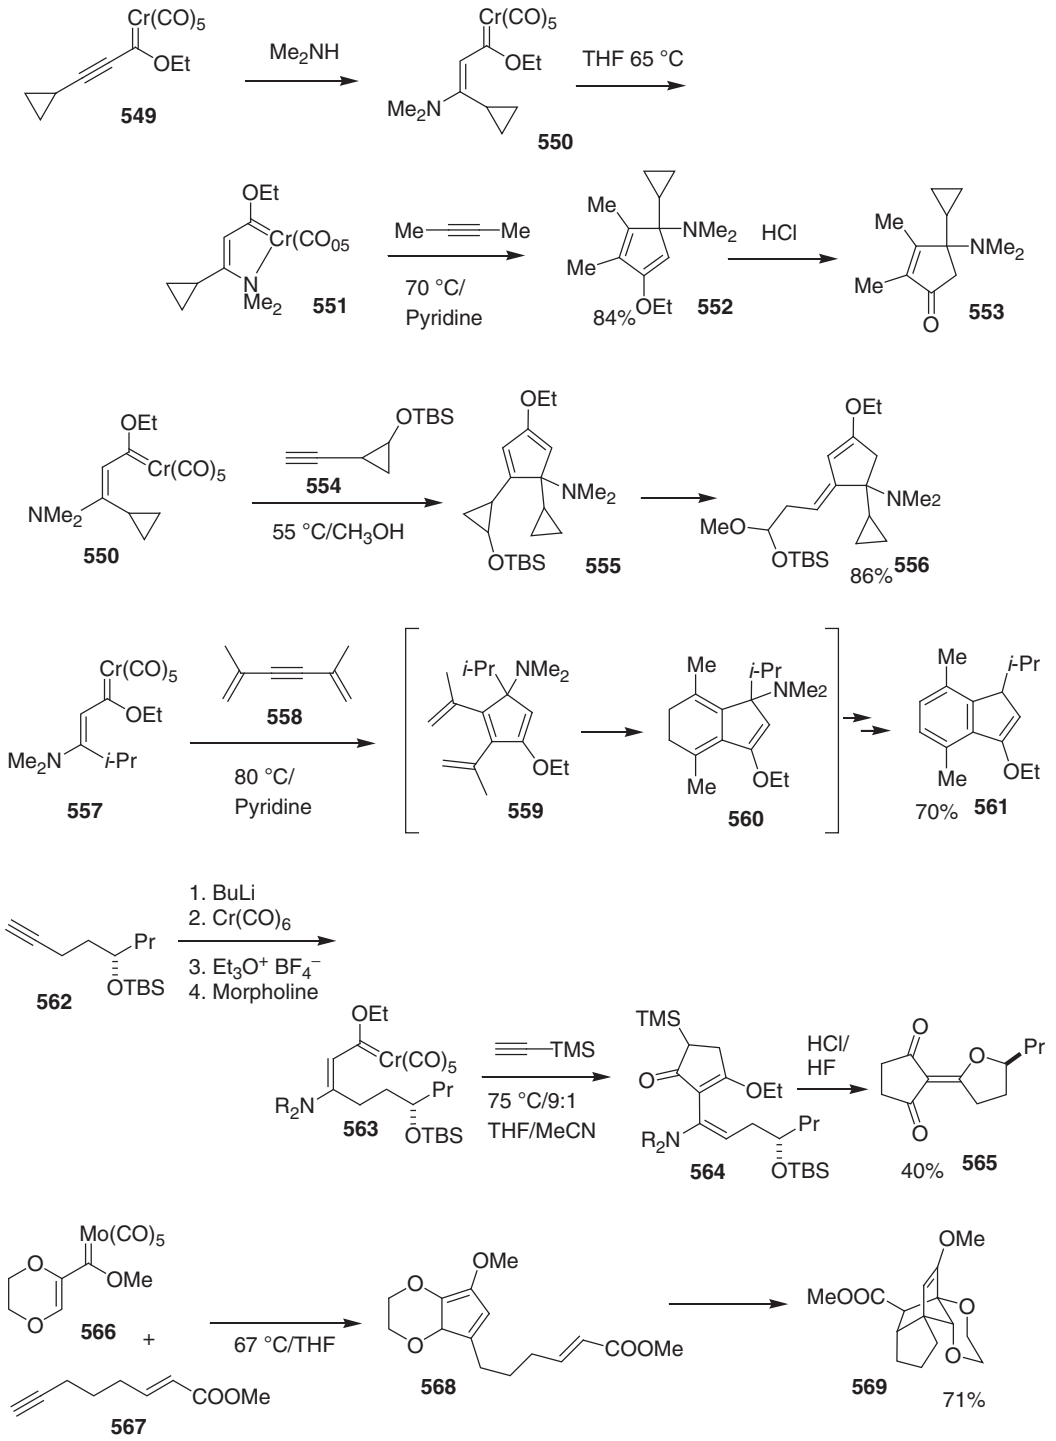
formation of the bis(alkenyl)aminocyclopentadiene **559**, followed by electrocyclic ring closure to form cyclohexadiene derivative **560**, followed by elimination of amine, aromatization, and enol ether hydrolysis.[229] The major products are 5-alkylidene-2-cyclopentenones or 2-alkenyl-2-cyclopentenones (e.g., **564**) if β-amino-α,β-unsaturated carbene complexes (e.g., **563**) are coupled with alkynes in ethereal solvents. This reaction process is the basis of a synthesis of the antihypertensive oudenone (**565**).[230] Synthesis of bulgaramine using a related intramolecular cyclopentannulation process was also reported.[231] In several cases, the reaction of β-amino-α,β-unsaturated carbene complexes and multiple equivalents of an alkyne leads to comparatively complex polycyclic ring systems.[232,233] Similar reaction pathways were observed for β-alkoxy-α,β-unsaturated molybdenum carbene complexes reacting with alkynes. The reaction of dioxenylmolybdenum carbene complex **566** and several enyne systems affords complex polycyclic ring systems (e.g., **569**) in a process that involves [3 + 2]-cycloaddition followed by intramolecular Diels–Alder reaction.[234]



Scheme 52

The coupling of alkynes with cyclopropylcarbene–chromium complexes affords cyclopentenone derivatives (e.g., **6**→**571**, Scheme 55).[235,236] The myriad of reactions that emanate from cyclopropylcarbene-Group 6 metal complexes have been reviewed.[237] The reaction produces a cyclopentadienone intermediate (**570**) through a complex mechanistic process involving loss of ethylene (a formal [4 + 2 + 1–2]-cycloaddition), which is reduced by the chromium byproduct of the cycloaddition process. In some cases the cyclopentadienones (e.g., **573**) can be isolated and are the major products when reactions are conducted in heptane solvent.[238] The reduction process involves cyclopentadienide intermediates (e.g., **576**), which can be intercepted if the starting alkyne features leaving groups in the propargyl position, resulting in alkylidenecyclopentenone derivatives (**6** + **579**→**582**).[239] The intramolecular reaction featuring carbene complexes that have chiral propargyl groups (e.g., **583** and **586**) proceeds stereoselectively to afford five-membered rings with a high degree of stereocontrol, affording the thermodynamically more stable ring system.[240] This process has been used as cornerstone for the preparation of vitamin D synthetic intermediates.[241] Cyclopentenone products similar to those from Section 5.25.3.2.1 can also be produced from the coupling of alkylcarbene complexes with alkynes;[242] however, the reaction is mechanistically quite different. This method is most effective for dialkylacetylenes; cyclobutenones and two-alkyne insertion products are formed as minor byproducts in most of these studies. Compounds of this type have also been observed in the coupling of molybdenum carbene complexes with alkynes,[211,243] and in intramolecular couplings involving aminocarbene complexes.[244] Mixtures of the vinylogous ester isomer **590** and the 4-alkoxy-2-cyclopentenone isomer **591** were obtained in most cases.

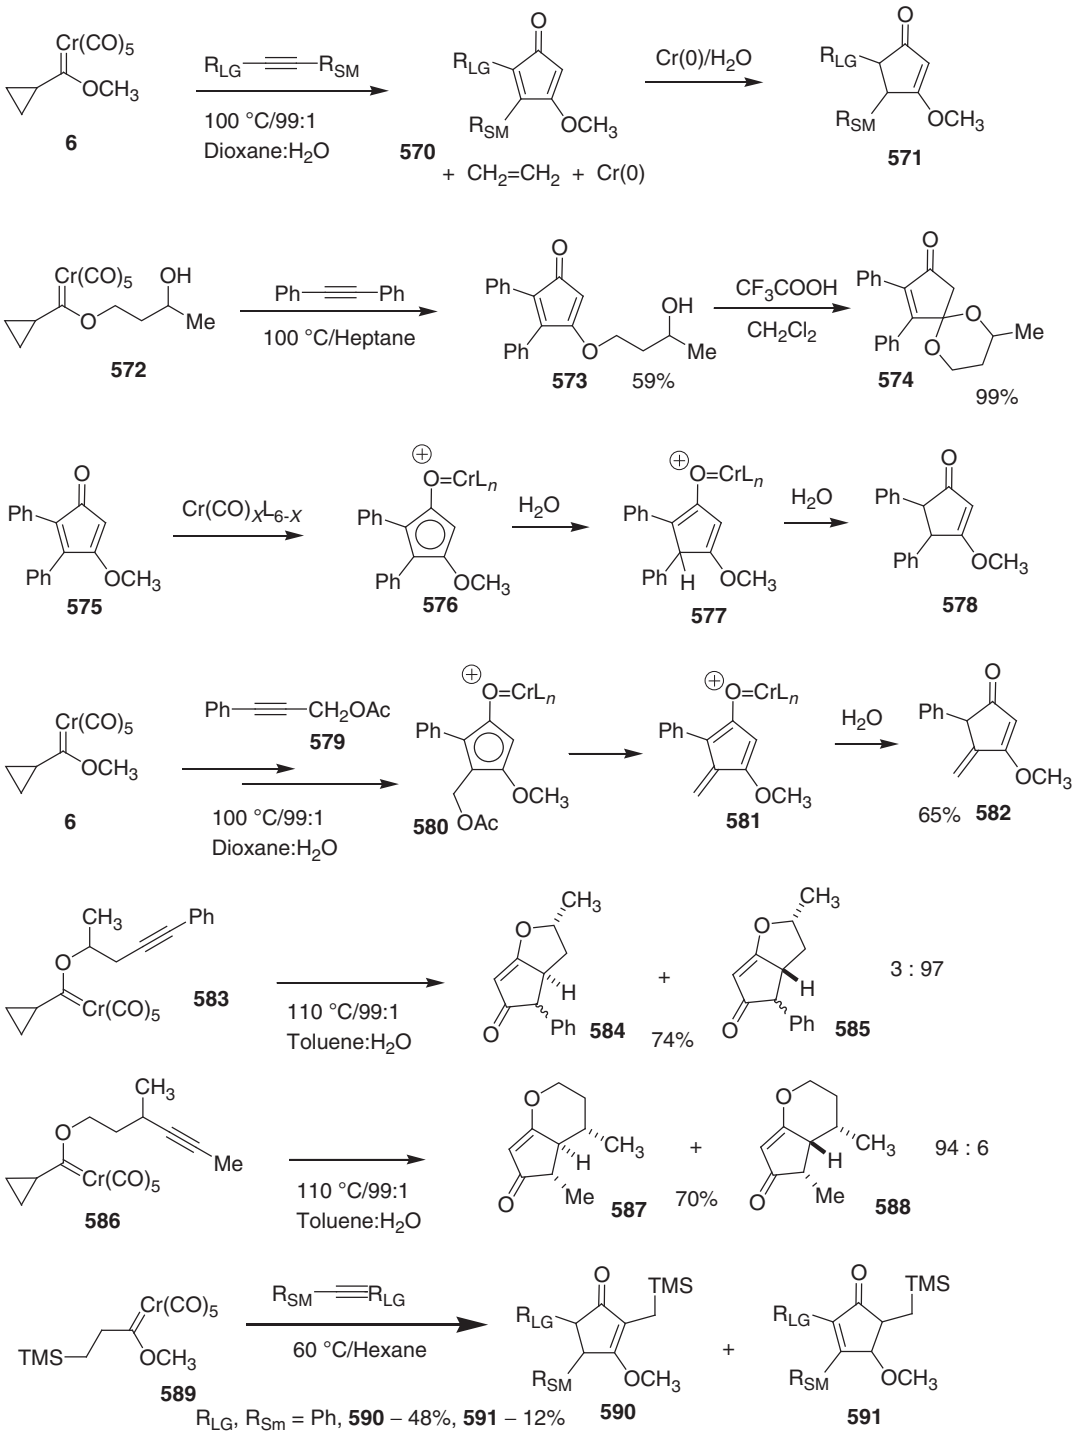
The coupling of alkynylcyclobutenols (**592**, Scheme 56), readily derived from cyclobutenediones, with Fischer carbene–chromium complexes leads to cyclopentendione derivatives (e.g., **595**).[245] A mechanism involving alkyne insertion, leading to the unstable but electrophilic vinylcarbene complex intermediate **593**, followed by acyl migration to the electrophilic carbene carbon and demetallation has been proposed. The reaction process is general for a variety of carbene complexes, including alkylcarbene, arylcarbene, vinylcarbene, and cyclopropylcarbene complexes. This reaction is unique to the cyclobutenedione-derived systems; other related systems, including the saturated cyclobutane ring systems, do not undergo the analogous ring expansion process. In cases where there is competition from Dötz-type benzannulation reaction pathways, the ring expansion pathway is the exclusive reaction pathway.



The reaction of methylcarbene complex **1** with enyne–aldehydes (e.g., **596**, Scheme 57) or enyne–ketones led to vinylfuran derivatives (e.g., **599**).[246] A mechanism involving nucleophilic attack of the carbonyl oxygen at the carbene carbon of the vinylcarbene complex intermediate **597** (forming carbonyl ylide **598**) followed by demetallation was proposed. The reaction of

Scheme 53

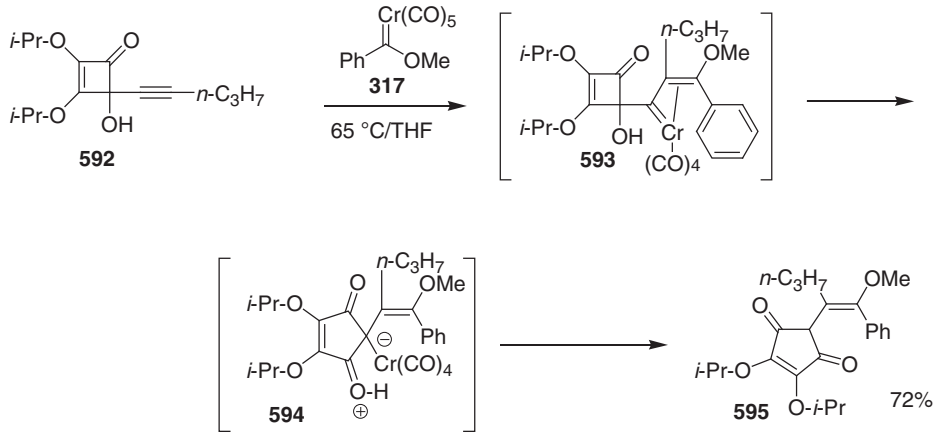
γ,δ-unsaturated Fischer carbene complexes (e.g., **601**) with enyne aldehydes afforded simple furans (e.g., **602**), which undergo Diels–Alder reactions at elevated temperatures leading to hydronaphthalenes (e.g., **603**).[247]



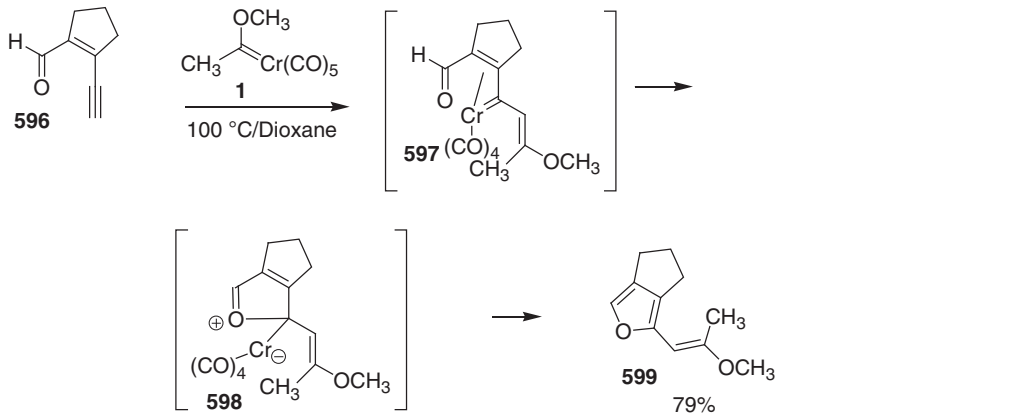
Coupling of carbene complexes with *o*-alkynylbenzaldehyde derivatives (e.g., **604**) led to the generation of isobenzofurans (e.g., **605**) (Scheme 58).[248,249] Simple coupling of carbene complexes with enyne–carbonyl systems resulted in the formation of alkylidenephthalans (e.g., **607**) via a net 1,7-hydrogen shift followed by enol ether hydrolysis. A three-component coupling was observed if the reaction was conducted in the presence of electron-deficient alkenes (e.g., **608**). The intermediate isobenzofuran undergoes a Diels–Alder reaction in this case. Coupling of γ,δ-unsaturated carbene complexes (e.g., **611**, Scheme 59) with *o*-alkynylbenzaldehyde derivatives led to the formation of hydrophenanthrene derivatives (e.g., **613**) in a single reaction pot,[250,251] and proceeds with enhanced efficiency in aqueous solvent systems.[252] A mechanism involving generation of an isobenzofuran (**612**), followed by intramolecular Diels–Alder reaction and oxanorbornene ring opening was proposed. The reaction proceeded with a very high degree of relative asymmetric induction. Additional variants include the preparation of dihydrophenanthrenes using electron-rich systems (e.g., **614**),[253,254] alternate tethering schemes (e.g., **617** + 1 → **620**),[255] and use of pyridine systems in place of benzene ring systems (e.g., **621** + **601** → **622**),[256–259] Less efficient processes include the use of amides in place of

Scheme 54

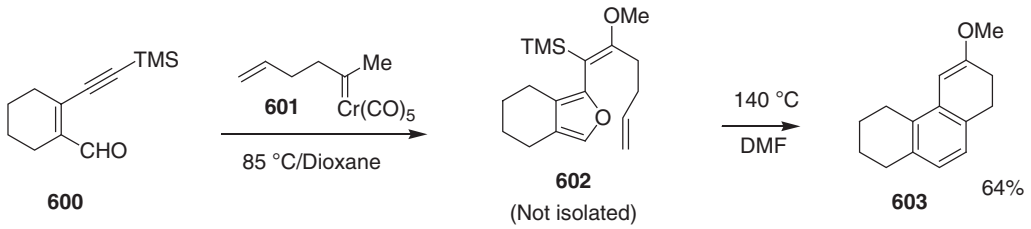
ketones and aldehydes,[260] and use of β-cyanocarbene complexes in place of γ,δ-unsaturated carbene complexes to afford phenanthrenes.[261]



Isobenzofuran intermediates (e.g., **625**, Scheme 60) that are derived from α,β-unsaturated carbene complexes (e.g., **624**) could be captured by dimethyl acetylenedicarboxylate (**626**) to provide [8 + 2]-cycloaddition products (e.g., **628**) as single diastereomers.[262] Both isobenzofuran Diels–Alder products (e.g., **627**) and [8 + 2]-cycloaddition products are typically produced in this reaction, and their ratio varies considerably with the carbene complex and alkyne–ketone substituents. In some cases, the Diels–Alder adducts thermally rearrange to [8 + 2]-cycloadducts.[263] Coupling of simple enyne aldehydes (e.g., **629**) with



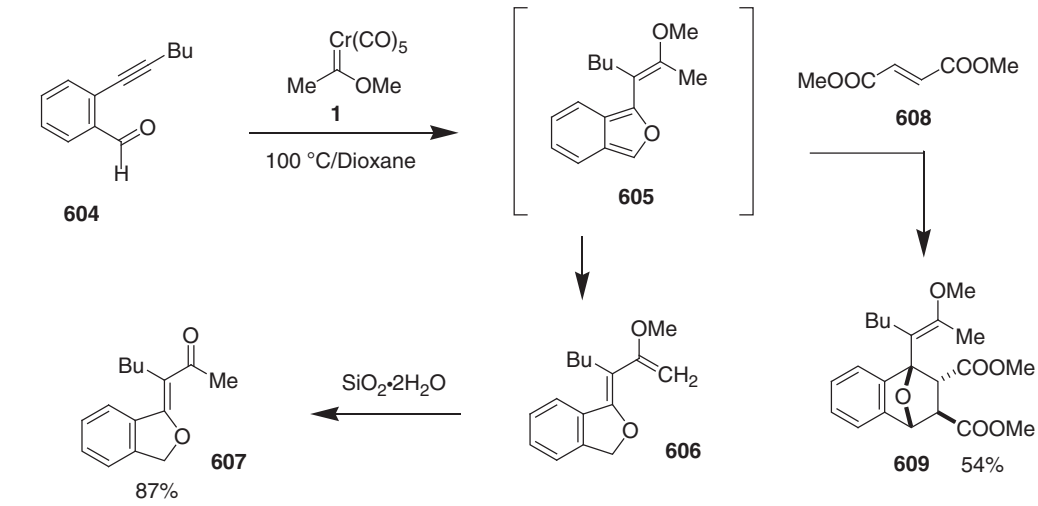
Scheme 55



alkenylcarbene complexes leads to dienylfurans (e.g., **630**), which undergo exclusive [8 + 2]-cycloaddition on treatment with dimethyl acetylenedicarboxylate.[264]

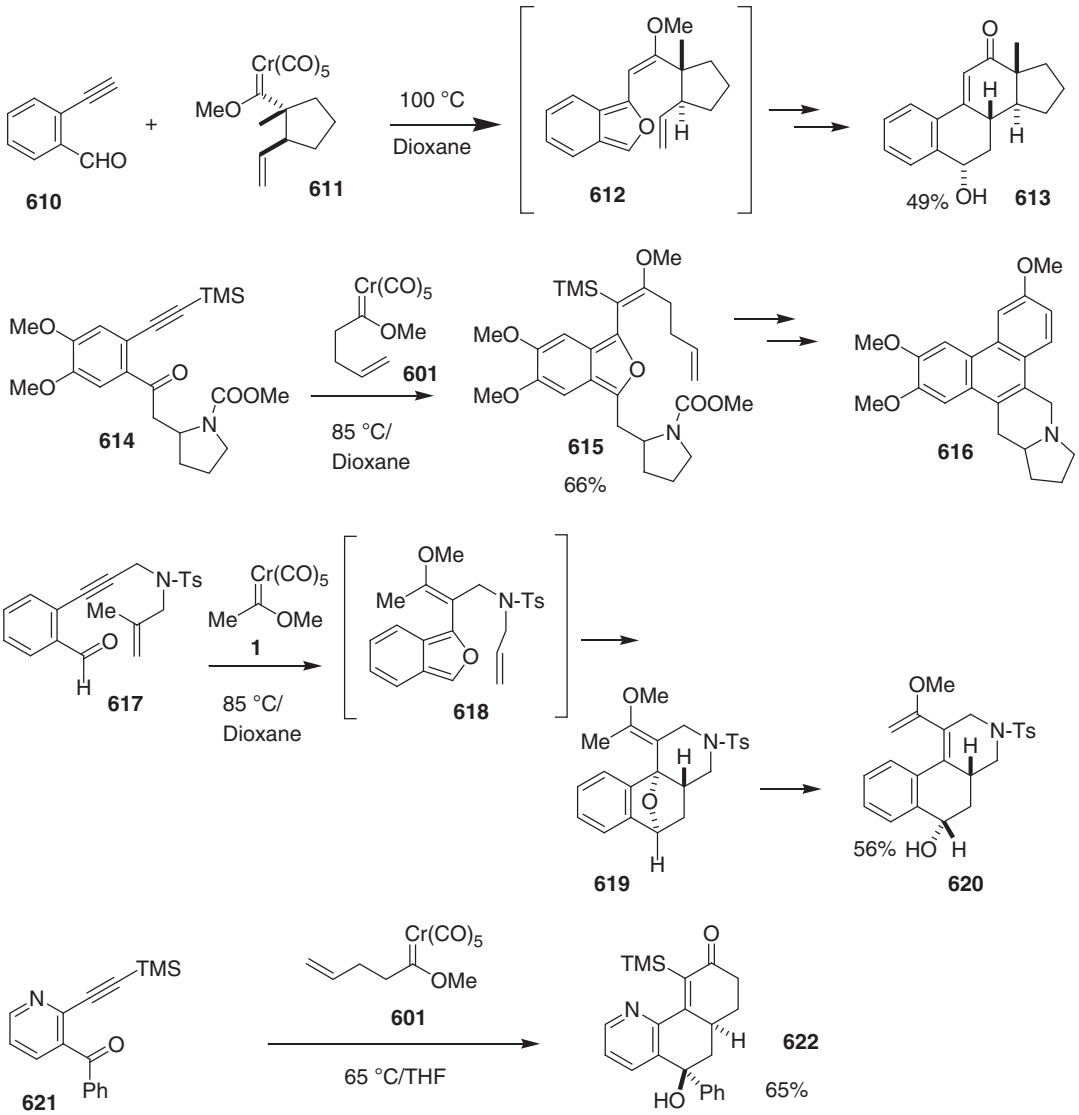
Coupling of carbene complexes with enyne–hydrazones (e.g., **632**, Scheme 61) affords pyrrole derivatives (e.g., **634**) through a mechanism involving alkyne insertion followed by nucleophilic addition of the imine nitrogen to the carbene carbon of the intermediate alkenylcarbene complex **633** followed by demetallation.[265] Benzo-fused analogs of these systems have also been demonstrated. The three-component coupling of 2-alkynylbenzaldehyde hydrazones (e.g., **635**), carbene complexes, and electron-deficient alkynes (e.g., **626**) leads to substituted naphthalene derivatives (e.g., **638**).[266] The carbene–alkyne coupling process results in isoindoles (**637**), which undergo Diels–Alder reaction with the alkyne followed by nitrene extrusion to provide the

Scheme 56



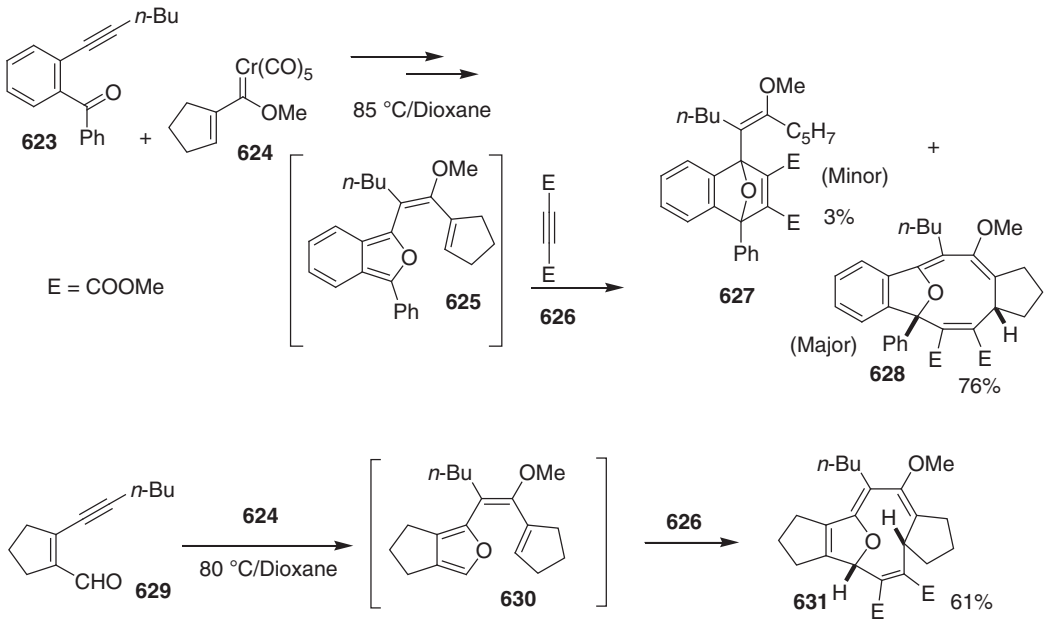
Scheme 57

naphthalene derivatives. Since the isoindole intermediates are more stable than isobenzofurans, the dienophile can be added after generation of the isoindole system.

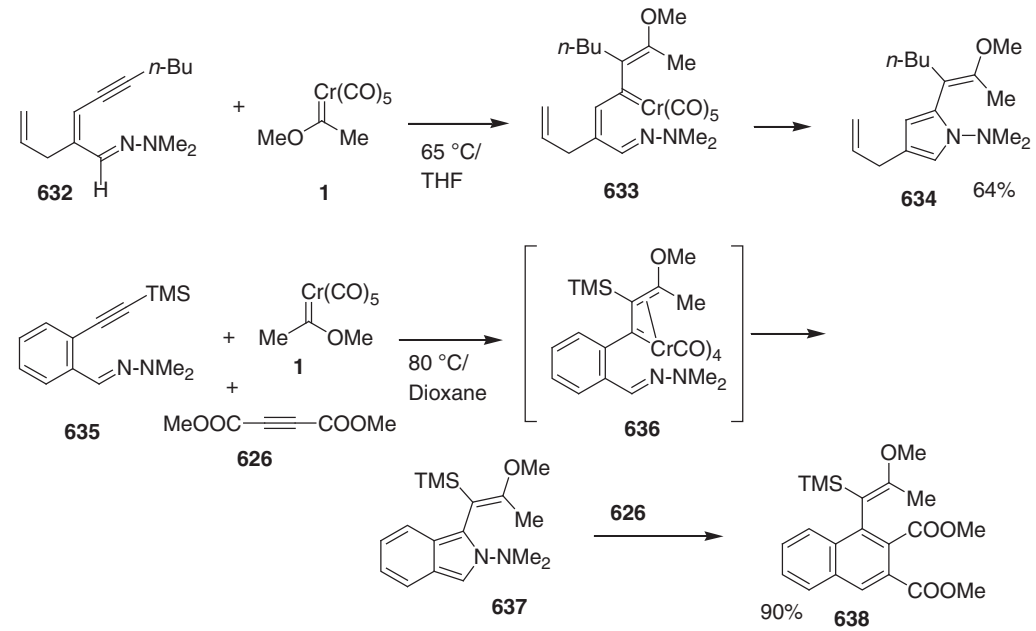


The coupling of iminocarbene complexes (e.g., **639**, **643**, Scheme 62) and alkynes led to pyrroles (e.g., **640**) analogous to those obtained from nitrile ylide cycloadditions.[267,268] These pyrroles were produced in a highly regioselective manner. In most of the cases, hydroxypyridines were minor products; however, these become the major products when using alkoxy-substituted iminocarbene complexes (e.g., **643**). Reaction with nitriles afforded imidazoles (e.g., **641**). Reaction with alkenes led to dihydropyrroles (e.g., **642**). The observed regioselectivity was attributed to resonance structure **639a**, with chromium doing a Michael addition to give the products after electrophilic capture and reductive elimination.

5.25.3.2.3 Six-membered rings

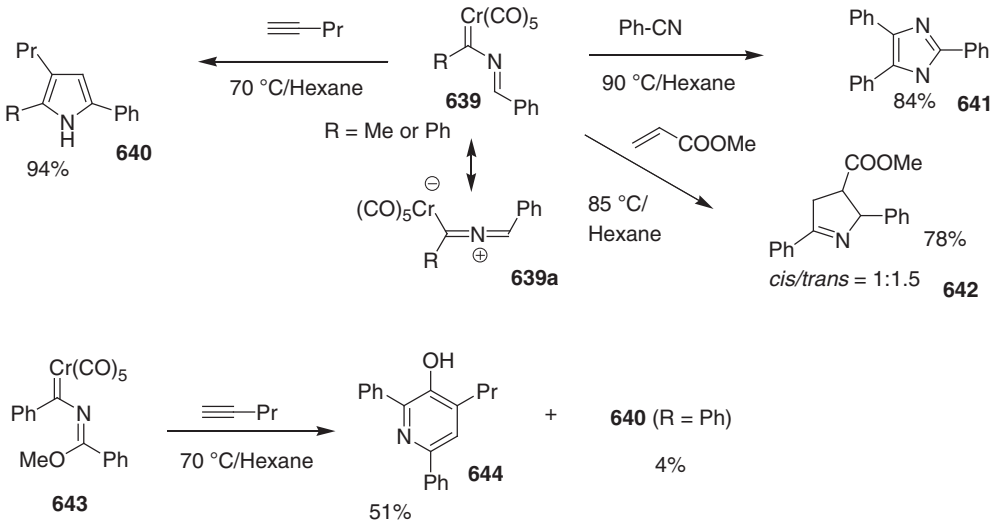


Among the most useful reactions of Fischer carbene complexes is the formation of phenols from the coupling of alkynes with α,β-unsaturated carbene complexes or arylcarbene complexes, which is commonly known as the Dötz benzannulation reaction (Scheme 63).[269] The normal product of this coupling is the *p*-methoxyphenol derivative. The generally accepted mechanism of

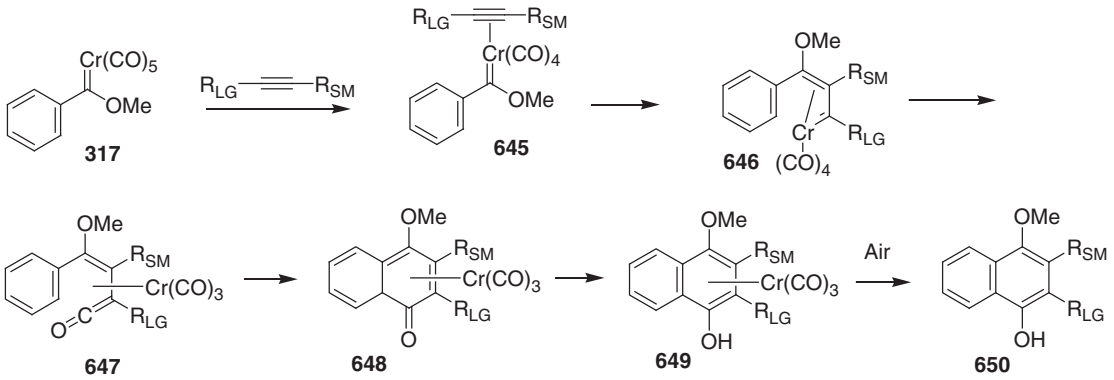


Scheme 58

Scheme 59

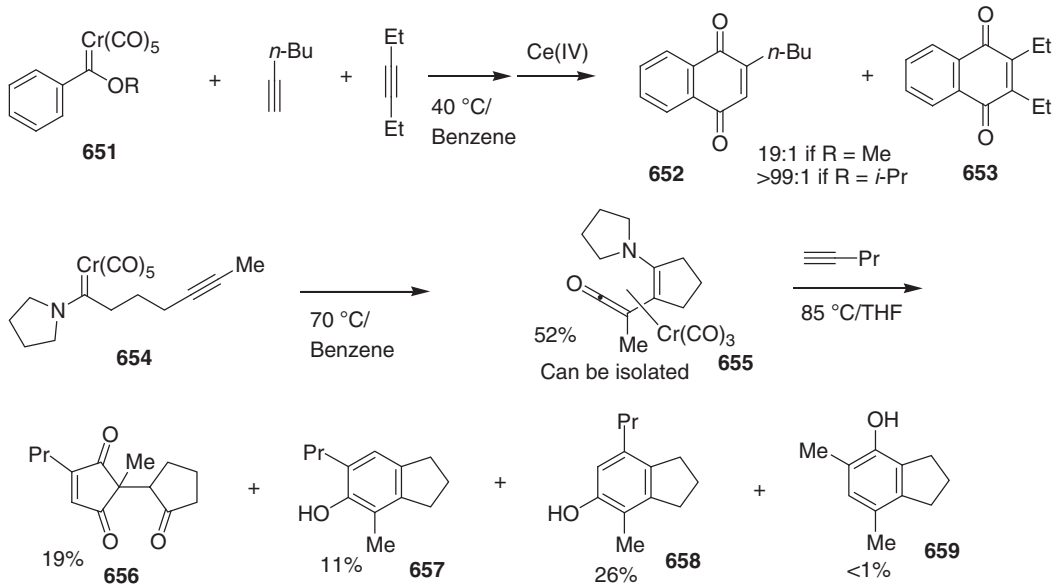


Scheme 60



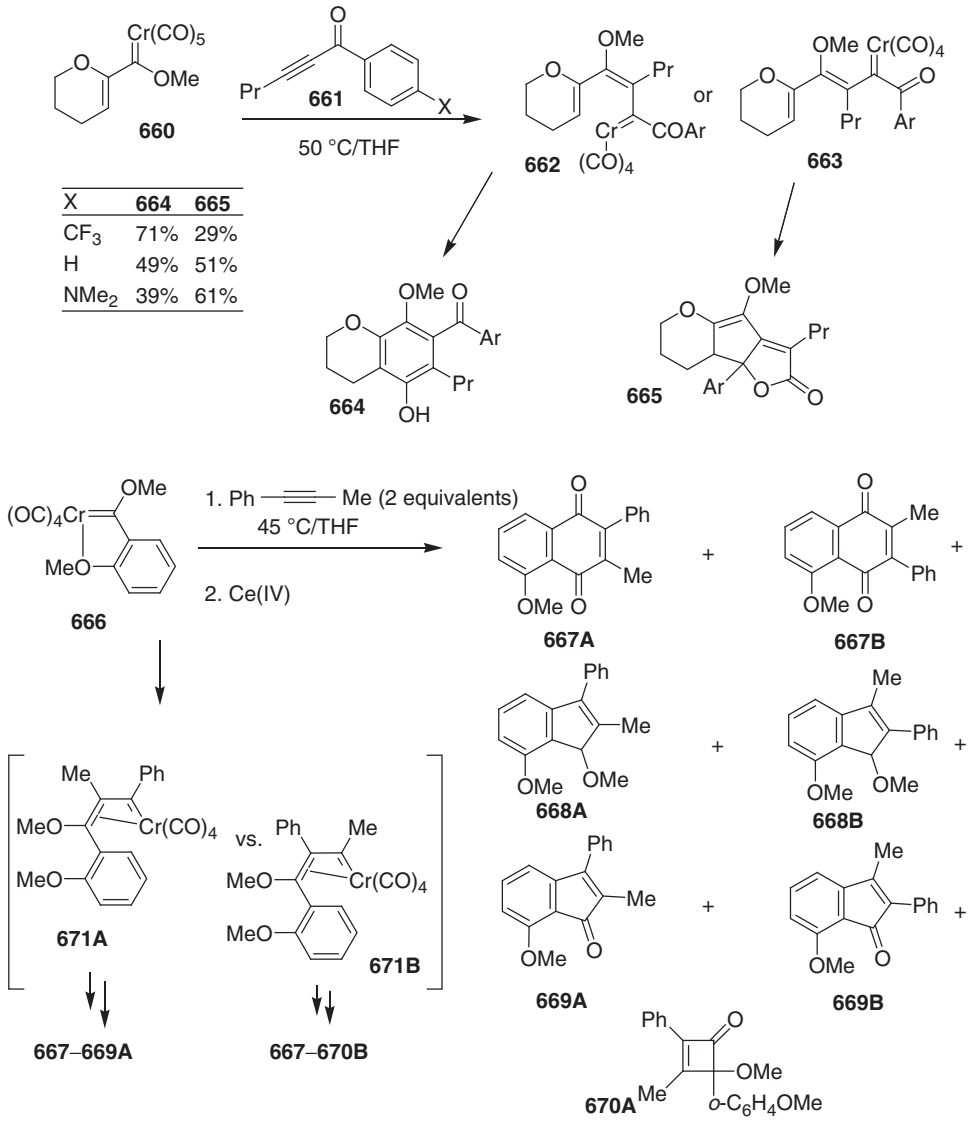
Scheme 61

the Dötz reaction is depicted in Scheme 63. The scope and limit of this reaction have been studied widely, and both inter- and intramolecular versions of this reaction have been reported for a diverse array of highly functionalized alkynes and carbene complexes. Numerous cases where this reaction has been employed for the synthesis of complex molecules have been presented.



