INTRODUCTION TO VOLUME 5: COMBINING C–C Π-BONDS

Olefins and, to a lesser extent, other π-systems are the principal starting point of the chemical value chain as long as mankind relies on crude oil as the major carbon source. It is therefore not surprising that the knowledge about the formation, manipulation, and functionalization of π-bonds in general is overwhelming.

Comprehensive Organic Synthesis II intends to assist the reader in navigating this vast sector of chemical space. In doing so, the present volume covers the immensely important methodologies that allow C–C–π-bonds to be combined; for the sake of coherence, some chemically closely related areas are also dealt with herein.

Even a cursory consideration makes clear that some of the most fundamental and powerful chemical transformations fall onto this thematic map. This refers to a very significant part of cycloaddition chemistry, independent of whether the reactions are photochemically or thermally induced, strain-driven, engendered by stoichiometric metal reagents, or effected with the aid of appropriate catalysts. Furthermore, the present volume has to cover a realm of pericyclic transformations, including electrocyclizations and sigmatropic rearrangements, the entire field of metathesis, hydroarylation and hydrovinylation, as well as the prolific area of reductive coupling chemistry.

This truly Herculean task has only been possible with the help of a panel of expert authors who kindly agreed to share their knowledge with the interested reader. Through their efforts, the 36 chapters of volume 5 capture the crux of the topics mentioned above and provide a highly inspiring source of information. To this end, the individual articles provide only a brief summary of the background, just enough to familiarize a novice reader with the essence of all prior knowledge; rather, they are clearly focused on the methodological advances made during the past two decades. The preparative scope of the presented methodologies is illustrated by a host of specific applications, including many examples of target oriented syntheses of natural products and other biologically active compounds. Great care has been taken that the corresponding schemes and figures allow the essentials of such transformation to be easily grasped.

In line with the general mission of this reference work, the thematic coverage is sufficiently 'comprehensive' in order to demonstrate the progress in a given field and to provide useful information even for a specialist; yet, the flood of material has been filtered by the highly knowledgeable authors to the extent that a less experienced practitioner will not get lost in a morass of details. Although different approaches were taken to reach this goal, I am convinced that the present volume in its entirety provides an invaluable service to all of us.

Arguably, the most important message conveyed by this volume, is the fact that it showcases the truly impressive ability of the chemical community to innovate, even in a field that has already experienced almost two centuries of intense scrutiny in academia and industry alike. A few examples must suffice here to illustrate this notion (**Figure 1**). In the first edition of Comprehensive Organic Synthesis published in 1991, metathesis filled 1 chapter of no more than 13 (!) pages. Two decades and a Noble Prize later, four massive chapters were needed to portray the current state of the art in this timely and exceptionally prolific field of research. During the same period, hydroarylation as well as cycloisomerization chemistry were revolutionized by the advent of carbophilic Lewis acids, notably those based on platinum and gold. But even more 'traditional' areas clearly demonstrate the inexorable force of chemical research: suffice it to mention, *pars pro toto*, the venerable Diels–Alder reaction. Whereas the 1991 edition contained hardly any successful cases of catalytic asymmetric [4+2] cycloadditions, the pertinent chapters in the current

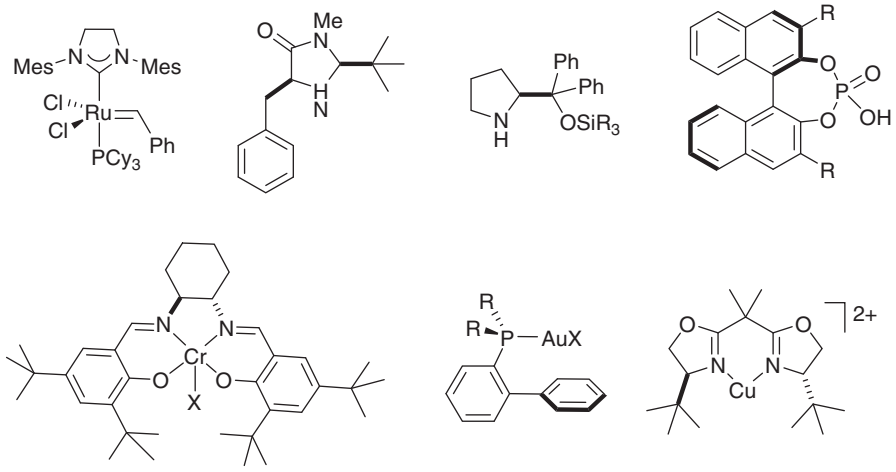

Figure 1 The inexorable power to innovate is exemplified by a small selection of catalysts that were basically unknown at the time when the first edition of Comprehensive Organic Synthesis was published; only two decades later, each of them stands for a prosperous field of research, as witnessed by the many different applications discussed in the present volume.

edition are dominated by this highly enabling methodology. A closer look also makes clear that contemporary asymmetric catalysis does not exclusively rely any longer on cleverly designed new organometallic entities or on the use of enzymes, but also embraces organocatalysis in its broadest sense, which constitutes an entirely new and rapidly growing branch of chemistry that was virtually inexistent two decades ago.

These are perhaps particularly striking examples but definitely not the only illustrations of the fabulous progress that continues to be made. The careful reader will appreciate that basically all chapters contained in this volume bear testimony to the vibrant and unabated development of organic chemistry in general and organic synthesis in particular. Therefore we have every reason to be optimistic about the future of our scientific discipline.

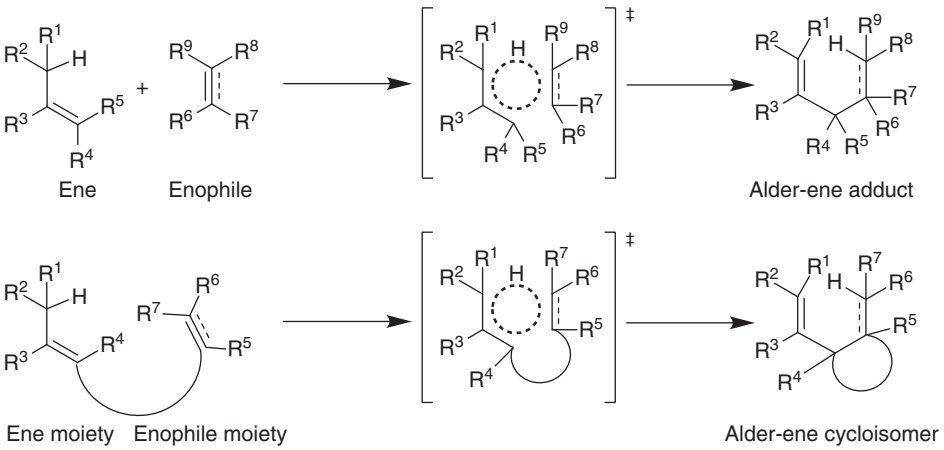
Glossary

β-H-elimination *syn*-Specific deinsertion of an unsaturated ligand with concomitant transfer of the β-hydrogen to a vacant coordination site of a metal complex.

Concerted reaction A single-step reaction through which reactants are directly transformed into products, i.e., without involvement of any intermediates.

Domino reaction A series of more than two bond forming elementary steps, often proceeding through reactive intermediates, where all reactants and catalysts or activators are present from the very beginning and which occur without isolation of intermediates.

Oxidative addition The insertion of a metal complex into a covalent bond involving formally an overall two-electron loss on one metal or a one-electron loss on each of two metals.



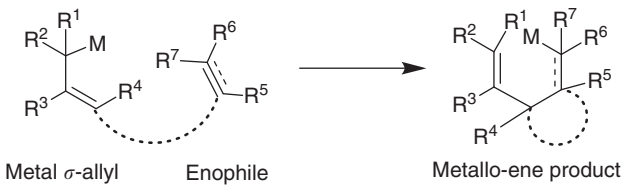
Reductive elimination The reverse of oxidative addition.

Transmetallation An organometallic elementary reaction that involves the transfer of ligands from one metal to another.

5.01.1 Introduction

Ene reactions are very important, versatile, and elegant bond forming reactions, which can be conducted with an enormous variety of substrates that are easily accessible. Therefore, ene reactions have been extensively reviewed in the past.[1] Ene reactions involving alkenes or alkynes as enophiles are called Alder-ene reactions. A special case, where the ene partner results from a population of an enol tautomer and which only proceeds in an intramolecular fashion, is the Conia-ene reaction.[2]

Alder-ene reactions either proceed as intermolecular additions of an ene component and an enophile furnishing an Alder-ene adduct or, intramolecularly, as a cycloisomerization of a substrate containing an ene and an enophile moiety giving rise to the formation of a cycloisomer (**Scheme 1**). If these reactions are pericyclic, they proceed in a concerted fashion via a cyclic transition state involving the rearrangement of six electrons (4π- and 2σ-electrons). Depending on the substitution pattern of both π-systems, Alder-ene reactions can be stereogenic because both combining sp^2-centers become tetrahedral. In addition, the migrating hydrogen from the ene component stereospecifically generates a double bond in the case of alkynyl enophiles or an sp^3-center in the case of alkenyl enophiles. In either case, a double bond is established in the former ene moiety.



Scheme 1 General mechanistic rationale of concerted Alder-ene reactions.

Mechanistically, uncatalyzed Alder-ene reactions might occur either pericyclically or stepwise. As in the case of Diels–Alder reactions, the favorable electronic combinations implement Alder-ene reactions under normal (electron-rich ene and electron-deficient enophile) or inverse electron demand (electron-deficient ene and electron-rich enophile). Alder-ene reactions can also be catalyzed with Lewis acids in the case where an electron-deficient functionality with Lewis-basic centers is present in either substrate. By lowering the lowest unoccupied molecular orbital (LUMO), asynchronous pericyclic pathways may be still followed.[3] However, combinations of electroneutral enes and enophiles display notoriously sluggish reactivity due to their high activation energy. They have been and still are often reacted under vigorous thermal conditions.

The advent of homogenous transition metal catalysis and the deeper comprehension of the underlying mechanistic principles have considerably enabled the development of formal Alder-ene processes by involvement of carbophilic metal complexes that are capable of coordinating and activating alkenes, alkynes, and allenes as weakly Lewis-basic ligands toward carbon–carbon bond formation via stepwise sequences. Although intramolecular Alder-ene cycloisomerizations have been already known since 25 years, metal catalyzed Alder-ene additions as bimolecular reactions have evolved in the 1990s.

Introduced by Oppolzer the formal replacement of hydrogen by a metal leads to 'metallo-ene' reactions (Scheme 2).[4] Mechanistically, a metal allyl species undergoes a carbometallation of an enophile giving rise to the formation of the metallo-ene adduct, which proceeds via intra- or intermolecular addition or elimination processes. Most interestingly, allyl metal species can be either generated stoichiometrically, or with certain transition metal complexes, in a catalytic fashion by oxidative addition from a suitable precursor.

Scheme 2 General mechanistic concept of metallo-ene reactions.

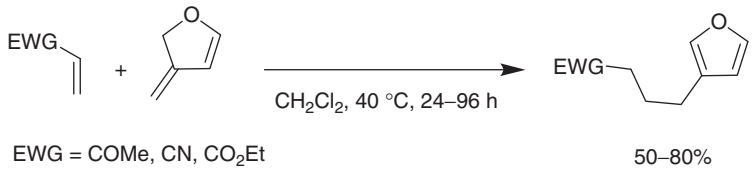
In this chapter only the developments of ene reactions with carbon enophiles in the past 20 years are considered. Therefore, only the formation of carbon–carbon bonds between ene components and alkenes, alkynes, and allenes are treated. First, new developments in the field of Alder-ene additions and cycloisomerizations are discussed and then metallo-ene reactions are presented. All other ene reactions are discussed in separate chapters.

5.01.2 Alder-Ene Additions

5.01.2.1 Alkenes as Enophiles

Alder-ene reactions, as all pericyclic processes, have been a field of theoretical and mechanistic studies ever since their discovery. More detailed insights in the course of the title reactions have been obtained in the past two decades, not least because of the rapid development and precision of computational methodologies. In particular, the nature of the transition state has been investigated in several remarkable studies.