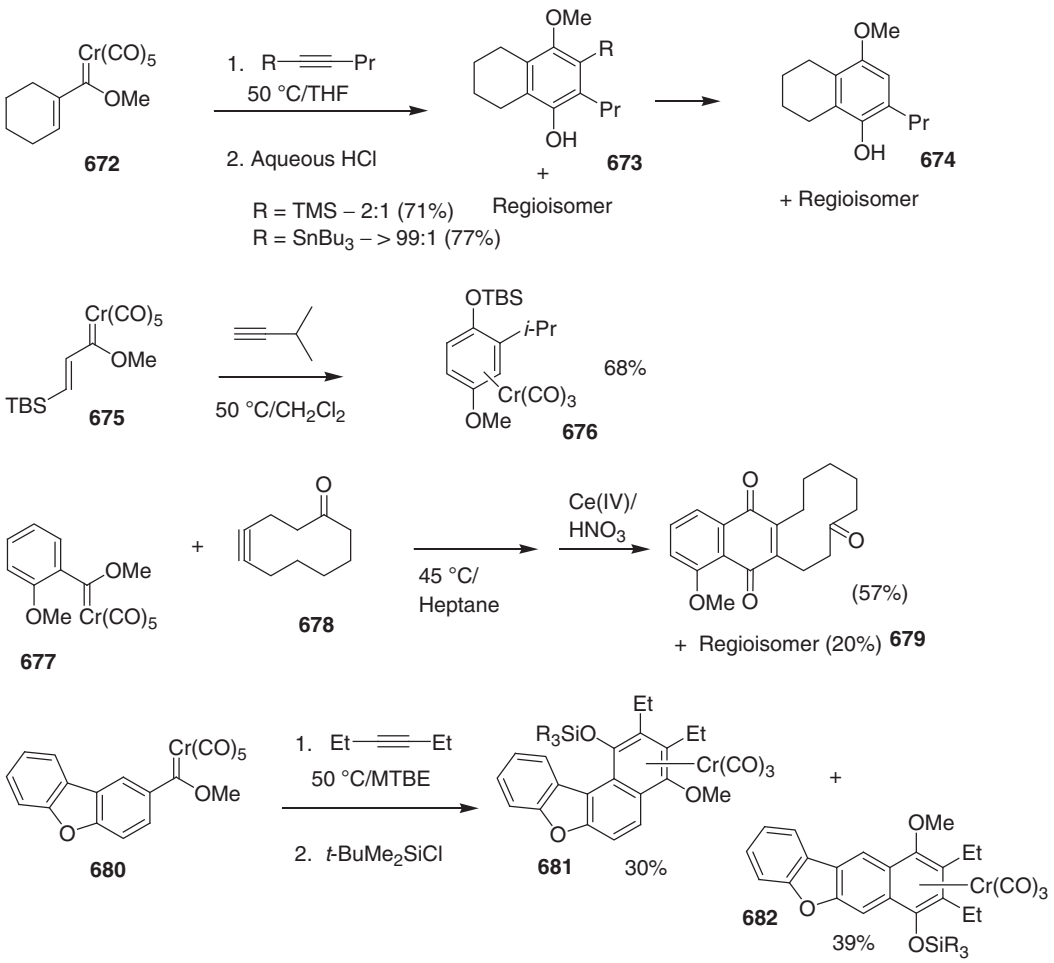
Several fundamental studies that advance the mechanistic understanding of the Dötz benzannulation reaction have been documented. A systematic examination focusing on the relative reactivity of various alkynes in benzannulation reactions was reported.[270] The relative reactivity of alkynes with arylcarbene complexes of general structure **651** (Scheme 64) was governed primarily by sterics, and the degree of selectivity was enhanced through use of sterically demanding carbene complexes. In some cases, intermediates of the Dötz benzannulation can be isolated. A study where the intermediate vinylketene complex can be isolated (**655**), followed by studies of its transformation to phenols (**657–659**) was reported.[271] Stepwise cyclopentannulation

Scheme 62

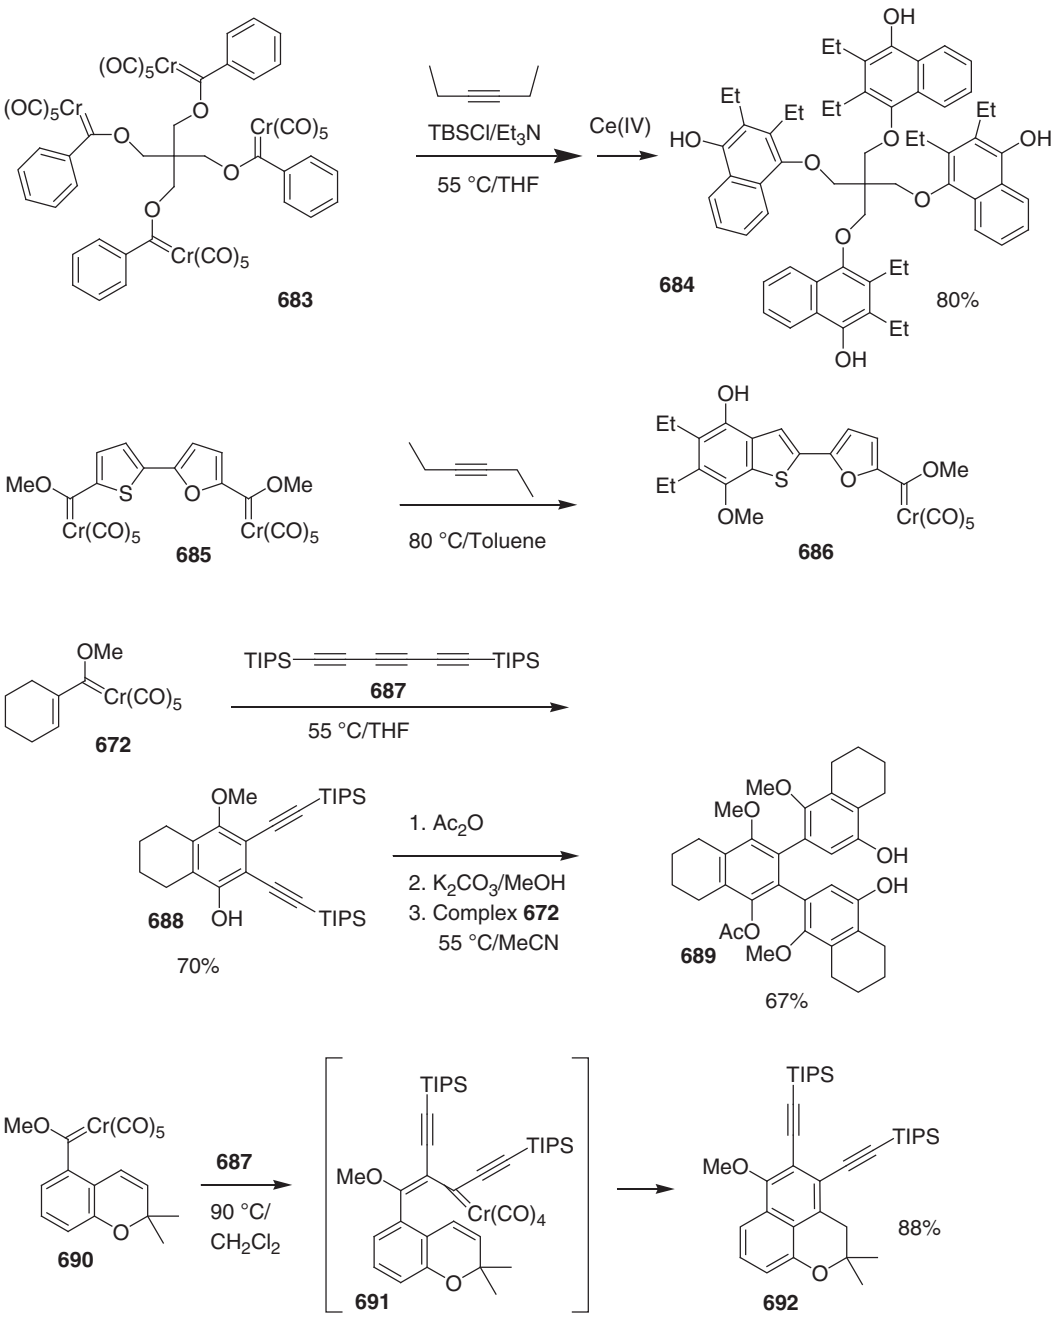


Scheme 63

Scheme 64



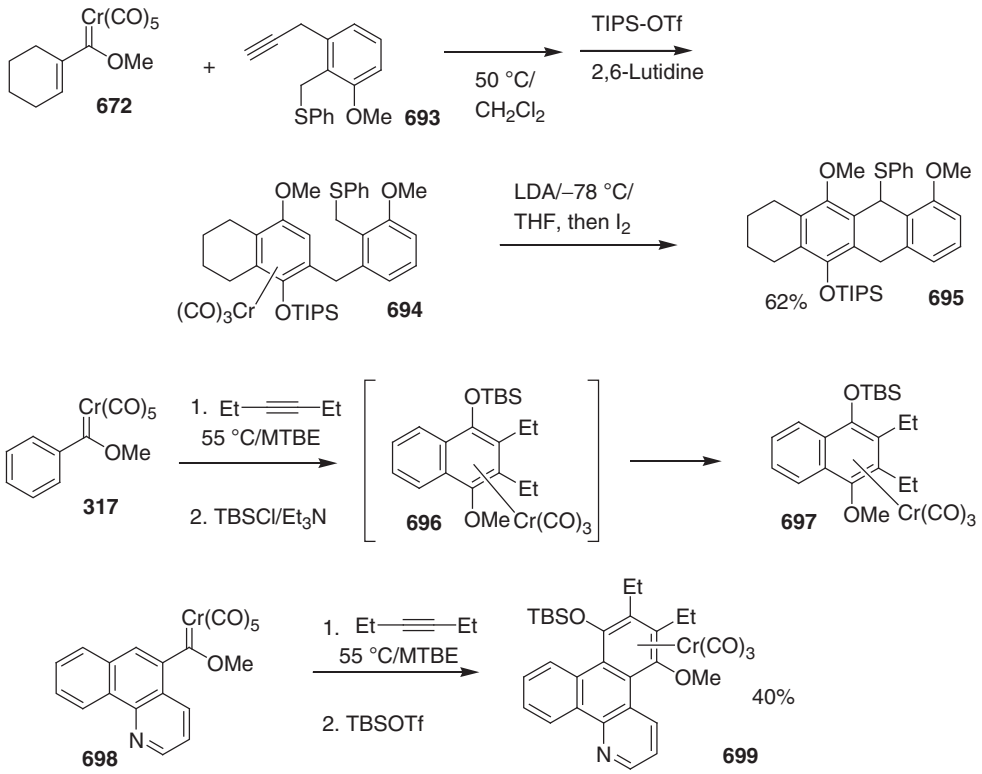
and Dötz benzannulation reactions were demonstrated for the coupling of α,β-unsaturated aminocarbene complexes and dimethyl acetylene dicarboxylate.[272] A detailed study of electronic effects in an early step of the Dötz benzannulation, vinylcarbene complex (**662** and **663**, Scheme 65) formation, was conducted.[273] The reaction of alkenylcarbene complex **660** and the aroylacetylene **661** afforded mixtures of the benzannulation product **664** (from the *Z*-vinylcarbene complex **662**) and the van Halban–White product **665** (from the *E*-vinylcarbene intermediate **663**). The electron density of the aromatic ring had a profound effect on this product distribution. Electron-withdrawing groups favored the benzannulation product due to a preference for *trans* orientation of the methoxy and the more electron-withdrawing substituent at the α-carbon in **662**. A similar electronic dependence was also noted for aryloxycarbene complexes. A detailed mechanistic study of the relationship between regiochemistry and alkyne concentration in the coupling of arylcarbene complexes (e.g., **666**) with alkynes was conducted.[274] The regiochemistry for reaction with 1-phenylpropyne was dependent on the concentration, and attributed to interconversion of the regioisomeric vinylcarbene intermediates (**671A** and **B**) followed by ligation to the alkyne in a later step of the reaction. It was also noted that benzannulation products (**667**) were formed with a higher degree of regioselectivity than the corresponding indene products (**668** and **670**). Two hypothetical pathways for isomerization of **671A** and **B** were deemed reasonable: (1) reversible insertion of the alkyne and (2) isomerization through a cyclopropene intermediate. An unusual bimolecular mechanism was noted in the coupling of *o*-methoxyphenylcarbene complex **666** with alkynes at high concentration. The intramolecular reaction of alkyne-containing carbene complexes and alkynes to afford benzannulation products in competition with cyclopentenediones was studied with respect to reaction conditions and solvents.[275] The Dötz benzannulation reaction can be totally mimicked through



Scheme 65

the rearrangement of alkynylcyclopropenes in the presence of Group 6 metal carbonyl derivatives.[276] Several computationally based studies of the Dötz benzannulation reaction have been reported.[277–282]

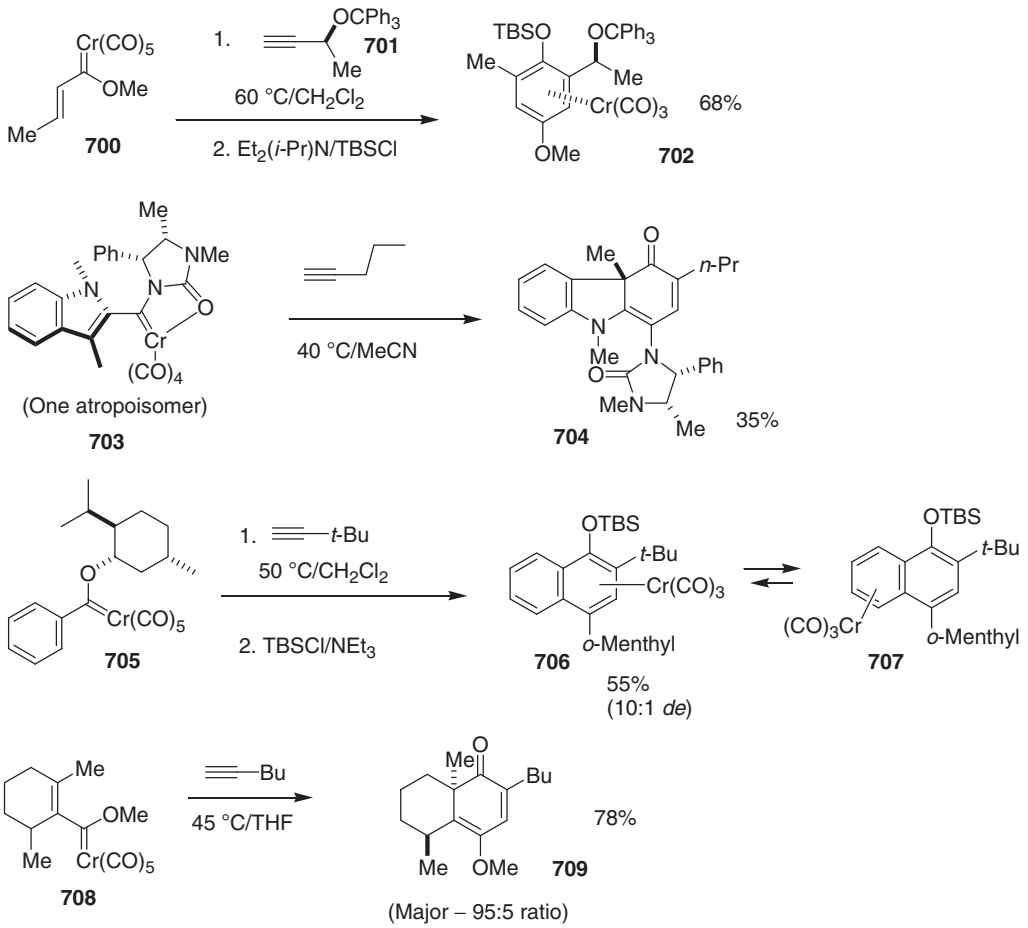
Many examples of benzannulation using α,β-unsaturated chromium–carbene complexes and alkynes (commonly known as the Dötz reaction) have been documented since the previous chapter. Several examples are depicted in **Scheme 66**. The use of stannylacetylenes resulted in products not anticipated based on the accepted notion of sterically controlled regiochemistry (see general structure **673**) using unsymmetrical alkynes.[283] To a lesser extent the process was also observed with silylated alkynes. Use of β-silyl-substituted vinylcarbene complexes (e.g., **675**) as synthons for the parent vinylcarbene complex was also reported.[284] In this process, the silicon migrates to the phenolic oxygen to afford a stable arene–chromium complex (**676**). C-aryl glycosides were prepared via the coupling of alkynylglycals with arylcarbene–chromium complexes.[285] Other examples employing carbohydrate-based carbene complexes or alkynes were successfully demonstrated.[286] Successful benzannulations using cyclic alkynes (e.g., **678**) were also reported.[287,288] Aminobenzannulation reactions were observed in the coupling of β-carbomethoxy-α,β-unsaturated aminocarbene complexes with simple alkynes.[289] Both linear and angular fused benzannulation products (formation of **681** vs. **682**) were obtained in the benzannulation of dibenzofuran–carbene complexes with 3-hexyne.[290] Formation of benzannulation products using diphenylacetylene derivatives that feature an ortho carbonyl group on one of the phenyl rings was reported.[291] Quinones fused to benzofurans were prepared through Dötz benzannulation reactions using benzofuranylcarbene complexes.[292] The synthesis of 5,8-quinolinedione derivatives was achieved using benzannulation reactions of dihydropyridylcarbene complexes.[293] Benzannulations using cyclic carbene complexes featuring an exocyclic alkene were also demonstrated.[294,295] Several examples of the use of densely functionalized alkynes in the Dötz benzannulation reaction have been reported.[296–298] The individual naphthyl rings of VAPOL ligands were prepared from arylcarbene complexes.[299] Coupling of tetracarbene complex **683** (**Scheme 67**) with 3-hexyne led to corresponding tetranaphthoxy ether derivative **684**; the crude product before decomplexation of chromium consisted of seven isomers.[300] A modified Fischer synthesis was also employed for the synthesis of heterocyclic bis(carbene) complexes (e.g., **685**).[301,302] Monobenzannulation and dibenzannulation reactions were reported for the bis(chromium) and mixed chromium/tungsten complexes. Other examples of benzannulation in the presence of



Scheme 66

Scheme 67

a bystander metal carbene complex group have also been reported.[303] Several examples of mono-, di-, and tri-benzannulation reactions were reported for the coupling of carbene complexes with conjugated diynes and triynes. Reaction of triyne **687** and cyclohexenylcarbene complex **672** led to the *o*-dialkyne-substituted naphthol derivative **688**.[304] Acetylation of the alcohol and desilylation of the bis(alkyne) followed by a double benzannulation using two equivalents of the carbene complex **672** led to tris(quinone) precursor **689**. This synthetic sequence was not successful for alkyl analogs of **687** due to preferential benzannulation of the outer triple bonds. The synthesis of naphthopyrans (e.g., **692**) via coupling pyran complex **690** with monoalkynes and triynes was followed by a secondary cyclization process to afford a tricyclic compound (**692**).[305] Benzannulation of 2,2-dimethylvinylcarbene-chromium complex and various alkynes was employed for the preparation of a 5,5-dimethylcyclohexen-1,4-dione combinatorial library.[306] Several technique-based improvements to the Dötz benzannulation reaction were reported, including (1) dry state adsorption,[307] microwave irradiation,[308] (2) solid-phase benzannulation,[309] (3) use of ionic liquid solvents,[310] (4) use of 1,2-dichloroethane as solvent, in which the reaction proceeds at 30 °C,[311] and (5) use of ultrasound

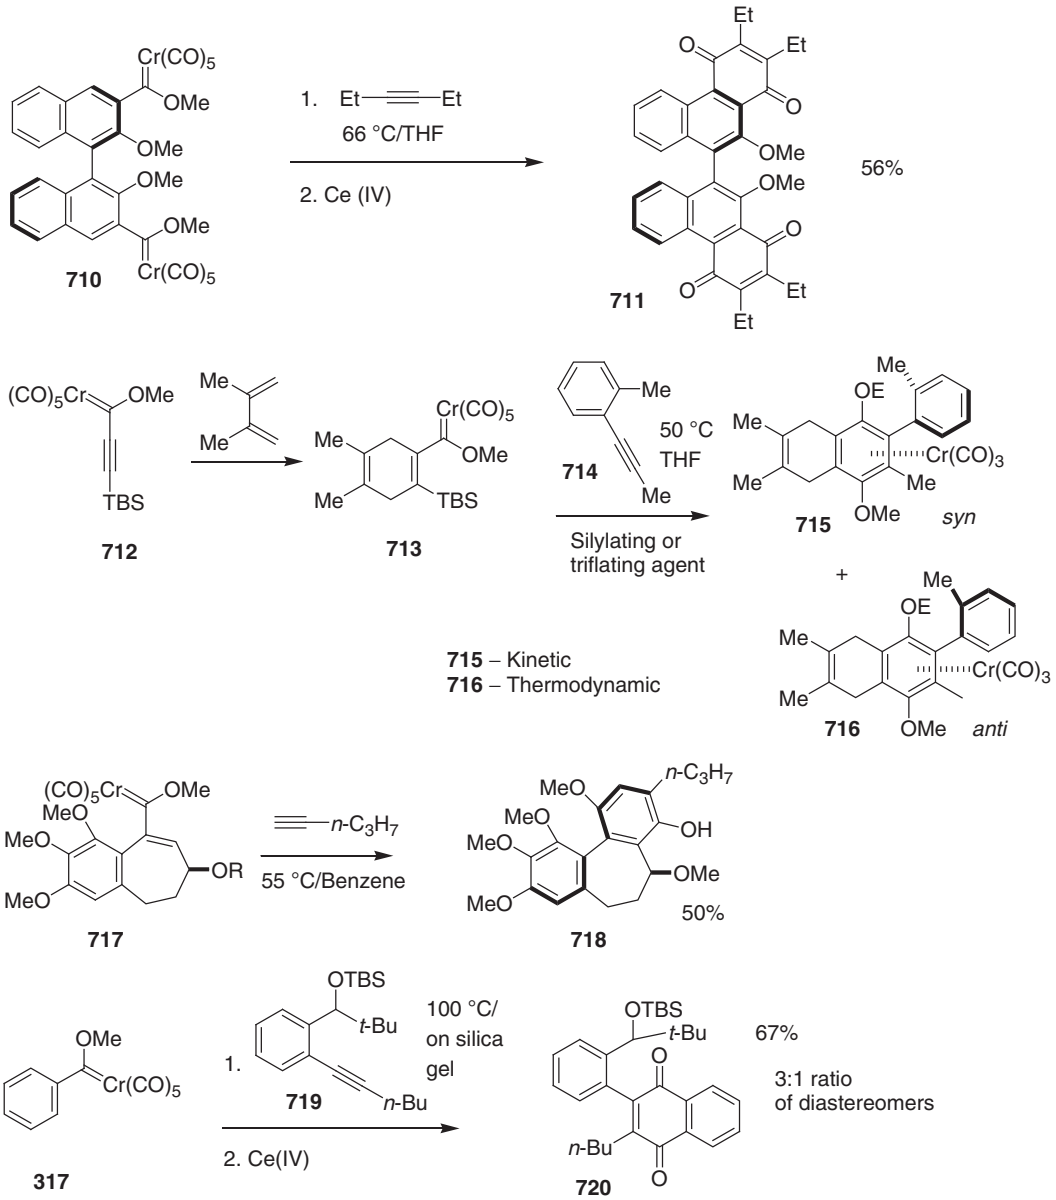


Scheme 68

conditions.[312] Pyrrolocarbene–chromium complexes serve as surrogates for alkoxycarbene complexes in cyclopropanation, benzannulation, and β-lactam syntheses.[313]

Isolation of a stable arene complex typically requires protection of the phenol group before purification. Representative examples of this process are depicted in Scheme 68. Sequential benzannulation followed by nucleophilic addition to the resulting isolable arene–chromium complex was employed for the synthesis of anthracene-type structures (e.g., **695**).[314] In many cases the complexes were subjected to haptotropic rearrangement. Examples of these studies include (1) formation of naphthalene-$Cr(CO)_3$ complexes (e.g., **696**) and subsequent studies of haptotropic rearrangements,[315,316] (2) formation and haptotropic rearrangements of phenanthrene-$Cr(CO)_3$ complexes,[317–319] (3) formation and haptotropic rearrangements of cymantrene-fused aromatic systems,[320] (4) benzannulation of quinoline–carbene complexes (e.g., **698**) followed by studies of haptotropic rearrangements of the resulting arene-complexes (e.g., **699**) (and *N*-complexed analogs),[321] and (5) related studies of stilbene–carbene complexes and azobenzene–carbene complexes.[322]

Numerous examples of stereocontrolled benzannulation or cyclohexadienone annulation leading to arene complexes of defined stereochemistry have been documented (Scheme 69).[43] In many of the cases, a chiral group on the carbene ligand controls the stereochemistry in the benzannulation product. Examples include (1) stereoselective benzannulation using chiral alkynes that contain a propargylic stereocenter (e.g., **701**),[323] (2) stereoselective benzannulations using chiral auxiliary-containing phenyl- and alkenylcarbene complexes,[324] (3) use of chiral ancillaries (e.g., **703**) in benzannulation reactions involving alkynes and Fischer carbene complexes,[325] (4) diastereoselective benzannulation reactions using menthyloxycarbene complexes (e.g., **705**) and studies of the haptotropic isomerization of the resulting naphthalene–chromium complexes,[326] (5) benzannulation using arylcarbene complexes fused to a ferrocene ring,[327] (6) coupling of alkynes with chiral *m*-cyclophanylcarbene complexes, which afforded naphthol–chromium complexes with a moderate degree of stereocontrol,[328] and (7) stereoselective cyclohexadienone annulations using alkenylcarbene–chromium complexes (e.g., **708**) and propargylic alcohol derivatives.[329] Benzannulation of carbohydrate-templated chromium carbene complexes proceeds with a high degree of relative asymmetric induction in some cases.[330] Stereoselective benzannulations that involve atropoisomerism are depicted in Scheme 70. Two diastereomeric benzannulation products were observed from the reaction of nonracemic and axial chiral bis carbene complexes of chromium (**710**) and 3-hexyne.[331] These isomers were converted to a single quinone (e.g., **711**) on oxidation. An atroposelective benzannulation reaction was observed in the coupling of cyclohexenylcarbene complex **713** (obtained by Diels–Alder reaction of alkynylcarbene complex **712** with 2,3-dimethyl-1,3-butadiene) with *o*-tolylacetylene derivatives (e.g., **714**).[332] Both of the expected isomers **715** and **716** were observed; however, either could be obtained as the major product depending on the timing of the addition of the phenol protecting group. The kinetic product **715** was obtained if the reaction was conducted in the presence of the silylating agent. The thermodynamic product **716** was obtained when the silylating agent was added later, or if a less bulky

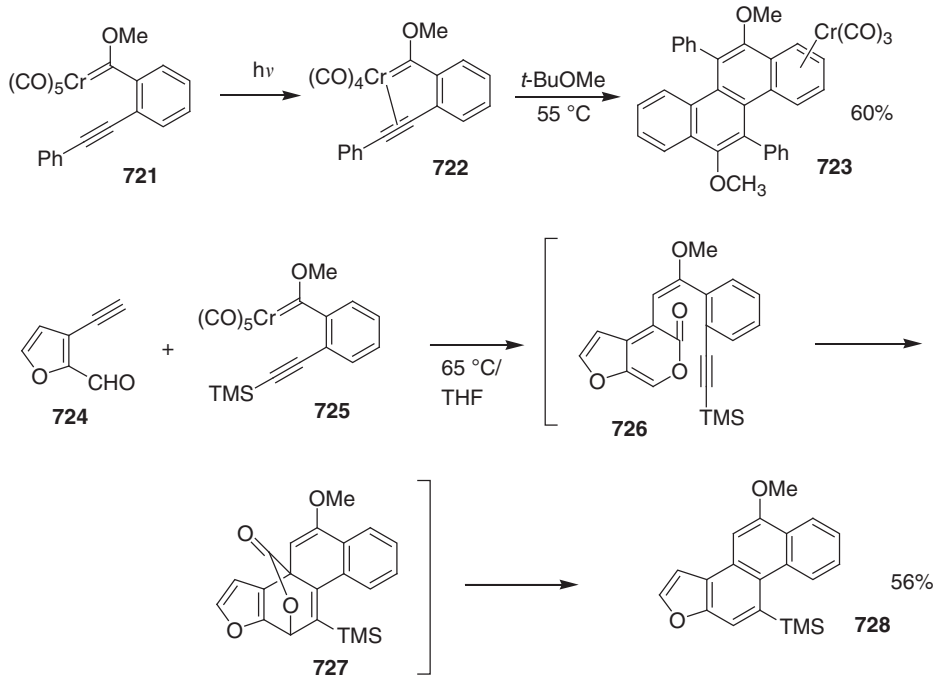


Scheme 69

group like a triflate was attached to the phenol. Atropoisomer-selective formation of benzene rings from coupling of carbene complex **717** with 1-pentyne was employed as a model system for the construction of allocolchicinoids.[333] Atroposelective benzannulation reactions involving arylacetylene derivatives that contain a chiral substituent ortho to the alkyne group (e.g., **719**) were also reported.[334] Helicene-type compounds were formed in the reaction of bis(carbene) complexes linked through binaphthyl systems.[335]

Photolysis of ortho–alkynylcarbene complex **721** (Scheme 71) afforded alkyne–carbene complex **722**, which was stable enough for spectroscopic characterization.[336] Thermolysis of **722** in refluxing methyl *t*-butyl ether led to chrysene derivative **723** (a single diastereomer), which results from an unusual benzannulative dimerization reaction. Direct thermolysis of either the chelated or the nonchelated carbene complex afforded predominantly the carbene dimerization product. The coupling of 2-alkynylphenylcarbene–chromium complexes (e.g., **725**) with alkyne–aldehydes linked through heterocyclic ring systems (e.g., **724**) led to polynuclear aromatic systems (e.g., **728**).[337] A mechanism that involves formation of a heterocycle-fused pyrone derivative (**726**), followed by intramolecular Diels–Alder reaction and elimination of CO_2 was proposed.

Several examples of the construction of unusual molecular architectures using the Dötz reaction have been documented (Scheme 72). The intramolecular coupling of alkynes and alkenylcarbene complexes featuring 6-atom and 13-atom tethers (**729**) led to *m*-cyclophane derivatives (e.g., **730**).[338,339] Optimal formation of the cyclophane was observed employing the 13-atom tether, and mostly dimeric cyclophanes were obtained using the 6-atom tether. The formation of *m*-cyclophanes via the intramolecular coupling of benzo analogs (e.g., **731**) was also observed.[340] Mixtures of *m*- and *p*-cyclophanes (e.g., **734** and **735**) were produced from benzannulation reactions using analogous compounds featuring a 1,1-disubstituted alkene group (e.g., **733**).[341] In addition to the expected *m*- and *p*-cyclophanes, additional products were observed, including cyclopropane **737** *m*-benzannulation product **736**. Formation of *m*-cyclophanes (e.g., **739**) in an intramolecular benzannulation was employed in the total synthesis of phomactin.[342] A complex benzannulation reaction was observed when bis(carbene complex) derivative **740** couples with bis(alkyne) derivatives (e.g., **741**).[343] This coupling resulted in the formation of calixarenes (e.g., **742**) in moderate yields.



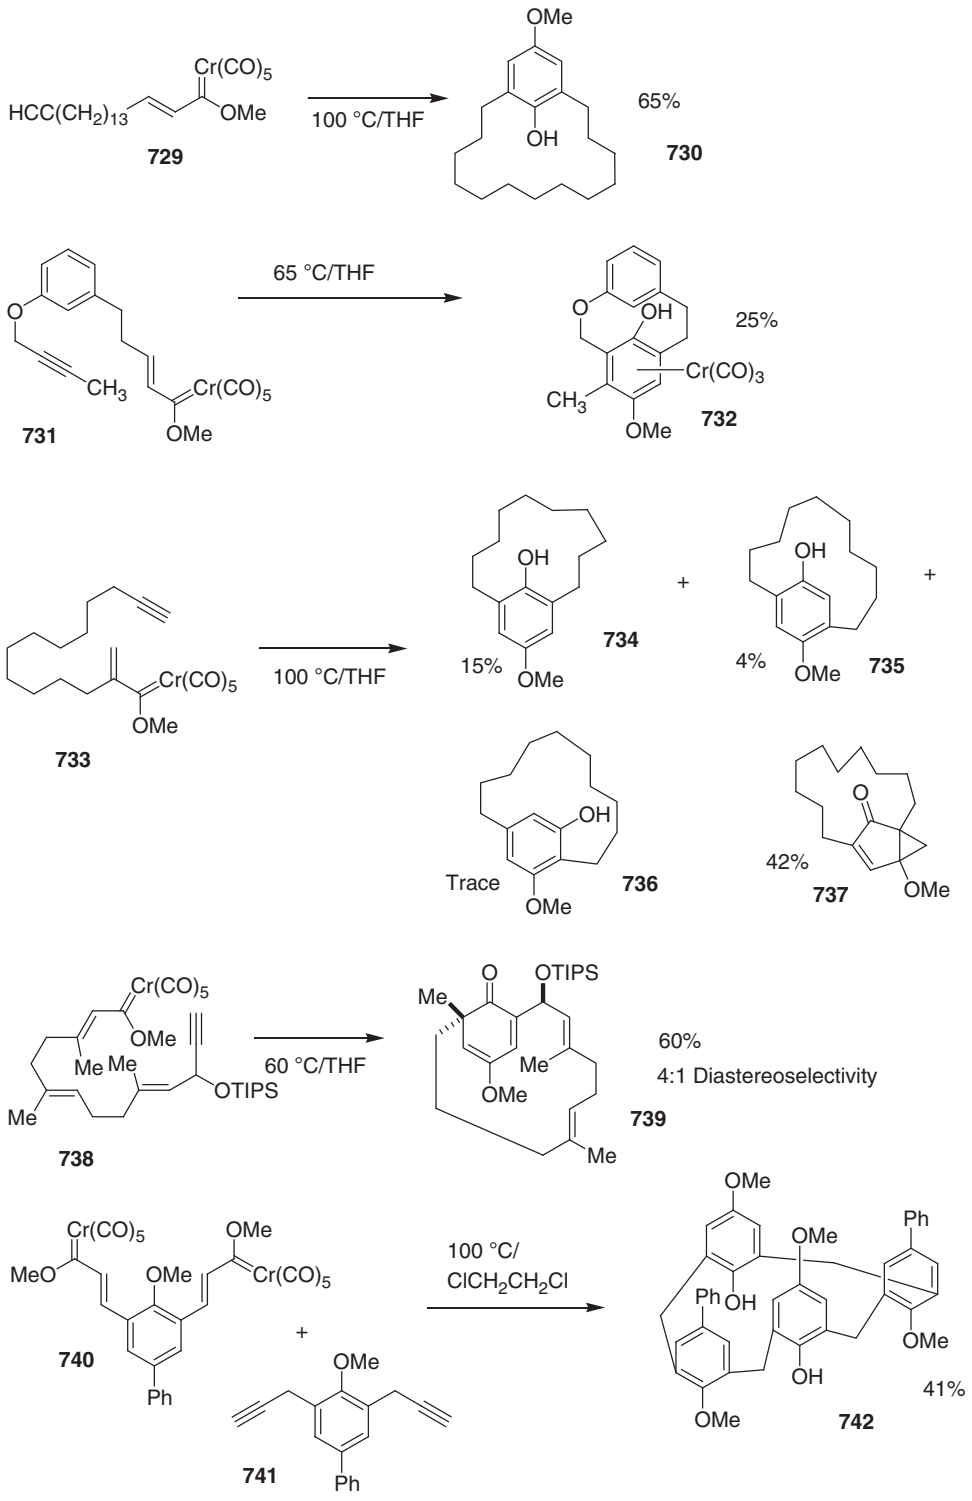
Several examples employing the Dötz reaction as a key step in natural product synthesis have been reported (Scheme 73). The carbon core of menogaril (**745**) was prepared through coupling of arylcarbene complex **743** and an elaborate alkyne (**744**) in

Scheme 70

acetonitrile.[344] A complex intermediate for olivin total synthesis (**748**) was prepared using a similar carbene complex (**746**) and a complex alkyne (**747**).[345] A formal total synthesis of 7-methoxyeleutherin was reported that utilizes the Dötz reaction as the key step.[346] The Dötz reaction was demonstrated for a selenium-containing alkyne, which was a key step for synthesis of naphthoquinone natural products.[347] A complex phenol derivative (**751**) for synthesis of kendamycin segments was prepared through Dötz benzannulation.[348] Benzannulation using dihydrofurylcarbene complex **752** was employed for the total synthesis of aflatoxin B_2.[349] The Dötz benzannulation using indane–alkyne **755** was employed as a key step in a synthetic approach to fredericamycin A.[350] Subsequent aldol reactions then afford the fredericamycin skeleton. Other compounds prepared through benzannulation include eleutherin,[351] curcuquinone,[352] parvaquone,[353] demethoxycardinalin 3,[354] hingconin,[355] and deoxyfrenolicin.[356] The macrocyclic compounds arnebinol (via **758**, Scheme 74)[357] and kendomycin (via **760**)[358] were prepared through intramolecular macrocycle-forming carbene complex–alkyne couplings.

Several examples of benzannulation using aryloxycarbene complexes have been reported (Scheme 75). These complexes are considerably less stable than the analogous alkoxycarbene complexes. Diaryl ethers (e.g., **762**) are produced from coupling of alkynes with aryloxy α,β-unsaturated carbene complexes (e.g., **761**). This process was demonstrated for a variety of aryl- and vinylcarbene complexes.[359] An intramolecular benzannulation process involving 2-alkynylaryloxycarbene complexes (e.g., **763**) was also reported.[360] Benzannulation of an aryloxycarbene complex (**766**) was employed for synthesis of isodityrosine.[361]

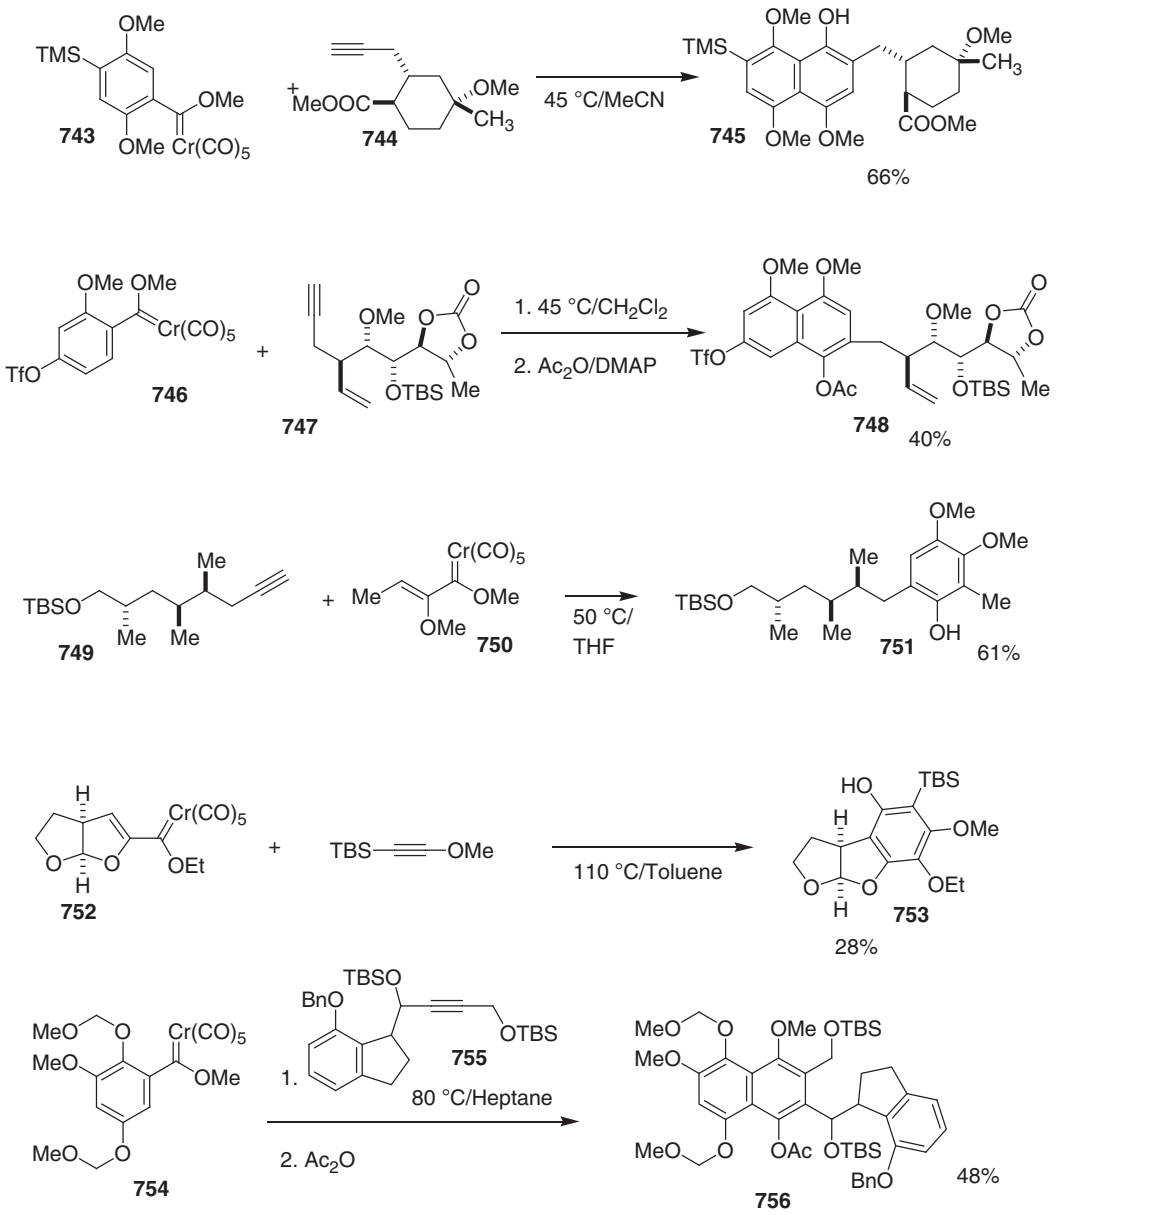
Scheme 71



More complex benzannulation processes have also been documented that use Group 6 metal carbonyls (Scheme 76). Benzannulation reactions have been demonstrated for nonheteroatom-stabilized chromium carbene complexes (e.g., **769**).[362] Low-temperature benzannulation reactions were also reported for 2-alkynylglucose derivatives (e.g., **771**) and diphenylcarbene–chromium complex **338**, which occurred at 25 °C.[363] Benzannulations involving alkynes that feature propargylic leaving groups and pendant alkene groups (e.g., **773**) and α,β-unsaturated carbene complexes (e.g., **106**) provide tricyclic compounds (e.g., **776**) in a process involving benzannulation, followed by elimination of the leaving group and formation of the *o*-quinonemethide (**775**), followed by intramolecular Diels–Alder reaction.[364] Coupling of 1,3-disubstituted-indol-2-ylcarbene-chromium complexes (e.g., **777**) and alkynes led to cyclohexadienone annulation products (e.g., **778**), which underwent a secondary thermal rearrangement under the reaction conditions, affording cyclohexadienone **779**; similarly hindered 2,6-disubstituted arylcarbene complexes lead to mostly indenones except in a single case involving an intramolecular reaction.[365]

The benzannulation pathway is largely unique to chromium carbene complexes and a few examples of other Group 6 metals. Some reports of other metals performing Dötz-like benzannulation processes have appeared (Scheme 77). The use of manganese carbene complexes (e.g., **780**) in the Dötz benzannulation reaction has been demonstrated. Both intermolecular[366] and intramolecular[367] processes have been examined. The intramolecular reaction employing complex **783** was assisted through the allelochemical effect achieved by the addition of diphenylacetylene as a spectator alkyne ligand.

Several alternative benzannulations have been designed based on the proposed mechanism. These processes primarily involve alternative procedures to access the reactive intermediates for the mechanism depicted in Scheme 63.

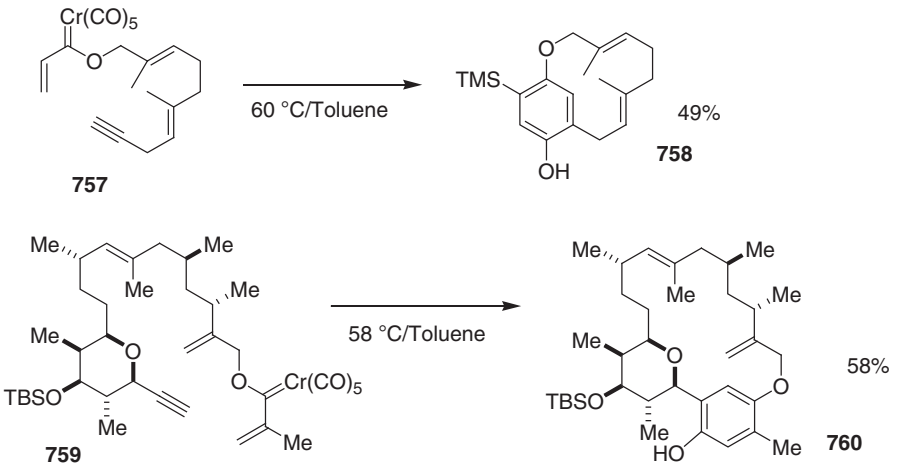


Alternative benzannulation through the coupling of simple carbene complexes with fully conjugated dienylacetylenes (e.g., **785**, Scheme 78) was reported.[368] The initially expected phenol–enol ether derivatives (e.g., **787**) are converted to benzofurans (e.g., **788**) during the oxidative workup procedure. This reaction was used as a cornerstone for formal total synthesis of the natural product egonol through coupling of triene-yne **789** with arylcarbene complex **790**.[369] Coupling of carbene complexes with conjugated dienynes where the middle ring is part of a heterocyclic ring (e.g., **792**) led to the heteroaromatic-fused benzofurans (e.g., **794**) after acidic workup.[370] Naphthalenes were formed in the coupling of carbene complexes with *Z*-alkynylstyrenes.[371]

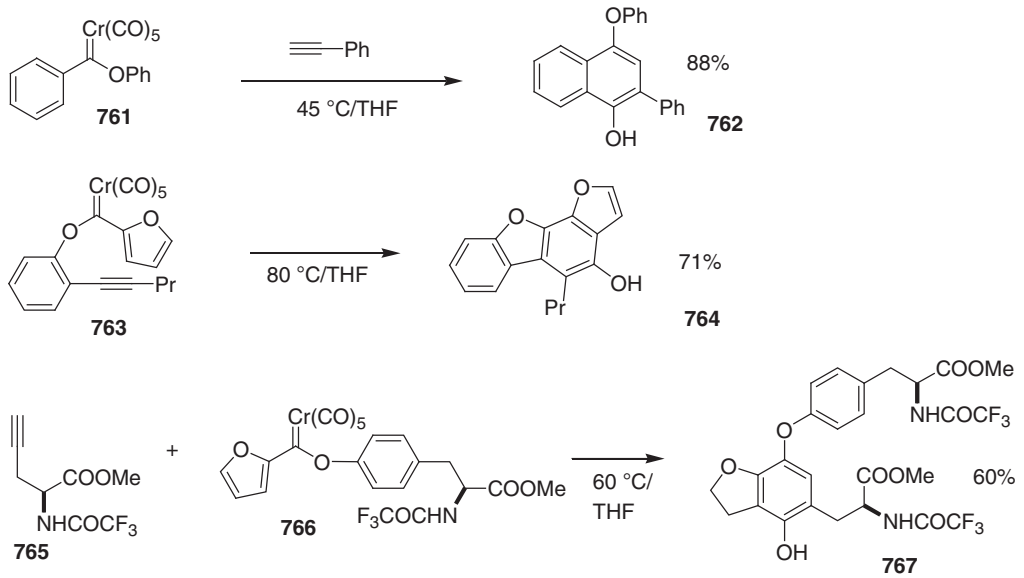
Coupling of carbene complexes with conjugated enediyne derivatives (e.g., **795**, Scheme 79) led to benzannulation products (**799** and **802**) via a diradical mechanism.[372,373] Formation of the major product **802** involves Moore cyclization of the predicted enyne–ketene intermediate **796**, followed by sequential intramolecular hydrogen atom transfers from intermediate diradical **797** to give an enol ether–phenol (**801**), which is converted to the benzofuran derivative **802** during workup. Reaction of diradical **797** with an external hydrogen atom source (the solvent dioxane) leads to butyl derivative **799**. The initially formed diradical could also be captured in a radical cyclization reaction. Through careful exclusion of hydrogen atom donors, selective remote functionalization processes occur, resulting in allylbenzene derivatives as the major products. The diradical intermediates could also be captured through chlorine abstraction processes, resulting in chlorinated analogs (e.g., **804**). The coupling of carbene complexes

Scheme 72

with conjugated enediynes that feature radical traps was also reported.[374] A free radical-based benzannulation process can also be initiated through thermolysis of aminocarbene complex-linked diynes (e.g., **806**).[375] In this case, the alkyne insertion affords an enyne–ketene (**807**), which undergoes Moore cyclization to afford the diradical (**808**), which reacts with added hydrogen atom donors to afford the benzannulation products.



Scheme 73

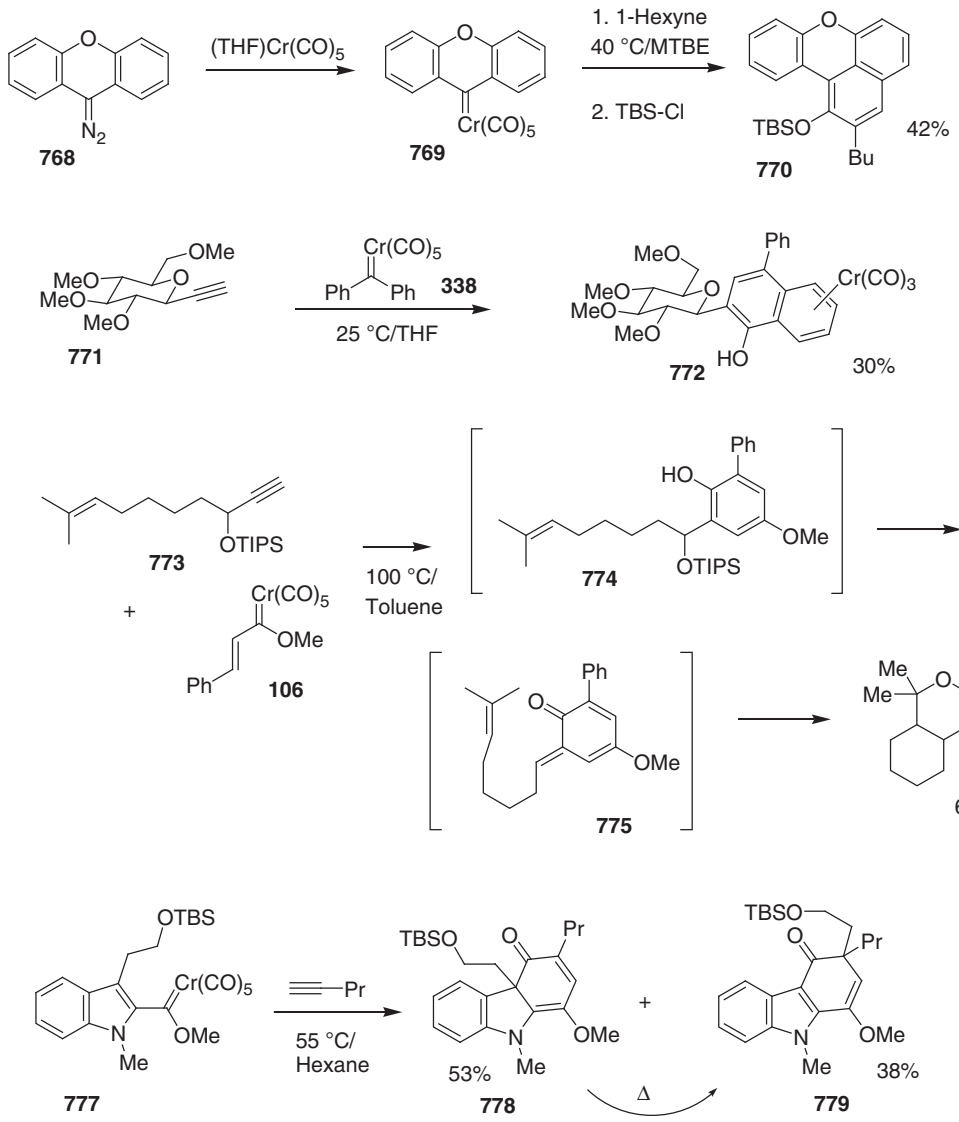


Coupling of enyne aldehydes fused to heteroaromatic ring systems (e.g., **811**, **814**, and Scheme 80) proceeds through *o*-quinoidal-like pyrone ring systems (e.g., **812**).[376] The products derived from these systems incorporate a molecule of CO relative to the arene systems depicted in Scheme 58. The differences for heteroaromatic carboxaldehyde substrates relative to arene analogs have been attributed to the enhanced ring strain in the bicyclo[3.3.0]octatriene systems. The reaction employing γ,δ-unsaturated carbene complexes led to intramolecular Diels–Alder adducts (e.g., **813**). Subtle variations in the reaction pathways for different ring systems were noted and were based on the relative electron-donating ability of different heteroaromatic ring systems. Diels–Alder adducts from furan derivatives (e.g., **815**) undergo a further loss of CO_2 leading to simpler tricyclic ring systems (e.g., **817**); this process was used as the cornerstone for a total synthesis of cadinene natural products. Imidazole-, pyrazole-, and indole-fused analogs have also been successfully demonstrated.[377]

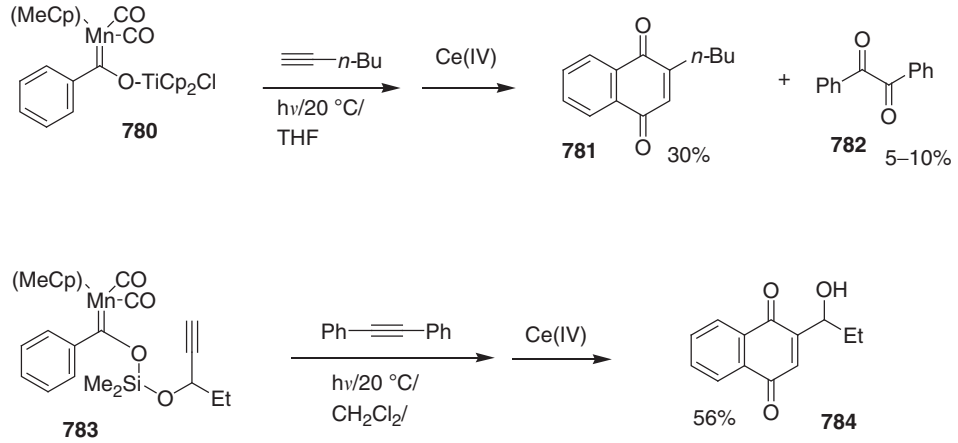
5.25.3.2.4 Seven-membered and larger ring systems

The coupling of alkynes with cyclopropylcarbene-Group 6 metal complexes (**818** and Scheme 81) leads to cycloheptadienones.[378] The homologous Dötz reaction depicted initially affords the cycloheptadinone **819**, which undergoes isomerization to the doubly

Scheme 74

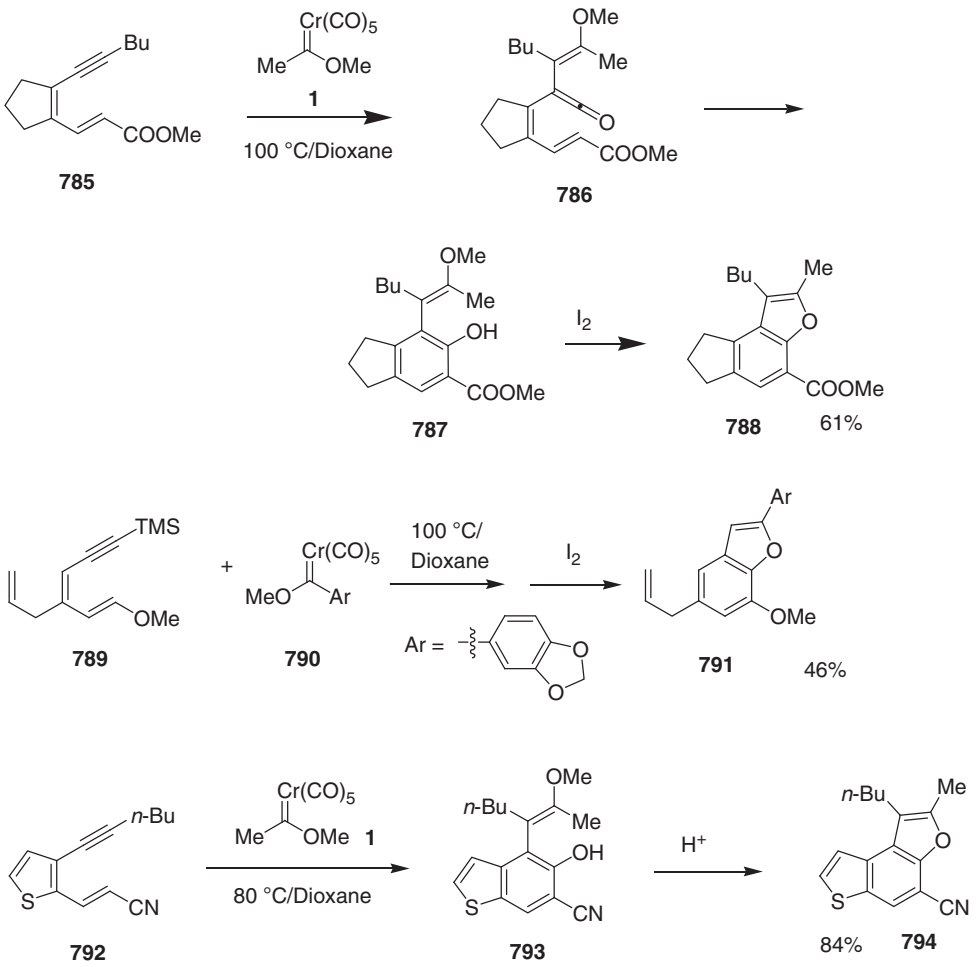


Scheme 75



vinylogous ester system **820** under the reaction conditions. This reaction was limited to simple cyclopropane systems and internal alkynes. Coupling of $\alpha,\beta,\gamma,\delta$-unsaturated carbene complexes (e.g., **821**) with monosubstituted acetylenes led to eight-membered ring derivatives (e.g., **822**).[379] The eight-membered ring forming reaction was limited to systems where the α,β-alkene was embedded in a cyclobutene ring, likely due to the ring strain in the unobserved benzannulation product.

5.25.3.2.5 Vinylketene capture and stable ketenes

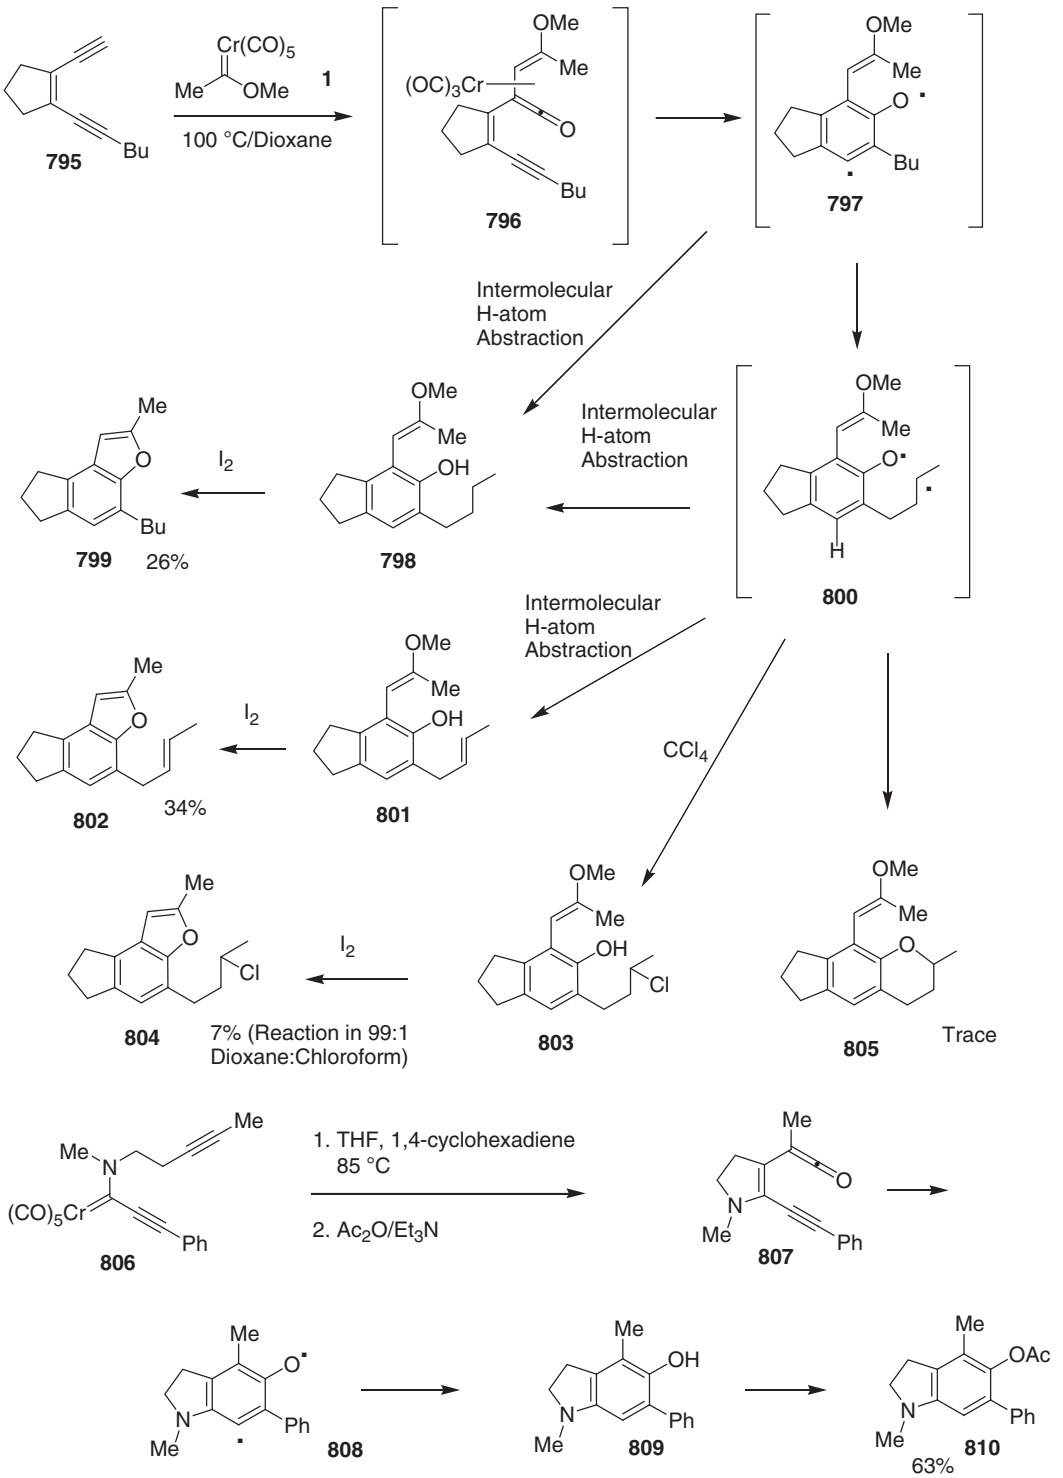


Several reaction processes have been designed, which capture the ketene intermediates of benzannulation reactions (Scheme 82). Capture of intermediate ketene complexes by intramolecular reaction with an alcohol led to β-lactone derivatives (e.g., **826**).[380] The reaction requires activation through the Thorpe–Ingold effect; examples devoid of the gem dialkyl substitution undergo benzannulation processes. Coupling of hindered arylcarbene complexes led to the lactone derivatives under thermal or sonication conditions.[381] The coupling of arylpropargyl alcohols (e.g., **827**) and Fischer carbene complexes under solvent-free conditions led to alkylidene-γ-lactones (e.g., **830**).[382] In these cases the regiochemistry of alkyne insertion is opposite to that from terminal alkyne propargyl alcohols. Subsequent treatment with acid in the air afforded the corresponding furanones (e.g., **831**). This reaction process likely involves the formation of a vinylketene intermediate (**829**),

Scheme 76

Scheme 77

Scheme 78

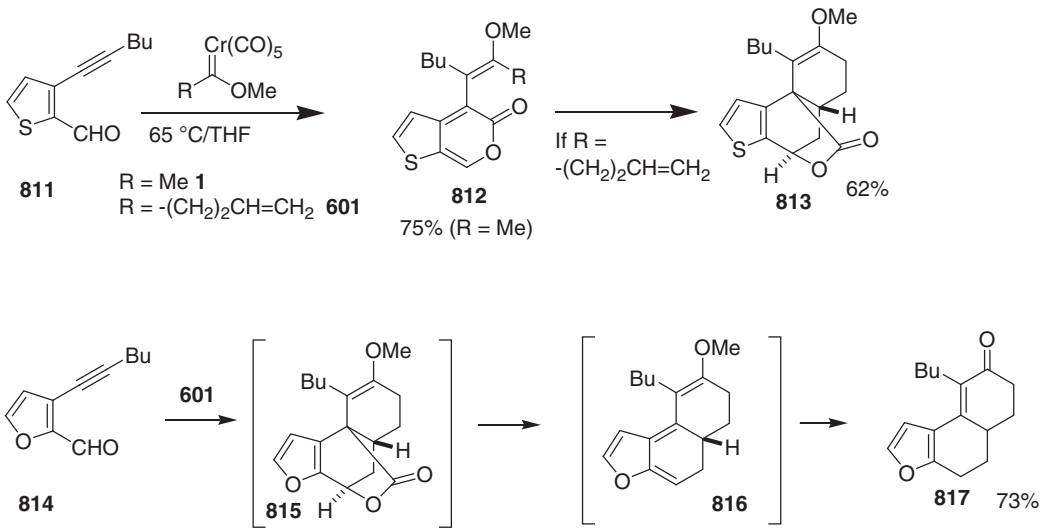


which reacts with the alcohol to afford the lactone. Intramolecular trapping by enol derivatives resulted in cyclopentanone derivatives (e.g., **835**).[383]

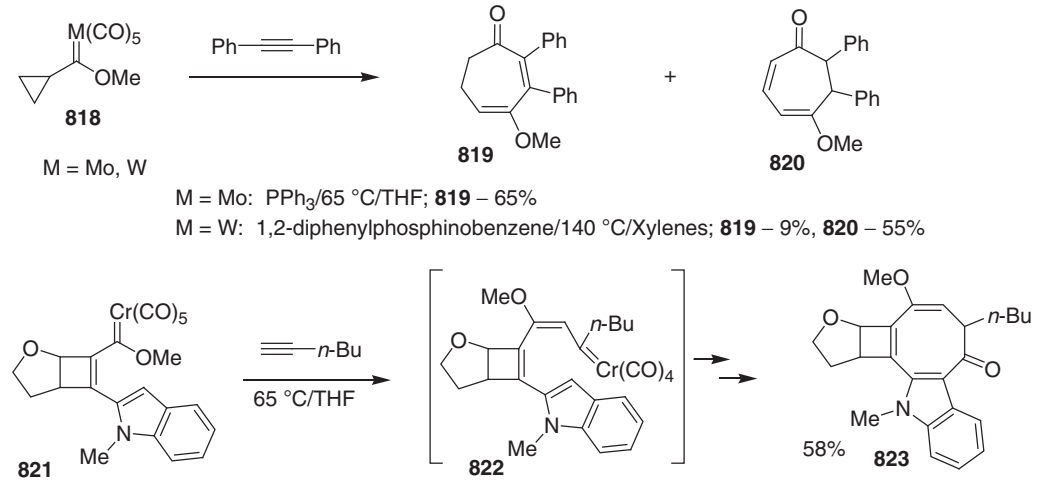
In some cases, stable ketenes can be isolated from alkyne–carbene complex coupling processes (Scheme 83). Formation of ketene complexes (e.g., **837**) was observed in the coupling of phenylcarbene complex **317** with sterically hindered silyl phenyl acetylenes (e.g., **836**).[384] Treatment of the ketenes with methylene sources led to cyclopentenones (e.g., **838**). Treatment of the ketene–arene complexes with photolysis or cerium (IV) followed by thermolysis of the resulting free ketenes at 80 °C led to the benzannulation products (e.g., **839**).[385] An intramolecular cyclopentannulation process using aryloxycarbene complexes (e.g., **842**) was also demonstrated.[386] The reaction initially affords stable α-silyl-vinylketene complexes (e.g., **843**), which subsequently react with carbene equivalents to generate cyclopentenone derivatives (e.g., **844**).

5.25.3.2.6 Coupling leading to intercepted products – tandem reactions

In many cases, the vinylcarbene complex intermediate from carbene complex–alkyne coupling can be trapped through reaction with pendant alkene and alkyne groups. A number of investigators have designed serial reaction processes for the vinylcarbene intermediates obtained from the reaction of carbene complexes with alkynes.[387] It is somewhat difficult to classify all tandem reactions equally, and numerous examples that could be classified this way have been presented elsewhere in this chapter. This section emphasizes examples where the 'trap' for the carbene complex is not in conjugation with the initially formed carbene complex.



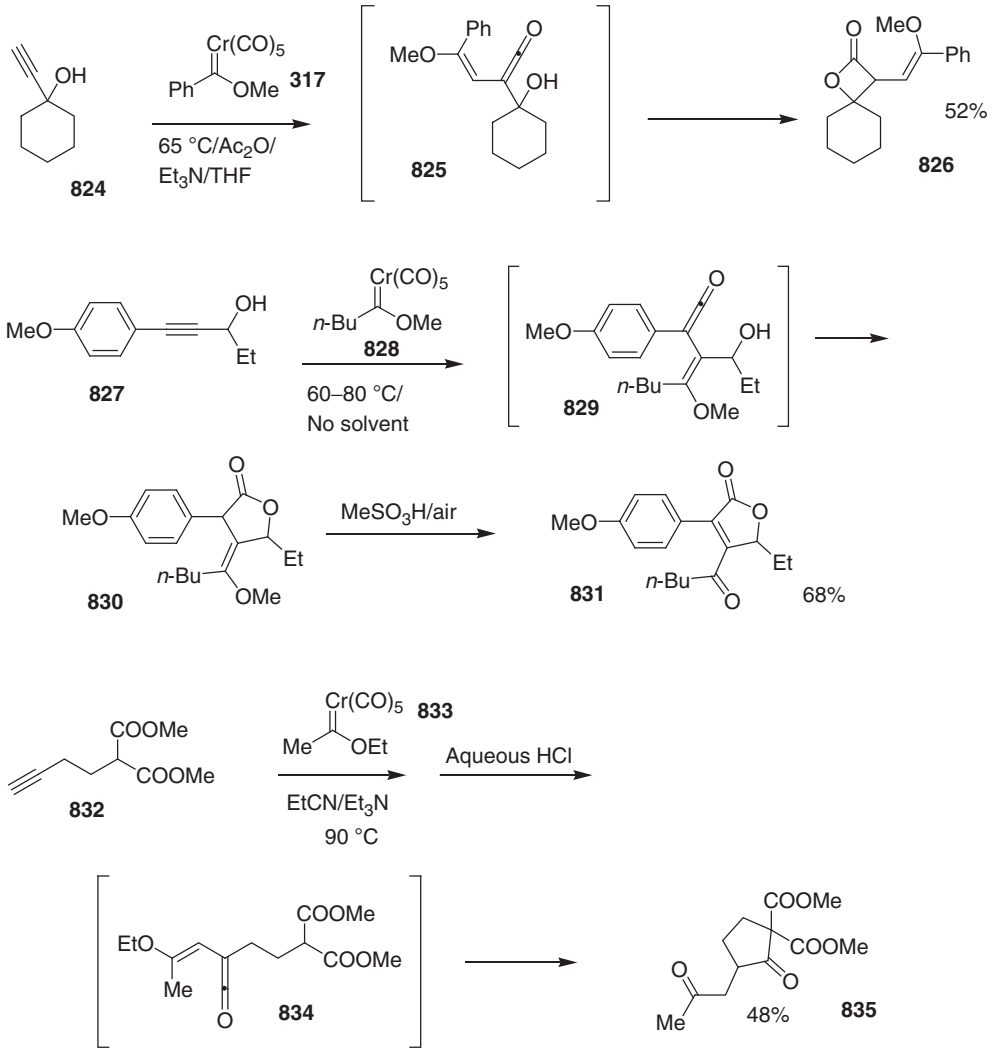
The coupling of Fischer carbene complexes with enynes (e.g., **845**) can proceed through a variety of reaction pathways, including cyclopropanation, ketene addition, and alkene metathesis (Scheme 84).[388] Numerous attempts to suppress the insertion process through use of electron-rich aminocarbene complex analogs,[389] manganese complexes (e.g., **851**),[390] tungsten complexes,[391] and molybdenum carbene complex (e.g., **413**)[392,393] analogs have been successful. The use of various carbene complex acylates was also found to increase the proportion of non-CO inserted products.[394] Formation of six-membered rings



Scheme 79

from 1,7-enynes has also been demonstrated for many of the examples. The reaction pathway observed is highly dependent on the alkene substitution pattern and on the reaction conditions. A higher proportion of olefin metathesis products were observed when more substituted alkene groups were involved. Fischer carbene complexes also catalyze the enyne metathesis reaction pathway if the starting compound has alkene substituents that match the carbene complex substituents (e.g., **856** + **857** → **858**).[395]

The reaction of the dienynes (e.g., **861** and Scheme 85) with a simple carbene complex affords the 5,7-fused ring system (e.g., **864**) after intramolecular cyclopropanation followed by divinylcyclopropane rearrangement (**863** → **864**).[396] The reaction is most



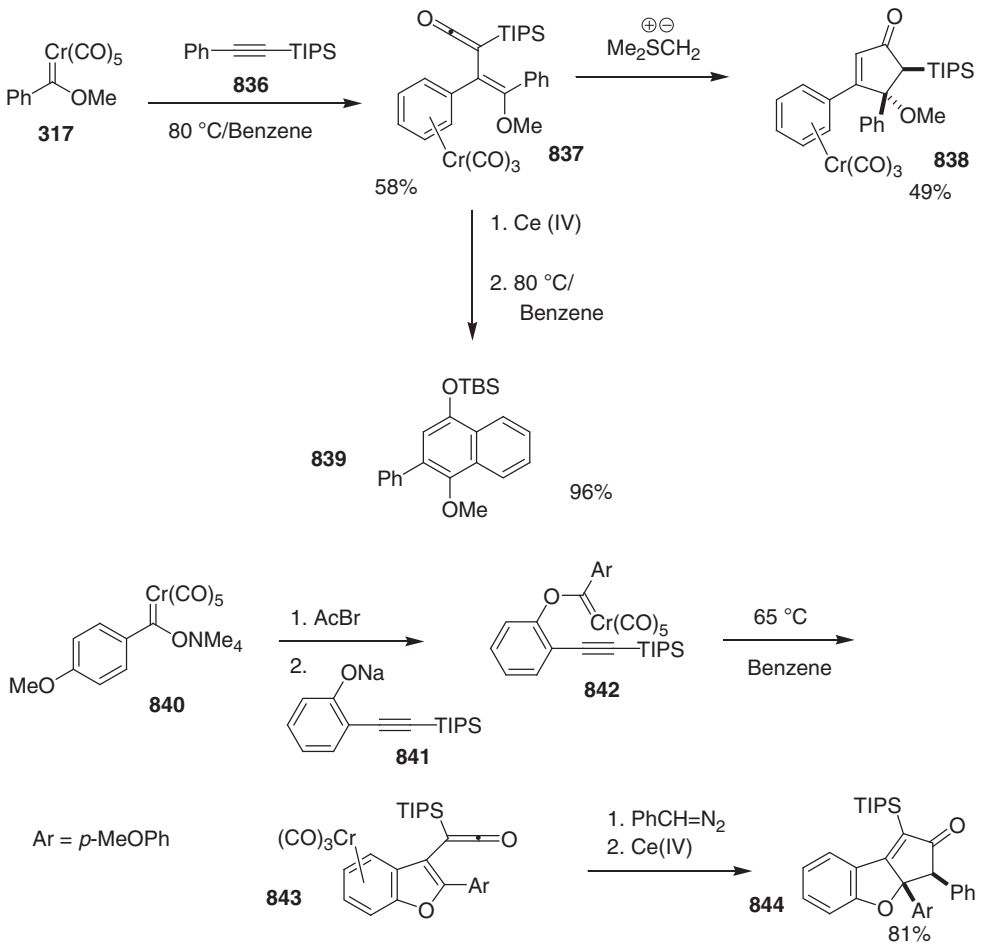
Scheme 80

Scheme 81

efficient when molybdenum carbene complexes are employed. The divinylcyclopropane derivatives can be isolated in some cases if the carbene–alkyne coupling is performed at 40 °C; however, only the hydroazulene derivatives are observed from the reaction conducted at 60 °C. The relative stereochemistry at the asterisked carbons is effectively controlled through stereospecific cyclopropanation followed by Cope rearrangement through a boat transition state. The stereochemistry at the remaining stereocenter is controlled by the alkene geometry of the enol ether, which is established as in the initial alkyne insertion step. An intramolecular version of this reaction has also been reported.[397] Molybdenum carbene complexes react with dienynes where the diene and alkyne functionalities are linked through the 2-position of the diene (e.g., **865**) to afford tricyclic compounds (e.g., **870**).[398] A mechanism involving alkyne insertion to afford vinylcarbene complex **866** followed by intramolecular cyclopropanation was proposed. Divinylcyclopropane **867** then undergoes a Cope rearrangement, followed by methanol loss, followed by electrocyclic ring opening to afford **870**.

Some efforts to enhance the ketene pathway for carbene complex alkyne coupling have been reported. This pathway is most predominant using chromium complexes and enynes that feature more highly substituted alkene groups (e.g., **871**, Scheme 86).[399] The coupling of carbene complexes with dienyne derivatives (e.g., **873**) was examined as a possible synthetic route to taxol derivatives.[400] Coupling of enyne **873** with methylcarbene complexes resulted in regioisomeric cyclobutenones (e.g., **875**

Scheme 82



and **876**). Formation of **875** is the desired process for taxol synthesis. A systematic study of this process involving aryloxycarbene complexes (e.g., **874**) revealed that electron deficiency in the ketene favors the desired reaction pathway.

The intermediate vinylcarbene complexes from alkyne–carbene complex coupling can also be intercepted by other alkynes to effect alternative strategies for benzannulation (Scheme 87). Treatment of 1,6-heptadiyne (**877**) with carbene complexes affords the benzannulation products (e.g., **880** and **881**) in high yield.[401] A secondary reduction process of cyclohexadienone **880** leads to phenol derivative **881**. Several tandem reactions have been developed that incorporate this general reaction pathway. The tandem Diels–Alder reaction of triynylcarbene complexes (e.g., **882**) followed by benzannulation was demonstrated in several examples.[402,403] In this process the initial Diels–Alder reaction affords an arylcarbene complex (**883**), which undergoes a series of intramolecular alkyne insertion processes to afford the stereoid skeleton (e.g., **886**).