Mechanistic investigations on model ene reactions by computations, also in comparison,[5,6] have been performed on various levels of theory and important insights on the atomistic pathways have been obtained. Besides predicting stereochemical features by force field models,[7] density functional theory (DFT) and *ab initio* computations have become state-of-the-art tools for studying ene reactions. For instance, an *ab initio* molecular orbital study on the ene reaction of methyl acrylate and propene has revealed a less asynchronous character in the bond reorganization as compared with the parent ene reaction.[8] In addition *exo* and *endo*-transition state structures suggest that the intrinsic *exo*/*endo* selectivity in the ene reactions is not as obvious as in the Diels–Alder reactions. On a similar basis, *ab initio* and DFT computations could support various degrees of asynchronicity. In particular, cyclopropene as an enophile accounts – through its relief of strain energy – for the preference of an *endo*-transition state.[9,10] In a combined experimental and theoretical study on the ene reaction between 1-alkenes and maleimide, an excellent agreement with *ab initio* post-Hartree Fock computations was achieved giving a deeper insight into transition state geometries.[11]

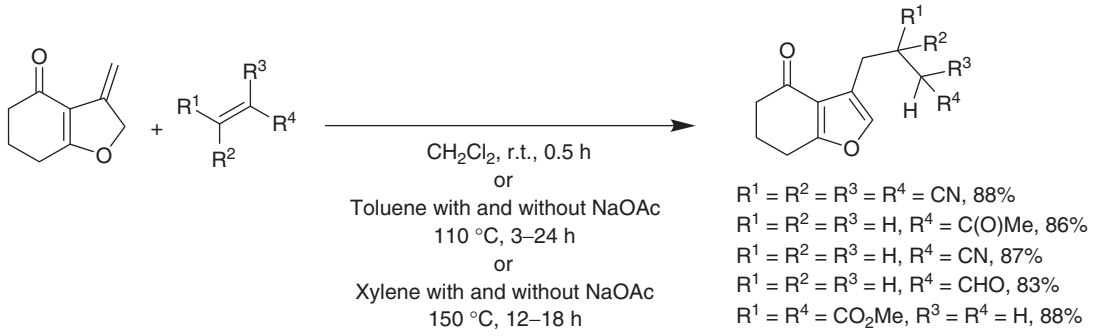


Several mechanistically challenging ene-processes and predictions were tackled by computational studies. For the elusive, highly strained bicyclo[2.1.1]hex-1-ene, the ene reaction with 2-phenyl prop-1-ene as a trapping process was performed experimentally and investigated by high-level DFT computations.[12] Recently, theoretical analyses of ene reactions between propene and several all-carbon or carbon-heteroatom enophiles were performed to quantitatively assign the reactivity on high levels of DFT and *ab initio* theory.[13,14] In addition, a computer-assisted mechanistic evaluation of ene and retro-ene reactions was also successfully carried out to allow predictions of the regioselectivity to be made based on the relative magnitude of frontier orbital coefficients at the interacting termini of the reactants.[15] Furthermore, the influence of geminal bonds of the reactants in pericyclic reactions was theoretically investigated. In a computational study Naruse et al.[16] have elaborated that the interaction between the σ-orbital at the *Z*-configurated position of the double bond of propene as the ene component and the π-orbital of ethylene as the enophile is bonding, whereas the corresponding *Z*-configurated position of the double bond of the ene component should be antibonding. Therefore, according to this theoretical analysis, an increase of the electron donor capability of the *Z*-configurated σ-bond predicts an enhanced reactivity. Finally, based on computationally modeled transition state analogs, Hase et al.[17] have devised and prepared antibodies for catalyzing an ene reaction between maleimide and 1-decene.

Experimental investigations, syntheses as well as kinetic studies, were performed to further scrutinize the concerted nature of these pericyclic processes. A mechanistic issue in concerted, electronically unsymmetrical ene reactions is always the nature of the transition states, i.e., whether either the carbon–carbon bond or the transfer of the allylic hydrogen occurs first. Huisgen and Brückner[18] have employed 2,2-bis(trifluoromethyl)ethylene-1,1-dicarbonitrile (BTF), a highly electrophilic enophile for ene reactions even with unactivated ene partners at room temperature, as a mechanistic probe to permit a classification of alkenes and to allow a prediction of the orientation of their ene reactions. Likewise, tetracyanoethylene (TNCE) was found to undergo a regiospecific ene reaction with γ-alkyl substituted allyltrimethylsilanes.[19] Deuterium as well as ^{13}C labeling in an experimental and computational study on kinetic isotope effects in the ene reaction of allyl benzene as an ene component and maleic anhydride as an enophile support the concerted nature of this process.[20] Finally, Lewis acid catalyzed ene reactions are strongly affected by the solvent polarity and a kinetic study supported the pronounced zwitterionic character of the transition state.[21] In addition, the rates of the model ene reaction between β-pinene and methyl acrylate catalyzed by various Lewis acids led to a linear free energy relationship between the experimentally determined ΔG and the computed LUMO energy as a mechanistic test for the influence of a Lewis acidic catalyst on a chemical reaction.[22]

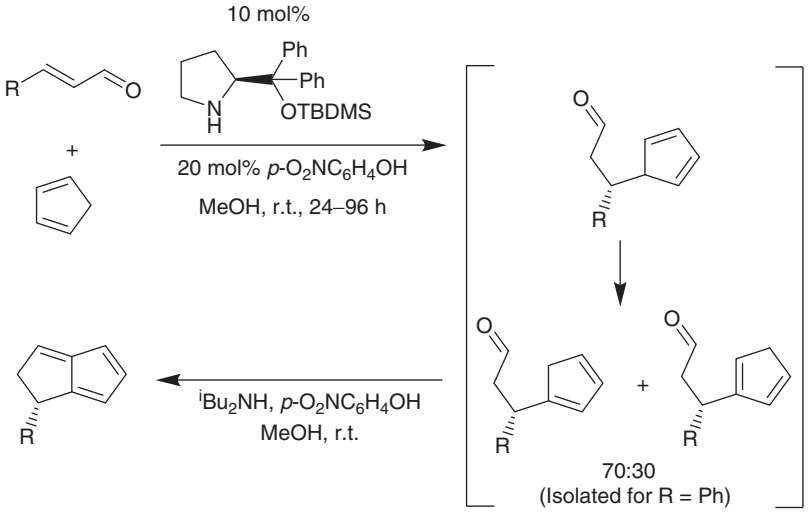
All these findings, obtained by computational and experimental work, not only have sharpened the mechanistic picture of Alder-ene reactions but also have further paved the way to the rational design of pericyclic key steps in all kinds of synthetic endeavors.

5.01.2.1.1 Electron-deficient alkenes as enophiles



Several electron-deficient alkenes readily react with 3-methylene-2,3-dihydrofuran as the ene component to give the corresponding 3-substituted furans in good yield (Scheme 3).[23] The driving force is definitely the accompanying aromatization, which was also operative when C_{60} was employed as an enophile.[24]

Scheme 3 Ene reaction of electron-deficient alkenes with 3-methylene-2,3-dihydrofuran.



Ojida et al.[25] demonstrated the efficient synthesis of annulated furans with various 3-substituents from various electron-deficient alkenes as enophiles and 3-methylene-2,3,6,7-tetrahydrobenzofuran-4(5*H*)-one as ene component (Scheme 4).

Iminium salt formation enhances the electrophilicity of an α,β-unsaturated aldehyde by considerably lowering the LUMO. This circumstance has stimulated organocatalytic approaches in pericyclic methodologies. The iminium salt intermediate formed for cinnamic aldehydes and diphenylprolinol silyl ether allows for an excellent one-pot synthesis of chiral bicyclo[3.3.0]octatrienes

Scheme 4 Ene reaction of electron-deficient alkenes with 3-methylene-2,3,6,7-tetrahydrobenzofuran-4(5*H*)-one.

via an organocatalytic ene reaction followed by a base mediated cyclocondensation of the cyclopentadiene intermediate (Scheme 5).[26]

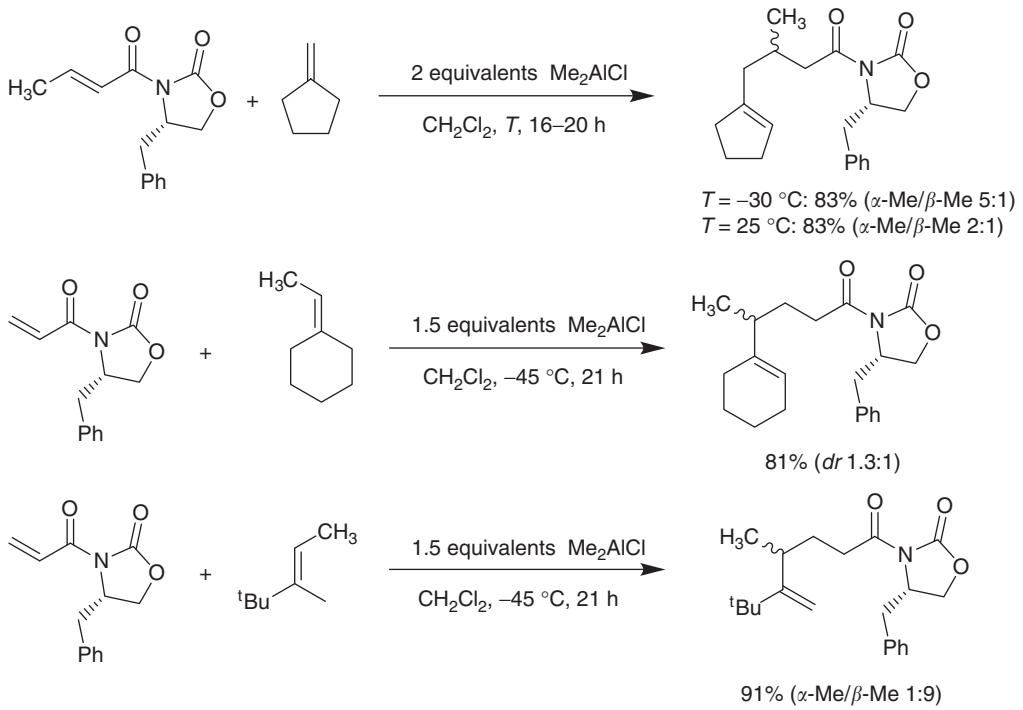
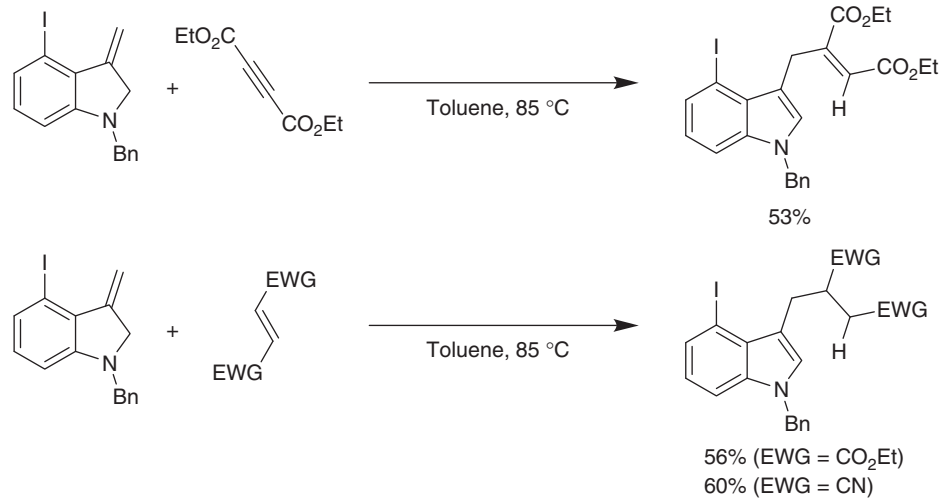
R = 2-thienyl, 43% (98% *ee*)



Scheme 5 One-pot synthesis of chiral bicyclo[3.3.0]octatrienes by way of a diphenylprolinol silyl ether-mediated ene-type reaction.

Snider and Zhang[27] showed that chiral α,β-unsaturated *N*-acyloxazolidinones as enophiles react under Lewis acid catalysis with ene components with moderate to excellent asymmetric induction, which depends on the alkene structure and the reaction conditions (Scheme 6).

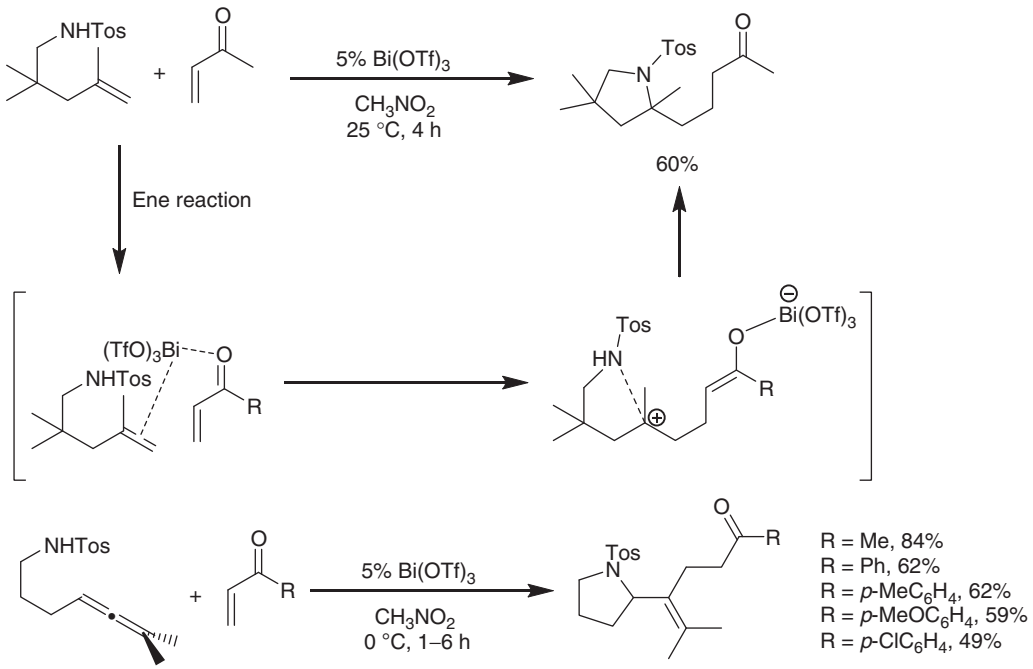


N-Benzyl-4-iodo-3-methyleneindoline, prepared by zirconium-mediated iodo-alkenylation of *ortho*-lithiated *N*-allyl-*N*-benzyl aniline, is an excellent ene partner for intermolecular Alder-ene reactions with activated enophiles, giving rise to the generation of 3,4-disubstituted iodoindole derivatives (Scheme 7).[28]

The advent of domino processes has considerably fertilized the conceptual implementation of pericyclic key steps including the Alder-ene reaction. Just recently, Komeyama et al.[29] have disclosed a domino ene-hydroamination sequence of amino olefins and amino allenes with enophiles using Bi(OTf)$_3$ as a Lewis acid catalyst, which gives rise to functionalized pyrrolidines and piperidines in good yields (Scheme 8).

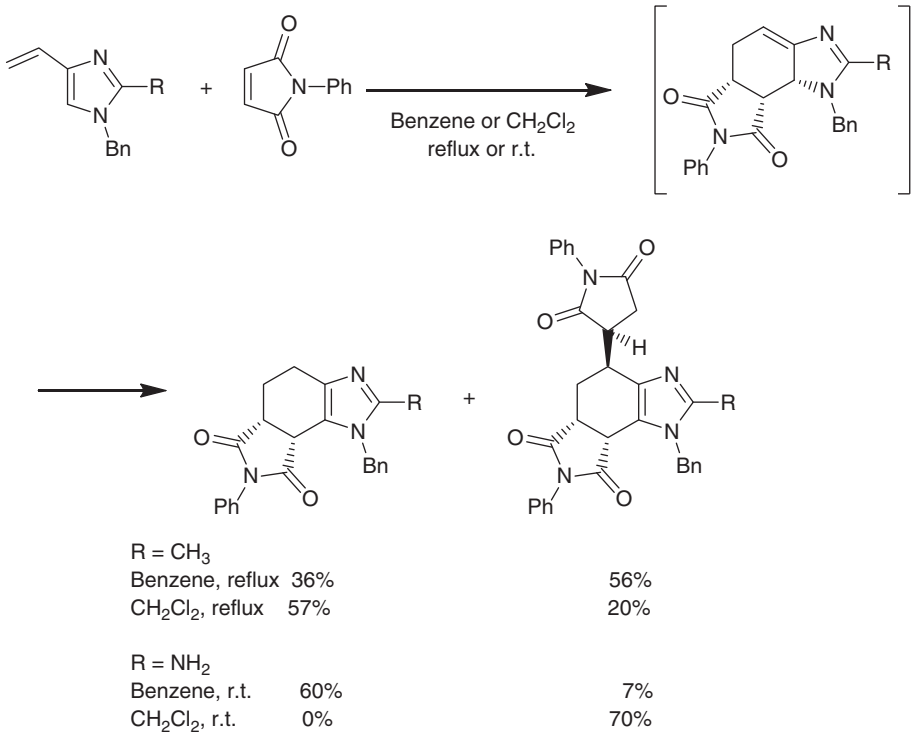
4-Vinylimidazoles are a peculiar type of electron-rich dienes that readily undergo [4 + 2]-cycloadditions with *N*-phenyl maleimide. The resulting cycloadduct either aromatizes by a formal 1,3-H-shift or via a subsequent ene reaction with excess

Scheme 6 Asymmetric Lewis acid catalyzed ene reactions of α,β-unsaturated *N*-acyloxazolidinones.



Scheme 7 3,4-Disubstituted indoles via an Alder-ene reaction.

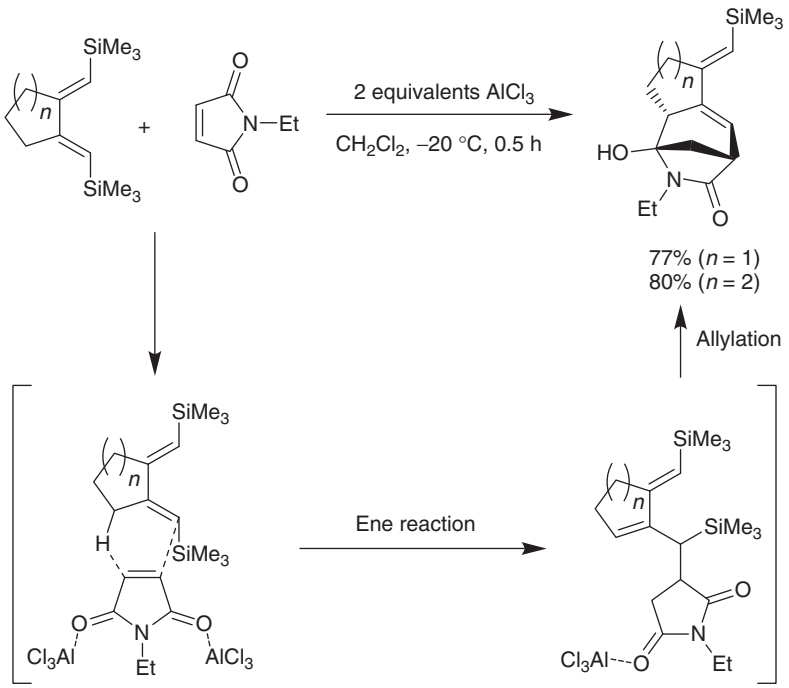
N-phenyl maleimide as enophile (Scheme 9).[30] The product ratios depend on the electronics of the substituent R, the solvent, and the reaction temperature.



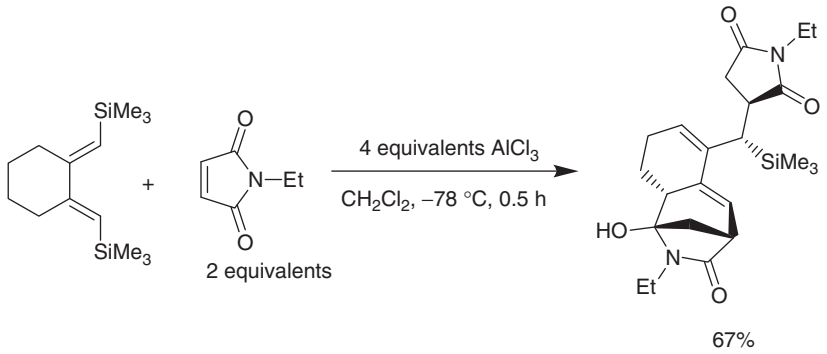
1,4-Bissilylated 1,3-butadienes are densely functionalized building blocks that can undergo pericyclic and organometallic elementary reactions. Li et al.[31] have recently demonstrated the domino-ene-allylation reactivity of these dienes with *N*-ethyl maleimide as an enophile, furnishing complex substituted tricycles (Scheme 10). The same group has elaborated this key steps into domino reactions consisting of ene/allylation/ene and ene/allylation/Diels–Alder sequences (Schemes 11 and 12).[32] In the latter case it was even possible to conclude the domino sequence by a second intramolecular allylation to give a complex polycyclic framework (Scheme 13).

Besides carba-ene partners, hetero-ene components as exemplified in the Conia-ene reaction,[2] have also found considerable interest during the past two decades, in particular, in the development of heterocycle syntheses.

Heterocyclic ketene aminals bearing an electron-withdrawing functionality at the β-position are well-suited to undergo aza-ene reactions with enones, thus opening an efficient entry to imidazo[1,2-*a*]pyridine derivatives (Scheme 14).[33] With methyl vinyl



Scheme 8 Domino ene-hydroamination sequence.



Scheme 9 Domino [4 + 2]/ene reaction sequence starting from 4-vinylimidazoles as dienes.

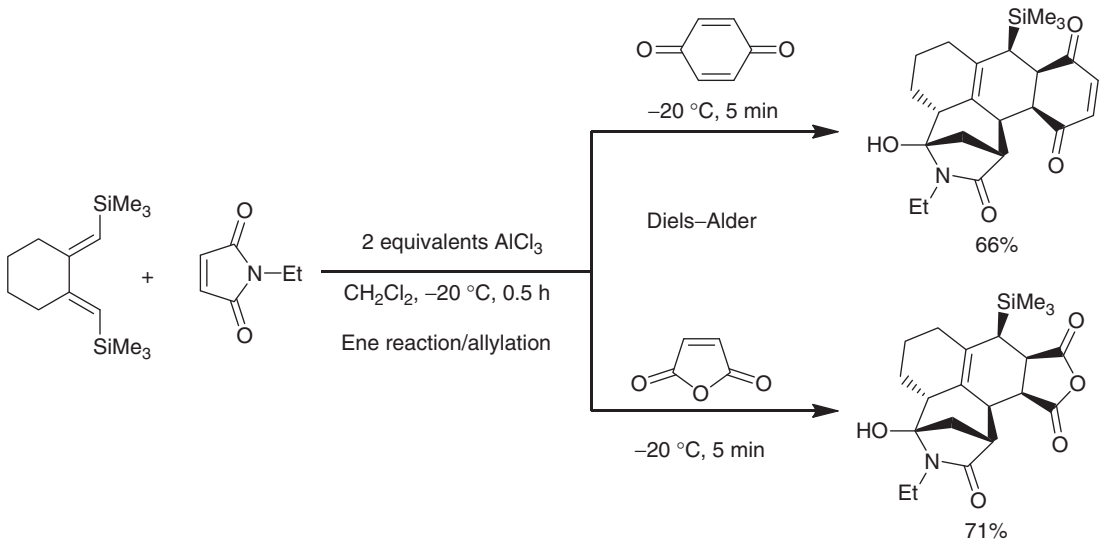
ketone as the enophile, the aza-ene-cyclization sequence proceeds twice and terminates under acyl cleavage in wet acetonitrile to furnish imidazo[1,2,3-*ij*][1,8]naphthyridinium salts (Scheme 15).

The *in situ* formation of the enophile via Knoevenagel condensation was elaborated by Wen et al.[34] and has opened new avenues to multicomponent syntheses of imidazo[1,2-*a*]pyridines and benzo[*b*]imidazo[1,2,3-*i,j*][1,8]naphthyridines via a domino sequence consisting of an aza-ene-cyclization and subsequent intramolecular nucleophilic aromatic substitution (Scheme 16).