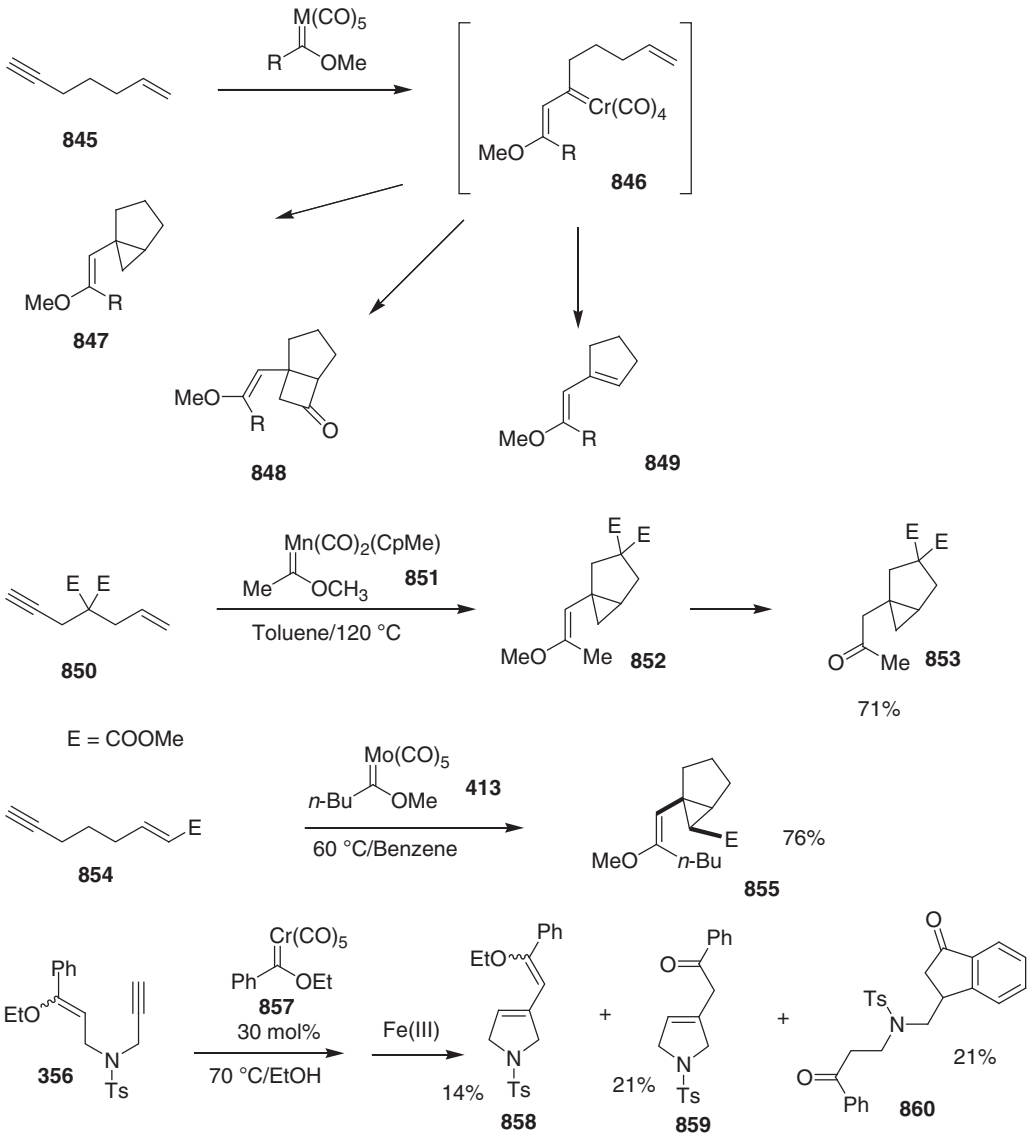
5.25.3.3 Coupling of Carbene Ligands with Cumulene and C–X pi Bonds

5.25.3.3.1 Allenes

Limited studies of the reactions of carbene complexes and allenes have been demonstrated (Scheme 88). Coupling of allenes (e.g., **887** and **890**) and Fischer carbene complexes affords trimethylenemethane derivatives (e.g., **888** and **891**), which afford cyclopentane derivatives (e.g., **889** and **892**) after subsequent cycloaddition with suitable alkenes.[404] Dialkylidenecyclopentane derivative **889** can be obtained by either isolation of complex **888** and treatment with allene **887**, or by prolonged coupling of complex **857** and allene **887**. The isolated trimethylenemethane derivatives (e.g., **891**) can also couple with alkynes in a separate

Scheme 83

step to provide mixtures of alkylidenecyclopentene (**893**) and alkylidenecyclohexenone derivatives (**894**),[405] which result from CO insertion processes. An efficient cycloaddition reaction occurs when trimethylenemethane complex **891** is treated with maleoyl derivatives, resulting in the exclusive formation of alkylidenecyclopentenes (**893**). Reaction of alkenylcarbene complexes with 1,1-dimethylallene led to 2-alkoxy-1,3-diene derivatives in a net metathesis reaction.[406]



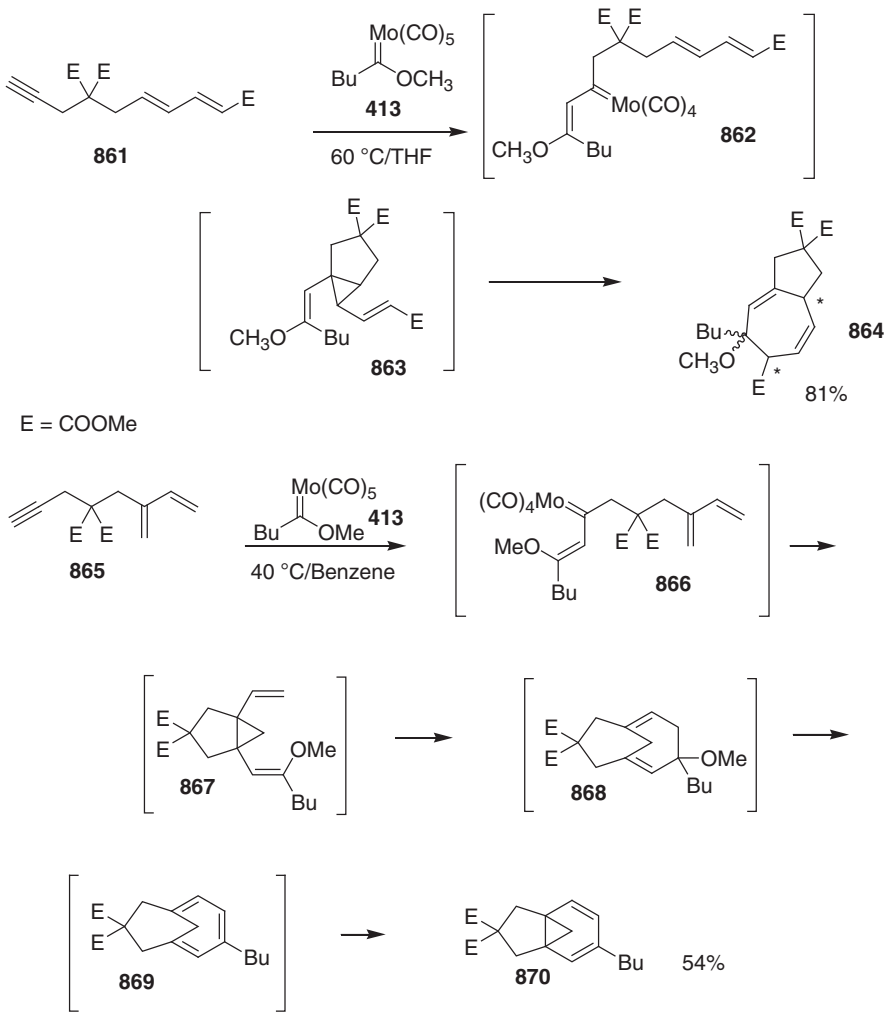
5.25.3.3.2 Imines

Most of the reactions reported with imines involve generation of metal complexes of ketene through photoinduced CO insertion followed by [2 + 2]-cycloaddition. These reactions are discussed in the section on CO and isonitrile insertion.

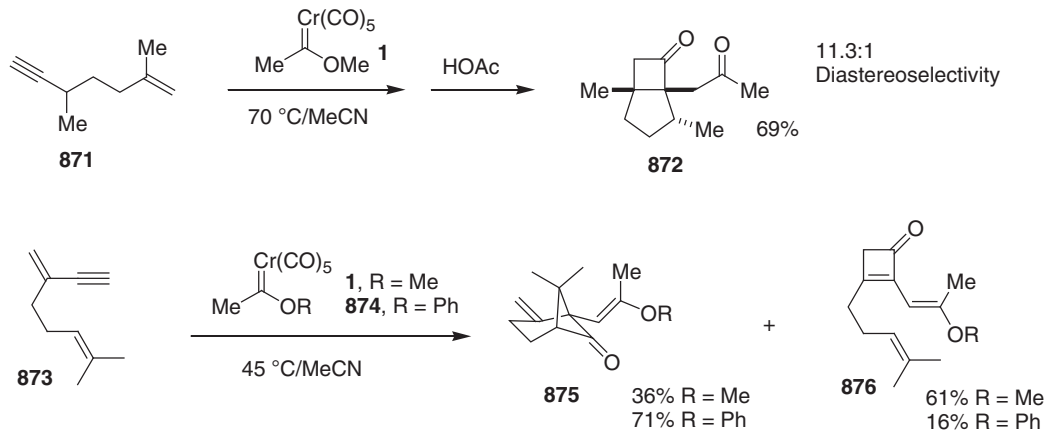
5.25.3.3.3 Isonitriles and CO

Photoinduced conversion of metal carbene complexes to metal–ketene complexes, followed by subsequent transformation of the ketene is the basis of many metal carbene cycloaddition processes. Several reviews on this topic have appeared.[407] This process is largely mimicked by the thermal reaction with isonitriles, which leads to ketenimines.[408]

Several examples of the coupling of β-lactams through the photolytic coupling of chromium carbene complexes and imines have been reported. Representative examples are depicted in Scheme 89. Penam-type β-lactams (e.g., **898**) were prepared from the photolytic coupling of dihydrothiazoles (e.g., **896**) with carbene complexes.[409] Azapenams were prepared with a very high degree of stereoselectivity through photolytic coupling of dihydroimidazoles (e.g., **899**) with methylcarbene complexes.[410] Synthesis of carbon-linked β-lactams (e.g., **902**) from the reaction of bis carbene complexes (e.g., **901**) with imines (e.g., **899**) was reported using both achiral and homochiral imines.[411,412] In several cases, the photolytic reaction of chromium carbene complexes and alkenes leads to cyclobutanones. The synthesis and photolytic reactions of α-alkoxycarbene–chromium complexes (e.g., **903**) were described.[413] The requisite carbene complexes could only be synthesized via the chromium pentacarbonyl dianion route; the Fischer route using alkoxymethyllithium derivatives failed. Successful cycloaddition with enamide derivatives (e.g., **904**) was

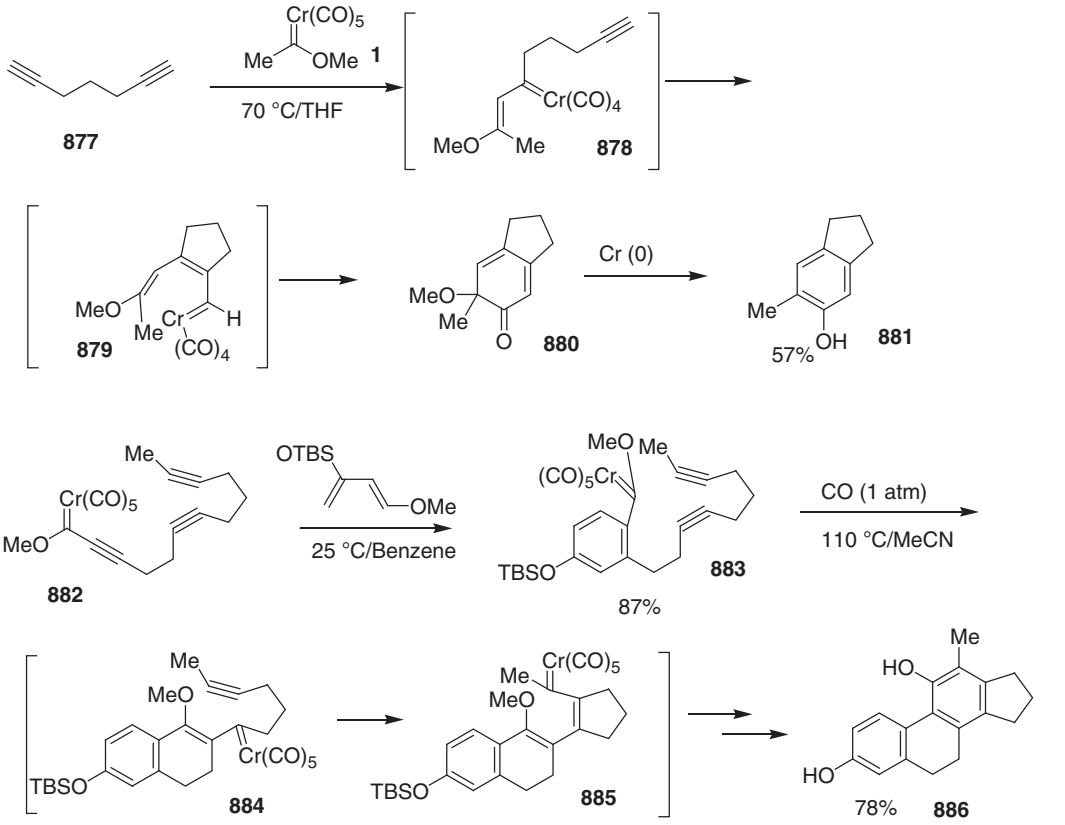


Scheme 84

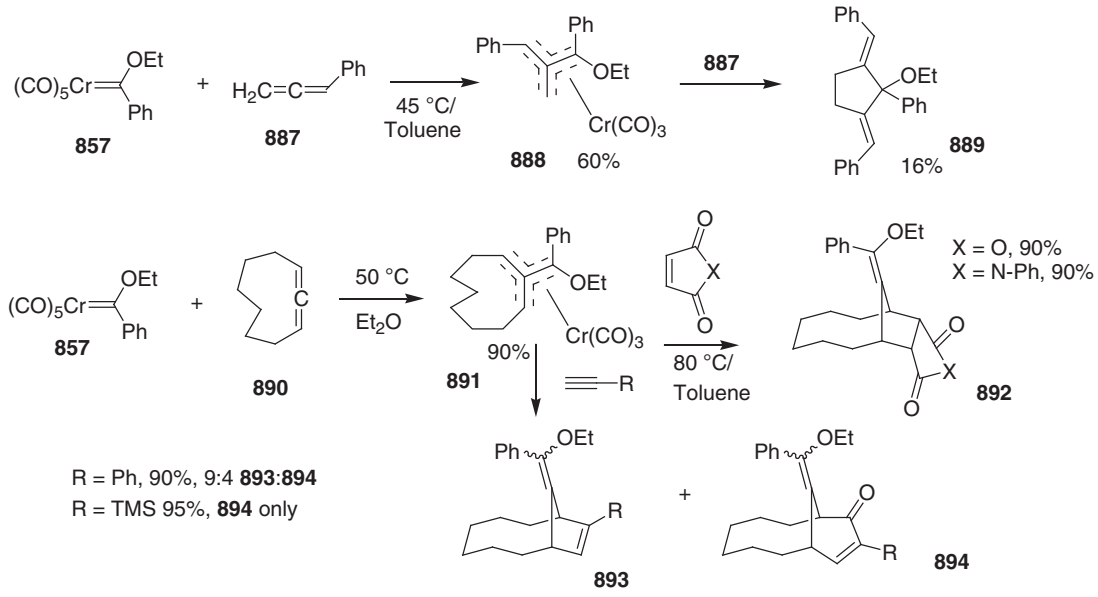


achieved using a DMF–carbazole solution as a filter. The photo-induced CO insertion process is specific to chromium carbene complexes. A combined experimental–theoretical study of the photolytic formation of β-lactams from chromium carbene complexes and imines was undertaken to address the issues that favor photolytic ketene formation over photolytic CO dissociation.[414]

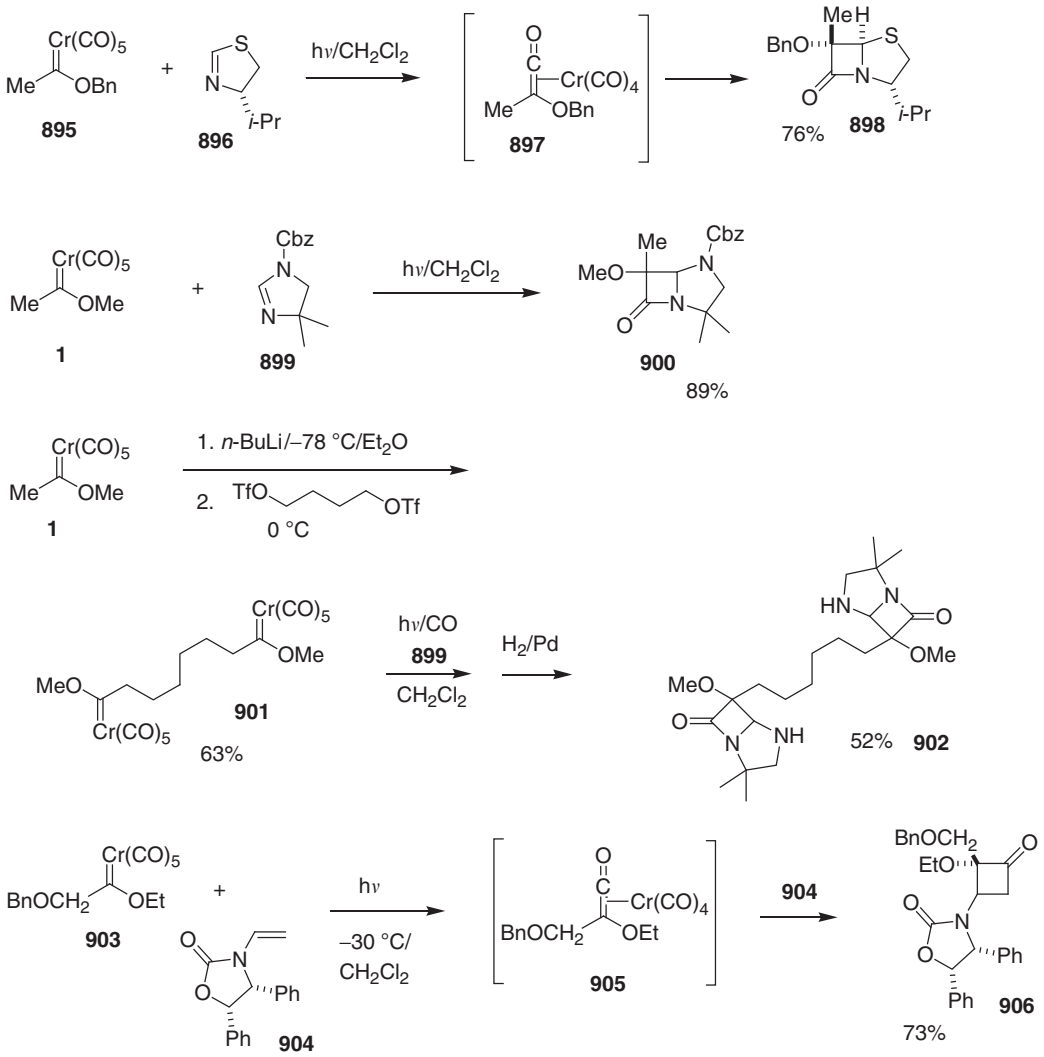
In several cases, photolysis of carbene complexes affords ketenes, which then undergo pericyclic ring closure reactions. Several examples of this process have already been discussed as this process is frequently a follow-up step in several reactions that lead to dienylcarbene complexes. Photolysis of carbene complex **907** (Scheme 90) resulted in carbazole derivatives (e.g., **909**). This process occurs via tandem photolytic ketene generation (**908**) and electrocyclic ring closure.[415] Indolocarbazoles (e.g., **911**) were produced in the photolysis of biindolecarbene derivative **910**.[416] Similar cyclizations of biphenylcarbene complexes (e.g., **912**) led to the corresponding phenanthrenes (e.g., **913**).[417]



Several examples of the analogous reaction of carbene complexes with isocyanides to afford ketenimines have been reported (Scheme 91). Numerous examples of isocyanide insertion followed by cyclization of the resulting ketenimine were applied to the alkenylcarbene complexes generated from additions to the triple bond of alkynylcarbene complexes (e.g., **914**), resulting in net aminobenzannulation. Several examples of the treatment of dienylcarbene complexes with isocyanides or CO to afford benzannulation products (e.g., **915** and **916**) have been demonstrated.[418,419] Reaction of chromium carbene complex **917** with *t*-butyl



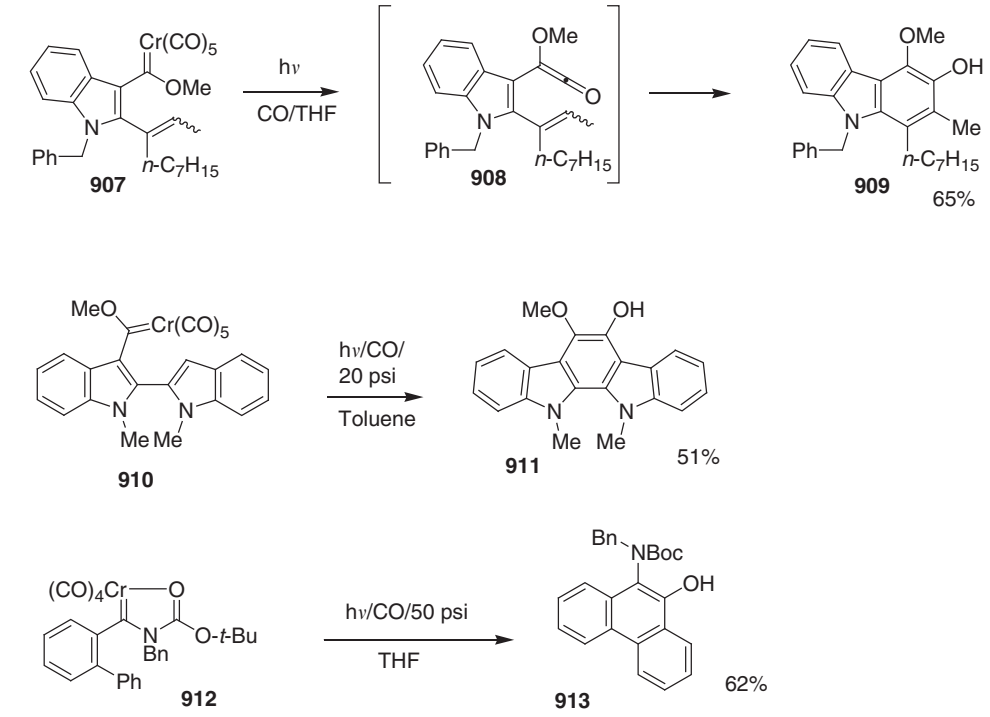
Scheme 85



Scheme 86

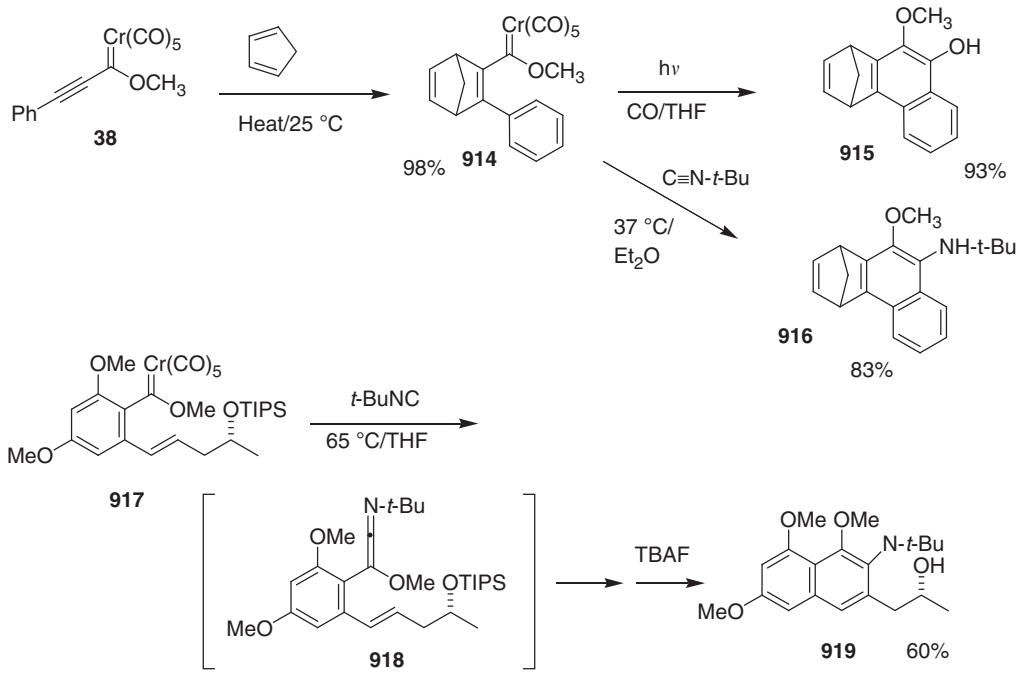
Scheme 87

Scheme 88



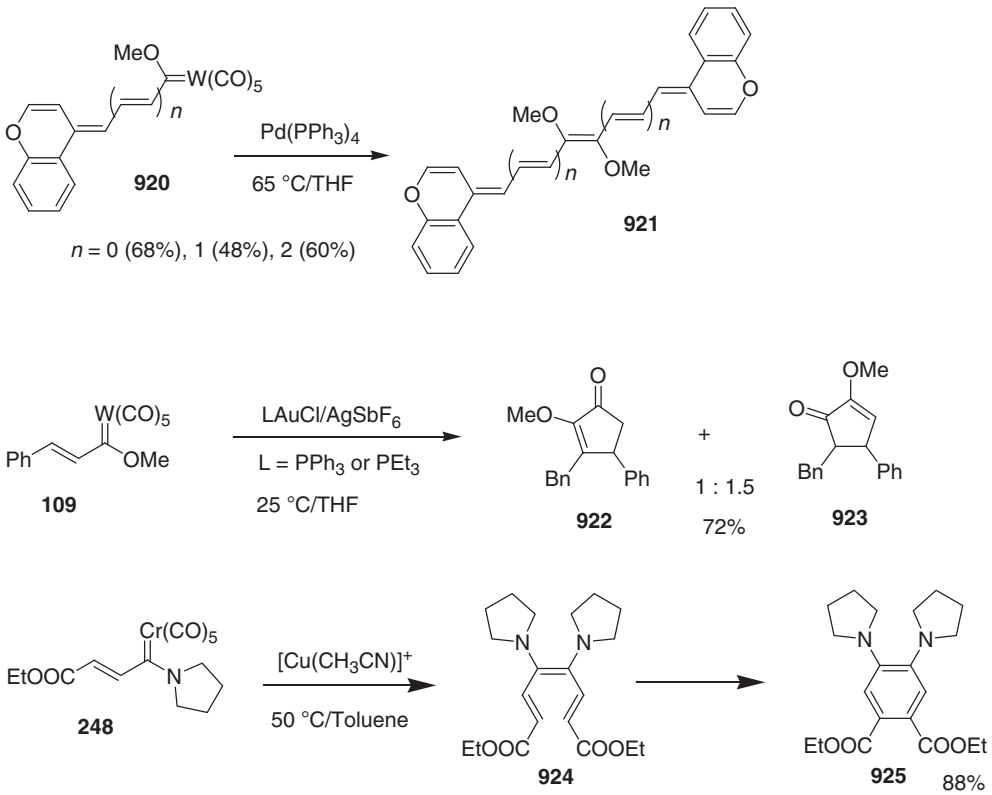
Scheme 89

isonitrile led to aminonaphthalene derivatives **919**, which was employed for the total synthesis of the calphostin natural products.[420]



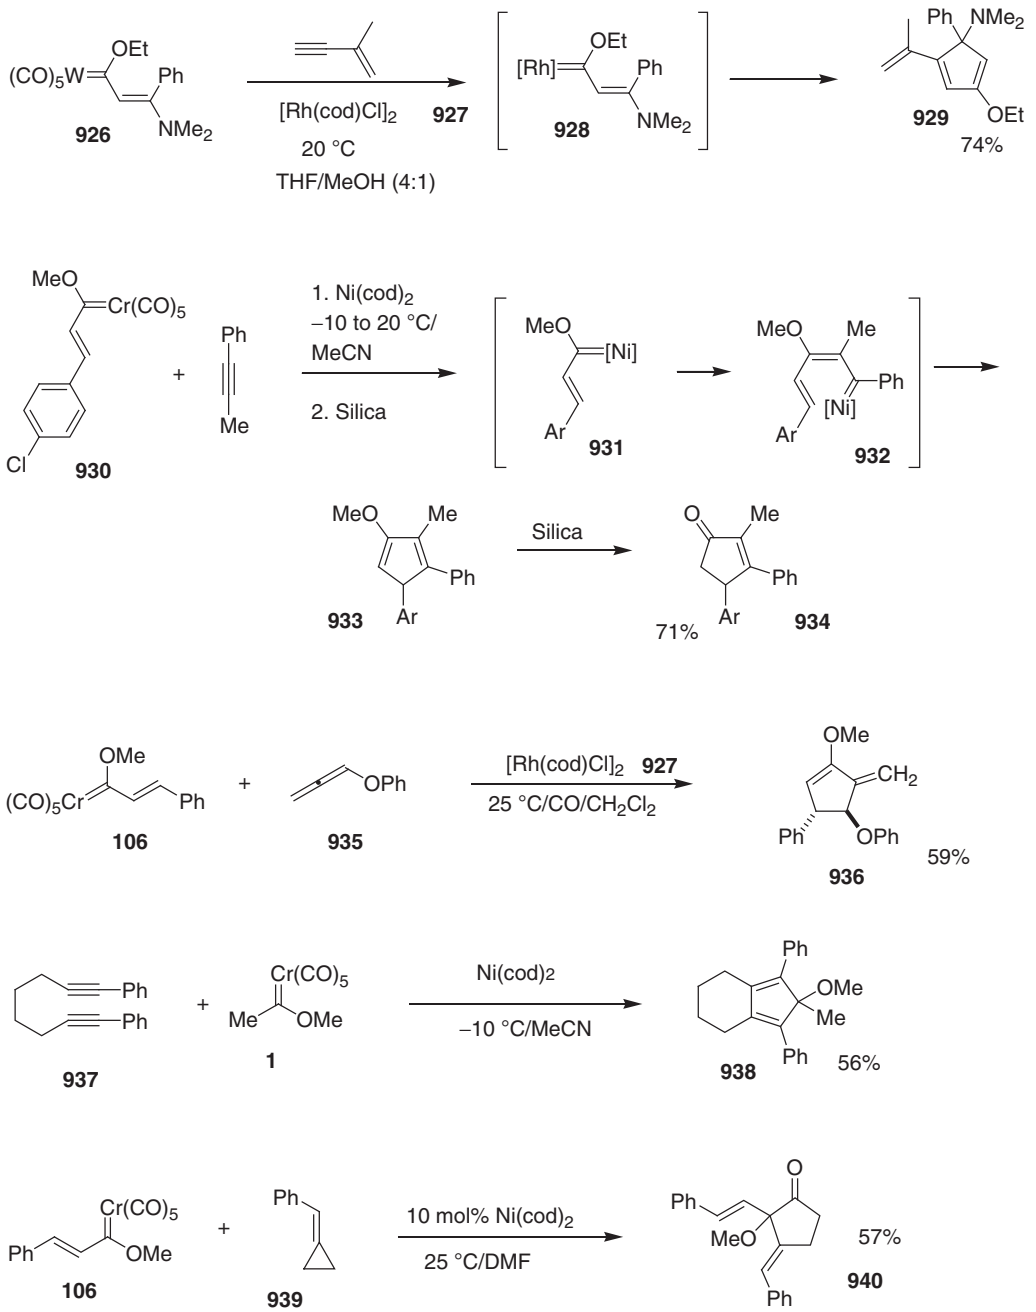
5.25.3.4 Transfer of the Carbene Ligand to Another Metal

In several cases, metal carbene cycloaddition processes require the transfer of the carbene ligand to another metal to accomplish the desired transformation. Some aspects of this research area have been reviewed.[421] The most well-developed processes invoking this reaction pathway are low-temperature carbene complex dimerization and cycloaddition reactions with alkenes, alkynes, and allenes. In a sense, this method is employing a stable transition metal carbene complex as a safe alternative to a diazo compound.



Numerous examples of metal-catalyzed carbene complex dimerization have been reported. Most examples of this process use palladium(II) complexes. Treatment of pyranylidene–carbene complexes (e.g., **920** and Scheme 92) with a palladium(0) catalyst led to the carbene dimerization product (e.g., **921**).[422] Gold complexes catalyze cyclopropanation and carbene dimerization reactions using α,β-unsaturated carbene complex **109**.[423] Treatment of tungsten carbene complex **109** with a gold complex led to dimerization/cyclization products (e.g., **922** and **923**). Copper-catalyzed dimerization of α,β-unsaturated carbene complexes (e.g., **248**) afforded conjugated trienes (e.g., **924**), which underwent electrocyclic ring closure and oxidation to afford 1,2-diaminobenzene derivatives (e.g., **925**).[424]

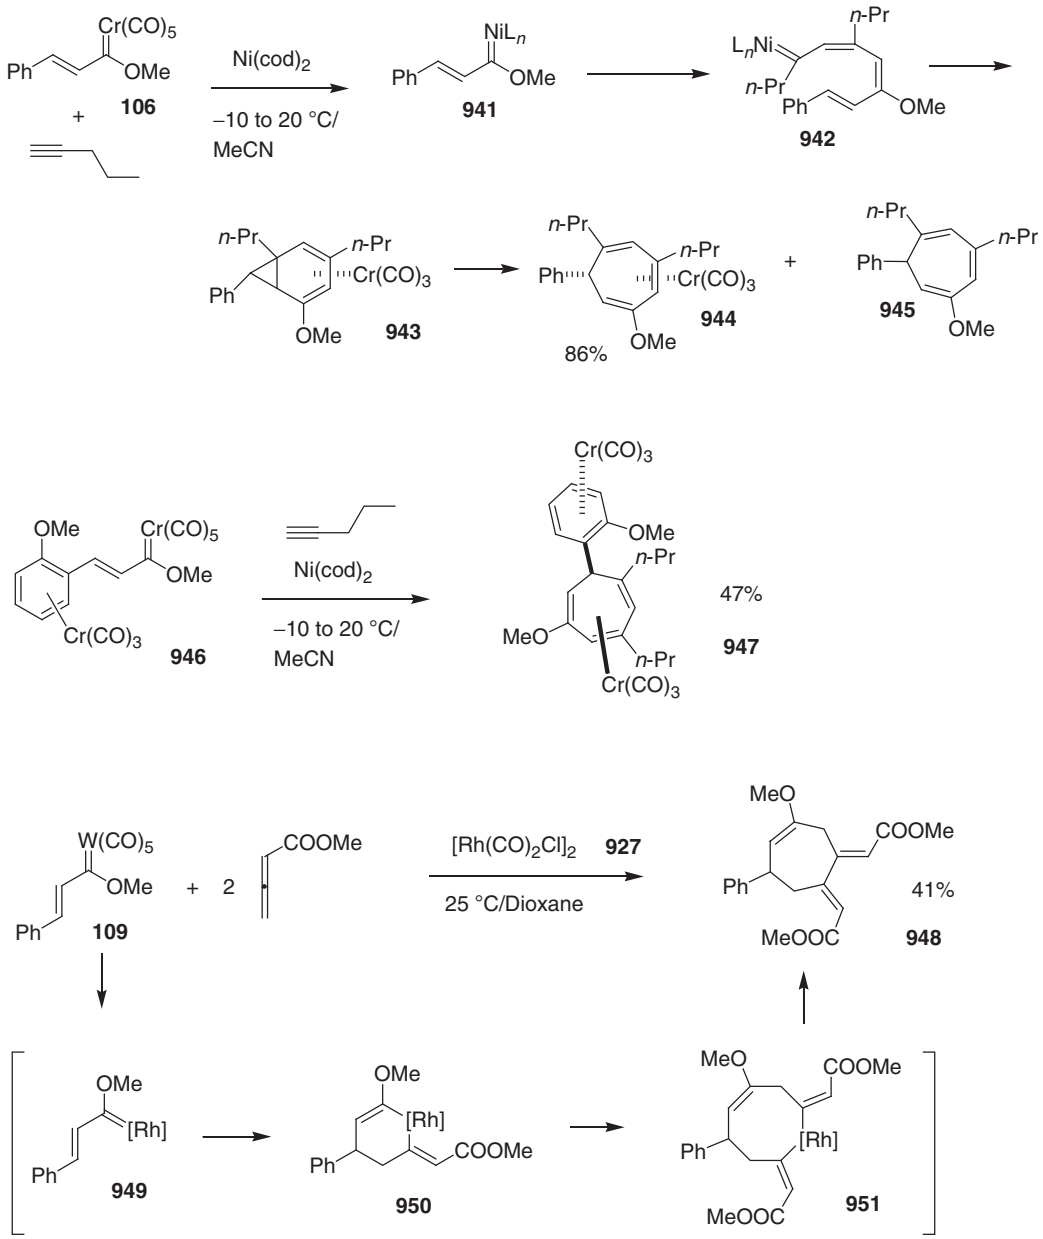
Scheme 90



Scheme 91

Scheme 92

Several cases of transition metal-catalyzed multicomponent couplings leading to five-membered rings have been reported (Scheme 93). The coupling of β-aminoalkenylcarbene–tungsten complexes (e.g., **926**) with conjugated acetylenes in the presence of various rhodium complexes (e.g., **927**) proceeded at 20 °C to provide the cyclopentadiene derivatives (e.g., **929**).[425,426] A mechanism involving initial carbene transfer from tungsten to rhodium was proposed. The nickel-catalyzed coupling of α,β-unsaturated Fischer carbene complexes (e.g., **930**) and alkynes led to cyclopentenones (e.g., **934**) in a net [3 + 2]-cycloaddition process.[427] The key step in the proposed mechanism is transfer of the carbene ligand from chromium to nickel to afford a nickel carbene complex intermediate (**931**), which undergoes alkyne insertion followed by cyclization to afford cyclopentadiene–enol ether derivatives (e.g., **933**). Enol ether hydrolysis on silica gel leads to the cyclopentenone products. The coupling of alkenylcarbene complexes (e.g., **106**) with allenes in the presence of a rhodium catalyst (**927**) resulted in the formation of alkylidenecyclopentene derivatives (e.g., **936**).[428] The coupling of two alkynes (or a dialkyne) (e.g., **937**) with a Fischer carbene complex in the presence of a nickel catalyst afforded cyclopentadiene derivatives (e.g., **938**) in a formal [2 + 2 + 1]-cycloaddition process.[429] Nickel carbene complexes were also proposed in the formation of cyclopentanones (e.g., **940**) through nickel-catalyzed cycloaddition reaction of carbene complexes with alkylidenecyclopropanes (e.g., **939**).[430]



Transition metal-catalyzed seven-membered ring-forming cycloadditions employing carbene complexes have been documented (Scheme 94). Cycloheptatrienes (e.g., **944** and **945**) were synthesized through either the coupling of an alkenylcarbene complex with two equivalents of an alkyne or through coupling of an alkylcarbene complex or arylcarbene complex with three equivalents of an alkyne.[431] A mechanism involving formation of a nickel carbene complex (e.g., **941**) through carbene transfer to nickel, followed by insertion of 2–3 mol of alkyne, followed by intramolecular cyclopropanation to afford an intermediate norcaradiene species (e.g., **943**), followed by an electrocyclic ring opening was proposed. The coupling of chiral alkenylcarbene-$Cr(CO)_3$ complexes (e.g., **946**) with alkynes in the presence of $Ni(cod)_2$ afforded chromium-complexed cycloheptatriene derivatives (e.g., **947**) with a high degree of diastereoselectivity.[432] A net [3 + 2 + 2]-cycloaddition affording bis(alkylidene)cycloheptanones (e.g., **948**) was observed in the rhodium-catalyzed reaction of α,β-unsaturated carbene complexes and allenes.[433] A mechanism involving transfer of the carbene unit to rhodium, followed by metalla-Diels–Alder reaction with an allene to afford the metallacyclohexene (**950**) followed by insertion of a second allene molecule and reductive elimination was proposed. A major side reaction is five-membered ring formation resulting from reductive elimination at the metallacyclohexene (**950**) stage. A similar reaction employing an excess of 1,1-dimethylallene led to cycloheptanone derivatives.[434]

Scheme 93

5.25.4 Conclusions

The use of metal carbene cycloadditions has emerged as an important method for the synthesis of complex ring systems. The most well-developed of these, the Dötz benzannulation reaction, is a powerful tool for aromatic ring construction and has been employed as a cornerstone reaction in many complex natural product syntheses. Through a thorough understanding of the mechanism of this and other processes, tandem reactions that rapidly transform simple molecules into complex systems featuring multiple functionalities and stereocenters have been developed. Although the majority of these reaction processes are stoichiometric in chromium and other transition metals, the source materials (metal hexacarbonyls) are relatively low molecular weight and readily available, and enable transformations that would require multiple operations if performed without these reaction

Scheme 94

processes. It should be noted also that all of the chromium processes depicted involve relatively low oxidation states (0 or +2) and not Cr(VI), the oxidation state associated with harmful health effects. A major underappreciated advantage of stoichiometric chemistry is the ability to perform sequential addition processes on intermediates that would otherwise have no lifetime, and several of these reaction processes take advantage of this unique attribute. Although these reaction processes defy modern-day buzzwords like 'atom economy' and 'catalysis,' they have proven themselves highly useful in advanced synthesis problems.

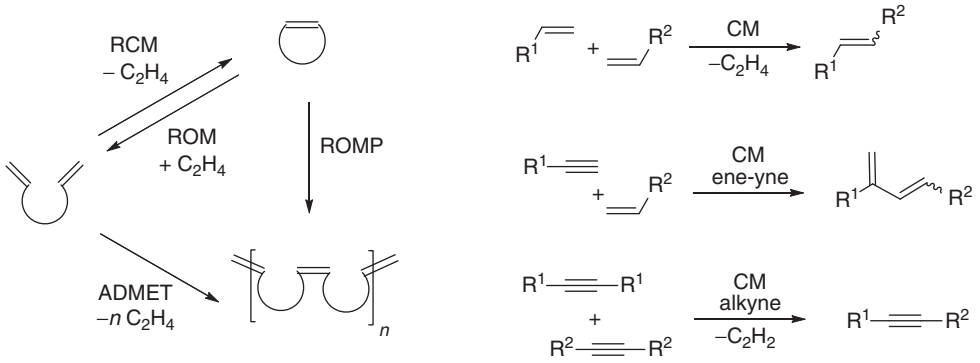
Glossary

Carbene A molecule containing a neutral carbon atom with a valence of two and two unshared valence electrons. Most carbenes are unstable, but persistent carbenes are also known, among them are a class of *N*-heterocyclic ligands often utilized in metal catalysis.