Scheme 10 Domino ene reaction/allylation of 1,4-bissilylated 1,3-butadienes.

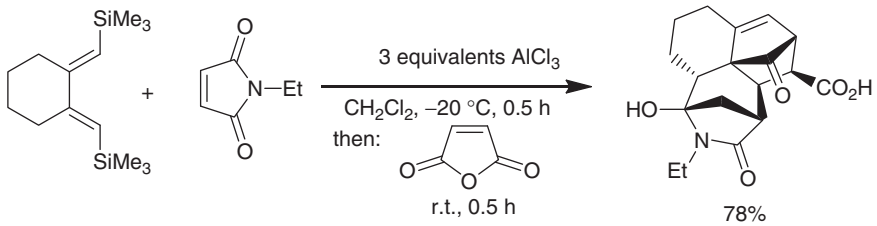
Scheme 11 Domino ene/allylation/ene reaction sequence.

5.01.2.1.2 Strained alkenes as enophiles



The reactivity of enophiles significantly increases through implemented strain, which directly influences the positioning of the frontier molecular orbitals. Therefore, in the past two decades, strained alkenes have found entry into Alder-ene reactions as enophiles that do not require catalysis in order to reach high rates. In particular, cyclopropenes are well known to readily undergo ene reactions.[35]

Ashirov et al.[36] have impressively demonstrated the use of 3-methylcycloprop-1-ene-3-carbonitrile as a strained enophile that can be favorably applied in prenylations of (–)-*β*-pinene and *R*-(–)-carvone (Scheme 17).



Lodochnikova et al.[37] have discovered a domino sequence where excess 1-methyl-2-cyclopropene-1-carbonitrile was successfully transformed with 1,4-cyclohexandiene or allocimene to give the products of an Alder-ene and a Diels–Alder reaction (Scheme 18). The strained cyclopropene derivative acts first as an enophile and then as a dienophile, giving rise to the formation of the 2:1 adduct as a single diastereomer.

Self-tetramerization of 3-methyl-3-cyanocyclopropene was observed at elevated temperatures. A mechanistic reasoning based on DFT modeling suggests biradical species as intermediates in the course of the process that occurs via cyano migration.[38]

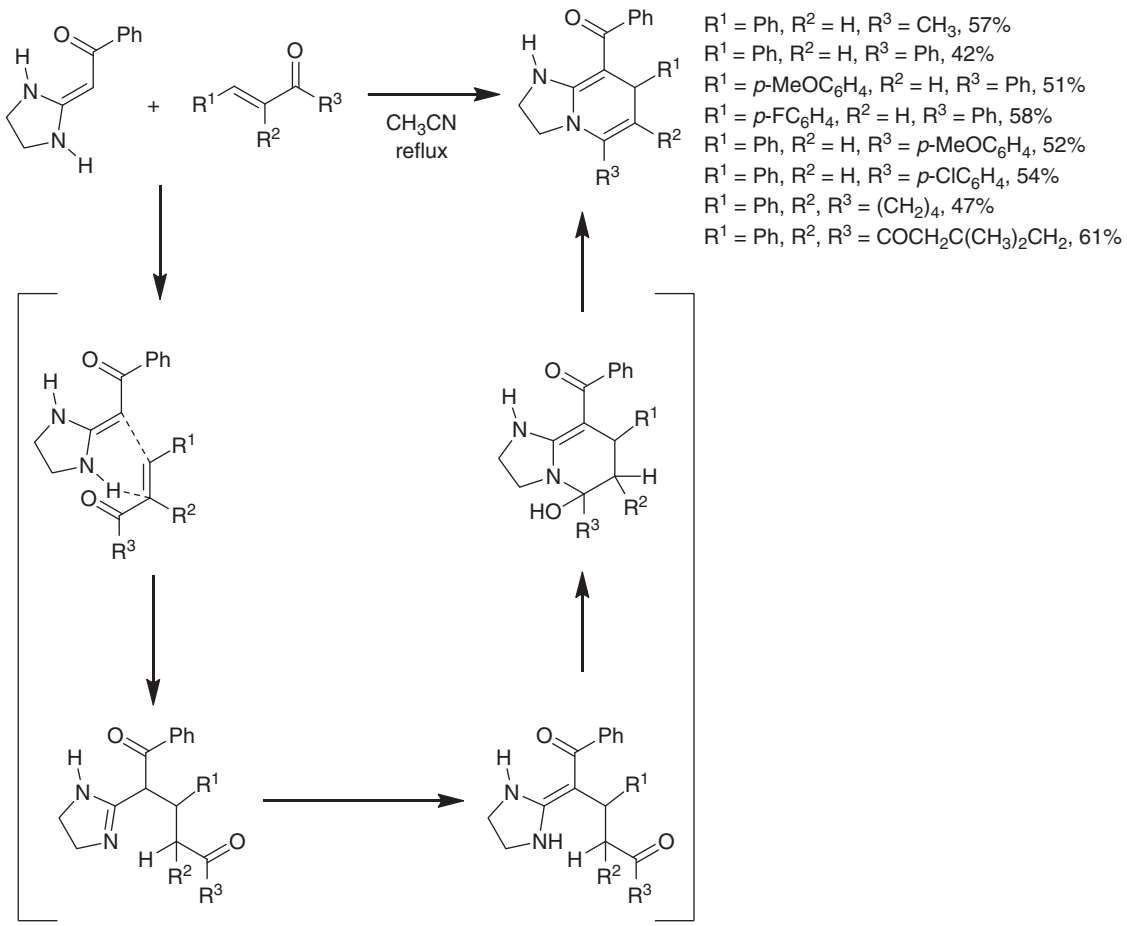
1-Phenylcyclopropene can be readily prepared by bromine–lithium exchange of 1,1,2-tribromo-2-phenylcyclopropane with methyllithium followed by protonation of the trapping cyclopentadiene (Scheme 19).[39] Under these trapping conditions, Lee and Chang also observed that 1-phenylcyclopropene undergoes a dimerization via an *endo*-transition state of an Alder-ene

Scheme 12 Domino ene reaction/allylation/Diels–Alder sequence.

Scheme 13 Domino ene reaction/allylation/Diels–Alder/allylation sequence.

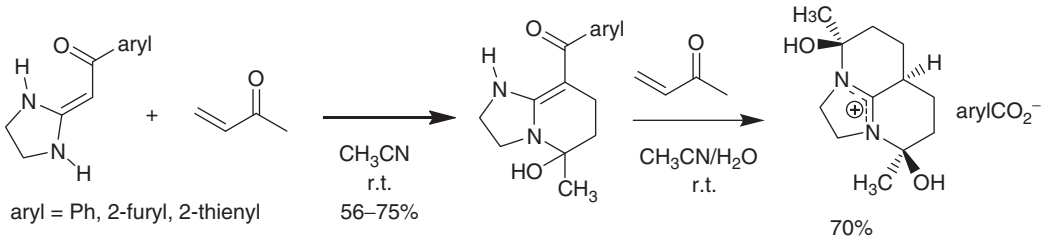
reaction. Without a trapping diene, 1-phenylcyclopropene predominantly trimerizes via the Alder-ene pathway in an *endo-endo*-fashion (Scheme 20). The minor dimer, which was detected under these conditions and identified by subsequent cyclobutane reversion and oxidation, is the product of a formal [2 + 2]-cycloaddition.

1-Trimethylsilyl-3-phenylcyclopropene, which is generated *in situ* from a tribromo phenyl cyclopropane by bromo-lithium exchange and subsequent trapping with trimethylsilyl chloride, readily dimerizes at room temperature to give an Alder-ene product in the absence of another ene partner as a trapping agent (Scheme 21).[40] At temperatures lower than –50 °C, 1-trimethylsilyl-3-phenylcyclopropene is stable toward dimerization; however, the mode of preparation already has a considerable influence on the yield. 1-Trimethylsilyl-3-phenylcyclopropene is the major product from the *trans*-dibromo cyclopropane, whereas the allene or the isomeric alkyne is preferentially formed from the *cis*-diastereomer (Scheme 22).



In the absence of a suitable trap, 1-trimethylsilyl-3-phenylcyclopropene reacts in highly stereocontrolled ene reactions to give a dimer and trimers (Scheme 23). The dimer can be trapped by a Diels–Alder reaction with cyclopentadiene.

When embedded in bicyclic and polycyclic frameworks, the reactivity of cyclopropenes is considerably increased. Therefore, characteristic alkene trapping reactions, such as Diels–Alder and ene reactions, can be well applied as an indirect evidence for the presence of highly strained alkenes.



Graf and Szeimies[41] have disclosed several ene trapping reactions. Starting from 1,6-dibromotricyclo[3.1.0.$0^{2,6}$]hexane, bromine–lithium exchange at low temperatures followed by elimination of lithium bromide generated the highly strained tricyclo[3.1.0.$0^{2,6}$]hex-1(6)-ene, which undergoes an instantaneous ene reaction with several allyl derivatives (Scheme 24).

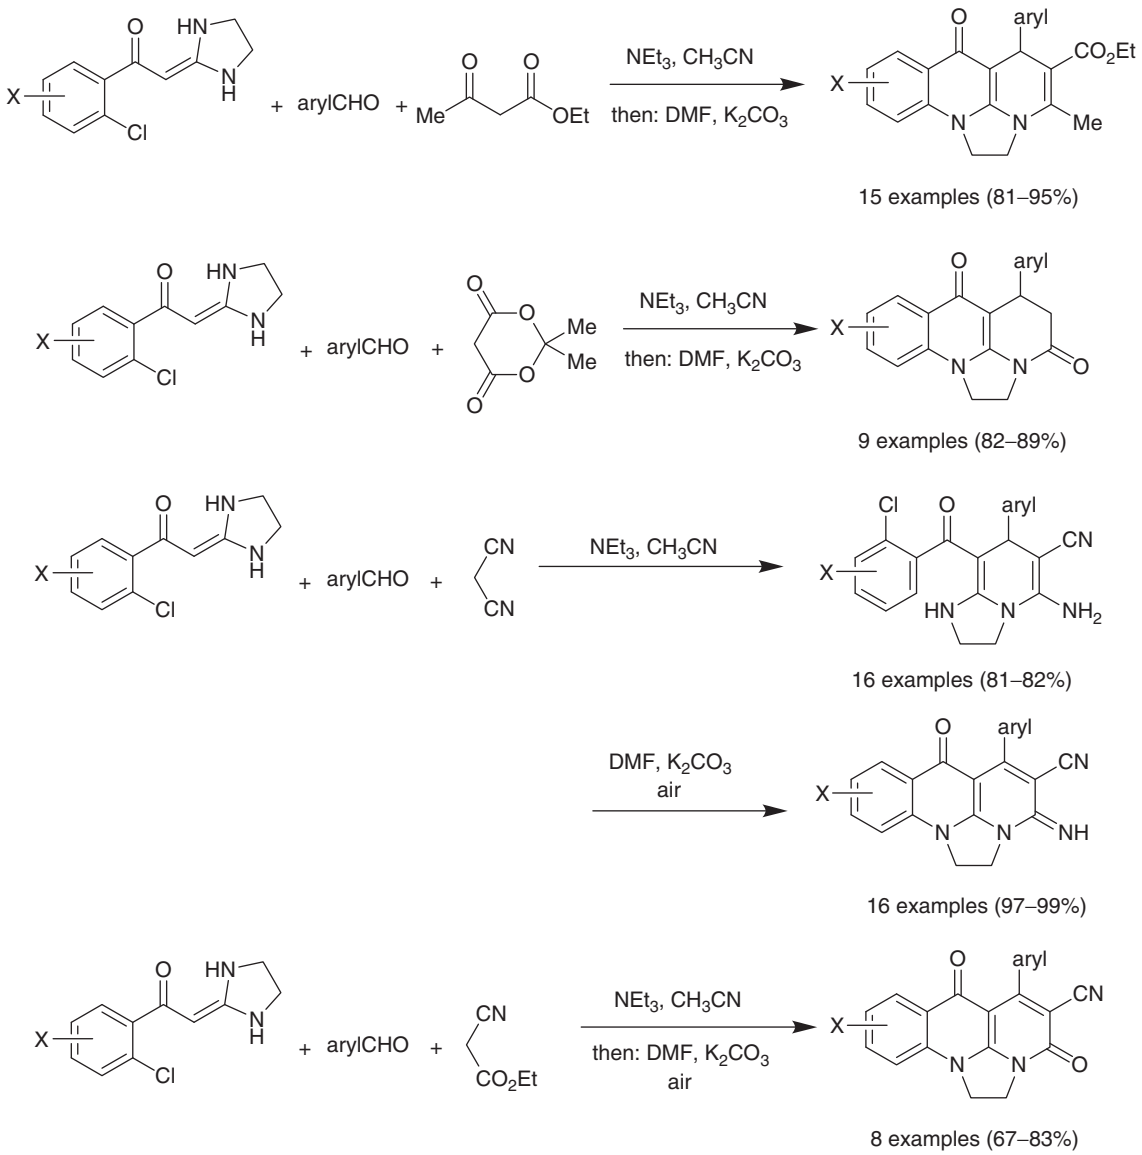
Billups et al.[42] generated bicyclo[4.1.0]hept-1,6-ene by fluoride-induced elimination in the gas phase, which immediately dimerized in an Alder-ene reaction to give two diastereomeric dimers **1** and **2** in a 1:2 ratio (Scheme 25). Likewise, bicyclo-[4.1.0]hept-1,7-ene dimerizes to give only diastereomer **1**.[43] Although the corresponding 7-chlorobicyclo[4.1.0]hept-1,7-ene rather undergoes a cyclopropene-vinyl carbene rearrangement, the homologous 8-chlorobicyclo[6.1.0]oct-1(8)-ene gives rise to the formation of the expected dimer by an Alder-ene reaction.[44] In a similar fashion, bicyclic 1,3-fused 2-(trimethylsilyl)cyclo-prop-1-enes give rise to the formation of dimers in high yields.[45]

Matsuura et al.[46] have isolated cycloprop-2-ene carboxylic acid from the toxic Asian mushroom *Russula subnigricans*. Interestingly, the toxicity, leading to fatal rhabdomyolysis (damage of muscle cells), is caused by this small ring trigger. Most amazingly, on polymerization via Alder-ene reaction, the toxicity is completely lost.

Scheme 14 Aza-ene reaction of ketene aminals with enones.

Scheme 15 Double aza-ene reaction with methyl vinyl ketone and subsequent acyl cleavage.

5.01.2.1.3 Fullerenes as enophiles



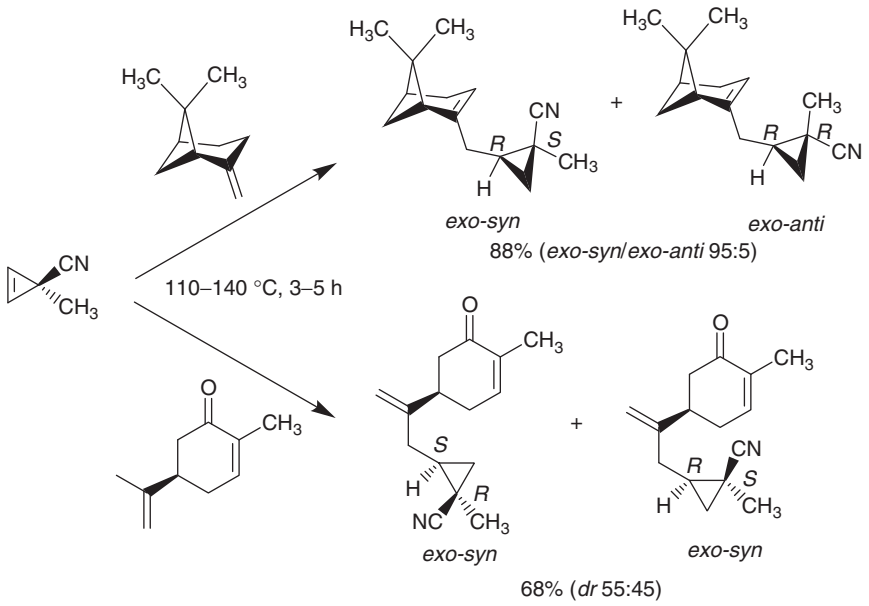
C_{60}-fullerene remarkably combines enhanced enophile reactivity with an unusual globular structural feature. Therefore, after Diels–Alder and [2 + 1] cycloadditions with fullerenes had been developed, it became obvious that ene reactions with fullerenes should also be feasible.

Independently, the groups of Wu[47] and Komatsu[48] reported successful ene reactions with C_{60} as an enophile and allylbenzene derivatives as ene partners at elevated temperatures (Scheme 26). Later, Chronakis and Orfanopoulos[49] determined the C–H breakage as a rate-determining step in the ene reaction of C_{60} with deuterated allyl benzene, hence, making the reversible formation of a charged or dipolar intermediate very likely in this particular case.

5.01.2.2 Alkynes as Enophiles

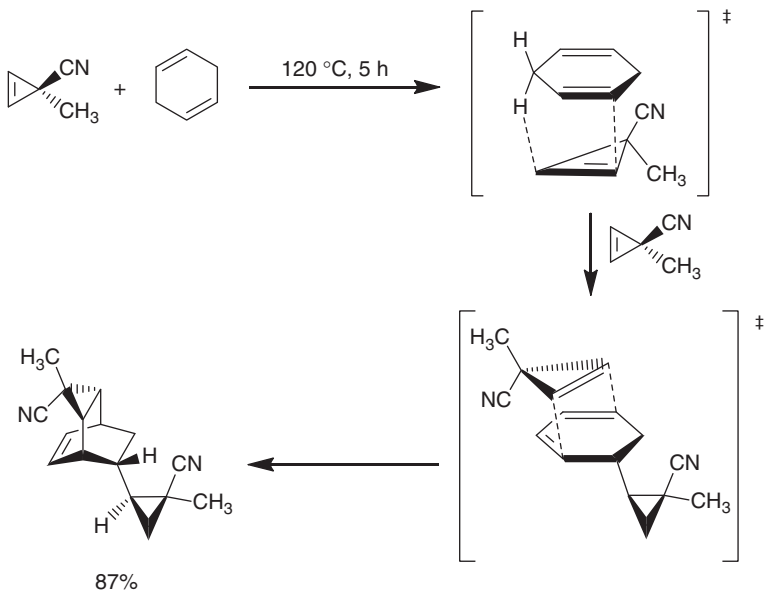
5.01.2.2.1 Electron-deficient alkynes as enophiles

2-(1-Cyclohexenyl)-1,2-dimethylindole, as well as other 3-vinylindoles,[50] is a favorable substrate for Diels–Alder reactions giving rise to more complex substituted carbazole derivatives. However, dimethylacetylene dicarboxylate (DMAD) not only acts as a



Scheme 16 Multicomponent synthesis of imidazo[1,2-*a*]pyridines and benzo[*b*]imidazo[1,2,3-*i,j*][1,8]naphthyridines.

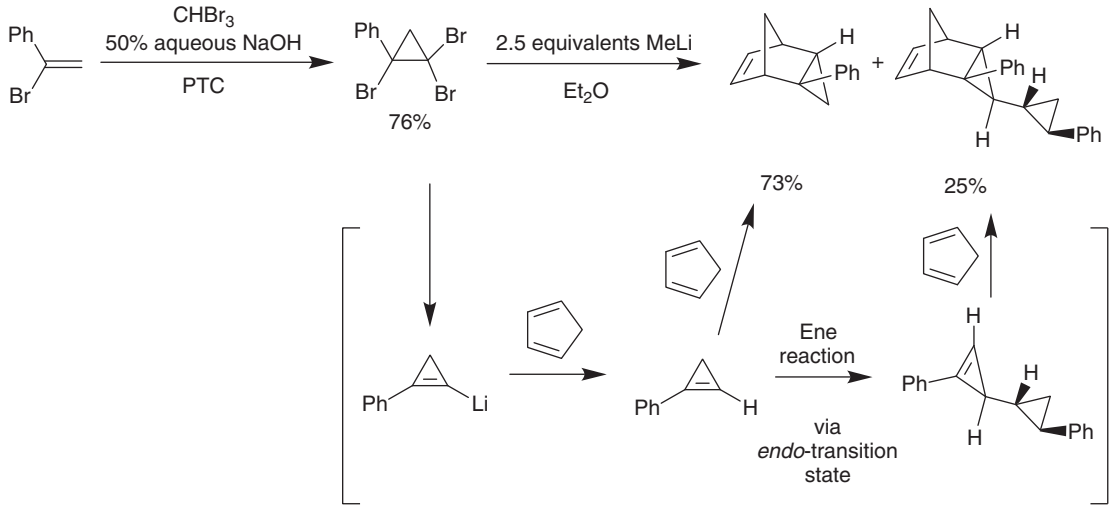
dienophile furnishing the (4 + 2) adduct in 27% yield, but also as an enophile to give the corresponding ene product in 26% yield as well as a formal Michael type adduct in 10% yield (Scheme 27).[51] A similar dichotomy was also reported for *N*-phenyl maleimide as dienophile/enophile, when 1,2-dimethyl-3-(1-methyl-1,2,3,6-tetrahydro-pyridin-4-yl)-1H-indole was applied as a substrate.[52]



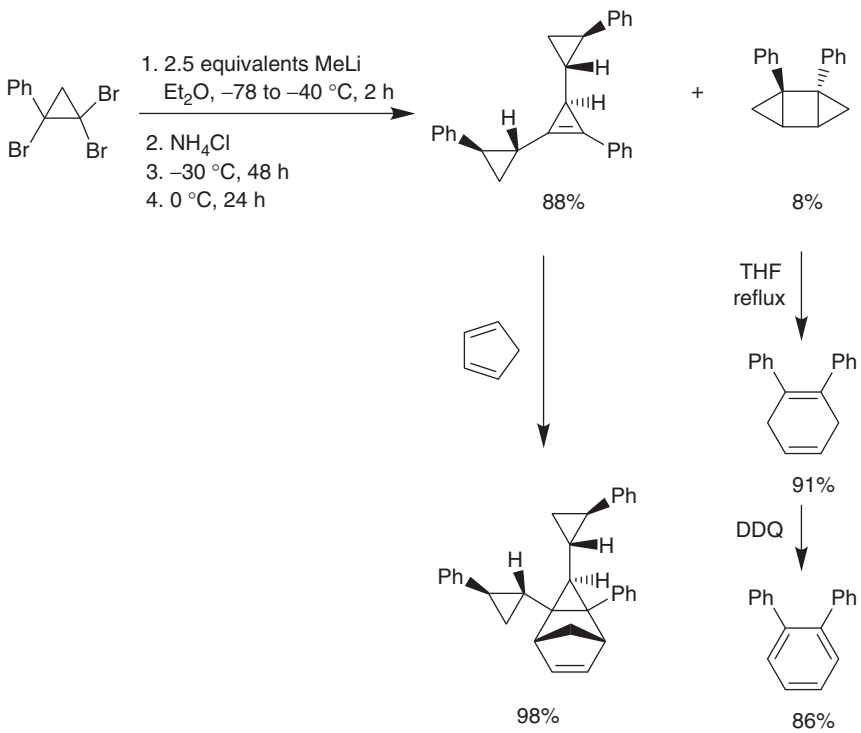
In the course of studies on synthetic transformations of abietic acid methyl ester with dienophiles such as DMAD, Haslinger and Hofner[53] found that DMAD adds to abietic acid methyl ester via an ene reaction to finally give an aromatized product in good yield (Scheme 28).

DMAD is well-suited to act both as a dienophile and as an enophile, a feature that was successfully applied in the formation of polycyclic terpenoid systems.[54] The domino process, where DMAD first reacts as an enophile followed by an intramolecular [4 + 2] cycloaddition of the ene product primarily formed, is known as the Alder–Bong reaction.[55] Giguere et al.[56] have applied this unique sequence, where two regioisomeric ene products are formed, to the stereoselective construction of the methanoazulene framework by acid catalyzed acetal cleavage and rearrangement of the major regioisomer (Scheme 29).