Homodimerization Described also as self-metathesis or homo cross metathesis – a metathetic process during which one alkene substrate yields the product composed of two identical units. This transformation is applied to the synthesis of symmetrical compounds, but is also an issue leading to secondary metathesis pathways when two complicated compounds are utilized.

Isomerization A process by which one molecule is transformed into another molecule with exactly the same atoms, but in a rearranged format. In some molecules and under some conditions, isomerization occurs spontaneously, but it may be a catalytic transformation as well enhanced by, for example, metal-based initiators.



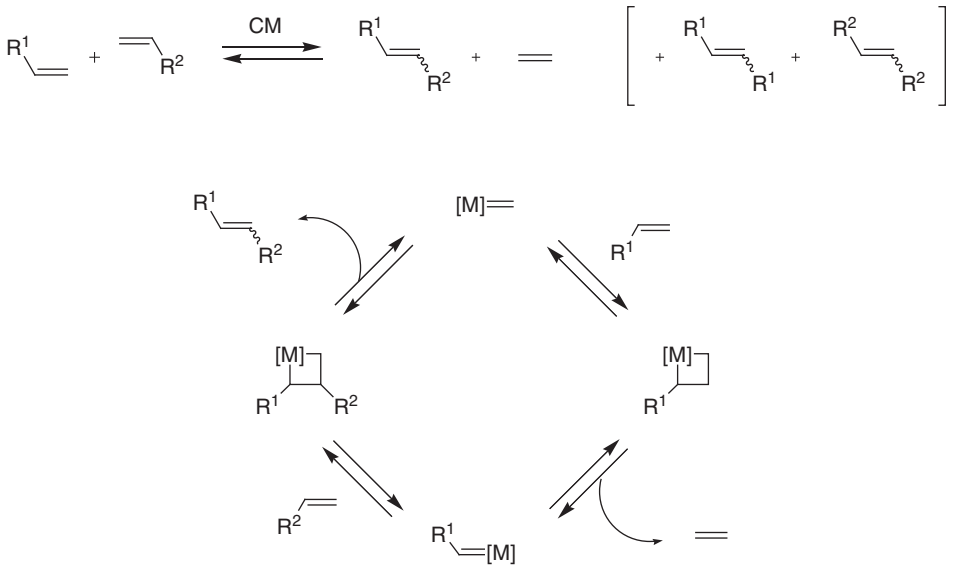
Metathesis An organic metal-catalyzed reaction during which a redistribution of alkene fragments takes place. The mechanism involves the [2 + 2] cycloaddition of an alkene double bond to a transition metal alkylidene to form a metallacyclobutane intermediate, which is later rearranged to form the product. Catalysts for this reaction are typically based on ruthenium, molybdenum, or tungsten, enabling a variety of applications.

Stereogenic-at-metal complexes Complexes bearing various ligands with different substitution patterns. This renders the metal a stereocenter and has a profound effect on the enantioselectivity of the catalysts. The main representatives of this class are molybdenum-based complexes containing a partially substituted alkoxide ligand and a pyrrolide moiety.

5.26.1 Introduction

5.26.1.1 General Information

Olefin metathesis[1] is one of the most powerful tools in organic chemistry leading to C–C double-bond formation. The importance of this transformation was underlined by awarding the Nobel Prize to Chauvin, Schrock, and Grubbs in 2005 (http://nobelprize.org/nobel_prizes/chemistry/laureates/2005/chemadv05.pdf). One of the reasons for the success is the variety of possible applications caused by the enormous compatibility of functional groups with the available well defined catalysts. There are examples of utilization of metathesis in the synthesis of natural products,[2] pharmaceuticals,[3] heterocyclic and macrocyclic compounds,[4] or speciality polymers.[5] The great potential of this transformation is partially caused by the fact that metathesis is a set of several different types of reactions: ring-closing metathesis (RCM), ring-opening metathesis (ROM), acyclic diene metathesis (ADMET) polymerization, ROM polymerization (ROMP), and cross metathesis (CM), which are presented in **Scheme 1**.[6]



Scheme 1 The main types of olefin metathesis.

It is crucial to underline that, by definition, olefin metathesis is a reaction of two olefinic substrates that are broken and rearranged to form two new olefinic products. Two types of CM shown in the above scheme do not fit into this category. These are the ene-yne CM and alkyne CM – cases when one or both substrates are alkynes. Although this chapter is devoted to CM, those methods will be discussed in Chapters 5.27 and 5.28.

5.26.1.2 Mechanism and Modifications

This review is devoted to discussing CM, its variants and applications, as considerable improvements have been made in this field. The mechanism of this powerful transformation, proposed by Chauvin and Hérisson,[7] is presented in Scheme 2.

Scheme 2 Mechanism of cross metathesis.

The first step is the coordination of the substrate to the catalyst – a transition-metal carbene complex – resulting in the formation of a metallacyclobutane. During the next stage it breaks forming a volatile olefin (ethylene when both the substrates are terminally unsubstituted) and a carbene. The released carbene interacts with the next substrate forming another metallacyclobutane. Decomposition of this species leads to the final product with simultaneous regeneration of the starting metal carbene. It is important to note that all of the steps are reversible, with the release of the volatile alkene being the driving force of the reaction.

5.26.1.3 Commercially Available Catalysts

According to the widely accepted mechanism, the reaction is catalyzed by a transition metal complex. Several metal catalysts have been tested in metathesis reactions, but the best outcome was achieved with molybdenum-, tungsten-, and ruthenium-based ones. A narrow selection of popular, commercially available catalysts is presented in Figure 1. Strem Chemicals offers six molybdenum and seven ruthenium catalysts (including **Ind-I**, **Ind-II**, and **Ind-II′**) were obtained in collaboration with Degussa-Evonik, Ciba

Specialty Chemicals, Umicore, and Zannan Pharma. Since 2003, Sigma-Aldrich has exclusively offered 11 Grubbs and Hoveyda catalysts (including **Gru-I**, **Gru-II** and **Hov-I**, **Hov-II**) produced by Materia Inc. **Gre-I**, **Gre-II**, and several other ruthenium catalysts available from Apeiron Synthesis. This wide selection is a great aid for the community of organic chemists willing to perform metathesis.

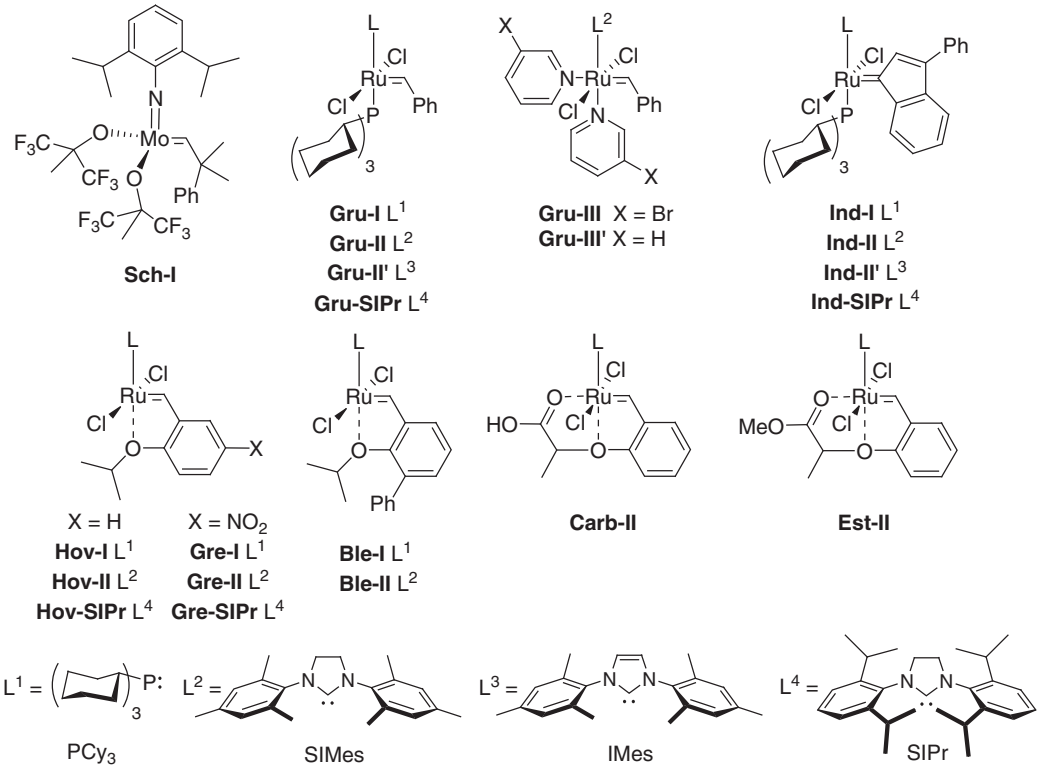


Figure 1 Selected commercially available metathesis initiators. Ph, phenyl.

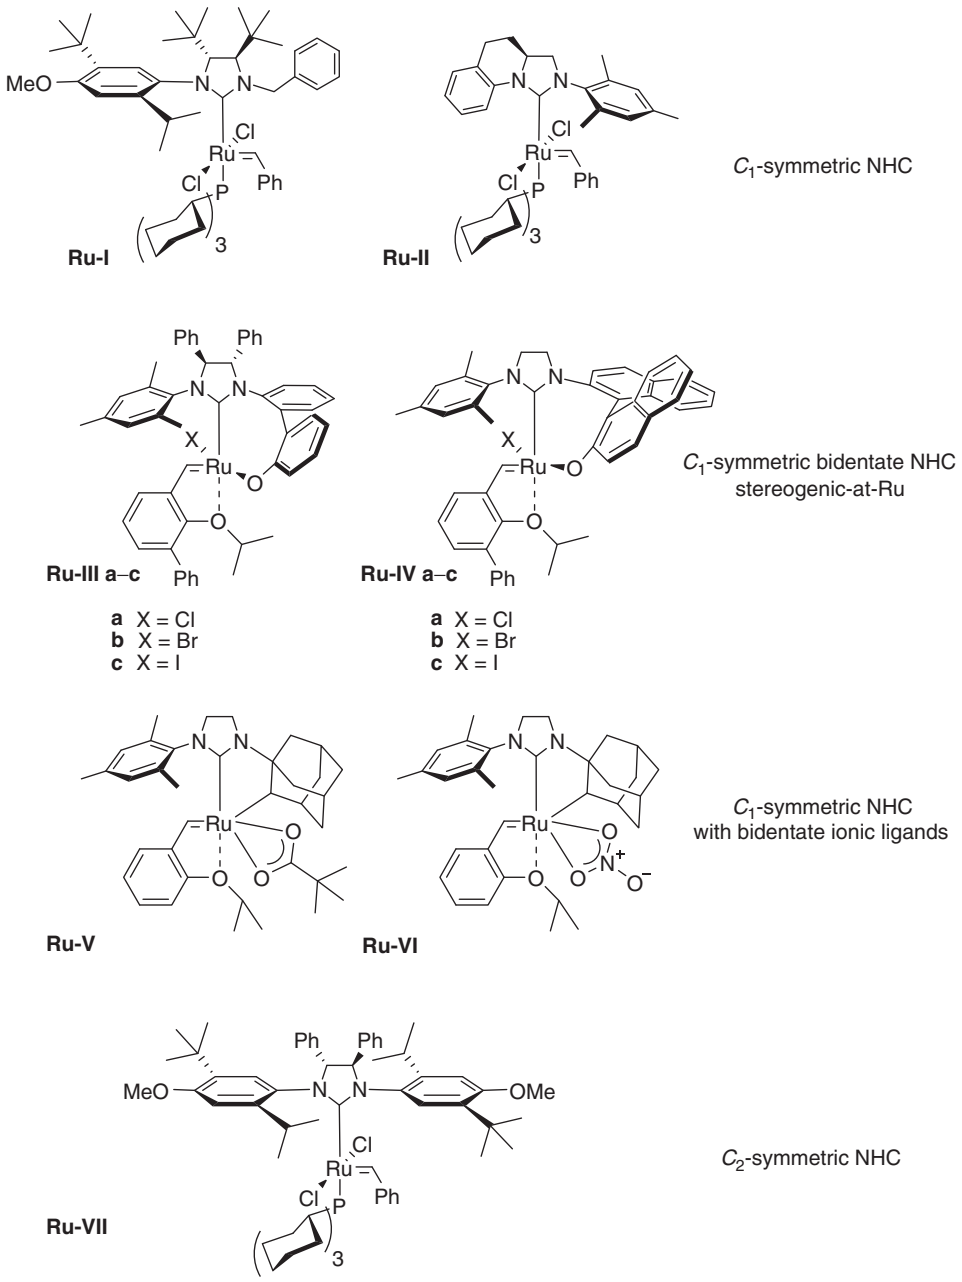
The most reactive catalysts to date are based on molybdenum. The class represented by **Sch-I**[8] was the first to be developed and possesses enormous synthetic potential. Although the activity of these kinds of initiators is very high, their sensitivity to air and moisture were the limiting factors in industrial applications. The discovery of ruthenium-based benzylidene[9] and indenylidene[10] catalysts, free of these drawbacks, was a real breakthrough. The original variants, known as 'first-generation,' contained two phosphine ligands. Later, one of the phosphines was replaced by an *N*-heterocyclic carbene (NHC) possessing a σ-donor character, thus leading to the 'second-generation' of ruthenium compounds. It is important to note that even slight modifications of the NHC ligand structure leads to changes in the catalytic behavior.[11] A good example is the implementation of chirality to the structure of the catalysts, which has been an important issue in metathesis studies for over a decade. So far the NHC was the only means of introducing chirality in Ru-based catalysts, as the strong bond connecting such ligands to the metal does not break during the catalytic cycle, thus allowing for efficient transfer of stereoinformation. NHCs applied to induce chirality are usually divided into two classes: those of C_1 and C_2 symmetry. Representatives of these classes are presented in **Figure 2**.[12]

Application of *N*-heterocyclic ligands of C_1 symmetry allows the influence of the chiral backbone to be enforced by the increase in the steric hindrance. Depending on the structure of the complex, various *syn*/*anti* rotamer ratios are observed. A variation of this class are bidentate C_1-symmetric NHCs. Their interesting feature is that the backbone does not have to be substituted and, as the ligand is chelating, no Ru-NHC rotation is observed. Moreover, the diastereoselective complexation of the ruthenium atom creates a stereogenic center at the metal (stereogenic-at-Ru complexes). This leads to a highly improved *E*:*Z*-selectivity, which is beneficial in a variety of asymmetric applications such as CM or ring-opening CM (ROCM). Additional modification of the anionic ligands – applying iodides instead of chlorides – magnifies this effect by increasing the steric interactions. Moreover, complexes of this class show outstanding stability. Research on C_1-symmetric NHCs led to further developments in the field. Mol et al. reported on a Grubbs-type initiator derivative bearing the bulky 1-(1-adamantyl)-3-mesityl-4,5-dihydroimidazol-2-ylidine NHC ligand,[13] whose X-ray structure showed a possible weak interaction of one of the adamantyl carbons with the metal center (2.883 Å). As this complex failed to initiate even the simple self-metathesis it was not further developed until, more recently, Grubbs obtained a Hoveyda-type complex (**Ru-V**) bearing the same NHC ligand used by Mol.[12e] In this complex the NHC is chelated to the metal center through a Ru–C covalent bond. Despite its relatively poor activity in metathesis reactions, it has displayed a fairly good *Z*-selectivity in CM. Continuing their efforts, Grubbs et al. obtained several new



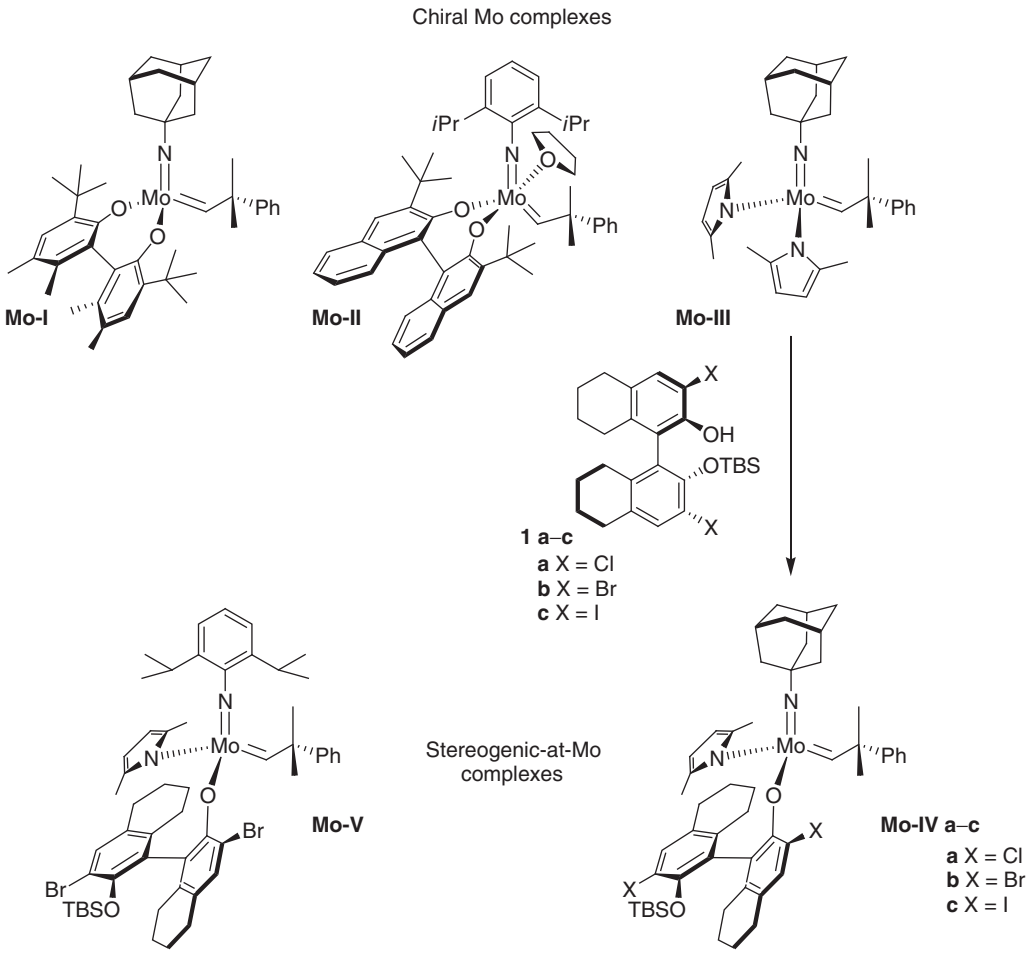


Figure 2 Chiral Ru-based metathesis catalysts.

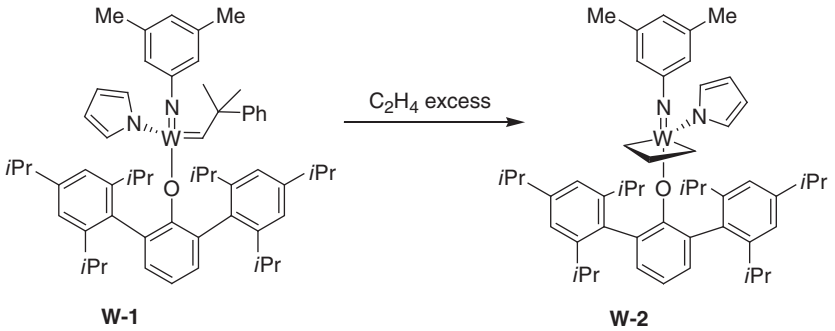
C–H-activated ruthenium catalysts for *Z*-selective olefin metathesis.[12e,f] It was found that bidentate anionic ligands (e.g., bulky carboxylates, **Ru-V**) led to the best metathesis activity and selectivity, whereas the monodentate ones were usually less optimal. The use of Chen's nitrato ligands[14] in place of carboxylates led to a significant improvement in the catalyst's activity and selectivity (**Ru-VI**).[12f] With these catalysts, turnover numbers approaching 1000 were possible for a variety of CM reactions, including syntheses of industrially relevant products. It shall be noted that, in contrast to Mo- and W-based systems, these catalysts are compatible with polar groups and protic solvents.

The last class of chiral ruthenium compounds is of higher C_2 symmetry. These complexes are highly stable. Another advantage is that the rotation around the Ru-NHC axis is inconsequential. The chiral backbone influences the *N*-aryl substituent's orientation with the aryl *o*-substituents being crucial for selectivity. The general pattern of enantioinduction seems to be the same for all Ru-based complexes. The substrate may coordinate to the complex in different ways, and due to the steric interactions with the NHC, one of the possible intermediates with the bound substrate is ultimately favored. This scenario has been confirmed by theoretical studies.[15]

Installing chirality in the molybdenum complexes requires a different approach, as the ligands do not dissociate during the catalytic cycle, thus strongly influencing the behavior of the complex. Two classes of Mo-based complexes utilized in asymmetric metathesis are presented in Scheme 3.[16]

Scheme 3 Mo-based complexes utilized in asymmetric metathesis. *i*Pr, *iso*-propyl; TBS, *tert*-butyldimethylsilyl.



Typical chiral Mo-based complexes contain biphenol and binol derivatives with different substitution patterns. Stereogenic-at-Mo complexes are obtained by utilization of a partially substituted alkoxide ligand and a pyrrolide moiety (the so-called monoalkoxide-pyrrolide (MAP) complexes). The combination of two different monodentate ligands leads to the establishment of a stereocenter at the metal, having a profound effect on the enantioselectivity of the complex. A great advantage of such systems is that they can be generated *in situ*. Although utilization of Mo-based catalysts seems beneficial, they have a major drawback – sensitivity to air and moisture, which still seems to limit their applications. There have been attempts to stabilize the complexes by specially designed additives (2,2′-bipyridine was utilized), which, although successful, resulted in initiators of diminished activity.[17]

Recently, Schrock and Hoveyda found that related tungsten-based MAP catalysts such as **W-1** can be transformed into fairly stable crystalline metallacyclobutane complexes such as **W-2** by exposing the alkylidene to an ethylene atmosphere (Scheme 4).[18] Importantly, it was shown that a number of α-olefins as well as many functionalized alkenes can be homo-metathesized in the presence of this complex in good-to-excellent yields with *Z*-selectivities of >99%.

Despite enormous improvements in the synthesis of chiral catalysts, their large-scale applications to date seem to be limited. The review will discuss principles and means of utilization of the described catalysts in the different variants of CM.

5.26.1.4 Olefin Types

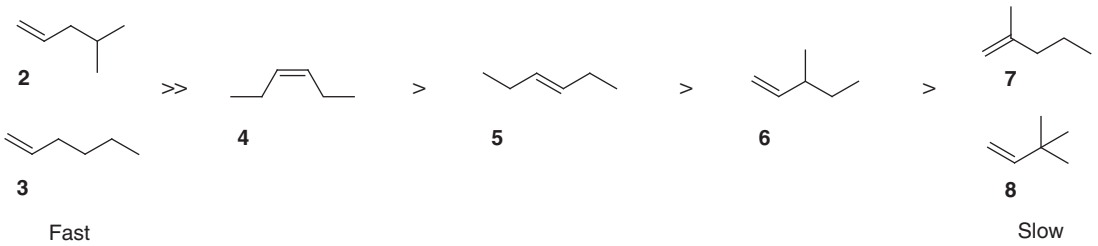
On the basis of the mechanism of CM (Scheme 2) one can easily tell that the reaction of two substrates can lead to up to four products. The possible formation of various metallacyclobutanes and the number of secondary metathesis pathways determine

Scheme 4 Chiral tungsten complexes.

the composition of the product spectrum, which depends on the properties of the substrates taking part in the reaction. Attempts to introduce some categorization of reactivity were made by Grubbs et al.[19] The authors suggested that the relative ability to undergo homodimerization, compared with other olefins, may be the key. This factor, combined with a willingness of the potential homodimers to undergo secondary metathesis, was established as the basis of the original categorization presented in Table 1. Since the publication of this significant paper, important advances have been made in the field, but the classification presented below remains a starting point for any reaction optimization.

Table 1 Olefin categorization according to Grubbs

Olefin type	*Properties*	*Examples*
I	Fast homodimerization, homodimers consumed	Terminal alkenes, allyl silanes, allyl halides, primary allylic alcohols, allyl boronates, allyl phosphonates, protected allyl amines styrenes (no large *ortho* substituent) allyl sulfides, allyl ethers
II	Slow homodimerization, homodimers sparingly consumed	Styrenes (large *ortho* substituent), allyl stannanes, acrylic acid, acrylates, acrylamides, vinyl ketones, vinyl epoxides, vinyl boronates, vinyl dioxolanes, olefins substituted by perfluorinated alkyl groups, secondary allylic alcohols, unprotected tertiary allylic alcohols
III	No homodimerization	Tertiary allyl amines, vinyl sulfones, 1,1-disubstituted alkenes, acrylonitrile, vinyl siloxanes, vinyl phosphonates, protected tertiary allylic alcohols, alkenes flanked by quarternary allylic carbons (all alkyl substituents)
IV	Spectators to cross metathesis	1,1-Disubstituted alkenes, nitroolefins, quarternary allylic carbon containing alkenes, protected tertiary allyl amines, protected trisubstituted allylic alcohols



According to this classification, type I olefins undergo homodimerization rapidly, but the resulting dimers are consumed in secondary metathesis processes. Olefins described as type II homodimerize slowly and their homodimers are slowly consumed in the following CM process. Type III olefins do not homodimerize. The last type of olefins – type IV – gives neither homodimerization nor CM products. The classification was applied only to olefins that can be metathesized or are inert toward metathesis initiators, but olefinic compounds that have a deactivating influence on the catalyst were not taken into consideration. It requires emphasis that the above classification, although informative, is not general, as many exceptions were found. Moreover, as the metathesis methodology improves, type IV cases can be placed in different categories, and indeed, since the original classification in 2003, this particular category has been significantly reduced.[20]

A great advantage of the above classification is that it allows the prediction of the reaction selectivity. The rules are presented in Table 2.

Table 2 Rules for selectivity in cross metathesis

	Type I	*Type II*	*Type III*	*Type IV*
Type I	Statistical	Selective	Selective	No reaction
Type II	Selective	Nonselective	Selective	No reaction
Type III	Selective	Selective	Nonselective	No reaction
Type IV	No reaction	No reaction	No reaction	No reaction

It should be noted that Table 2 is based on generalized experimental data, which sometimes leads to results that are slightly different from the ones suggested by the model. One reason for that is the complexity of the problem, as the reactivity of olefins is a combination of steric and electronic factors. These aspects determine not only the selectivity of the reaction but also the relative reaction rates toward the catalyst. Scheme 5 summarizes the data for the ruthenium complex **Gru-I**.[21]

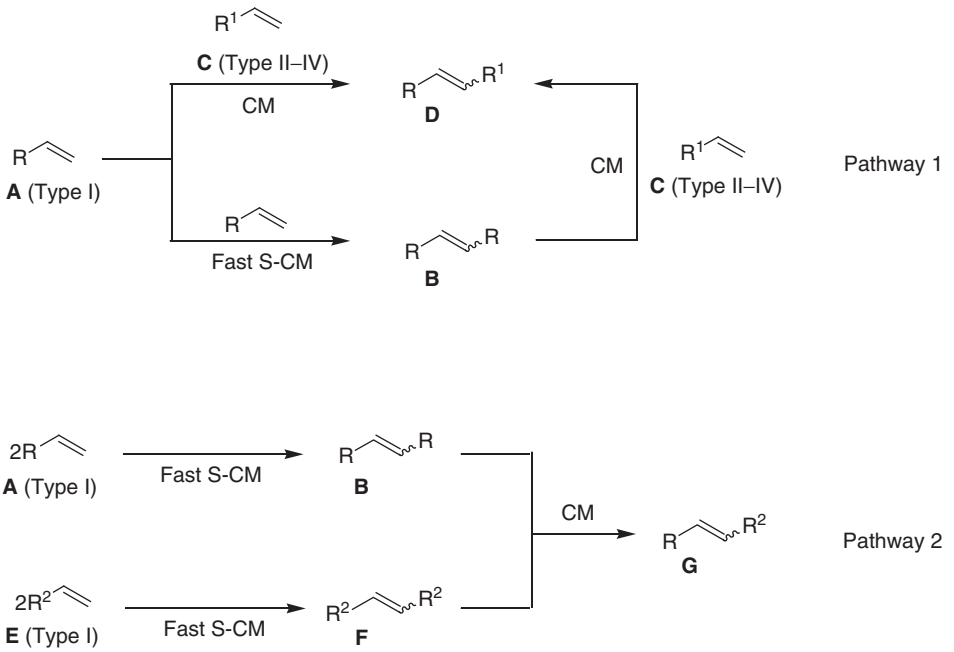
Scheme 5 Relative reaction rates with **Gru-I**.

When we compare the reaction rates of *E*- and *Z*-olefins (**5** and **4**, respectively) with the ruthenium benzylidene **Gru-I**, the catalyst reacts approximately twice as fast with the *Z*-isomer. The explanation seems to be simple: when the *Z*-olefin binds to the metal, the substituents point away from the bulky phosphine; this is not the case for *E*-olefins, which therefore bind more slowly. As the steric bulk increases, the reaction rate decreases placing 2,2-substituted olefins on the right as they do not react under the applied conditions. This results in the above reactivity order. Many studies on the influence of electronic effects have been conducted, which do not seem to be straightforward and cannot be discussed in general.

It should be noted that the above considerations based on the homodimerization rate may lead to certain confusion. Although a lot of examples seem to support this classification, in recent years many papers contain opposing data. Direct application of this concept to the experiments planning may occasionally result in a failure. The review will proceed to describe particular examples and applications of CM.

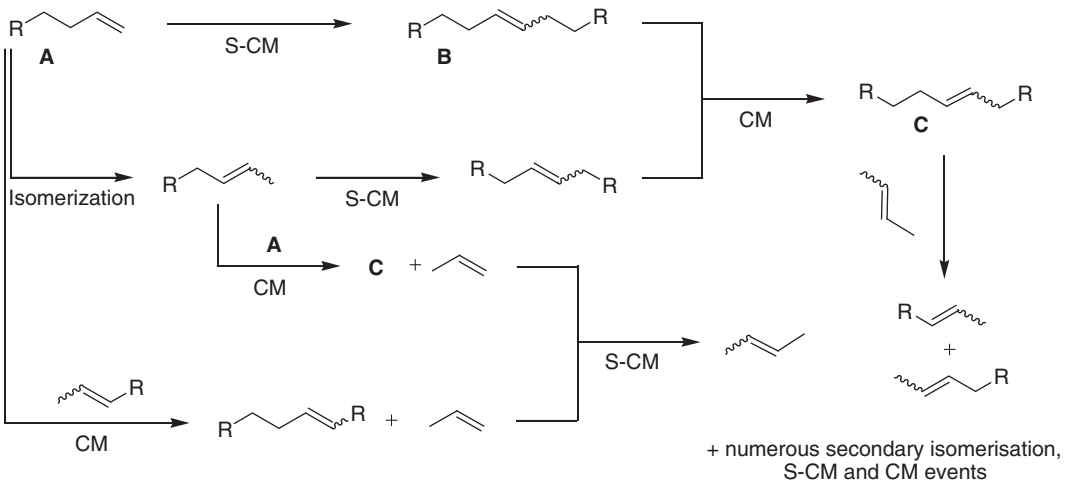
5.26.2 CM

5.26.2.1 Reaction with Fast Homodimerizing Metathesis Partners



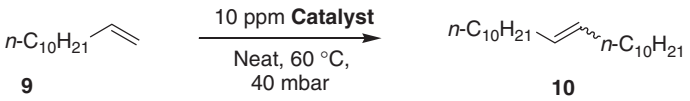
5.26.2.1.1 CM between two partners of type I

According to the general classification proposed by Grubbs,[19] olefins of type I (**A**) undergo self-CM (S-CM, sometimes referred in the literature as 'homo metathesis' or even as 'dimerization') and such 'dimers' (**B**) can also be used in CM with other olefins (Scheme 6). Most terminal alkenes can be classified as Type I olefins. Usually, in order to obtain acceptable selectivity levels, type I olefins (**A**) are used as CM partners for types II–IV olefins (**C**) according to pathway 1. A number of successful examples of this approach have been reported in the literature.

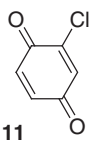


When two different type I olefins, **A** and **E**, undergo a CM reaction, the rates of homodimerization are usually very similar, leading to pathway 2. Therefore, the desired cross product **G** is always accompanied by the respective homo metathesis products **B** and **F**, resulting in a statistical product mixture, which makes the transformation impractical. To obtain good yields of the desired cross product, usually high excess of one of the type I olefins is required. Practically, 2–10 equivalents of one partner may be necessary to obtain a CM product of two type I olefins in a reasonable yield.[22,23] Better results can be obtained by utilizing internal olefins **B** and **F** for the CM reaction. If the CM product **G** can be separated from the substrates and further recycled, such transformation can be of significant practical value. Such strategies involving S-CM (sometimes described as homo metathesis) of simple alkenes can be attractive industrial methods allowing, for example, the conversion of low value feedstock such as Fischer–Tropsch olefin fractions and other *n*-olefins into useful chemicals. Unfortunately, a mixture of products can be formed due to alkene C–C double-bond isomerization during the metathesis reaction. As the products of this transformation can also undergo CM reactions, a range of alkene products is usually formed (Scheme 7).

The number of different processes taking place during such reactions prevented potential applications; therefore, efforts were made to reduce the undesirable reaction pathways. Utilization of first-generation ruthenium complexes was found to be beneficial in such cross metatheses because they do not cause isomerization to a high extent. The more active second-generation catalysts are known to cause shifts of the double bonds more easily, which can be effectively suppressed by the addition of benzoquinones.[24] Czaban et al. recently checked the influence of the reaction parameters on the conversion and selectivity of the metathesis of 1-dodecene (Scheme 8).[25]



As expected, it was found that the addition of benzoquinone derivative (in this case **11**) tremendously increases the selectivity of the process. The catalyst screening led to less obvious results. The best catalysts were found to be **Gru-II**, **Gre-II**, and **Carb-II**.[26] Despite structural similarities between the utilized catalysts (**Hov-II** and **Gru-II**, **Carb-II** and **Est-II**) the reaction outcomes varied



Scheme 6 Reactivity pathways of type I olefins.

Scheme 7 Isomerization problem.

Catalyst	Additive	Conversion (%)	Selectivity (%)

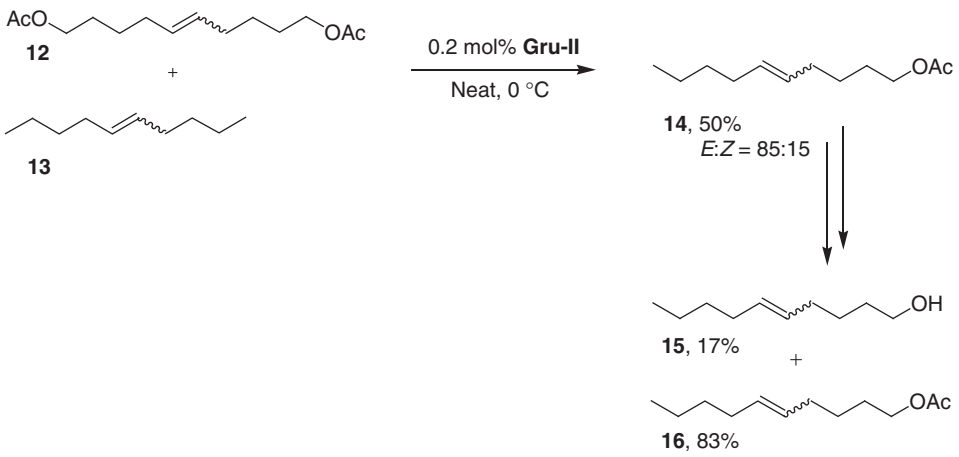
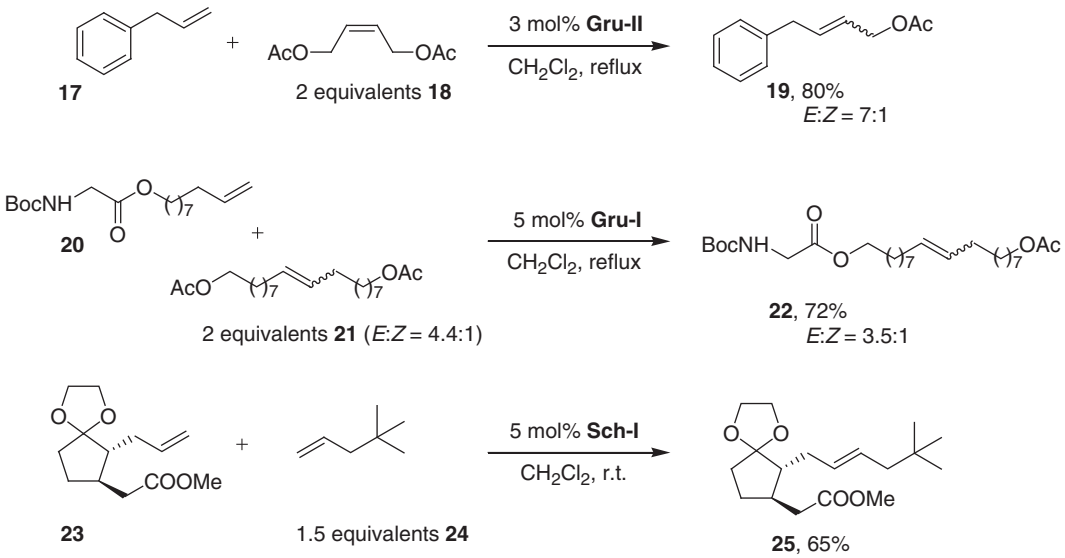
Hov-II	20 ppm **11**	35	98
Gre-II	20 ppm **11**	51	98
Ind-II	20 ppm **11**	83	82
Carb-II	20 ppm **11**	53	98
Est-II	20 ppm **11**	21	99



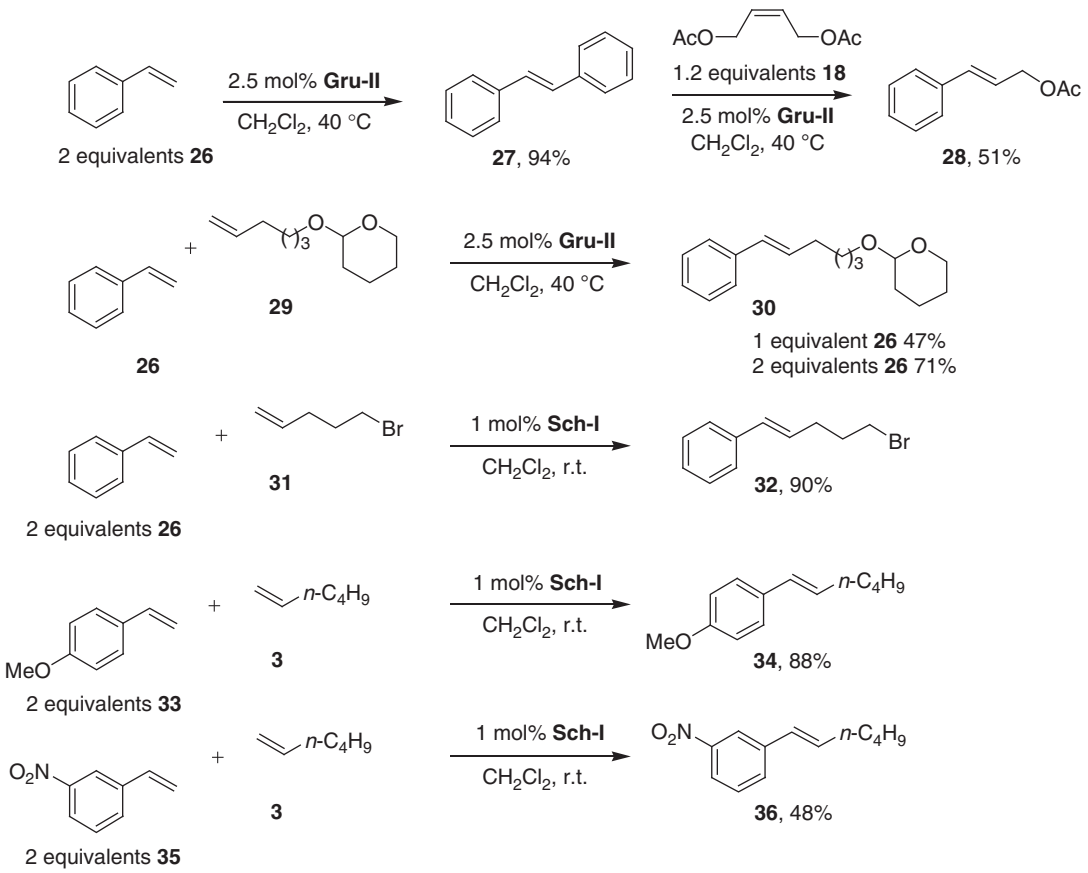
11

Scheme 8 Utilization of quinones in S-CM.



highly, suggesting an electronic effect as the cause of the observed differences. The study also pointed out that another method of increasing the conversion was the efficient removal of ethylene.