Alkynones behave particularly well as enophiles under Lewis acid catalysis in combination with allyl silanes as ene partners.[57] The group of Thomas has synthesized the C(1)–C(16) fragment of the bryostatins based on this methodology (Scheme 30).[58]

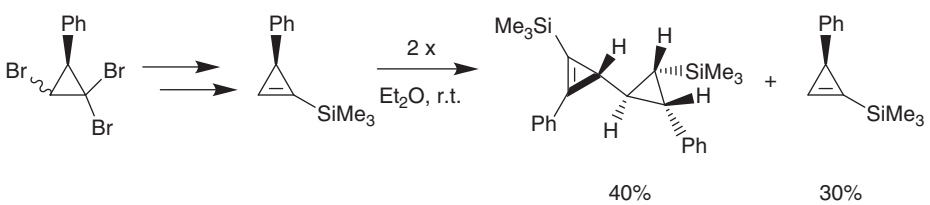


Scheme 17 3-Methyl-3-cyanocyclopropene as a building block for terpene syntheses via Alder-ene reactions.



Scheme 18 3-Methyl-3-cyanocyclopropene as an enophile and dienophile in a domino Alder-ene/Diels–Alder sequence.

In a related method, the four step synthesis of (+)-(2*R*,6*R*)-trans-γ-irone was achieved in 68% overall yield starting from (+)-(*R*)-3,4-dimethylcyclohex-2-en-1-one by Monti et al. (Scheme 31).[59] However, in this case the choice of the Lewis acid catalyst is crucial and the allyl silane rather than the vinyl silane becomes the exclusive ene product with Me_2AlCl as catalyst. The synthesis concludes with a regioselective $TiCl_4$-induced protodesilylation.



The reactions of heterocyclic ketene aminals with electron-deficient alkenes as enophiles have already been discussed in Chapter 2.1.1. The synthetic potential of reactions with electron-deficient alkynes is comparably broad. Huang and Wang[60] reported on the ene reaction of certain ketene aminals with ethyl propiolate and the subsequent transformation of the ene adducts into annelated heterocyclic systems (Scheme 32, Table 1). Depending on the substrate ratio and on the ring size of the heterocyclic ketene aminal, variable amounts of bisvinylation products can be formed. Later on, the same group scrutinized the substituent effects of this peculiar aza-ene-reaction/δ-lactamization in more detail, also with respect to other electron-withdrawing groups modulating the Michael donor/ene electronics of the aza-ene.[61]

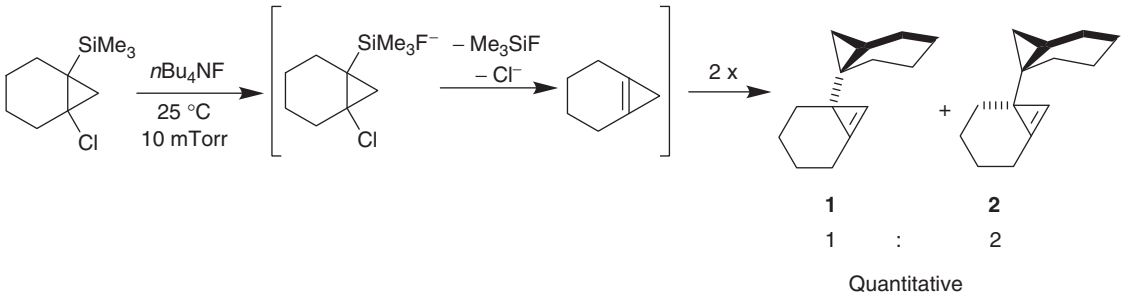
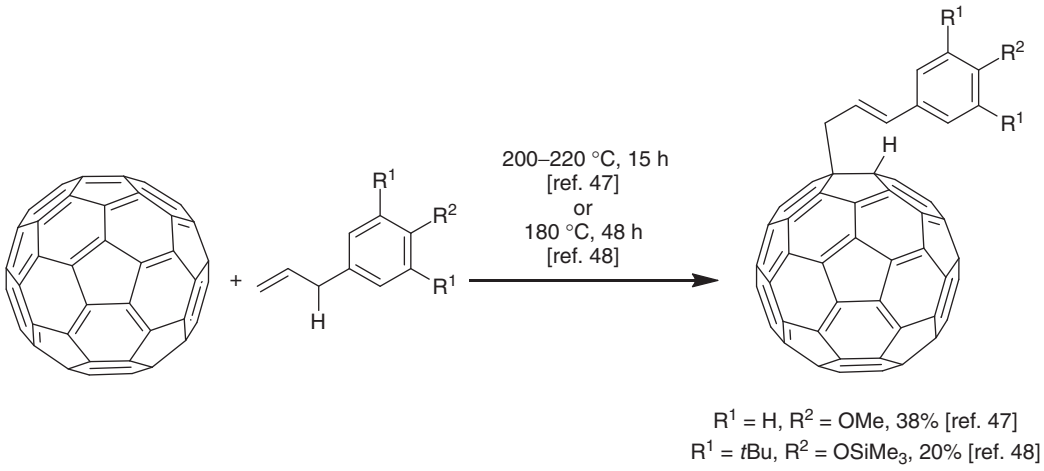


Scheme 23 Di- and trimerization of 1-trimethylsilyl-3-phenylcyclopropene via Alder-ene reaction.



The fairly electron-deficient ethyl 4,4,4-trifluorobut-2-ynoate reacts with cycloheptatriene, a highly versatile dynamic triene (tropylidene-norcaradiene equilibrium), as the ene partner in an intriguing manner. Whereas an electrocyclic ring closure with subsequent Diels–Alder reaction accounts for the formation of the major product, two isomers arising from an initial ene reaction with subsequent intra- and intermolecular pericyclic reactions are formed in constant ratios under thermodynamic and under kinetic control (Scheme 33).[62]

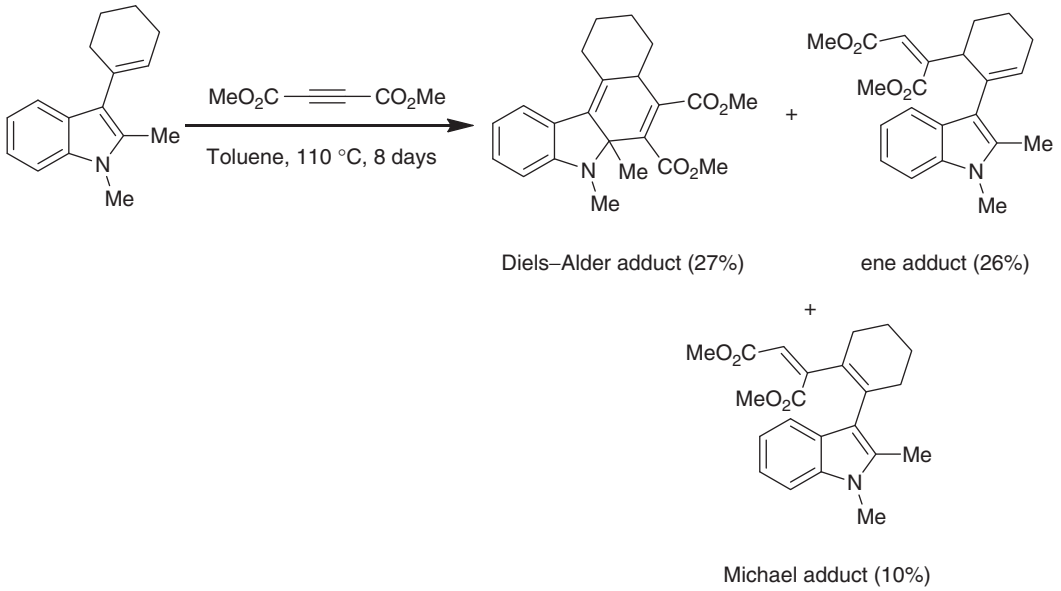
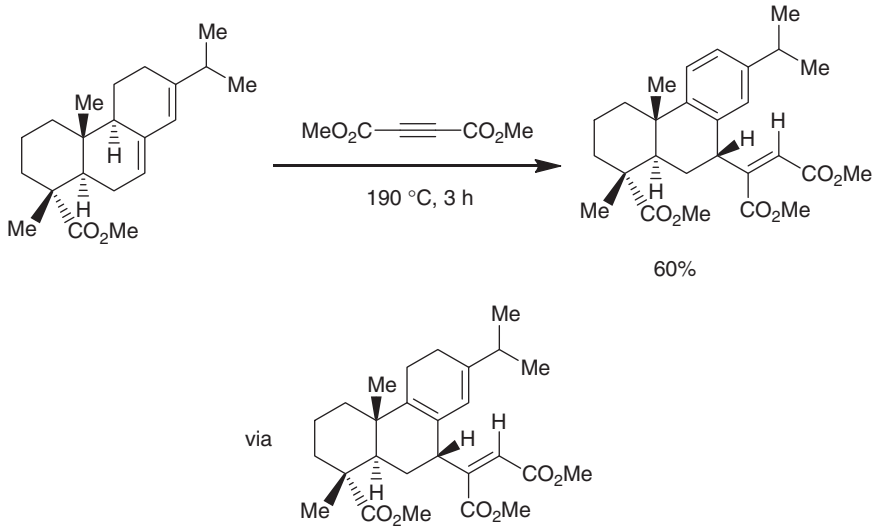


Scheme 26 Alder-ene reactions with C_{60} as an enophile.

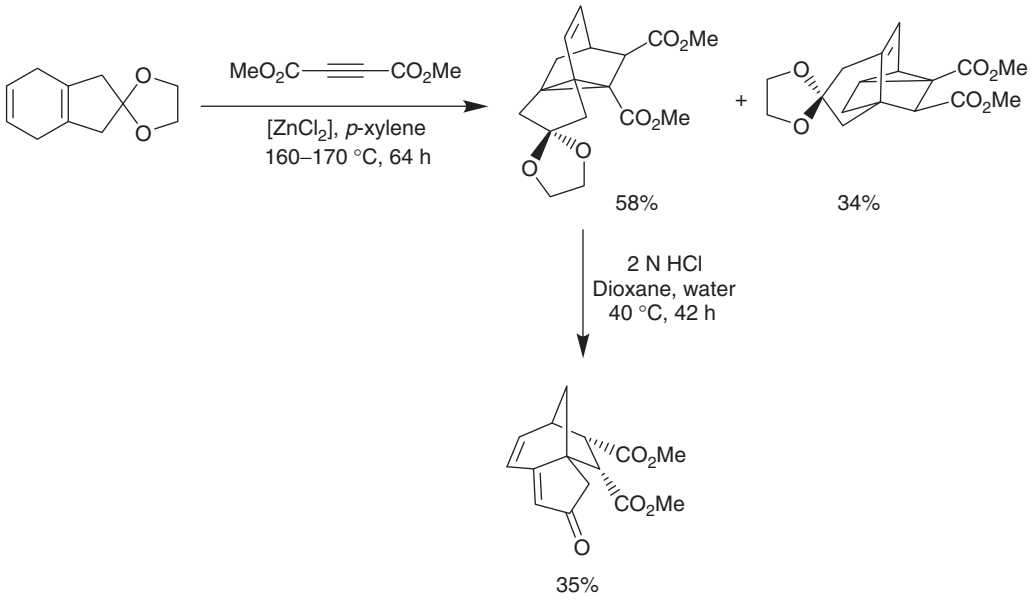


5.01.2.2.2 Electroneutral alkynes as enophiles

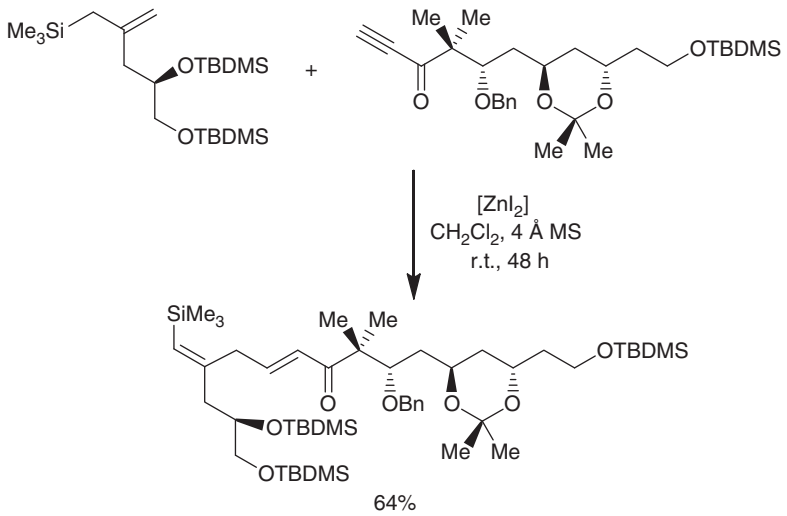
As already observed for Diels–Alder reactions, electroneutral alkynes represent relatively unreactive substrates as enophiles within the framework of pericyclic reactivity. This lack of reactivity can be partially compensated by imposing ring strain on the enophile. Protopopova and Galminas[63] have reported the first example of an ene reaction with a strained heterocyclic alkyne as an enophile and cyclopropenecarboxylic acid as an ene partner, which proceeds in good yield (Scheme 34).