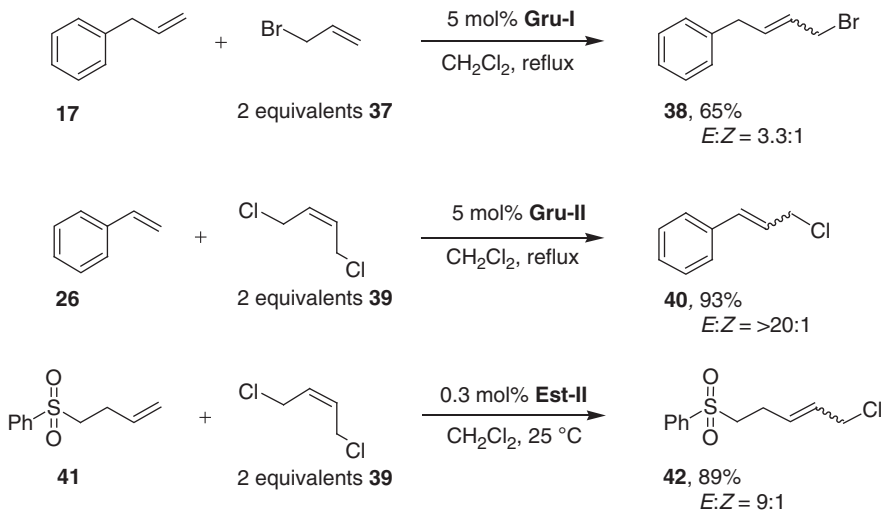
The solvent-free CM of **12** and **13** represents an example of the use of two different type I olefins to obtain a commercially relevant product (Scheme 9). Product **14** is readily converted into a pheromone of the peach twig borer moth (mixture of **15** and **16**), which can be used as an environmentally friendly alternative to classical pesticides.[27] In an attempt to design a more cost-effective process, the symmetrical internal olefins **12** and **13** (individually derived from S-CM of the corresponding α-olefins) were equilibrated by CM in the presence of 0.2 mol% of the second-generation Grubbs catalyst. The product was separated by distillation and the starting materials were recycled. The reaction was conducted at 0 °C to minimize unwanted C–C double-bond isomerization. Despite much slower ratios of the CM reaction at low temperatures, these conditions were found optimal as the separation of olefin isomerization byproducts formed at higher temperatures was problematic.[28,29]



Scheme 9 CM of type I olefins in a commercial application. Ac, acetyl.

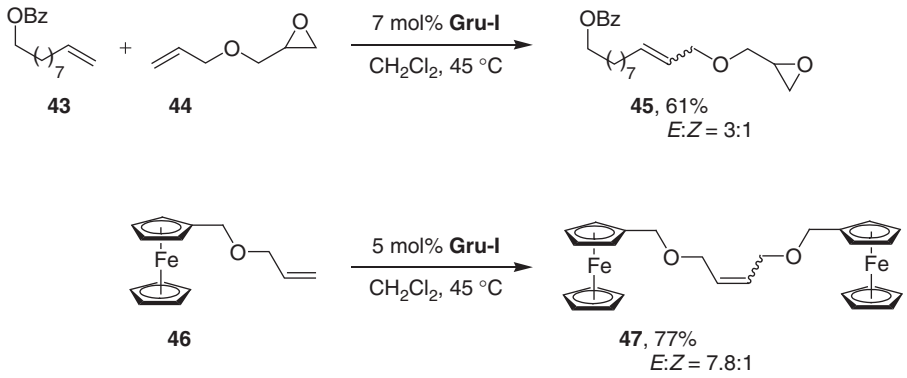
CM reactions involving type I olefins are widely reported in the literature, as this route represents an efficient means to generate valuable compounds starting from relatively inexpensive starting materials (Scheme 10).[22,23]

Scheme 10 Examples of CM involving type I olefins. Boc, *tert*-butoxycarbonyl; r.t., room temperature.



These examples demonstrate the applicability of CM for the synthesis of unsymmetrically substituted and functionalized olefins, where a broad variety of functional groups is tolerated. Further studies proved that styrenes that are not substituted in the *ortho* positions easily undergo S-CM in reactions promoted by **Gru-II**[19] (Scheme 11). Stilbene (**27**) obtained in this reaction reenters CM reactions with other type I olefins. This result clearly indicates that styrene is a type I olefin, at least if active catalysts

Scheme 11 Styrenes as type I partners.

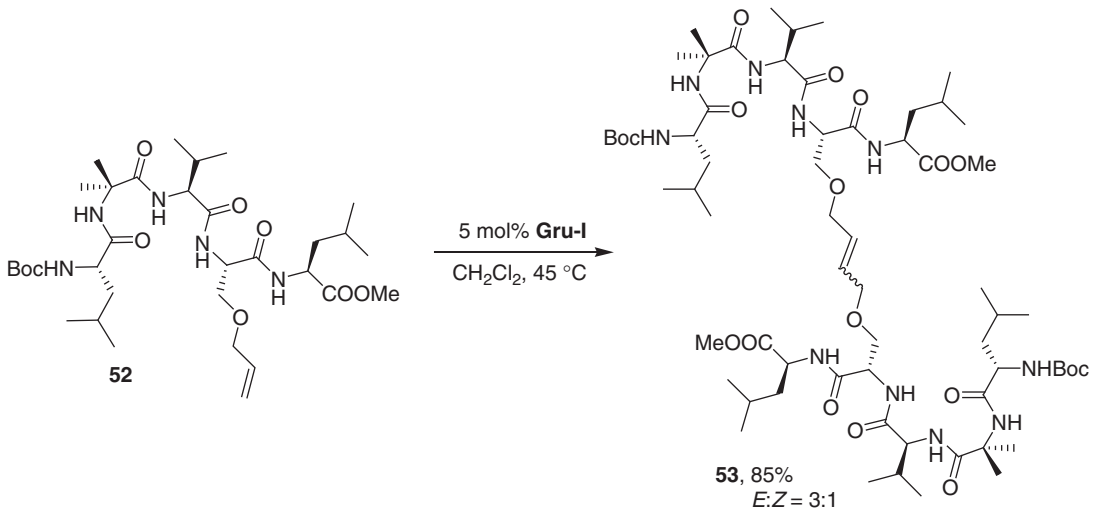


are used. A study concerning the utilization of the molybdenum catalyst **Sch-I** proved that, under properly selected conditions, CM involving styrenes can lead to a variety of synthetically valuable building blocks.[30]

Another class of easily dimerizing CM partners are allyl chlorides and bromides. The example of CM between allylbenzene, a type I olefin, and allyl bromide, promoted by **Gru-I**, was published by Castedo et al. (Scheme 12).[31] Further improvements in terms of yield were made by using the more active **Gru-II**,[32,33] **Hov-II**,[34] and finally **Est-II**[35] catalysts. It was noted that the internal alkene **39** can act as a convenient replacement for the more volatile allyl chloride. However, in the case of allyl fluorides and allyl iodides, the CM reactions are more challenging.

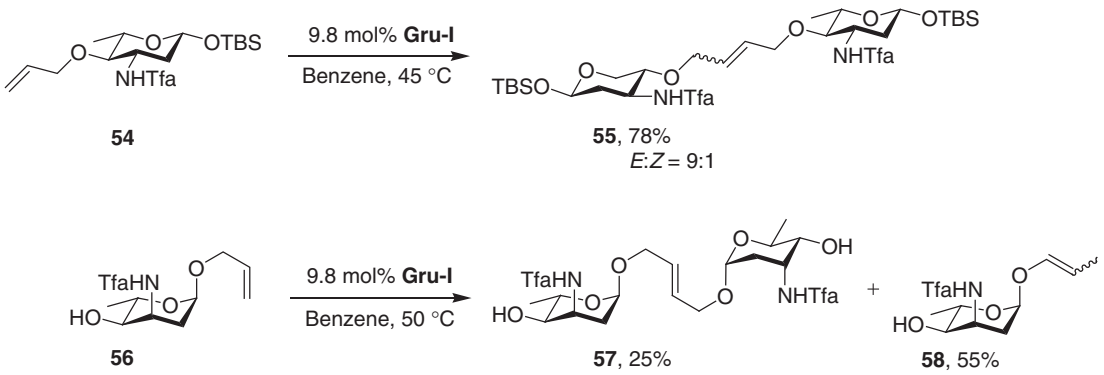
Scheme 12 CM reactions involving allyl halides and type I olefins.

Allylic ethers are another example of olefins efficiently employed in various CM reactions, as demonstrated by a large number of literature reports.[6d] For example, in a CM reaction of the allyl glycidyl ether **44** with benzoate **43**, the cross product **45** is formed in 61% yield (**Scheme 13**). Allylic ethers undergo S-CM easily, leading to useful products, like compound **47**, which was formed from 1-ferrocenecarbinol allyl ether.[22]

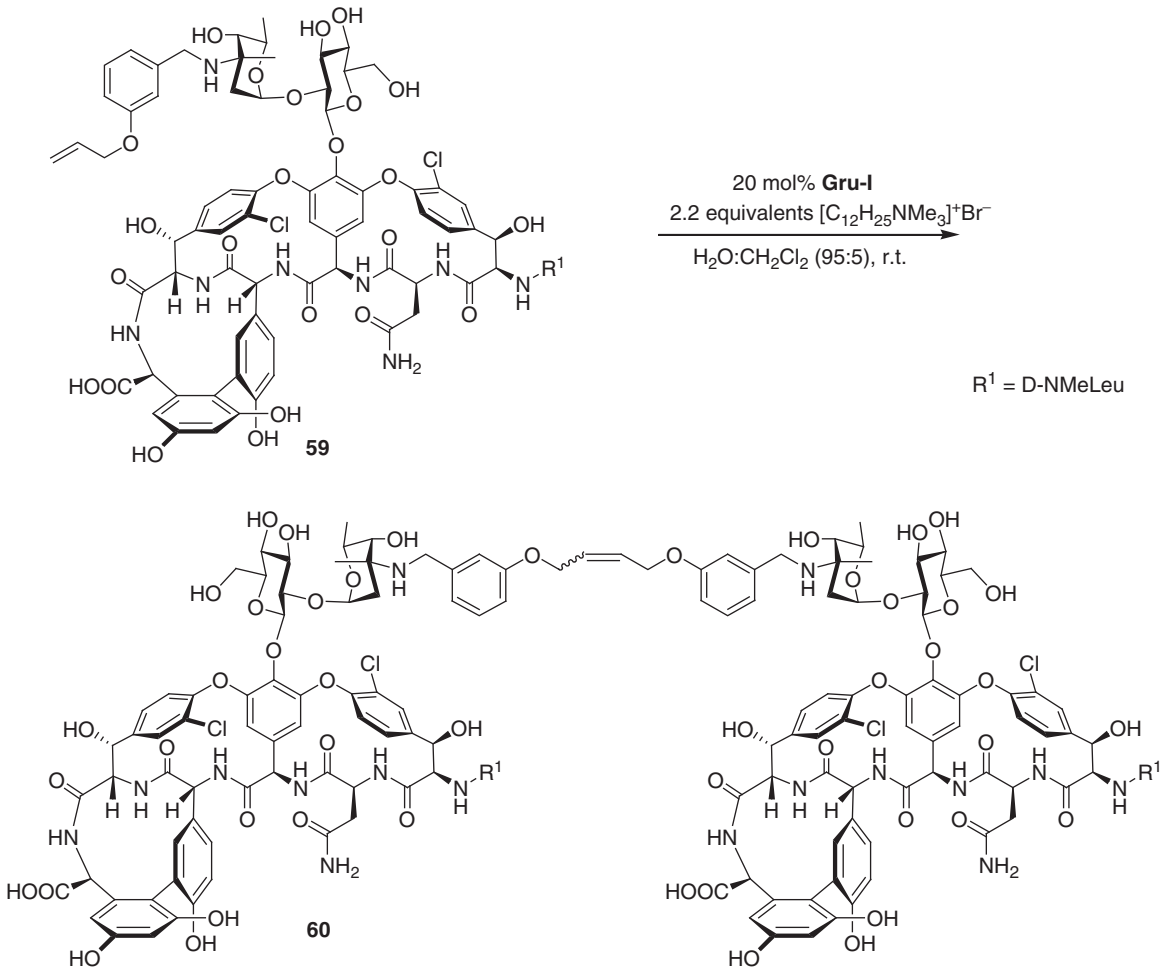


Scheme 13 CM of allylic ethers.

To modify the biological activity of amino acid derivatives and O-allylated peptides, various compounds of this class were subjected to S-CM. Grubbs reported on the synthesis of a series of amino acid and peptide homodimers (**Scheme 14**). O-allyl ethers of protected L-serine (**48**) and L-homoserine (**49**) derivatives, on treatment with **Gru-I**, afforded good yields of their respective homodimers with moderate *E*-selectivity (*E*:*Z* = 3:1). In some cases the self-metathesis was performed *in vacuo*, allowing for a more efficient removal of ethylene, thus shifting the reaction equilibrium to the right. In the presence of the ruthenium catalyst **Gru-I**, a pentapeptide **52** bearing an L-serine O-allyl ether fragment led to the side chain-bridged homodimer **53** in good yield, demonstrating the utility of the self-metathesis methodology for the synthesis of advanced peptidic architectures.[22]



Substrate	Product	*n*	Yield (%)	*E*:*Z*
48	**50**	1	73	2.6:1
49	**51**	2	75	2.7:1

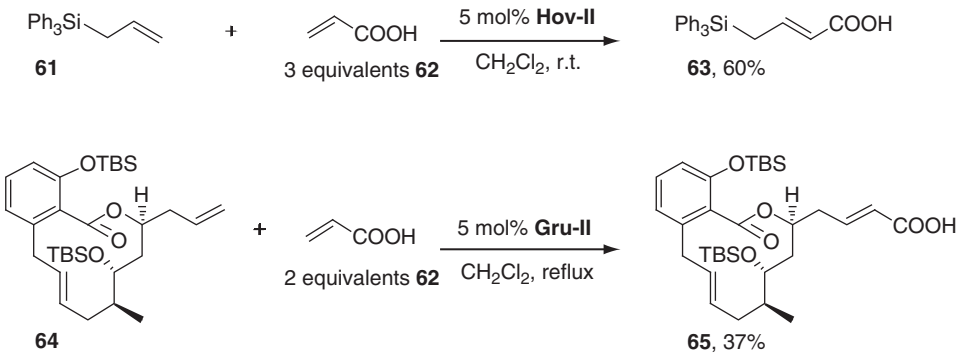


Scheme 14 Self-metathesis of amino acid derivatives.

The preparation of cyclic 1,4-butanediol-linked oligoaminodeoxysugars – potential binders to polynucleotides – was disclosed by Kirschning (Scheme 15).[36] Saccharide dimers, such as **55** and **57** were assembled by self-metathesis reaction of aminodeoxy monosaccharides. The resulting C_2-symmetric *E*:*Z* mixtures were further transformed into the targeted cyclic oligoaminodeoxysugars. The first-generation Grubbs catalyst **Gru-I** turned out to be the catalyst of choice for this reaction. In the case of allyl glycoside **56**, in addition to the expected product **57**, a byproduct **58** was formed that contained a shifted alkenic double bond.

Scheme 15 Dimerization of allylated saccharides. Tfa, trifluoroacetyl.

Another example of the synthetic utility of a metathetical dimerization of allylic ethers (and homoallylic ethers) was provided by Nicolaou and coworkers, who used this method to generate libraries of vancomycin dimers (Scheme 16).[37] It was found that



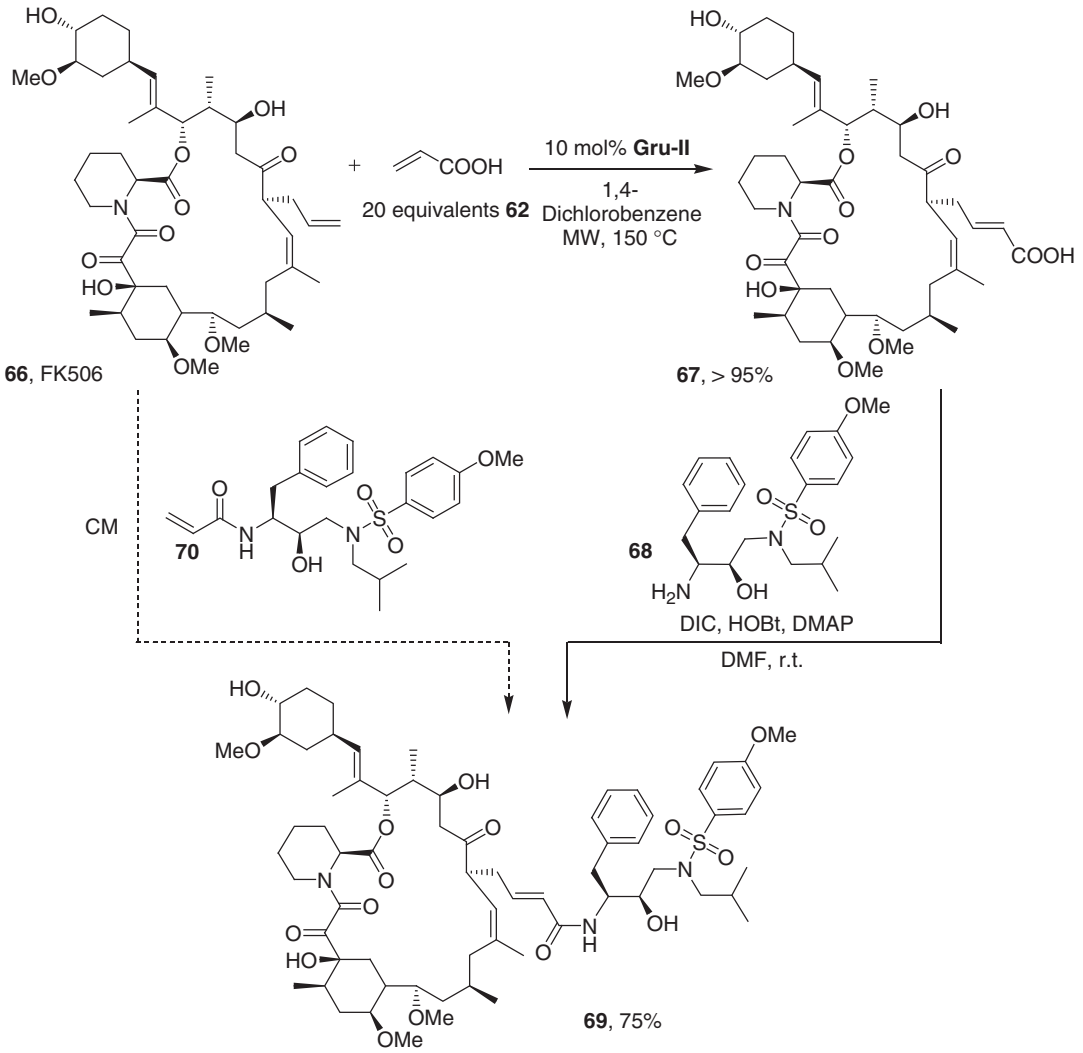
Scheme 16 S-CM of a vancomycin analog.

dimerization of the vancomycin derivative **59** catalyzed by **Gru-I** proceeds best in a heterogeneous mixture composed of water and methylene chloride (95:5 v/v) in the presence of $[C_{12}H_{25}NMe_3]Br$ as the phase transfer catalyst. Under such conditions, dimer **60** was cleanly obtained as the sole product.

The described examples of CM between type I partners prove that the method is particularly useful for the functionalization of advanced intermediates in the organic syntheses or the synthesis of diverse combinatorial libraries. This, along with the construction of dimeric molecules, affords compounds that can potentially exhibit modified biological activity and are therefore of interest for use in molecular biology.

5.26.2.1.2 CM between partners of type I and type II

Although CM of two 1-alkenes, belonging to type I, usually results in a statistical product distribution, the reactions between terminal alkenes and a variety of unsaturated compounds, such as α,β-unsaturated esters, amides, ketones, and nitriles, are usually characterized by excellent selectivity. In this case, according to the Grubbs classification,[19] substrates such as acrylic acid and its derivatives are type II olefins because they undergo homodimerization only to a small extent under typical reaction conditions and hence allow for selective crossing with 1-alkenes (type II + type I). Acrylic acid enters CM with olefins, leading to a number of useful building blocks like compound **63** (Scheme 17).[38] Direct CM of alkene **64** with the same partner was employed in the total synthesis of salicylihalamides A and B.[39]

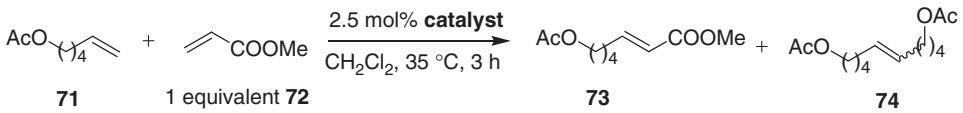


Scheme 17 Examples of CM with acrylic acid.

Under carefully optimized conditions, CM can be used to functionalize natural products in order to change their biological mode of action. Such modular assembly may lead to the formation of compounds that posses interesting biological properties. Using this approach, a powerful immunosuppressant FK506 (**66**), normally used to prevent allograft rejection in transplant patients was modified with an array of functional groups, including a carboxylic acid residue (Scheme 18).[40] Intermediate **67** formed in the CM reaction with acrylic acid was coupled with a core of the known human immunodeficiency virus (HIV) protease inhibitor **68** to produce a bifunctional molecule **69** that exhibits modified antiprotease activity.[40] It shall be noted that this two-step strategy (first CM and then coupling with amine **68**) seems to be much more efficient than a direct attaching of the whole HIV protease inhibitor fragment by a CM reaction with a hypothetical amide **70**. The use of a large excess (20 equivalents) of acrylic acid, required to obtain a good yield of the CM product **67**, is more convenient from the economy point of view as the unreacted acrylic acid can be much more easily removed from the reaction mixture by aqueous extraction than the much more expensive amide partner.

CM of methyl acrylate found utility not only in target-oriented synthesis but also as a tool for the comparison of the activity of various Ru-based catalysts. Grubbs et al. presented a model reaction of **72** and 5-hexenyl acetate (**71**), which is discussed in detail in Scheme 19.[41] Although the first-generation initiators do not catalyze this reaction to a synthetically useful extent, the NHC-based complexes show a much higher reactivity. According to the researchers, the following activity trend was observed within the series of NHC-based catalysts: **Gru-II** > **Hov-II** > **Gru-II′** ≫ **Gru-III**.[19] The only CM product observed is the *E*-isomer, presumably due to the strong preference to form the more stable *E*-configured unsaturated ester. It should be noted that the CM of methyl acrylate and terminal olefins promoted by activated Hoveyda catalyst analogs such as **Ble-II**[42] and **Gre-II**[43] is possible even at ambient temperatures; at elevated temperatures, however, practically all second-generation catalysts can be used, sometimes at much lower loadings.

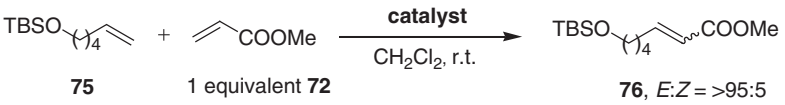
CM with acrylic acid esters was used in a number of syntheses, which renders this reaction a useful, predictable, and reliable method for the preparation of functionalized molecules, including indoles[44] and steroids (Scheme 20). CM of allylestrone **79** was optimized utilizing various catalysts, with **Gru-II** showing the best results.[45] Kalesse et al. used the CM with methyl acrylate to install the conjugated ester functionality for an intramolecular Michael addition *en route* to the synthesis of the ABC-ring system (**83**) present in hexacyclinic acid and other bioactive compounds.[46] Several metathesis catalysts have been screened in this transformation, and the Hoveyda-Grubbs second-generation catalyst **Hov-II** and its activated analog **Gre-II** were proved to be the



Scheme 18 CM in the modification of FK506. DIC, *N,N*′-diisopropylcarbodiimide; DMAP, 4-(*N,N*-dimethylamino)pyridine; HOBt, hydroxybenztriazole; MW, microwave irradiation.

most potent, leading to the formation of **82** in 80% yield. CM of the same allylestrone **79** with the acrylamide derivative **84** was also evaluated for the synthesis of a 17β-hydroxysteroid dehydrogenase-type 1 inhibitor **86** (Scheme 21).[45]

Grubbs et al. reported a study on CM reactions of various α,β-unsaturated amides with terminal olefins and styrene (Scheme 22).[47] Several unsaturated amide substrates were utilized and it was found that the CM efficiency is affected by the substituents on the amide nitrogen.



α,β-Unsaturated aldehydes were also proved to be excellent CM partners with terminal olefins. This method allows for an efficient one-step formation of functionalized α,β-unsaturated aldehydes like **95** under mild conditions (Scheme 23).[48] A sequence of three CM reactions, two with acrolein and one with ethyl acrylate, was very elegantly employed by Cossy and BouzBouz in the total synthesis of the C1–C14 fragment of Amphidinol 3 (**102**).[49] In each case the *E*:*Z*-selectivity of the CM step was better than 50:1. The second and the third CM events were fully chemoselective, as only the homoallylic terminal double bond (type I olefin) reacted and the internal C–C double bonds were inert under the applied conditions.

It is to be noted that the strongly odorous and rather unstable acrolein can be easily replaced in CM reactions with a more user-friendly crotonaldehyde (**104**). List and Michrowska reported an efficient, highly enantioselective and diastereoselective total synthesis of ricciocarpin A (**106**) utilizing this CM partner (Scheme 24).[50] Substrate **105** for the key transformation of the total synthesis – the one-pot, three-step organocatalytic, reductive Michael–Tischenko cascade – was easily obtained from **103** by a CM reaction. The CM reaction promoted by 10 mol% of the commercially available Grubbs second-generation catalyst in the presence of crotonaldehyde (**104**) led to the formation of aldehyde **105** with 84% yield. Again, the internal type III double bond of **103** was completely inert during the CM reaction with the α,β-unsaturated aldehyde, allowing for excellent chemoselectivity. With the more active catalyst **Gre-II** only 2 mol% loading was needed to obtain enal **105** in a 90% yield.

In addition to α,β-unsaturated esters, amides, and aldehydes, α,β-unsaturated ketones are also valuable and relatively easily reacting type II partners in CM transformations. The use of active second-generation Ru catalysts provides good yields in CM reactions between methyl vinyl ketone and type I olefins (Scheme 25).[42,44,48]

The CM with α,β-unsaturated ketones has been used in numerous target-oriented syntheses. Randl and Blechert reported an efficient enantioselective synthesis of (+)-carpamic acid **114**, with the key strategy based on a CM reaction between an α,β-unsaturated ketone and a terminal alkene.[51] Interestingly, it was found that the CM of ketone **112** and alkene **110** afforded the desired product **113** in rather unsatisfactory yields ($<60\%$) due to competing homodimerization of **110** as the major side reaction. When using the protected precursor **111** as the CM partner the homodimerization was almost completely suppressed. The authors suggest that the decreased tendency toward self-metathesis of **111** is related to the increased steric demand of the bulky trimethylsilyl (TMS) group. After applying this modification and utilizing 5 mol% of **Hov-II** as the catalyst, the CM product **113** could be obtained in good yield. The subsequent removal of the protecting group, cyclization, and saponification afforded (+)-carpamic acid **114** in good overall yields (Scheme 26). Using a similar strategy, xenovenine (**118**), indolizidine 209D (**122**), and other natural products were synthesized by the same group[52] (Scheme 27).

Protected and unprotected secondary allylic alcohols are another class of type II olefins, which give products in good yields and stereoselectivities in CM reactions with type I olefins. It should be noted that, depending on the substitution pattern at the allylic

position or bulkiness of the protecting group installed at allylic alcohol, these substrates can be sometimes classified as type III olefins (see the next section). Grubbs studied the CM of a number of protected and unprotected allylic alcohols (Scheme 28).[19] It was found that substrates of type II like **123** and **125** react with a number of type I olefins usually in good yields; however, excess of one of the CM partners is required.

An interesting example of a successful CM of the advanced polyfunctional substrate **127** bearing a β-substituted alkene fragment (type II olefin) with the internal olefin **128** (type I partner) was published by Barrett et al. *en route* to the biologically

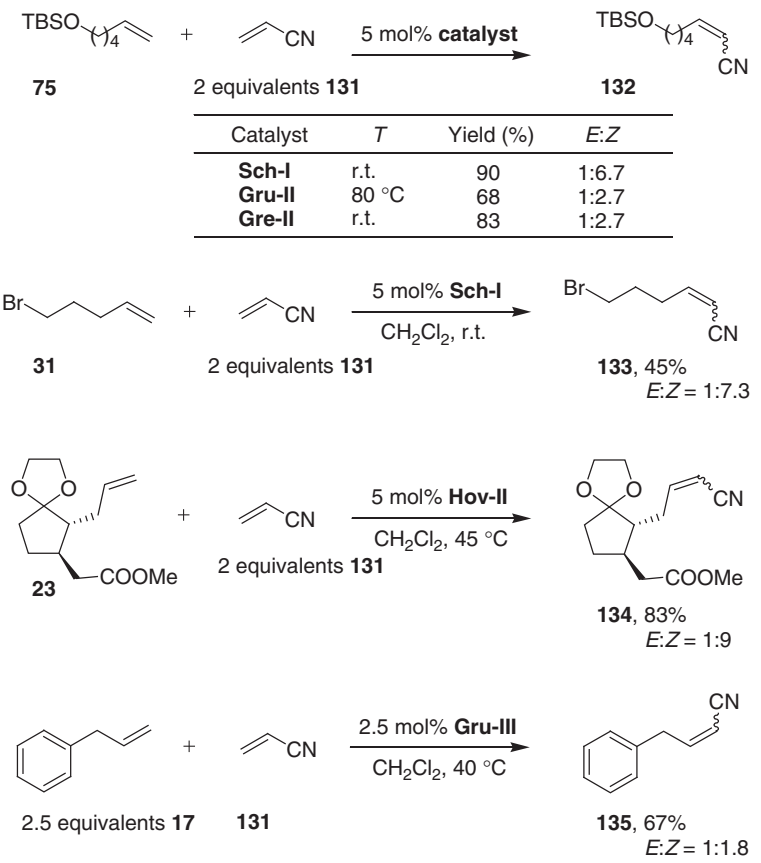
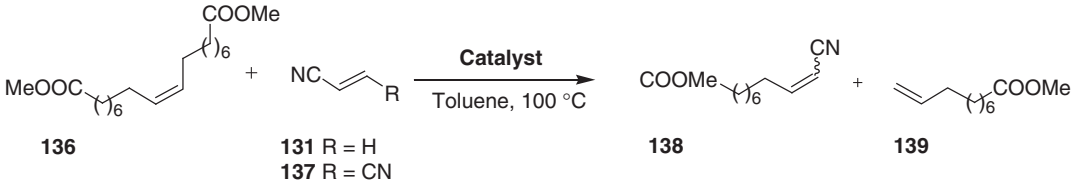
active viridiofungin derivatives (Scheme 29).[53] After selecting the best catalyst and a careful optimization of the reaction conditions, it was possible to obtain the expected CM product **129** in excellent yields (>95%) as determined by ^{1}H nuclear magnetic resonance (NMR). Unfortunately, extensive chromatography, which was required to remove ruthenium residues from the polar acid **129**, limited the isolated yield to only 57%.[53]



Scheme 29 CM leading to viridiofungin derivative 130. *t*Bu, *tert*-butyl.

Numerous reported results show that α,β-unsaturated compounds are valuable partners in CM reactions. Usually, the best results can be obtained when more active catalysts, like **Sch-I**, **Gru-II**, and especially phosphine-free catalysts (**Hov-II**, **Gre-II**), are used.[54]



5.26.2.1.3 CM involving partners of type III

Acrylonitrile (**131**) is usually regarded as a rather challenging CM partner, and as a type III olefin according to Grubbs' classification.[19] The CM reactions involving **131** have been successful with Schrock's arylimido molybdenum alkylidene catalyst **Sch-I**,[55] whereas within the Ru-family the best results were obtained with the ether-tethered derivative **Hov-II** (reaction with **23**)[56] and its activated nitro analog **Gre-II** (Scheme 30).[44] There are also literature reports that microwave irradiation combined with the Hoveyda-Grubbs catalyst **Hov-II** allows for an even more effective CM of acrylonitrile.[57] Phosphine-containing ruthenium catalysts, such as **Gru-II**, usually give slightly lower yields; however, addition of copper chloride as a phosphine scavenger is known to highly improve the results.[58] It was shown by Grubbs that the pyridine-containing catalyst **Gru-III** is a very effective catalyst in the CM of terminal olefins and acrylonitrile.[59] Actually, this catalyst was claimed to be the fastest initiator amongst the ruthenium-based catalysts studied. Independently, He et al. provided more examples showing the superiority of the third-generation Ru-catalysts in the CM reaction of acrylonitrile.[60]

The CM of fatty acids and esters, as renewable raw materials, with acrylonitrile **131** was presented by Bruneau and Dixneuf (Scheme 31).[61] Subsequent hydrogenation of the C=C and CN bonds in the metathesis products allows for the generation of linear amino acid monomers that are useful for the production of polyamides. Importantly, the authors were able to utilize fumaronitrile **137** instead of acrylonitrile (the latter is classified as type III olefin,[19] so its 'dimer' is inert in the metathesis process)

Scheme 30 CM of acrylonitrile.

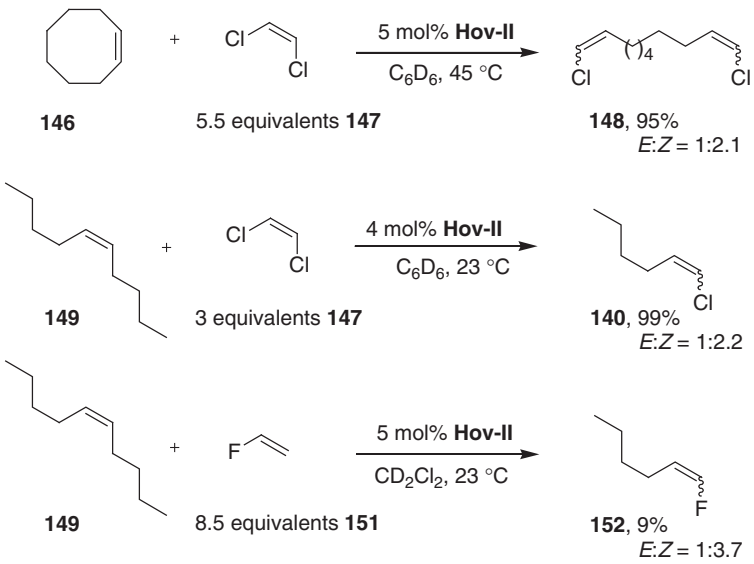
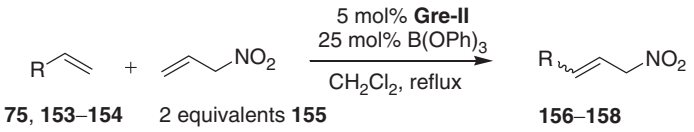
as a source of unsaturated nitrile entity in CM. Reaction of the internal olefin **136** and both nitrile sources led to an interesting result. In the examined cases, **Hov-II** catalyst gave the best results whereas the phosphine-containing catalysts **Gru-II** and **Ind-II** were less effective in this reaction. When utilizing **131** as the cross partner, the reaction led to a mixture of the expected product **138** and large amounts of monoester **139**. Application of fumaronitrile provided the main product with 50% conversion with a loading of only 1 mol% of the ruthenium complex **Hov-II**. When 5 mol% of the same catalyst was used, the conversion was estimated to be 97% leading to the isolation of **138** in 92% yield. The result shows that fumaronitrile, if treated with Hoveyda second-generation catalyst, is a valuable CM partner.[61]



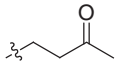
Alkenyl halides are key building blocks in numerous transition-metal-catalyzed syntheses, particularly in various Pd-catalyzed coupling reactions.[62] Unfortunately, it was reported that phosphine-containing Ru catalysts such as **Gru-II** fail to mediate CM of

vinyl halides.[63] On the contrary, CM of various type I alkenes with *E*-1,2-dichloroethylene **140** promoted by phosphine-free catalysts like **Gre-II** and **Est-II** led to the formation of the expected chloroalkenes in acceptable yields (Scheme 32).[64]

Scheme 32 CM with alkenyl halides.

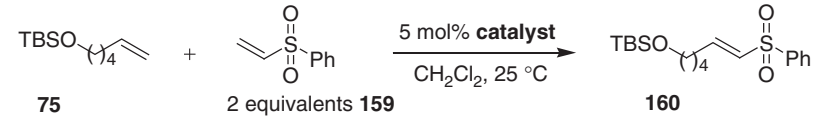


In the same work, Grela et al. studied the reaction of **142** and *E,Z*-1,2-dibromoethylene. The dibromide product, analogous to **143** can be formed, albeit in a much lower yield (34%). Application of *Z*-1,2-dichloroethylene **147** as a CM partner was also examined, but resulted in a decreased yield and selectivity of the product. At the same time, Johnson et al. reported a number of impressive examples of CM reactions promoted by **Hov-II** as the catalyst, such as ROM-CM of cyclooctene **146** and the CM of the internal olefin **149** (Scheme 33).[65] Unfortunately, the reaction with vinyl fluoride **151** was unsuccessful.



Scheme 33 CM with vinyl halides.

α,β-Unsaturated nitroalkenes are known to be reluctant in CM reactions (type IV olefins).[19] However, nonconjugated nitroolefins, such as 4-nitro-1-butene, 5-nitro-1-pentene and 6-nitro-1-hexene, are typical type I olefins that can be successfully used as partners in CM with olefins.[66] Interestingly, 3-nitropropene **155**, unlike the above-mentioned nitro-containing type I substrates, does not undergo self-metathesis, suggesting that β,γ-unsaturated nitro compounds should be classified as type III substrates in metathesis. CM of terminal alkenes with 3-nitropropene promoted by **Gre-II** in the presence of triphenyl borate leads to the formation of functionalized β,γ-nitroolefins in good yields (Scheme 34).[67] Substituted β,γ-nitroolefins are versatile



building blocks in organic synthesis, but unfortunately, they are relatively difficult to prepare via the conventional synthetic methods.[68] Therefore, catalytic CM seems to be a convenient alternative.[67]

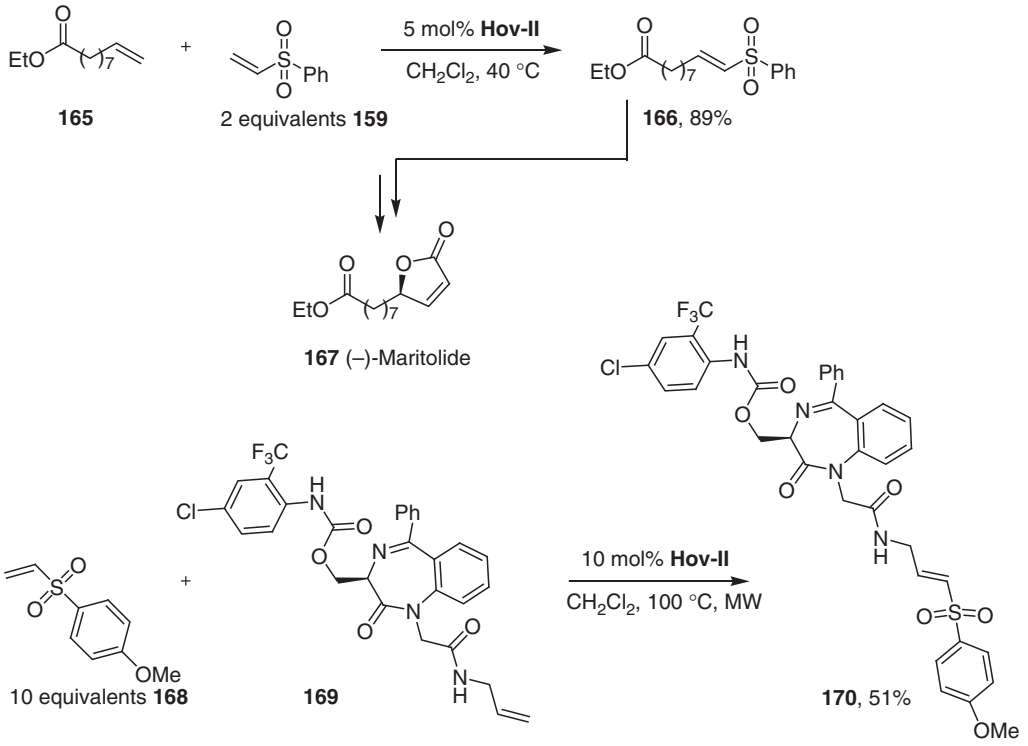
Another group of functional compounds useful as building blocks are α,β-unsaturated sulfones. These compounds can be transformed into versatile synthetic intermediates when utilized, for example, as Michael acceptors or as partners in cycloaddition reactions.[69] The ease of further transformations via elimination or either reductive or alkylative desulfonylation renders further advantages. Additionally, vinyl sulfones have recently been shown to potently inhibit a variety of enzymatic processes, providing unique opportunities for drug design and medicinal chemistry (a vinyl sulfone warhead).[70] Compatibility of remote sulfone function (type I olefins) with ruthenium and molybdenum-based metathesis catalysts is well established, thus CM is a well-suited method for their synthesis.[71,72] Although CM of β,γ-unsaturated sulfones (such as allyl phenyl sulfone) has been reported by Grubbs,[73] α,β-unsaturated sulfones (type III olefins) were considered challenging substrates in CM, even for the second-generation Ru catalysts.[74] Grela et al. have described CM of phenyl vinyl sulfone **159** as a simple *E*-selective method for the preparation of substituted unsaturated sulfones (**Scheme 35**). This reaction was catalyzed by the second-generation Grubbs' carbene **Gru-II**, leading to functionalized sulfones in good yields. Later, it was found that application of phosphine-free catalysts such as **Hov-II** and **Gre-II** can sometimes give slightly better yields.[75] Interestingly, in the case of divinyl sulfone **162**, it is possible to selectively

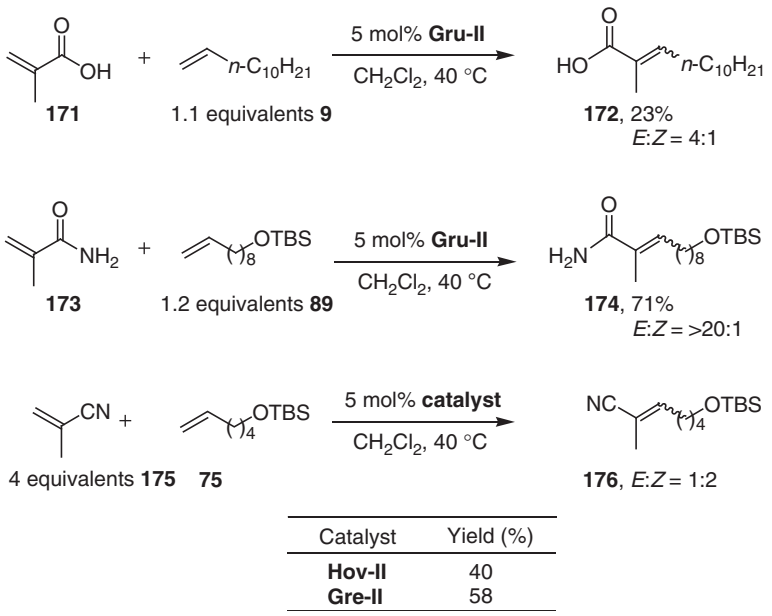


Catalyst	Yield (%)
Gru-II	68
Gre-II	86

Scheme 35 CM with vinyl sulfone partners.