However, a major breakthrough in intermolecular Alder-ene-type reactions with unactivated alkynes as enophiles was disclosed by Trost two decades ago, which has opened considerable new avenues toward convergent syntheses of natural and

Scheme 27 Diels–Alder, ene, and Michael dichotomy with DMAD as electron-deficient alkyne.



Scheme 28 Ene reaction between abietic acid methyl ester and DMAD as an enophile.

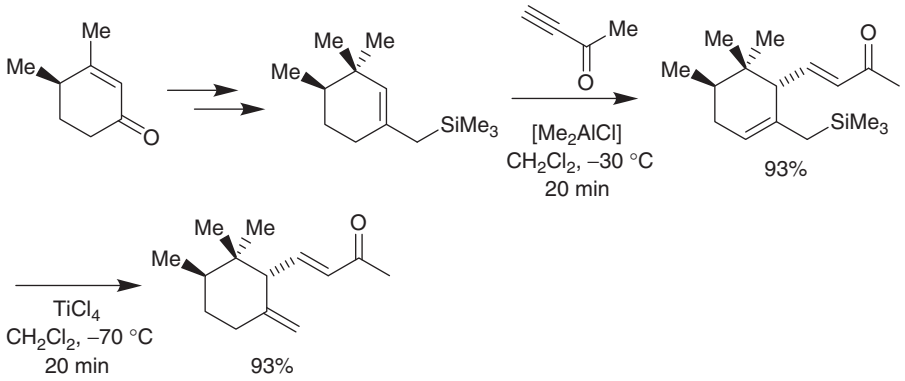


nonnatural targets. This development was based on a conceptual change of mechanism toward transition metal catalysis, in particular enabled by ruthenium catalysts.[64] In this case, a pericyclic one-step mechanism does not apply but rather multiple organometallic elementary steps are very likely involved (coordination, oxidative cyclometallation, β-hydride elimination, and reductive elimination in analogy to other transition metal-mediated processes). Later, other transition metal complexes were also discovered to catalyze the unique combination of unactivated alkyne enophiles and alkenes as ene components.

Trost and Indolese[65] reported first on the Alder-ene-type addition of alkenes to acetylenes catalyzed by CpRu(COD)Cl giving rise to the formation of a branched and a linear adduct in a 5:1 ratio in good yield (**Scheme 35**).

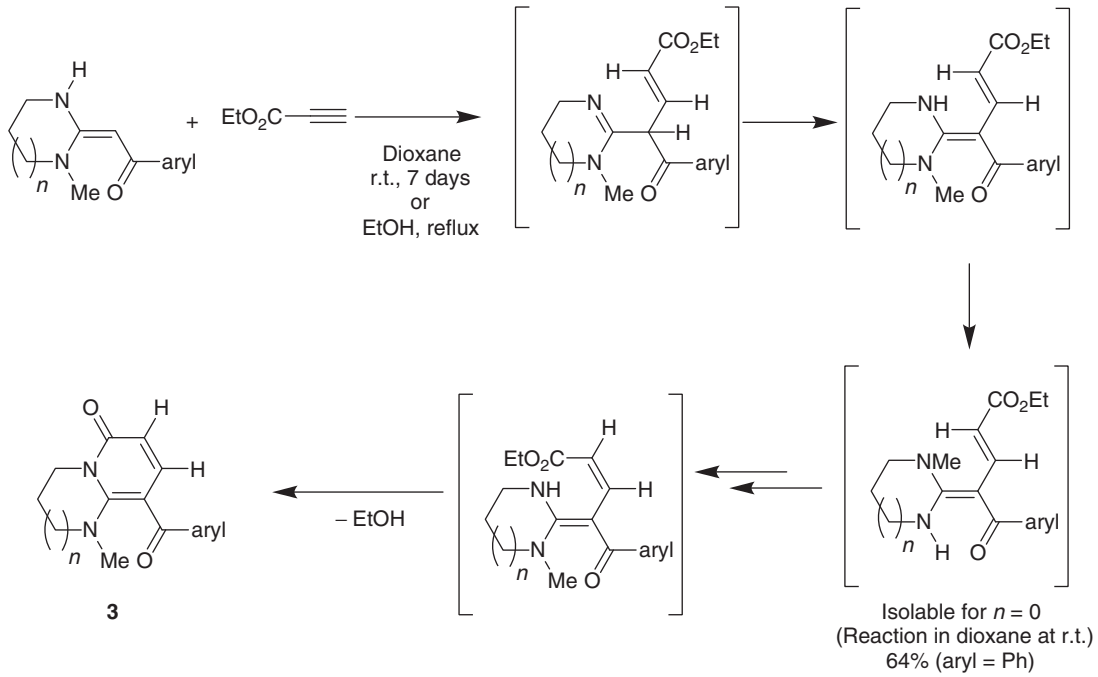
The methodology was soon generally established with terminal and internal alkynes and terminal monosubstituted olefins giving rise to numerous examples of adducts in variable regioisomeric ratios (**Scheme 36**). A broad tolerance of polar functional groups was observed, ranging from aldehydes, esters, ketones, alcohols to internal alkenes and even α,β-unsaturated carbonyl groups.[65,66] Later, Chen and Li[67] have computationally studied the mechanism of Ru-catalyzed Alder-ene-type reaction on the level of DFT, indicating a clear energetic preference of a ruthenacyle arising from an oxidative cyclization of the coordinated alkyne and alkene over Ru-allyl intermediates. However, the clear preference of the ruthenacyle pathway cannot be unambiguously determined for cationic ruthenium species as intermediates.

Scheme 29 Methanoazulene framework formation by Alder–Bong reaction, a domino ene/Diels–Alder reaction sequence with DMAD as an enophile.



Scheme 30 Allyl silane-ynone ene reaction in the synthesis of the C(1)-C(16) fragment of bryostatins.

Most interestingly, the regioselectivity is largely controlled by steric and coordination effects of the substrates, which become dominant within the coordination sphere of the metal. As a consequence, with propargyl alcohol derivatives such as γ-hydroxy alkynoates, the Alder-ene-type addition even gives rise to the contra-electronic addition of the alkene to the α-position of the ynoate, favoring the formation of α-allylated butenolides **3** over the uncyclized β-allylation product **4** (Scheme 37, Table 2).[68] Likewise γ-amino alkynoates react with monosubstituted alkenes to give the corresponding Alder-ene adducts, which can be subsequently cyclized with a tin catalyst to furnish pyrrolinones.[69]



Hartley and Pyne[70] have found that the efficiency of the Ru-catalyzed Alder-ene reaction of hydroxyl substituted alkenes seriously depends on the nature of the O-protecting groups as well as on the number of methylene groups between the hydroxyl and the alkene group (Scheme 38, Table 3).

With the cationic complex $CpRu(MeCN)_3PF_6$, the regioselectivity can be even more enhanced and a broad range of internal alkynes as enophiles can be transformed with moderate to high levels of selectivity, thus opening a stereoselective and versatile access to trisubstituted alkenes.[71,72]

Trost et al.[68–73] and others have impressively demonstrated the utility of this unique reaction as a key step in the total syntheses of the acetogenins (*S*,*S*)-ancepsenolide, and *cis*-solamin,[74] the furanocembranoid (±)-bipinnatin J,[75] the macrolides

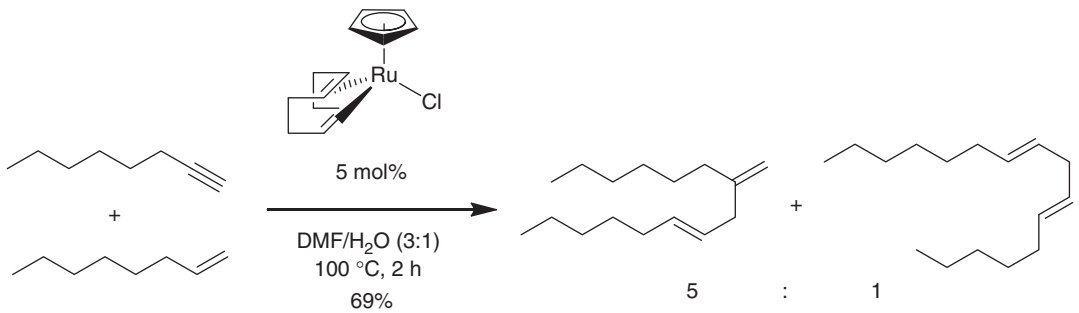
deschlorocallipeltoside A,[76] callipeltoside A,[77] and (–)-dactylolide,[78] and in the formal synthesis of the fungal germination inhibitor alternaric acid (Table 4).[79]



Finally, several further methodological developments have considerably extended the synthetic utility of Ru-catalyzed Alder-ene reactions. Trost et al.[80] could show that vinyl silanes, which are suitable substrates for subsequent Hiyama-type

Scheme 38

cross-couplings, are very efficiently obtained via Ru-catalyzed Alder-ene reaction from terminal benzyldimethylsilyl-substituted alkynes (Scheme 39).

Lee and his group impressively showed that di- and triynes are enophiles that can be efficiently coupled with terminal alkenes with high regio- and site-selectivity (Scheme 40, Table 5).[81]

Borylated alkynes as enophiles can be transformed with high selectivity into β,β-disubstituted vinyl boronates (Scheme 41),[82,83] which are valuable building blocks for cross-coupling reactions. It is remarkable that these reactions occur with the opposite stereochemistry as compared to reactions of many other types of internal alkynes.

In recent years, Hilt and his group have developed cobalt-catalyzed Alder-ene-type reactions in the course of their methodological and synthetic studies on transformations of alkynes with low-valent cobalt catalysts.[84] Functionalized 1,4-dienes are obtained in good yields and with excellent chemo-, regio-, and stereoselectivity (Scheme 42, Table 6).[85]

Yet, some remarkable differences to the dominant Ru-catalyzed Alder-ene reactions have become apparent. With ynoates as enophiles, the opposite regioselectivity is obtained in comparison to Trost's CpRu-based catalyst systems. Cyclopentene as an ene component furnishes the Alder-ene product **5** if dppe is employed as a ligand on cobalt, whereas dppp gives rise to the formation of the [2 + 2]-cycloadduct **6** (Scheme 43).[86] Mechanistically, this ligand- and substrate-dependent dichotomy is rationalized by the tendency of the cobaltacyclopentene to either undergo reductive elimination (toward cyclobutene anellation) or β-hydride elimination (toward the Alder-ene product).