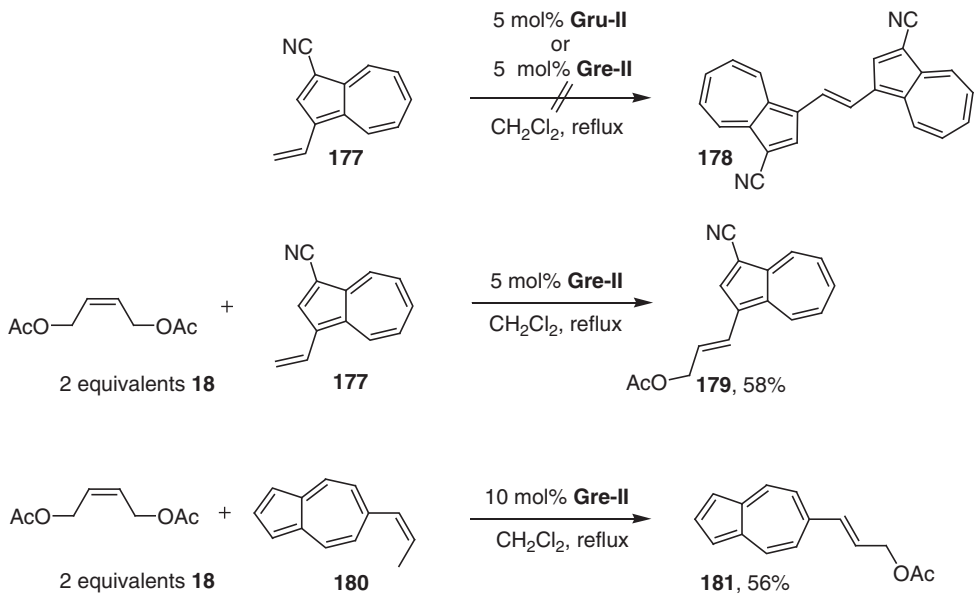
functionalize only one of the two vinyl groups present in this substrate.[76] Next, by repeating the CM event, the second vinyl group can be functionalized by CM, leading to asymmetrically substituted products, such as **164**, with no or only very little scrambling. This result revealed that the CM technology gives easy access to synthetically useful desymmetrized mono- or disubstituted divinyl sulfones with excellent *E*-selectivity under mild conditions.

Given the synthetic potential of sulfones as both Michael acceptors and substrates for cycloaddition reactions, these findings are of interest in organic synthesis, including the total synthesis of natural and biologically active compounds. For example, CM of alkene **165** with **159** led to the functionalized α,β-unsaturated sulfone **166**, which was then easily converted into the furanone natural product (–)-maritolide (Scheme 36).[77] Additional biological activity of vinyl sulfones is connected with covalent inhibition of falcipain-2 (FP-2), a cysteine protease isolated from *Plasmodium falciparum* – the most dangerous parasite species causing malaria. The parasitic cycle can be effectively stopped by irreversible addition of the thiol group of the active site Cys-25 to the electrophilic vinyl sulfone moiety, which behaves as a Michael acceptor. The CM-based synthesis of a new class of peptidomimetic cysteine protease inhibitors based on a 1,4-benzodiazepine scaffold decorated with a vinyl sulfone moiety was described by Ettari et al.[78] Studies on biological activity of compound **170** proved it to be a potent and selective inhibitor of FP-2, displaying antiplasmodial activity.[78] CM reactions involving α,β-unsaturated sulfones were also used for the preparation of quercus lactone,[77] swansonine,[79] myrioxazine A,[80] and other natural products.



Scheme 36 Vinyl sulfones in CM-based syntheses of biologically active compounds.

Although acrylic acid and its esters can be categorized as relatively reactive type II olefins, metacrylic acid and its esters are much less reactive, thus being type III olefins.[19] CM of type I partners with α-substituted α,β-unsaturated compounds and requires a careful selection of the catalyst to secure a satisfactory yield of the CM products (Scheme 37).[44] However, under optimized conditions this reaction can be very useful.

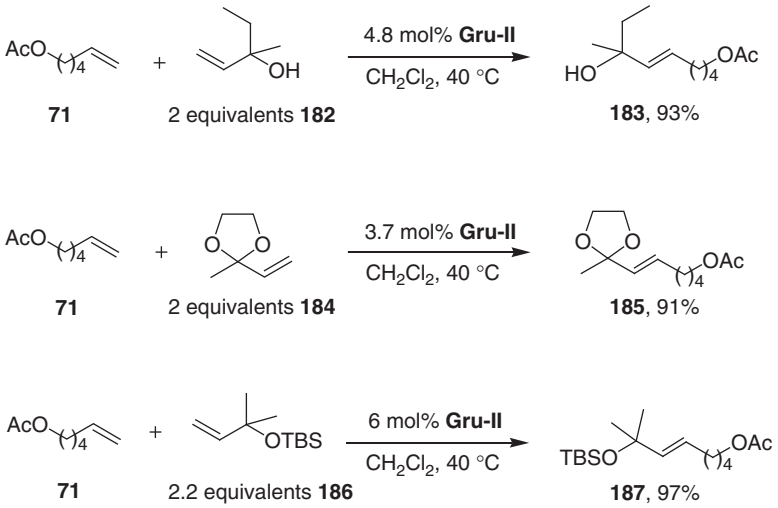


In contrast to non-*ortho*-substituted styrenes, which are type I olefins, vinyl azulenes do not undergo any homo metathesis reaction (Scheme 38).[81] Selected alkenyl-substituted azulenes were subjected to CM reactions with type I olefins to obtain valuable azulene-containing building blocks such as **179** and **181** under very mild conditions.

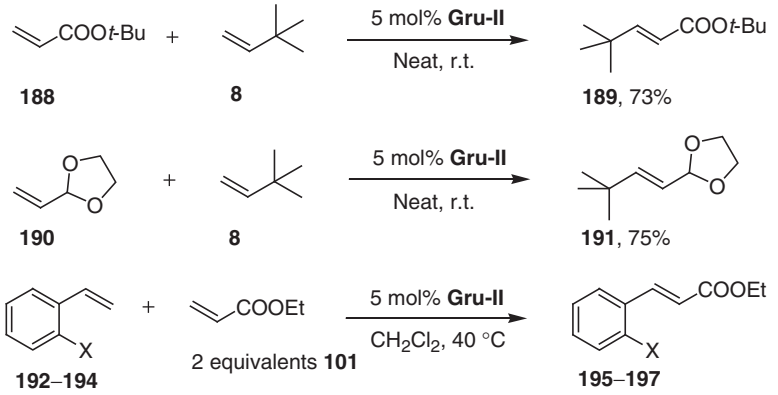
Grubbs noted that quaternary allylic olefins undergo CM reactions promoted by highly active **Gru-II** with excellent stereoselectivity, leading to the formation of *E*-configured products in good yields (Scheme 39).[19] According to Grubbs, these reactions are the first example of exclusive olefin *E*-selectivity in CM, based solely on the sterics of the alkyl substituents. For example, the unprotected (**182**) and protected tertiary alcohol (**186**) provide excellent yields of the CM products with only the *E*-isomer being observed by ^{1}H NMR. The steric bulk of the tertiary allylic substrates hinders their homo CM in most cases; therefore, these substrates can be classified as type III olefins. Moreover, in the case of **184** no dimerization was observed, allowing for a greater CM product selectivity. It should be noted that these substrates are usually inert in the presence of the first-generation catalysts such as **Gru-I**.[22]

Catalyst	Yield (%)
Hov-II	40
Gre-II	58

Scheme 37 CM with α-substituted α,β-unsaturated compounds.



Scheme 38 CM of vinyl azulenes.



CM reactions involving type III olefins are extremely useful in organic synthesis as they provide highly functionalized building blocks for the preparation of complex molecules. The possibility of attaching highly substituted fragments at a C–C double bond in a stereodefined manner and perspectives of further modification make these reactions a valuable tool for organic synthesis.

5.26.2.1.4 CM reactions involving type II and type III olefins

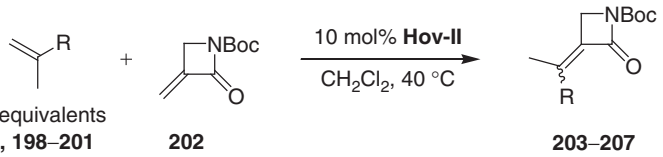
Selective CM of type II with type III olefins, despite being challenging, are generally very selective, as both partners hardly homodimerize. This leads to the formation of CM products in high yields. However, given the low reactivity of some type III olefins, reduced yields may be obtained, especially when nonoptimal catalysts and conditions are used. Sometimes, excess of the less reactive olefin should be used to achieve good conversions. Usually, the excess of the CM partner can be easily separated from the expected product. For example, neat 3,3-dimethyl-1-butene **8** was successfully used by Grubbs in the CM with various type II olefins (Scheme 40).[19] In the same work, Grubbs et al. investigated the CM of *o*-substituted styrenes with a variety of nontype I olefins such as acrylates. Smaller *ortho*-substituents did not reduce the reactivity of a styrene (for example **192**) with acrylates;

Scheme 39 CM of quaternary allylic olefins.

Substrate	Product	X	Yield (%)
192	**195**	F	72
193	**196**	Cl	62
194	**197**	Br	49

Scheme 40 CM between type II and type III olefins.

however, when electron-withdrawing functionalities[19] or bulky ones (**193** and **194**) were present at the *ortho*-position, the CM yields fell dramatically due to the low reactivity of both the partners even with a reactive catalyst such as **Gru-II**.



Howell et al. reported the CM of terminal alkenes with the β-lactam **202** to obtain the tetrasubstituted unsaturated β-lactams **203–207** in a surprisingly high yield (Scheme 41).[82] A range of types I–III olefins were utilized as partners in CM catalyzed by **Hov-II**, resulting in numerous α-alkylidene-β-lactams. However, the methodology seems to have a disadvantage: substrates with any α-branching completely prevented the reaction. Nevertheless, these results are the first example of the formation of tetrasubstituted alkenes by a CM reaction.

CM of type II with type III olefins is not as well developed as the variants described before. This is mainly due to the additional difficulties such as a diminished reactivity of the substrates. Taking into consideration the constant introduction of catalysts of enhanced activity and selectivity, further development in the field is predicted.

5.26.2.2 Recent Achievements in *Z*-Selectivity Control

One of a few unsolved problems in CM is the lack of stereocontrol of the formed product. Although some fully *Z*- or *E*-selective CM reactions have been reported, mixtures of *E*- and *Z*-isomers have been obtained in less lucky cases. Many bulky olefins or

α,β-unsaturated substrates give predominantly *E*-configured products in CM, but selective access to the corresponding *Z*-olefins is limited in most cases. This constitutes a significant drawback in target-oriented synthesis, preparation of specialty polymers, as well as in other fields where metathesis can be used. For this and other reasons, increasing attention is being focused on the development of *Z*-selective catalysts for olefin metathesis.

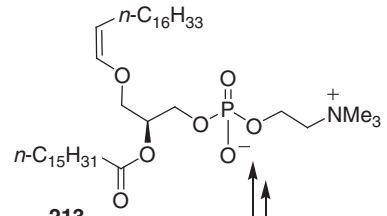

Scheme 41 CM reactions of lactams.

During a study directed toward the development of efficient *Z*-selective CM reactions, Schrock and Hoveyda utilized the stereogenic-at-Mo alkylidenes **Mo-IV** (see Scheme 3) that were recently developed to promote enantioselective RCM.[16e] These complexes were found to promote CM of enol ethers, a class of substrates for which a CM reaction has not been previously reported (Scheme 42). Although the Ru-complex **Hov-II** was ineffective in this transformation, the Mo-based complex **Sch-I** gave very good conversion in a model CM reaction, but with no *Z*-selectivity. Finally, it was found that stereogenic-at-Mo complexes, such as **Mo-IVb** and **Mo-IVd**, promote this reaction in a fully stereoselective way, leading to the disubstituted enol ether **209** in 98% *Z*-selectivity and up to 73% yield. The same authors demonstrated the utility of the catalytic *Z*-selective CM by using it as a key step in a diastereoselective synthesis of an antioxidant plasmalogen phospholipid, C18 (plasm)-16:0 (PC) **213**. As enol ether

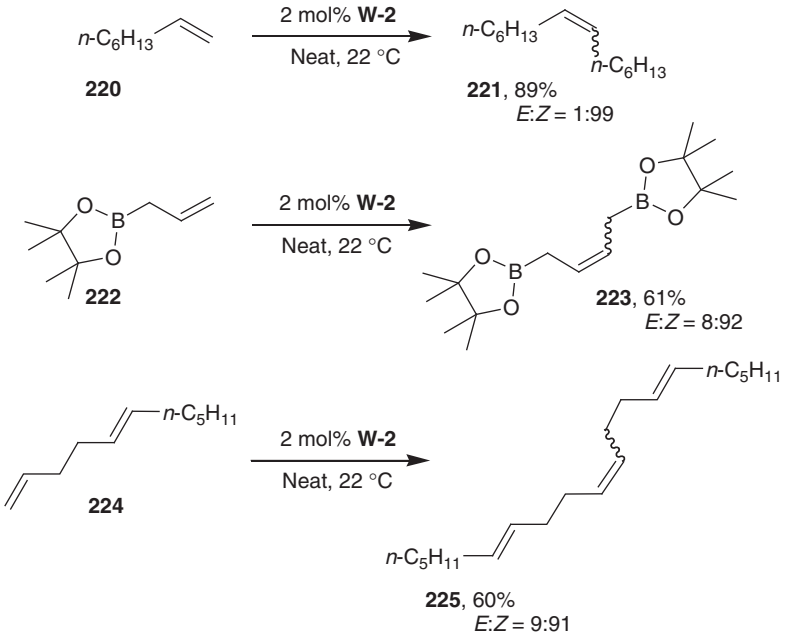
Scheme 42 *Z*-Selective CM of enol ethers with Mo-catalysts.

210 is more difficult to obtain and thus more valuable than the commercially available cheap 1-octadecene **211**, the researchers opted to use an excess of the latter to assure good conversion and chemoselectivity of the process. Unfortunately, increasing the amount of **211** was found to have a diminishing effect on the observed *Z*-selectivity. This was related to the increased ethylene generation from a competing S-CM of **211**. According to the authors, ethylene causes diminished stereoselectivity by increasing the concentration of the Mo-methylidene, which promotes isomerization. To attenuate the negative effect of ethylene, the CM was performed under vacuum. Under such conditions, an efficient CM reaction was made possible with only a relatively slight excess of the aliphatic alkene. It led to the disubstituted enol ether **212**, obtained with 97% selectivity, which was in turn converted to C18 (plasm)-16:0 (PC) **213** in a small number of steps.

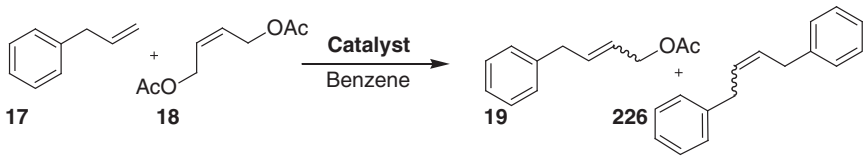
Another class of CM reactions that can be conducted selectively with Mo alkylidenes is the transformation involving allylic amides as substrates.[16e] As a large number of biologically active molecules can be obtained from disubstituted alkenes bearing nitrogen at the allylic position, the synthesis of functionalized allylic amines is of great importance. As some allylic amides, such as **214**, can undergo S-CM (type II substrates), it can be difficult to control the chemoselectivity of the reaction (Scheme 43).[2] Preliminary investigations with enantiomerically pure allylic amide **214** and 1-hexadecene **215** indicated that the optimal catalyst is complex **Mo-IVb**, affording the desired *Z*-alkene in 88% yield and with 97% stereoselectivity. As stated before, mild vacuum should be used to assure good *Z*-selectivity of this process. It should be noted that the achiral Mo alkylidene **Sch-I** and the representative Ru-complex **Hov-II** furnish the *E*-isomers predominantly.



Catalyst	Yield (%)	*E*:*Z*
Mo-IVb	88	3:97
Sch-I	68	88:12
Hov-II	64	89:11

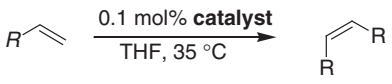
Scheme 43 *Z*-Selective CM involving allylic amides.

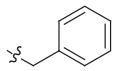
The *Z*-selective CM of allylic amides was also utilized in a stereoselective synthesis of the antitumor agent KRN7000 (**219**), thus underlining the utility of the method.[2] The key step – CM of the carbohydrate derivative **217** containing an allylic amide fragment with the terminal alkene **215** – gave a product **218** in 85% yield and with excellent (96%) *Z*-selectivity. Further transformations, such as diastereoselective dihydroxylation, esterification, and carbohydrate deprotection, gave the target molecule **219** in excellent overall yield.

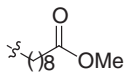


As shown in the previous examples, the MAP complexes are excellent catalysts in *Z*-selective CM. On the basis of the knowledge that tungsten appears to be superior to molybdenum for the *Z*-selective formation of olefins, Hoveyda et al. continued their research in that direction.[18] In fact, the tungsten complex **W2** described in their work allows for homocoupling of olefins with high *Z*-selectivity (Scheme 44). The authors state that the reaction rate and the conversion can be improved by performing the reaction in a neat substrate, whereas elevating the temperature leads to relatively low yields of the product as a consequence of

catalyst decomposition. S-CM of **224** seems to be a particularly interesting example because the resulting triolefin **225** was obtained in 60% yield as *E,Z,E*-isomer with excellent selectivity. It is worth noting that such a formation of a high percentage of a *Z*-homocoupled product in the presence of *E*-olefinic bonds elsewhere in the molecule was observed for the first time.







Scheme 44 *Z*-Selective CM with complex W-2.

In contrast to molybdenum- and tungsten-based catalysts, which have shown outstanding *Z*-selectivity in CM and S-CM (homocoupling) of terminal olefins, only a few ruthenium-based catalysts have been reported that show an enhanced *Z*-selectivity.[83] Their selectivity is still not satisfactory for precisely stereocontrolled syntheses. However, the recent development of catalysts bearing bidentate anionic ligands such as **Ru-V** and **Ru-VI** changed this situation. The outcome of the CM of **17** and **18** highly depends on the catalyst (Scheme 45).[84] The *Z*-selectivity is excellent in the reaction promoted by **Ru-V**. The authors

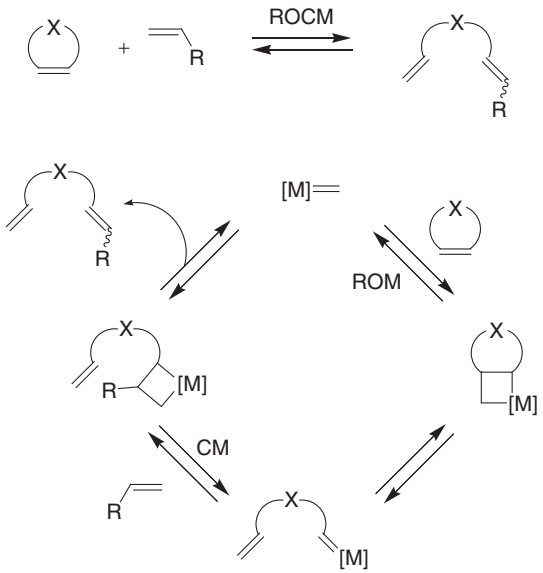
Scheme 45 *Z*-Selective CM with Ru-complexes.

presented a number of similar S-CM reactions of various terminal olefins using as catalyst **Ru-VI** bearing nitrato ligands, which proved to be superior in all cases. Notably, this complex was also able to 'dimerize' some more challenging substrates, such as unprotected alcohols, with excellent conversion and good *Z*-selectivity.

The scientific community witnessed an enormous development of CM over recent years. A variety of substrates considered impossible to metathesize were successfully utilized in CM reactions due to the introduction of new catalysts and conditions. Development of Ru, Mo, and W catalysts enabling selective CM transformations is expected to account for the progress in academic syntheses, where the stereoselective construction of *Z*-olefins is required. There is a great chance that this powerful methodology will be adapted by the chemical industry.

5.26.3 Tandem Metathesis



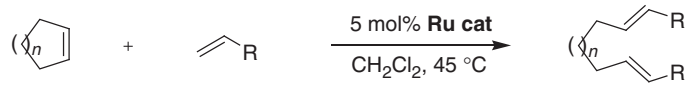
The utility of metathesis reactions is not limited to a single CM step. A double-bond generated in one reaction can serve as a substrate in another transformation, which also may be metathetic. Often such sequences are conducted in a one-pot manner and are called 'tandem metathesis.'

5.26.3.1 Two-Step Domino Metathesis

The simplest metathetic sequences are those consisting of two steps. Examples include ROCM, CM-RCM, or ring-opening/ring-closing sequences (ROM-RCM). In this chapter we will discuss only those that include at least one intermolecular step.

5.26.3.1.1 ROCM

ROCM is a tandem process involving an interchange between an endocyclic olefin and a double bond of an acyclic substrate. The mechanism of this transformation (Scheme 46) is very similar to that of CM discussed previously in Section 5.26.1.2. In the first step, the metal carbene reacts with the cyclic olefin to generate a metallacyclobutane, which after reversion reacts with the acyclic olefin. A second metallacyclobutane is formed and cleaved, resulting in a desired product and regeneration of the starting carbene.



Scheme 46 Mechanism of ROCM.

Contrary to most other types of metathesis, the ROM-CM sequence is in the majority of cases driven by the release of the ring strain energy (release of a volatile alkene is also an option, but usually it is enthalpically disfavored). Considering these mechanistic issues, it seems fairly obvious that the strained cyclic alkenes are the most common substrates. Table 3 summarizes the thermodynamic data for alkenes often utilized as ROCM substrates.[85]

For the ROCM sequence to be efficient, it has to proceed faster than the competing ROMP pathway. The crucial factors are the nature of cyclic olefins and high dilution conditions. In most cases, ROMP can be outperformed. Yet another risk is the possibility that the cross partner undergoes homodimerization. The mentioned problems can be solved by a careful substrate selection, which is absolutely crucial in tandem processes. Although most applications of ROCM include a strained substrate, successful attempts to metathesize unstained carbocycles were also published (Scheme 47).[86]

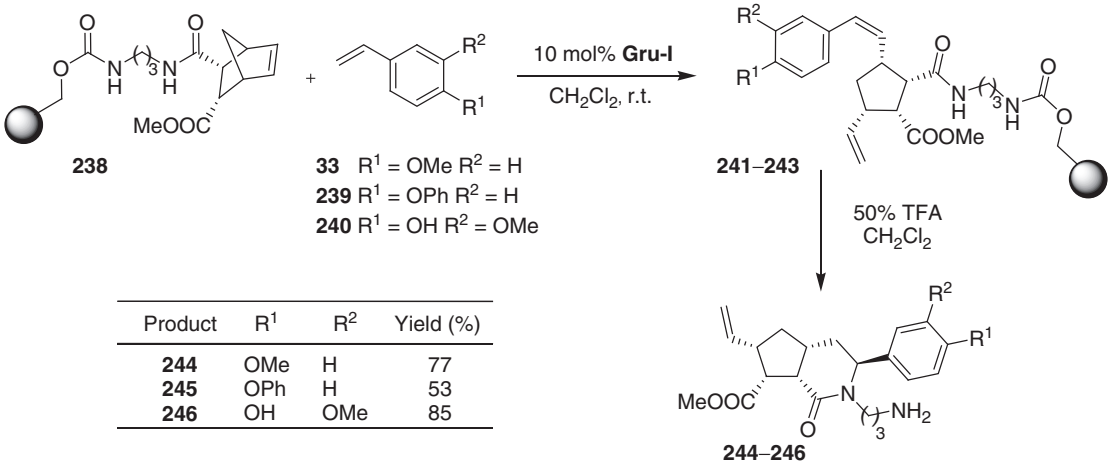
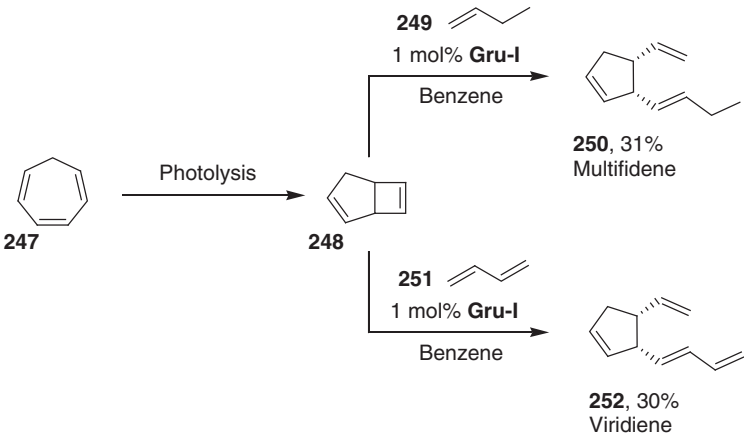
237	3	COOMe	80	97



Scheme 47 ROCM of unstrained carbocycles.

Modification of the ring size of the cyclic olefin proved that cycloheptene is a better substrate than cyclopentene, thus underlining the influence of the ring strain on the overall efficiency of the reaction. In all the examples presented in the study, the catalyst **Hov-II** was proven to be superior to **Gru-II**. The most interesting point is that all the products were obtained as *E*-isomers only, but one should note that this selectivity is largely substrate dependent. A mechanistic study by Arjona et al. considered interactions of a substrate bearing a small and a large substituent with ruthenium complexes (Scheme 48).[87]

Scheme 48 Reasons for the selectivity of ROCM.

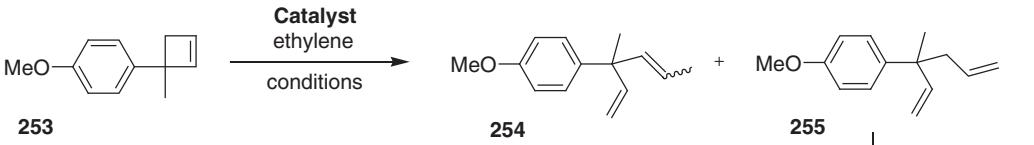


The selectivity can be derived either from the cycloaddition reaction or from the later CM reaction. If the difference between the large and the small substituent is significant, the steric factors affect largely the first stage of the reaction. In such cases, the addition is preferable from the side of the small substituent creating the more favorable metallacyclobutane. This causes the *Z*-isomer to be the major product. The understanding of the mechanism of the reaction was soon followed by methodology studies. Over the years attempts were made to establish a method of utilization of ROCM on solid support. Wang resin-bound norbornenes made that possible.[88] The developed protocol resulted in a variety of substituted cyclopentene-fused piperidinone rings (Scheme 49).

Product	R^1	R^2	Yield (%)
244	OMe	H	77
245	OPh	H	53
246	OH	OMe	85

Scheme 49 ROCM on solid support. TFA, trifluoroacetic acid.

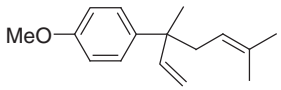
As the studies devoted to ROCM selectivity contributed to the development of knowledge on the subject, the first attempts of applications in target-oriented synthesis soon followed. Scheme 50 presents an example of the synthesis of pheromones of brown algae.[89] Although the results do not seem impressive at first glance, they can be considered to be a milestone in the synthesis of these compounds. Previous syntheses required more than nine steps to produce either compound in approximately 3–8% overall yield. This meant that the synthesis was shortened by 5 times and turned out to be more than 10 times as effective.



Scheme 50 ROCM in target-oriented synthesis.

Another application of ROCM is the synthesis of (±)-sporochnol,[90] which is isolated from the Caribbean marine alga *Sporochnus bolleanus*, presented in Scheme 51. During this synthesis various conditions were explored. The authors utilized catalysts of first- and second-generation. **Gru-I** gave poor results, allowing product formation only at a loading of 45 mol%. Switching to the second-generation catalyst, **Gru-II** led to improved results. Further variation of solvent, temperature, and catalyst loading allowed the synthesis to be completed with a satisfying result both in terms of yield and isomer ratio.

It is worthy of note that ROCM strategies have also been used in the synthesis of more sophisticated compounds. Furthermore, tandem metathesis processes are increasingly used in sequences with other reactions of significant synthetic potential. The synthesis of (+)-asteriscanolide[91] presented in Scheme 52 can serve as a great example. In this particular sequence, after the ROCM conditions were successfully applied, the reaction mixture was refluxed to allow for a Cope rearrangement of the product primarily formed. Thus, **258** is a product of a one-pot cascade synthesis obtained in more than reasonable yield.



The part devoted to two-step tandem metathesis consisted mainly of examples of the ROCM sequence, as it has been the most investigated, but there are also other possibilities including an intermolecular step, for example, CM followed by RCM (CM-RCM). One of the most important examples of its utilization was the synthesis of the cylindrocyclophanes[92] presented in Scheme 53.

The authors employed a variety of conditions in their synthetic attempts to discover that the Mo-based catalyst **Sch-I** gave the best result in this case. The CM-RCM strategy led to a noticeable increase in the overall yield of the (–)-cylindrocyclophane F synthesis; a previous pathway had required 20 steps with an overall yield of 8.3%, whereas the modified one containing the

metathesis tandem provided the product in only 11 steps with an overall yield of 22%. A noteworthy observation made by the authors was that when substrate **260** was metathesized, only **262** was observed, exclusively as the required *E*,*E*-isomer. The dimerization of compound **260** could lead to up to seven products when all possibilities are taken into account. As only one of those was observed, a conclusion was made that thermodynamic factors contribute largely to the course of the reaction. To prove that, an additional synthetic experiment was performed (Scheme 54).

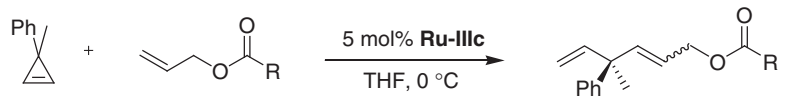
Scheme 54 Reversibility of CM as a synthetic approach.

The theoretical studies conducted revealed that the observed isomer possessed the lowest energy. Many other research studies had suggested that the reversibility issue leads to the formation of the most thermodynamically stable products. To obtain an experimental proof for this assumption, the authors designed and synthesized trienes **266** and **267**. It was assumed that during the RCM process, they would lead to the formation of an [8,6]-cyclophane. Despite the predispositions of the substrates to do so, the only product observed was the thermodynamically most stable [7,7]-cyclophane **262**. This experiment shows that this kind of tandem metathesis process is self-editing in order to reach the most stable of all possible isomers.

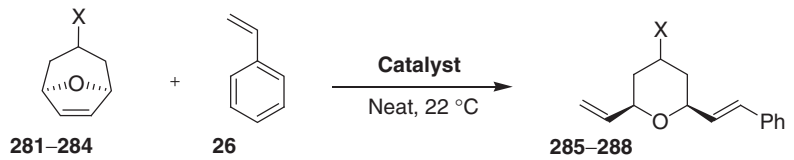
5.26.3.1.2 Asymmetric ROCM (AROCM)



The previous section was devoted to ROCM catalyzed by commercially available achiral complexes. The only means of inducing chirality was the utilization of a chiral substrate, resulting in a diastereoselective process. However, there has been an important improvement – introduction of chirality into the catalyst structure allowed metathesis to be taken to an entirely new level, as enantioselective transformations can now be considered (Scheme 55). With the chiral catalysts described in Section 5.26.1.3 in hand, one can utilize substrates with no chirality and install stereoinformation in an enantioselective metathetic process. One of the most investigated areas of this asymmetric metathesis is the ROM-CM sequence, which – in its asymmetric variant – is abbreviated as AROCM.

Scheme 55 Inducing chirality in metathesis.

Principles of AROCM are very similar to those of its achiral version. Thus, one of the first cases of its applications utilized a substituted cyclopropene compound as a strained alkene substrate.[93] Metathesis with unsaturated carbonyl compounds afforded the corresponding products that contained a quaternary carbon center (Scheme 56). It is worth noting that a wide variety of functional groups is well tolerated within the reaction. Functionalities such as trisubstituted cyclic alkenes, terminal alkenes, or alkynes are compatible and the resulting products are formed with outstanding enantioselectivities. Since the structures of the obtained products allow further functionalization, they are valuable starting points for the synthesis of sophisticated compounds. The noticeable drawback of this method is that in all cases of diene cross partners some amounts of lactone were formed by RCM.



Cyclopropene was not the only strained ring utilized in such reactions. Substituted oxabicycles are often utilized in synthesis, giving access to a range of tetrahydropyrans presented in Scheme 57.[94] The data also allow for a comparison of the chiral ruthenium catalysts. The general conclusion that can be drawn is that in most cases the complex Ru-IIIc is more reactive than Ru-IVc, whereas the enantioselectivity of the products seems to be on a similar level. Further research on catalyst behavior was conducted in AROCM reactions of anhydrides and protected diols (Scheme 58).[95] The study utilized both aromatic and aliphatic

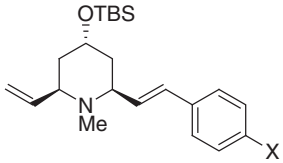
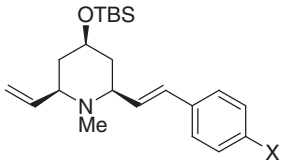
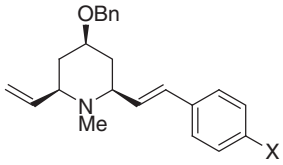
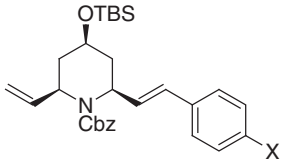


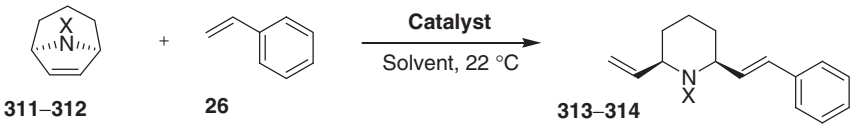






Scheme 58 Ruthenium-catalyzed AROCM reactions.

AROCM studies did not focus on ruthenium-catalyzed reactions only. Molybdenum-based chiral catalysts were utilized in the syntheses of substituted piperidines presented in Scheme 59.[96] The catalyst promotes the reaction effectively, although the level of success depends on the steric and electronic factors of the substrates. Reaction with the electron-rich styrene **3** proceeds faster and in a more enantioselective manner. The nitrogen protective group does not seem to affect the efficiency of the transformation. The same research attempted to compare the behavior of Ru- and Mo-based complexes in piperidine synthesis. The results are summarized in Scheme 60.



In the cases presented in Scheme 60, **Mo-I** is superior in efficiency. In the discussed examples, the metal catalysts exhibit an opposite enantioinduction, thus constituting a complementary approach for the synthesis of chiral compounds (negative values of enantiomeric excess (*ee*) represent products of opposite configuration). Ruthenium-based complexes seem to catalyze only the reaction of the azabicyclic substrates lacking a C4 substituent; in the other cases, the conversion is rather poor for steric reasons. Further comparison of the catalytic abilities of different catalysts was conducted in metathesis reactions of enol ethers presented in Scheme 61.[97] The only examined ruthenium complex (**Hov-II**) gave poor results despite acceptable conversions, which might be due to a competing oligomerization pathway in this case. This is further proven by an even lower yield in case of metathesis with a more sterically demanding substrate **208**. The Ru-catalyzed reaction was moderately *E*-selective, whereas in the same example **Sch-I** provided both the isomers in equal ratios. When stereogenic-at-Mo complexes were applied, the *Z*-selectivity improved noticeably. In all cases, the reaction tended to proceed less enantioselectively when the cross partner **316** was utilized. This may stem from an increased steric hindrance when compared with **208**. All **Mo-IV** catalysts in the study were obtained *in situ* from the same amount of precursors. This leads to the conclusion that, when bigger halogen substituents in the complex structure were utilized, the catalysts are generated more efficiently. The mentioned exchange seems to have little or no effect on the outcome of the reaction. Thus, considering the preparative pathway, catalyst **Mo-IVb** was selected for further tests in the AROCM of carbocyclic compounds and enol ethers (Scheme 62).

Higher enantioselectivities were observed with a cyclopropene substrate. The significantly lower enantiomeric ratio (*er*) for the benzyl-protected substrate **320** can be explained by the elevated temperature required for its transformation. Generally, the benzyl

protection was found to be an obstacle during the reaction. Its smaller size (compared with the *tert*-butyldimethylsilyl (TBS) group) did not turn out to be beneficial, as it might allow for chelation between the substrate and the Mo-catalyst. Interestingly, a tendency to give higher enantioselectivities was noticed for certain cyclic compounds, when a larger excess of vinyl ether was utilized. What seems peculiar is that increasing the amount of the acyclic partner did not alter the *Z*-selectivity in any of the examined cases.

Although AROCM is a relatively new research area, it has immediately gained attention in the context of possible applications. One of the most recent examples is its application in the total synthesis of baconipyrone presented in Scheme 63.[98] The different catalysts employed in the study gave similar results. Generating 2 mol% of **Ru-IIIc** *in situ* noticeably improved the yield of **287**

(64%, 89% *ee*). The described case proves that there is room for further improvements of the efficiency of metathetic steps by application of *in-situ*-generated catalysts. In spite of that, AROCM is already a valuable source of optically enriched compounds that can be accessed by significantly shortened pathways. Mo- and Ru-based chiral catalysts have been developed, which let the field flourish. The former provide better reaction outcomes, but the latter are tolerant toward a wider substrate scope. Further development is to be expected as ever more new chiral complexes are introduced.

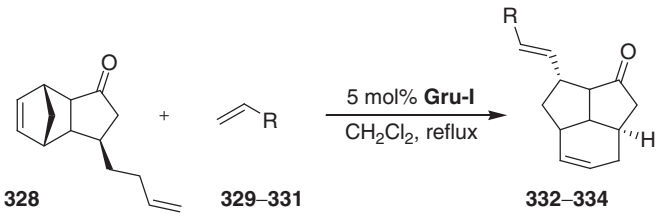
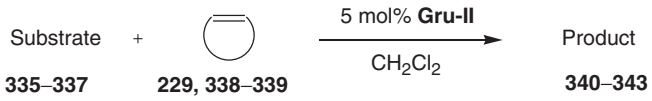
5.26.3.2 Transformations Involving Several Metathesis Steps

In the previous paragraphs, only two-step sequences of metathesis were discussed. However, this is not the only possibility, as cascade reactions can consist of more metathetic steps. The most common way of utilizing such transformations is ring-rearrangement metathesis known as RRM.[99] The general concepts of this transformation are presented in Scheme 64, but it should be noted that only those examples that possess at least one intermolecular step are described here.

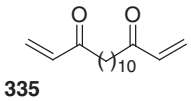


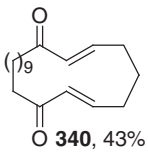
Scheme 64 General principle of RRM.

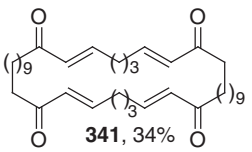
The RRM processes have the same features as the single metathesis reaction steps that are combined. Thus the driving forces are the same – release of ring strain or the formation of a volatile alkene. The most important feature of RRM is the preservation of stereochemical information contained in the substrate and its transfer to the product, which seems to be particularly important for applications of RRM processes in the synthesis of biologically active molecules, being often fused carbo- or heterocycles. An interesting example of fused-ring synthesis by means of RRM was presented by Prunet et al. (Scheme 65).[100]

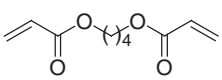


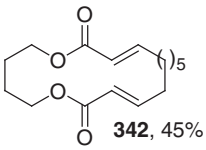
The authors examined the formation of tricyclic frameworks by a ROM-RCM-CM sequence. In all cases the result of the intermolecular step was an *E*-olefin only. Surprisingly, the reaction proceeded more efficiently when a substituted olefin was utilized as the cross partner instead of ethylene. In contrast to the other substrates, ethylene is a gas and as such cannot favor the domino process over competing polymerization. Attempts were made not only to form cyclic products but also to utilize cyclic substrates in ring-expansion reactions. A study containing applications of a ROM-CM-RCM sequence is presented in Scheme 66.[101] Modification of either substrate enables the size and substitution pattern of the resulting product to be adjusted, which leads to a powerful strategy for macrocycle formation. The conducted research proved that a number of factors such as the substitution of the acyclic substrate and the ring size of the cyclic one affect the product formation. The effect of concentration on product distribution was also investigated.

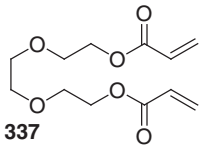


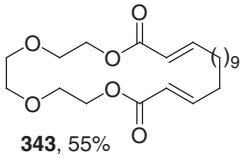












In several synthetic applications selectivity of the reaction is a major issue. This seems to be a problem especially when the intermolecular step of the sequence may take part in more than one place (Scheme 67).[102] In the presented ROM-ene-yne-RCM-CM sequence, substituted cyclopentene derivatives were targeted. The authors obtained olefin **346** as the expected product of

Substrate	Product	R	Yield (%)

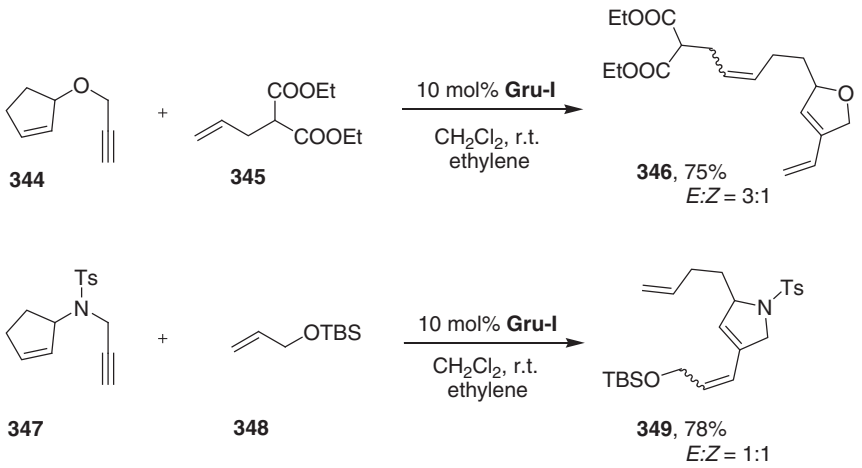
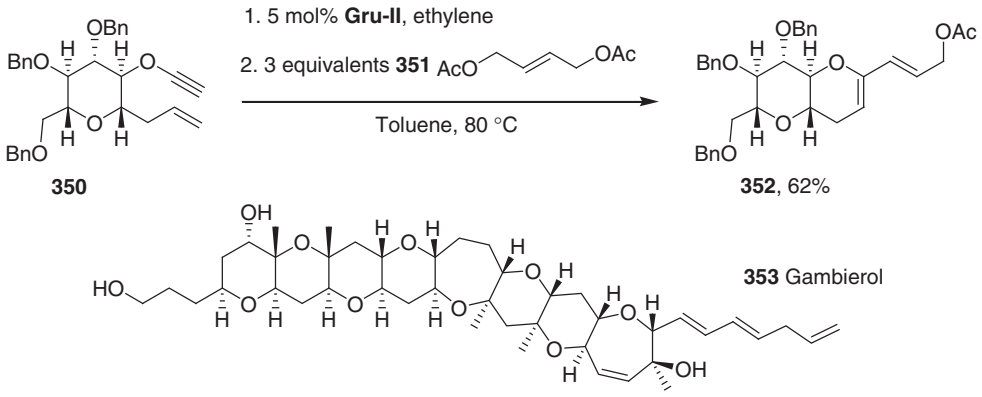
 **337**	**339** 12	5 mM	 **343**, 55%	



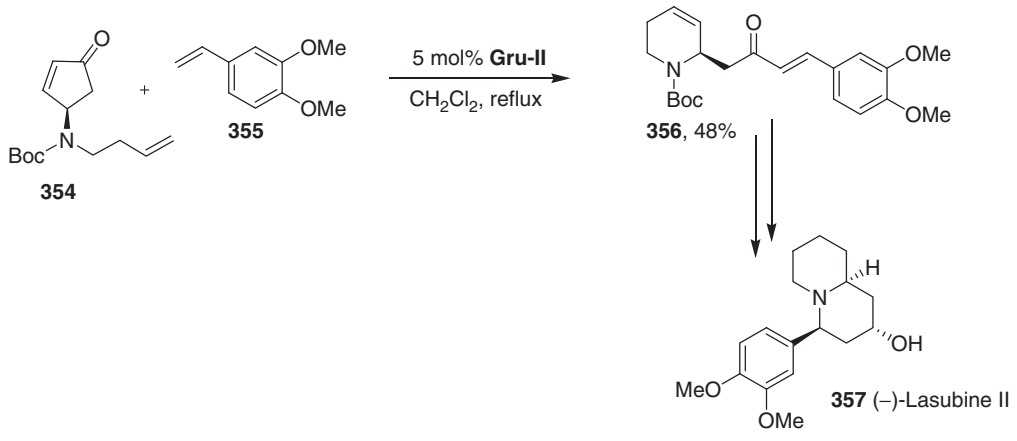
Scheme 66 Ring expansion by a ROM-CM-RCM sequence.

RRM. Surprisingly, the analogous transformation of substrates **347** and **348** led to another outcome. This regioselectivity may probably be explained by electronic or steric effects of the particular substrate pair, but the mechanism is still unknown.



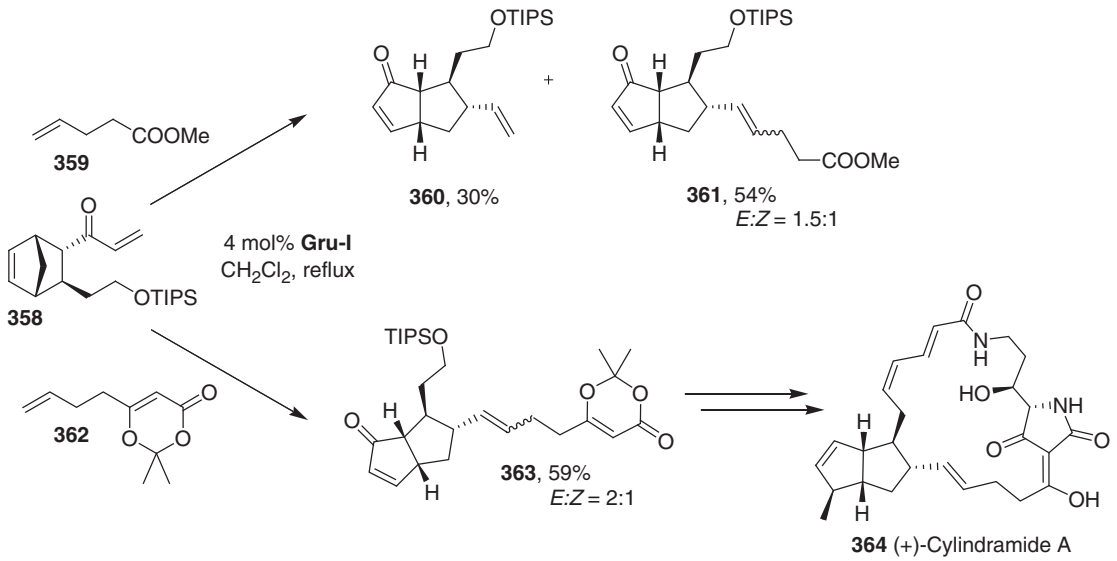
Although problematic in some cases, RRM transformations have found application in the syntheses of various natural products. An example of the construction of polyether substructures common in biologically active compounds is shown in Scheme 68.[103] The utilized metathetic sequence provided product 352 in an overall yield of 62%, proving the efficiency of this methodology.

Another natural product synthesized by this methodology was (–)-lasubine.[104] The reaction between **354** and **355** presented in Scheme 69 resulted in the *E*-configured product **356** in a 48% yield. The main drawback of this approach is the concurrent CM reaction between the substrates, which causes byproduct formation.

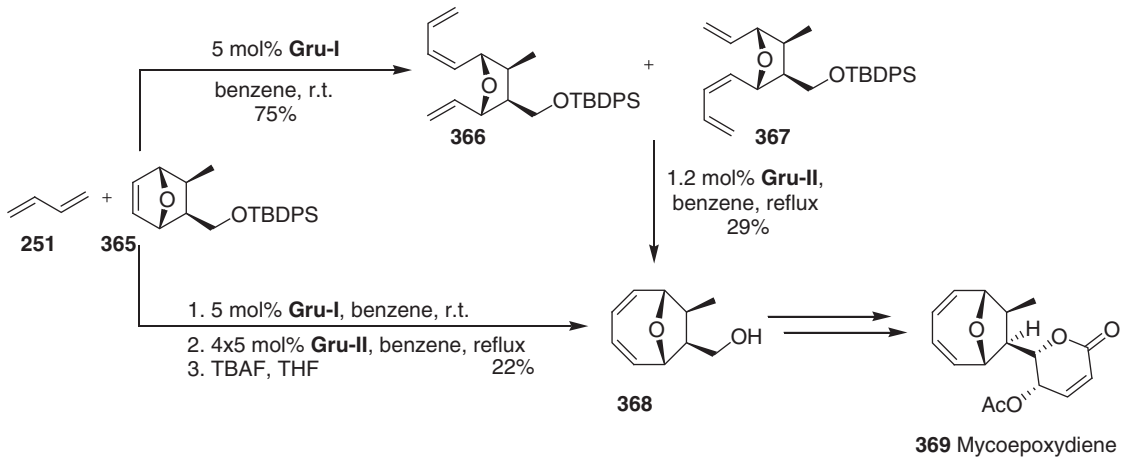


The ROM-RCM-CM methodology was utilized by Phillips et al.[105] to synthesize (+)-cylindramide A (Scheme 70). The bicyclic substrate **358** was metathesized in a ROM-RCM sequence with compounds **360** or **363**. In the first approach a mixture of products

Scheme 67 Selectivity of RRM.



Scheme 68 Synthesis of polycyclic ether framework.

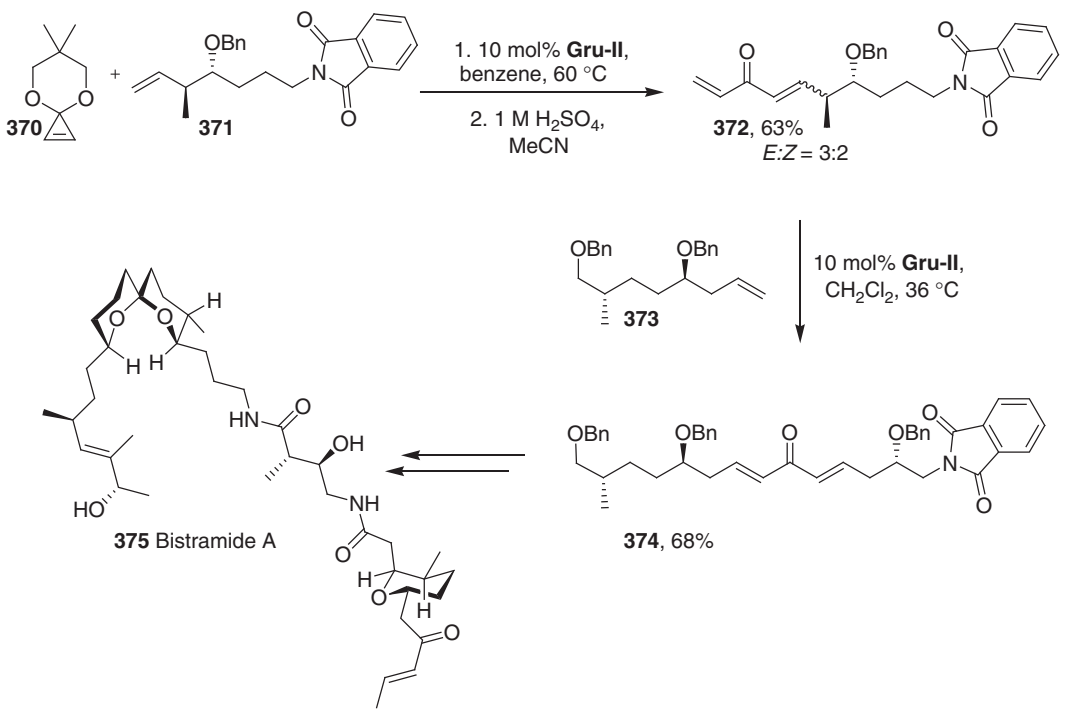


Scheme 69 RRM synthesis of (–)-lasubine.

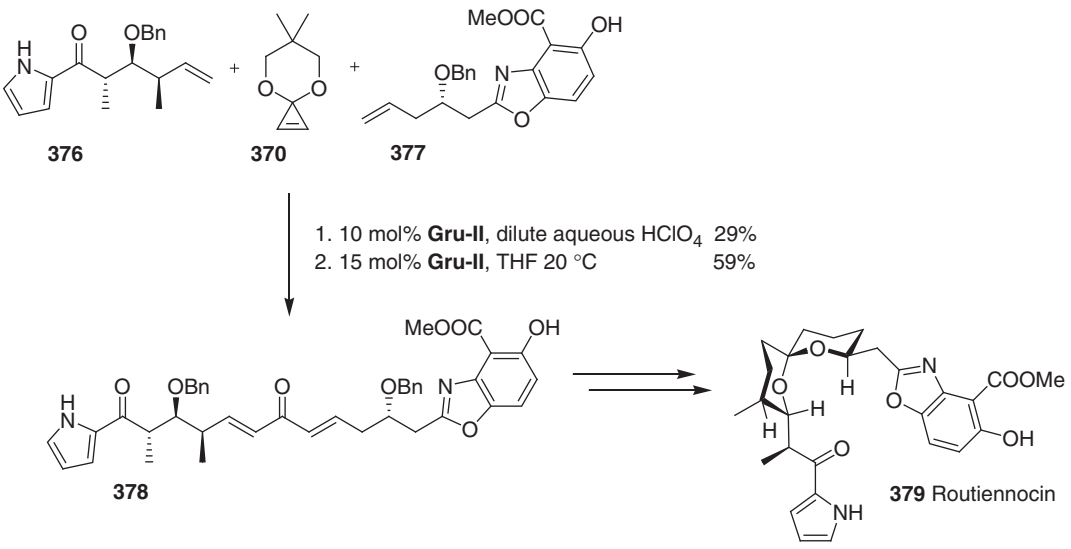
was obtained, indicating an incomplete CM step when using **359** as the reaction partner. Utilizing olefin **362** as the cross partner led to a complete conversion of **358** and better selectivity.

Another natural product obtained by this methodology is mycoepoxydiene (Scheme 71).[106] This compound was synthesized utilizing two different protocols. The first one divided the sequence into two separate steps: ROM-CM and RCM, whereas the other

Scheme 70 Synthesis of (+)-cylindramide A by means of RRM. TIPS, triisopropylsilyl.



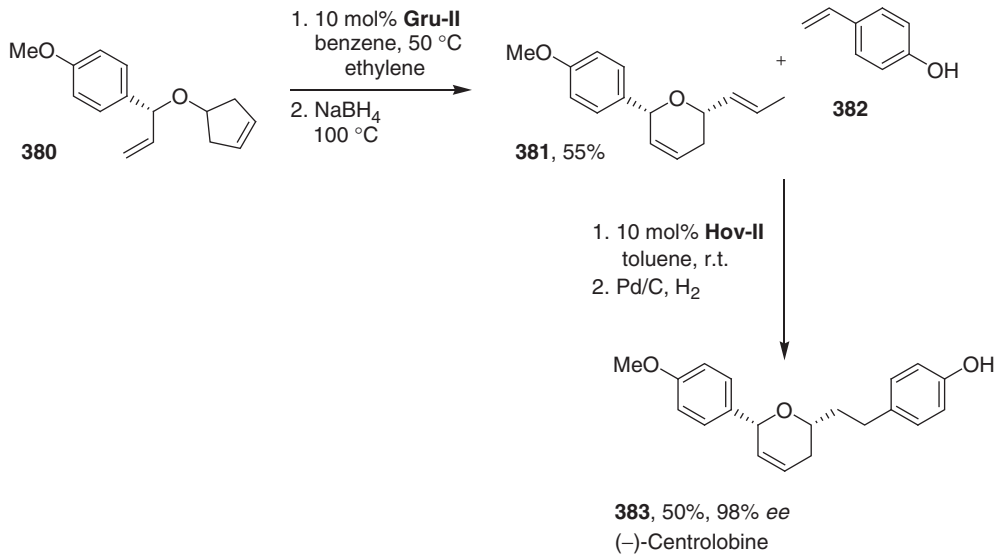
Scheme 71 Mycoepoxydiene synthesis utilizing different protocols.



was a stepwise one-pot procedure. The second procedure turned out to be more effective overall, although it has to be noted that it utilized a much higher catalyst loading during the CM step.

Most RRM synthetic pathways contain only one intermolecular step, as incorporating another such transformation usually doubles the difficulty of obtaining the expected product. Therefore, such transformations are usually conducted in a stepwise manner. The synthesis of bistramide A[107] presented in Scheme 72 is a great example of such an approach. The first stage of the synthesis is a ROCM between **370** and **371**. After the formation of **372**, the next cross partner **373** is added resulting in the formation of **374** as the product of the sequence. The same concept was successfully utilized in the synthesis of another complicated compound – routiennocin[108] (Scheme 73).

The last and probably the most sophisticated example of RRM is a synthesis of (–)-centrolobine, an antibiotic isolated from the heart wood of *Centrolobium robustum*, which is presented in Scheme 74.[109] Among many synthetic approaches toward that rather simple structure, a sequence comprising a diastereoselective variant of RRM (dRRM) followed by CM proved to be superior. During a RRM, an existing stereocenter can be transferred from the side chain to the ring (or vice versa), but their total number remains unchanged. The diastereoselective variant, however, usually involves prochiral rings with a stereocenter in the side chain, which after metathesis leads to carbo- or heterocycles containing a new stereocenter. The greatest challenge of such a



Scheme 72 Synthesis of bistamide utilizing ROM-CM-CM sequence.

Scheme 73 Routiennocin synthesis.

transformation is the formation of the rearranged product in an acceptable diastereoselectivity, which was nicely achieved in the discussed example.

As proven above, tandem sequences have found applications in many syntheses. They provide access to complex structures that would otherwise be very difficult to obtain. Apart from the obvious advantages, some issues remain to be solved. One of the most serious ones is the often poor diastereo- and enantioselectivity, which are crucial in natural product chemistry. The final issue, probably the most limiting for large-scale applications, is that natural product synthesis usually requires high catalyst loadings, which are unacceptable for the industry. Solving those problems would certainly lead to widespread use of tandem metathesis sequences in the synthesis of specialty chemicals.

Scheme 74 dRRM in natural product synthesis.

5.26.4 Outlook/Perspectives

Functionalized olefins are important building blocks in organic synthesis. Catalytic olefin CM in all its flavors is a convenient route to functionalized olefins from simple alkene precursors. One of the most appealing facets of this transformation is that a carbon–carbon double bond produced in CM can be substituted by heteroatom-containing groups (in this respect, CM can be seen as a formal C-H activation reaction of the olefinic substrate). Additionally, advanced architectures such as polycyclic frameworks can be relatively easily prepared using multicomponent processes, where a CM reaction is paired with another metathetical transformation, such as ROM or RCM.

A lot of effort has been made toward understanding of the mechanism and the origin of selectivity in CM transformations. Of note, the general empirical model for olefin reactivity in CM, developed by Grubbs, provides a simple yet convenient tool for the prediction and design of new selective CM reactions. Development of new efficient catalysts and conditions is another key factor, which allows the use of previously incompatible substrates. Although some problems related to controlling of chemo- and stereoselectivity during CM reactions remain unsolved, this reaction has already become a valuable tool for organic chemists and further development is expected.

Glossary

Alkylidene-first mechanism In an ene–yne metathesis, a mechanistic sequence where the alkene reacts first to form a reactive metal carbene. This is sometimes called the 'ene-then-yne' mechanism.

Diversity-oriented synthesis Synthesis activity that aims to create various cyclic or polycyclic templates to project functional groups in three-dimensional space. This approach offers a complement to the structural diversity represented in Nature and aims to access additional three-dimensional arrays of organic functional groups.

Double-directional synthesis A bifunctional or symmetrically functionalized substrate is extended by bond formation in two directions at once or sequentially.

***Endo*-selectivity (in ene–yne metathesis reactions)** In a ring-closing enyne metathesis, the alkene carbon becomes bonded to the more distant alkyne *sp*-hybridized carbon. This process may be triggered by the addition of ethylene to the alkyne, or by ring closing of an alkene-derived alkylidene to produce an endocyclic metal carbene intermediate. This is common in macrocyclizations.

Metallotropic shift An alkynyl-substituted metal carbene undergoes propargylic transposition to form a new alkynyl-substituted metal carbene. This has been used to migrate metal carbenes so that they can participate in cascade metathesis sequences.

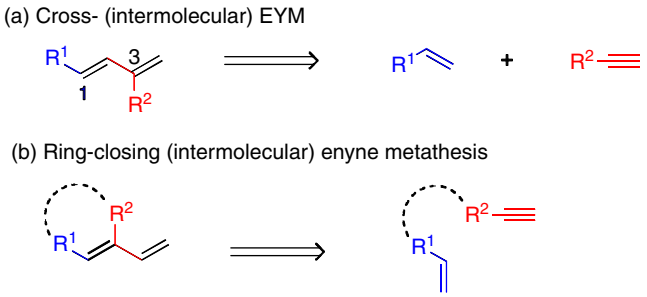
Methylene-free ring synthesis The use of an unsaturated four-carbon chain to build a cyclohexadiene ring from an alkyne without any methylene (CH_2) sources. Lack of methylene sources favors the metathesis cascade that produces a cyclized product.

Mori's conditions The use of an ethylene atmosphere to increase yields of ring-closing enyne metathesis products.

RCEYM Ring-closing ene–yne metathesis.

Relay metathesis or relay ring-closing metathesis The use of a more reactive alkene to position a new metal carbene through a ring-closing metathesis. This can be used

 doi:10.1016/B978-0-08-097742-3.00528-0



to make metal carbenes that would be otherwise difficult to form, or as a means to position a metal carbene at a desired site to initiate metathesis cascades.

Ring rearrangement metathesis The intramolecular exchange of a cycloalkene with an alkyne to form a new cycloalkene or unsaturated heterocycle.

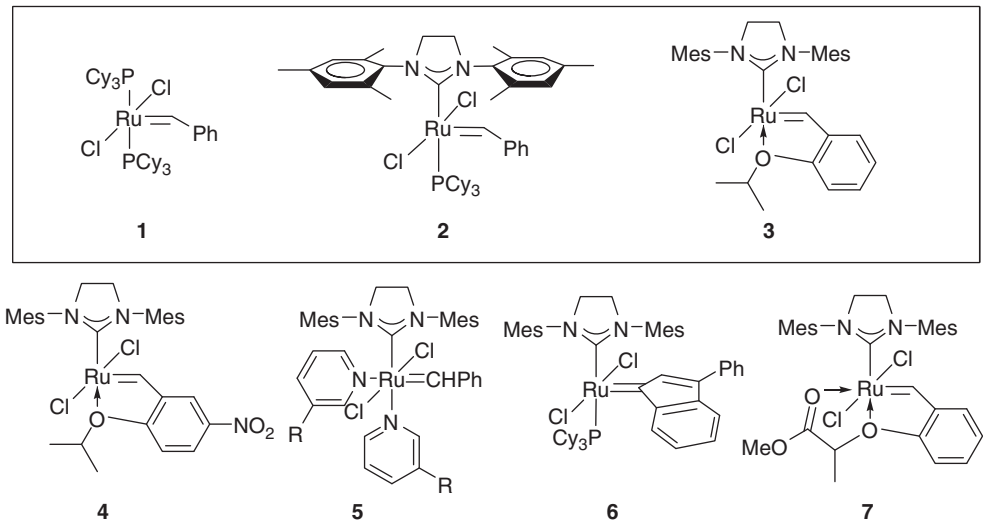
Transalkylidenation Conversion of a metal carbene to a new metal carbene by reaction with an alkene. This is a fundamental process in alkene metathesis. For example, the Grubbs benzylidene $L_nCl_2Ru{=}CHPh$ is converted to $L_nCl_2Ru{=}CHR$ by reaction with $RCH{=}CH_2$. The process occurs via a ruthenacyclobutane intermediate.

5.27.1 Introduction

Ene–yne metathesis (EYM) is a synthetically useful method for the synthesis of 1,3-dienes. Conjugated dienes are valuable building blocks for organic synthesis. For example, conjugated 1,3-dienes are widely used in Diels–Alder reactions for the synthesis of six-membered rings. With catalytic EYM, the 1,3-diene is synthesized in a single reaction step from alkene and alkyne reactants. Notably, the alkene and alkyne reactants do not require preactivation: Their π-bonds provide the origin for their reactivity. The ruthenium carbenes are uniquely matched to react with π-bonds, which is the origin of their remarkable chemoselectivity. This preference is also known as functional group tolerance. The EYM reaction is a catalytic transformation and usually employs the mild and readily available Grubbs carbene catalysts. The ruthenium carbenes known as the Grubbs catalysts promote EYM with excellent chemoselectivity (Scheme 1).

Scheme 1 Enyne and EYM.

Carbon–carbon bond coupling between an alkene and an alkyne with π-bond reorganization is EYM. When the reaction occurs between two separate molecules in an intermolecular reaction, it is known as a 'cross' EYM (Scheme 1, panel a). In simple terms, the reaction can be described as a cleavage of the alkene π-bond and the attachment of the individual carbene components across the triple bond with a defined regiochemistry. Accordingly, a 1-alkene combines with a 1-alkyne to give a 1,3-disubstituted 1,3-diene. The alkene must be reactive with the metal carbene being used. If the reactants are joined by a tether, as in a 1,ω-enyne, then the reaction is intramolecular and known as ring-closing *1,n*-enyne metathesis (RCEYM). The RCEYM produces the 1,2-disubstitution pattern with ring formation (Scheme 1, panel b). This reaction is successful for the synthesis of a wide assortment of carbocycles and heterocycles. For the synthesis of small rings, the tether geometrically restricts the ene and yne fragments from joining in the 1,3-orientation; instead they join with 1,2-substitution on the 1,3-diene. In this chapter, intermolecular reactions will be denoted as EYM and intramolecular ring-closing metathesis (RCM) of 1,*n*-enynes will be called 'enyne' metathesis. Collective or generic references to metathesis of each molecularity will be called 'ene–yne metathesis'.



EYM is used in diverse synthetic applications. The intermolecular EYM between alkenes and alkynes produces acyclic dienes. The EYM is also used to create rings. The simple RCM of an enyne produces a diene that is contained in the newly formed ring. This version of EYM has seen applications to the widest variety of complex small molecules in organic synthesis. These applications have progressed to more complex cascading processes, where multiple rings are formed in a metathesis cascade. A number of excellent review articles have appeared.[1–4] Mechanistic aspects of the EYM will be discussed before the synthetic examples.

5.27.1.1 Catalyst Overview

The development of EYM has paralleled improvements in well-defined ruthenium carbene catalysts. Katz and Sivavec showed the catalytic effectiveness of RCEYM in 1985.[5] However, the use of early transition metal carbene complexes limited the reaction's effectiveness and scope of application. After a decade, Mori's group applied the metathesis to challenging nitrogen heterocycle synthesis.[6–8] However, the real breakthrough came from alkene metathesis when the Grubbs group reported a well-defined, group VIII ruthenium carbene complex.[9] This led to a number of applications by Grubbs and Fu, which captured the attention of the synthetic community (ruthenium,[10] molybdenum[11]). Having already investigated catalytic enyne metathesis, the Mori's group revisited the problem using the ruthenium carbene complex and found an excellent reactivity in enyne metathesis.[12] Mori and

coworkers followed this work with additional studies using ethylene, which have helped advance enyne metathesis in the synthetic community.[13–15]

Much of the recent work in metathesis has gravitated toward the use of the second-generation Grubbs carbene complex **2** (Scheme 2). During the past several years, synthetic chemists have embraced the Grubbs catalyst because of its availability, bench stability, improved reactivity, and chemoselectivity for alkenes and alkynes. The Grubbs catalysts are extremely easy to use. Chemoselectivity is also called functional group tolerance. The evolution of catalysts from gloveboxes to the benchtop has made metathesis a standard tool in the synthetic chemist's arsenal. Due to ease of use and catalyst availability, the use of metathesis in a synthetic plan has become very easy. This has facilitated exploratory chemistry and adventurous synthetic pursuits. Moreover, it can partly explain the explosion in metathesis applications and the widespread use of the Grubbs catalyst. The widely accepted utility of this catalytic carbon–carbon bond formation led to recognition of the groundbreaking work and leadership from Grubbs,[16] Schrock,[17] and Chauvin,[18] who were awarded the Nobel Prize in Chemistry in 2005.

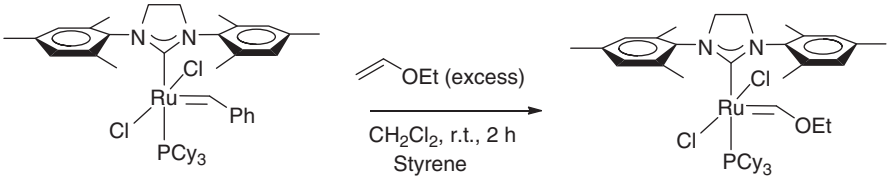
Scheme 2 The Grubbs family of ruthenium carbenes used in metathesis.

Although the Grubbs catalysts **1** and **2** are primarily used in EYM, several new carbene complexes have seen increased use. New carbenes are continually being developed for challenging applications in alkene metathesis, to give improved stereoselectivity and for asymmetric applications. The bisphosphine complex **1** is called the first-generation Grubbs complex.[19,20] Carbene complex **2** is known as the Grubbs second-generation complex. Ruthenium carbene complex **2** bears a single *N*-heterocyclic carbene (NHC) ligand, reported by the Grubbs group in a highly cited 1999 paper.[21] The ruthenium complex containing the unsaturated NHC ligand, IMes, is the Nolan catalyst.[22,23] The replacement of a tricyclohexylphosphine ligand with a coordinating ether in the arylidene ligand was developed by Hoveyda and coworkers. With the saturated NHC ligand, dihydroIMes, the chelated complex **3** is known as the Hoveyda–Blechert complex, as it was independently developed by the Hoveyda[24,25] and Blechert research groups[26] (the catalyst is also sometimes called the Hoveyda–Grubbs complex). The electron-poor complex **4** is the Grela complex,[27] which has a more weakly coordinated ether and, like the Hoveyda–Blechert complex, is phosphine-free. The Grela complex also falls into the Hoveyda–Blechert family, and a new bidentate complex **7** has also been employed for enyne RCEYM. The indenylidene catalyst **6**, sometimes called the Umicore catalyst, has also been used for EYM with performance comparable to that of the Grubbs complex **2**.[28–30] In catalysis, activity refers to a combination of catalyst attributes including favorable initiation rates and long propagation lifetime (catalyst longevity). Though the phosphine-free initiators are more active, they are not necessary for most applications. Typically, these phosphine-free catalysts are reserved for cases where catalyst longevity at higher temperatures is desired, or in cases involving less reactive alkenes such as enones or enoate esters. The pyridine adduct **5** is known as the Grubbs pyridine solvate.[31] All of these complexes derive their lineage from the first well-defined ruthenium carbene discovered by the Grubbs group in 1993,[9] the ground breaking discovery that opened the door to this entire family of ruthenium carbene catalysts. As of this writing, the second-generation Grubbs carbene **2** and the Hoveyda–Blechert complex are the most widely used catalysts for EYM. New catalysts continue to be developed and this assessment is merely a static snapshot of an evolving and active research area in catalyst development (in the fields of both alkene and EYM).

5.27.1.2 General Considerations

The Grubbs-type complexes **1**, **2**, **3**, **4**, and **6** are commercially available and easy to use. The carbene complexes are not hygroscopic and can be weighed in the air under normal laboratory conditions. The shelf-life of the complexes is quite good and

they can be stored for extended periods in a darkened cabinet under nominal atmospheric conditions. Purification of commercial lots is generally not necessary and not recommended. Some carbene complexes can be purified by column chromatography with varying material losses; the second-generation carbene can be purified this way, but substantial loss of material occurs. The Hoveyda–Blechert chelated complexes are generally easy to purify by column chromatography on silica gel with good mass recovery.[24] Usually purification is needed only if degradation is observed by ^{1}H or ^{31}P NMR spectroscopy. The Grubbs first-generation carbene **1** gives a diagnostic proton signal at δ 20.02 ppm (CD_2Cl_2) and a single ^{31}P resonance at δ 36.61 ppm (CD_2Cl_2).[19] The second-generation Grubbs carbene **2** gives a diagnostic proton signal at δ 19.16 ppm (CD_2Cl_2) and a single ^{31}P resonance at δ 31.41 ppm (CD_2Cl_2).[21] The Hoveyda–Blechert carbene **3** gives a diagnostic proton signal at δ 16.56 ppm ($CDCl_3$) and has no phosphorus nucleus.[24]

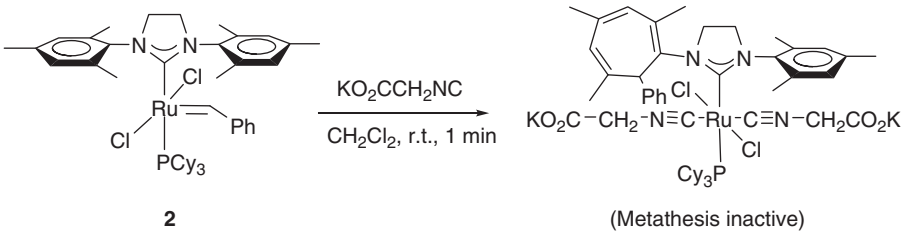


Metathesis can be performed in a wide variety of solvents. The most common solvents are dichloromethane, benzene, and toluene. Alkene metathesis initiation studies have shown that catalyst **2** reacts effectively in CH_2Cl_2, benzene, toluene, and tetrahydrofuran (THF).[32] Due to the greater thermal stability of carbene complex **1**, higher boiling solvents such as benzene and toluene are commonly employed. Solvents such as ether, THF, and 1,2-dimethoxyethane (DME) have seen little use in metathesis. Interestingly, though THF is not commonly used, it is a good solvent for *Z*-selective alkene cross-metathesis.[33–35] Carbene complex **2** has poor solubility in methanol and water. In the best cases, metatheses can be performed in degassed, commercially available solvents.

Alkene concentrations vary depending on the molecularity of the application. Typical RCM or RCEYM employ high dilution (1–20 mM) of diene or enyne. In the intermolecular or cross-EYM (CEYM), the alkene is used in molar excess (3–6 equivalents) and the concentrations as high as 1 M are not unprecedented. The mechanistic studies show that alkene concentration is important in the rate-determining step of one carbene complex, the commonly used second-generation complex **2**. Cross-metathesis typically uses 0.02–0.1 M alkyne as the limiting reagent. An ethylene additive is sometimes used with catalyst **1** in promotion of RCM of 1,*n*-enynes. Ethylene is not commonly used in cross-metathesis applications due to the possible formation of ethylene–alkene cross-metathesis products. When used, ethylene delivery is not always specified. Typically, an ethylene atmosphere is achieved with an ethylene-filled balloon.

5.27.1.3 Quench and Removal of Ruthenium

At the end of a metathesis reaction, the ruthenium carbene activity must be quenched and the residual metal must be removed from the isolated organic product. In most cases, the ruthenium carbene catalyst is used at a loading between 2 and 10 mol%. In some of the earlier applications with catalyst **1**, no quench method was necessary because the catalyst decomposed during the reaction. Similarly, sampling the recent literature shows that quenching methods are not always used. Since the newest Grubbs carbenes are particularly robust, quenching is highly recommended. Many metatheses catalyzed by **2** occur quickly, and due to the thermal stability of the carbene complex, active metal carbenes derived from **2** remain at the end of the organic reaction. Longer reactions or those conducted under heating will decompose the metal carbenes to metathesis-inactive ruthenium-containing species. Thus, the purification procedure must successfully remove different forms of the metal, both carbenic and noncarbenic Ru(II) species. Because of the many ruthenium species present, a removal procedure must inactivate the metathesis-active intermediates and convert the remaining nonmetathesis reactive metal species into those that are readily removed.



Quenching carbenes does not necessarily aid in the removal of ruthenium from the organic products. By far the most common way to stop a metathesis reaction is to add an enol ether such as ethyl vinyl ether after the limiting reactant has been consumed. This requires a brief period of heating to convert the remaining metathesis-active alkylidenes into stable Fischer carbenes which are not cross-metathesis active[36,37] (equation 1). Although this procedure is effective for stopping EYM, it does not aid in the removal of all the ruthenium by-products. A decomposed form of ruthenium(II) that is no longer a metal carbene is incapable of reacting with the enol ether.

2 93% (1)

Though there are many methods to remove ruthenium, there are two that are widely used and recommended. Often a crude metathesis reaction has a lingering yellow color associated with residual ruthenium. A mild oxidative procedure was reported by Georg et al.[38] using either DMSO or $O{=}PPh_3$ as an oxygen transfer agent. This is an attractive method due to its simplicity and mildness. Though the mechanism is not known, the oxidant is thought to convert the metal species into polar oxides that can be removed during column chromatography. The Georg procedure is an effective way to remove the yellow color associated with ruthenium residue in the crude sample. The main disadvantage of this procedure is that it is very slow: Oxidation requires 12–24 h to fully convert the ruthenium into polar species. Nonetheless, the mildness and simplicity have led to the wide use of this procedure.

A polar isocyanide procedure is dually effective in both quenching the carbene activity and removing the ruthenium (equation 2). The main advantage of the procedure is its very rapid reaction rate (1 min is typical), and the use of small amounts of isocyanide KO_2CCH_2NC (40–50 mol%) and that it results in a demonstrated 'quench' of carbenic activity for a wide variety of Grubbs carbenes.[39] The 'quench' destroys metathesis activity completely and arrests any further metathetic processes. The quench of carbene activity is accomplished by transferring the carbene into one of the aromatic rings of the NHC ligand (e.g., in complex **2**)[39,40]: an intramolecular Buchner cyclopropanation, which is followed by a norcaradiene-to-cycloheptatriene rearrangement. Catalysts bearing NHC ligands are the most active and are currently the most commonly used catalysts in organic synthesis applications. However, it should be noted that the first-generation Grubbs complex **2** also undergoes an effective quench and is itself transformed into a polar, removable Ru(II) complex, albeit by a distinct pathway.[41] After the isocyanide-promoted Buchner insertion, a simple plug filtration (silica gel) or a column chromatography step removes the polar – and metathesis-inactive–ruthenium isocyanide complex.