Alkenyl-silanes and -boronates as ene components can be efficiently employed in cocatalyzed Alder-ene-type reactions furnishing valuable building blocks for silicon and boron mediated C–C bond forming reactions such as Suzuki cross-coupling, Sakurai allylation, or Prins-type cyclization.[87]

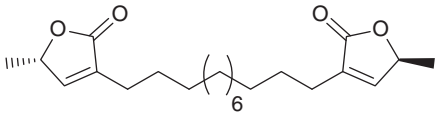
5.01.2.3 Benzynes as Enophiles

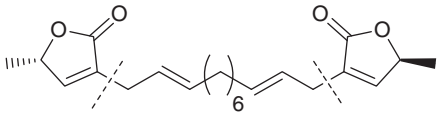
Benzynes are particularly reactive π-systems, which can only be selectively reacted on *in situ* generation in the presence of suitable trapping agents.[88] With alkenes as traps, benzynes can well behave as enophiles giving rise to the formation of Alder-ene adducts. Mechanistically, this unique type of ene reaction has also been studied by a combination of mass spectrometry and quantum chemical computations.[89]

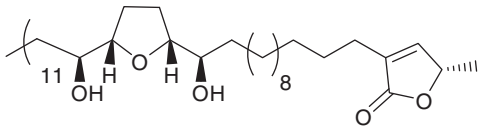
Drouin and Jacq[90] showed that the *in situ* generation of benzyne from *o*-bromofluorobenzene and magnesium in THF in the presence of β-pinene is well suited for an efficient synthesis of 10-phenyl-α-pinene in the sense of an ene reaction (Scheme 44).

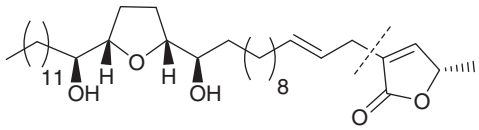
Dolbier et al.[91] have demonstrated the generation of (dehydro)octafluoro[2.2] paracyclophane using the Cadogan method (N-nitrosation of acetanilides followed by thermal elimination of nitrogen and acetic acid) and the *in situ* trapping of the benzyne intermediate with alkenes in the sense of ene reactions (Scheme 45). Likewise, 1,3,5-cycloheptatriene was found to react with the same benzyne derivative via a sequence of an ene reaction, an electrocyclic ring closure (tropylidene–norcardiene equilibrium), and subsequent Diels–Alder reaction with excess aryne.[92]

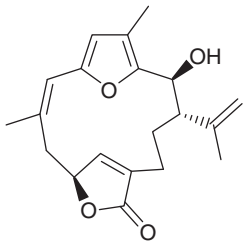
Arynes can also be prepared under mild conditions (moderate temperatures) from *ortho*-silyl aryltriflates.[93] Jayanth et al.[94] have employed this peculiar *in situ* aryne generation for ene reactions with alkynes possessing a propargylic hydrogen to furnish arylsubstituted allenes in good yields (Scheme 46).

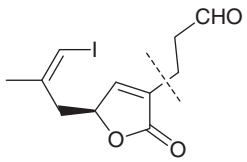


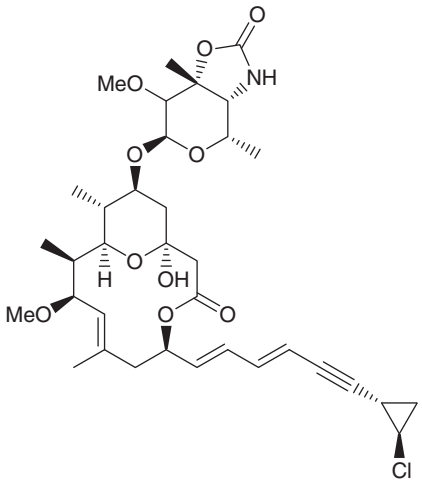


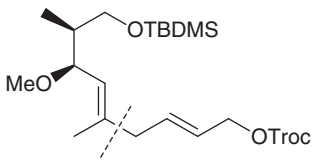


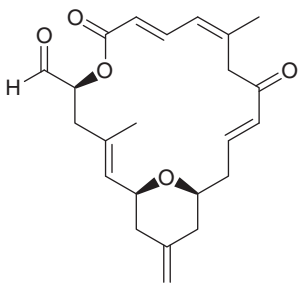


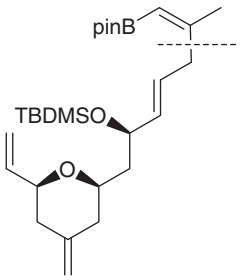


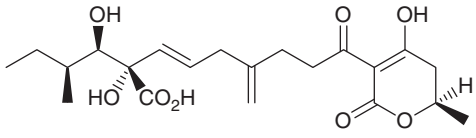


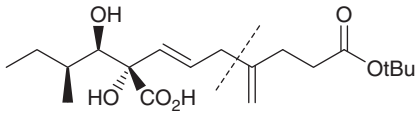




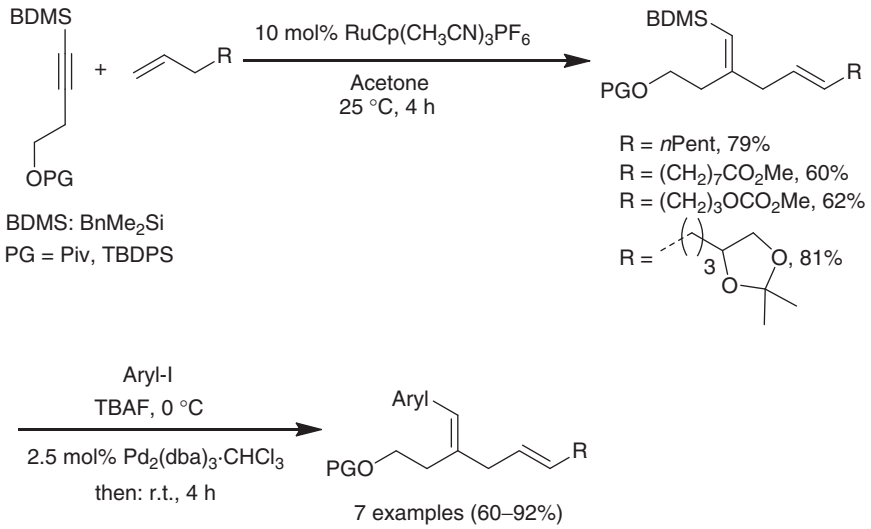






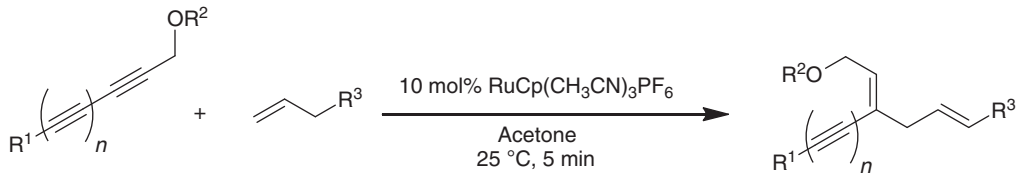


5.01.2.4 Intermolecular Photo-Ene Reactions



The first photo-ene reactions were observed with methyl-substituted psoralen derivatives, such as 4′-(hydroxymethyl)-4,5′,8-trimethylpsoralen and 4,5′,8-trimethylpsoralen, that preferentially reacted with cyclic olefins in deoxygenated solution via an ene reaction, whereas simple *n*-alkenes rather formed the [2 + 2] cycloadducts.[95] 9-Methylene-9,10-dihydrophenanthrene was found to undergo ene reactions with alkenes as enophiles under irradiation with UV-light, giving rise to the formation of the photo-ene adducts (Scheme 47).[96]

5.01.3 Alder-Ene Cycloisomerizations



Intramolecular reactions are often entropically favored due to lesser degrees of rotational freedom. As a consequence of unimolecular elementary steps, higher rates are found. In addition, pericyclic reactions always have aroused considerable interest for the rapid construction of complex molecular frameworks. Therefore, many synthetic applications of intramolecular ene reactions have been developed in the past 20 years, additionally enriched by the advent of novel organometallic catalytic methodologies.

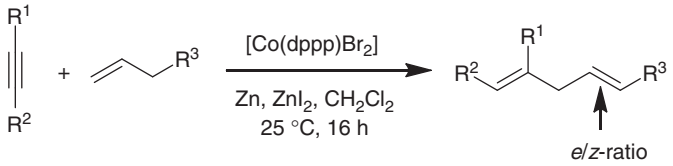
5.01.3.1 Alkenes as Enophile Moiety

5.01.3.1.1 Electron-deficient alkenes as enophile moieties



The intramolecular ene reaction with enoates as enophile component and an ene tethered by an alkyl chain opens a general access to substituted cyclopentanes.

Taber et al.[97] have developed a potential route to neuroprostanes and isoprostanes with an intramolecular ene reaction as a key step (**Scheme 48**).

Sarkar et al.[98–100] could show that the Alder-ene cycloisomerization of activated 1,6-dienes allows for a facile access to cyclopentanoid allylsilanes and that the formation of three contiguous stereocenters can be controlled. For illustration, the thermal cycloisomerization at 235 °C found use in the syntheses of two jasmonoid natural products, (±)-methyl cucurbate and

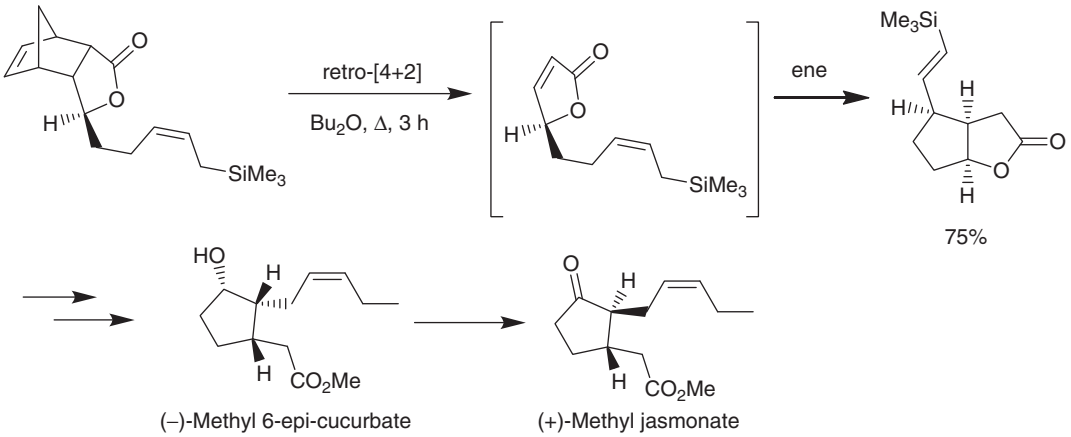
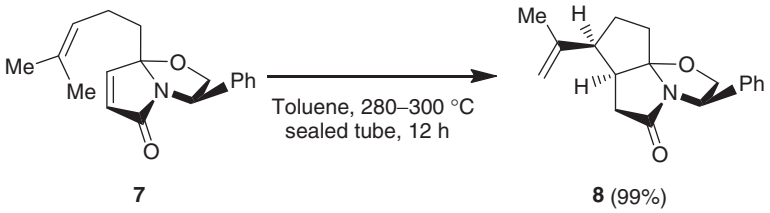
(±)-methyl epijasmonate (Scheme 49). Likewise, the same group has applied this methodology to the synthesis of di- and triquinanes and has illustrated the versatility in the synthesis of the fungal metabolite (±)-hirsutene. The use of $LiClO_4$ as a Lewis acid catalyst was demonstrated by Sarkar et al.[101] to cause a dramatic acceleration of the ene reaction, providing a mild and effective methodology for synthetic applications.



Scheme 48 Thermal intramolecular ene reaction as a key step in the synthesis of isoprostanes and neuroprostanes.



Scheme 49 Ene key step in the synthesis of (±)-methyl cucurbate and (±)-methyl epijasmonate.

In a related fashion, Suzuki et al.[102] successfully used a thermal retro-Diels–Alder/ene domino process, activated by a trimethysilyl substituent, as the key step in an enantiocontrolled synthesis of (–)-methyl 6-epi-cucurbate and (+)-methyl jasmonate (Scheme 50).

Scheme 51 Intramolecular ene reaction of a chiral bicyclic lactam.

As Michael systems, vinyl sulfoxides are electronically favorable enophiles, in particular, for ene reactions with normal electron demand. In addition, the inherent chirality of asymmetrically substituted sulfoxides has opened new avenues for applications in asymmetric syntheses.

Hiroi and Umemura[104,105] have disclosed a chiral α-cyanovinyl sulfoxide as an efficient chiral enophile for intramolecular ene reactions with high levels of stereoselectivity, provided that diethylaluminium chloride is employed as a catalyst (Scheme 52). A chiral α-sulfinyl α,β-unsaturated ketone rather furnishes a mixture of Diels–Alder and ene products.[106]

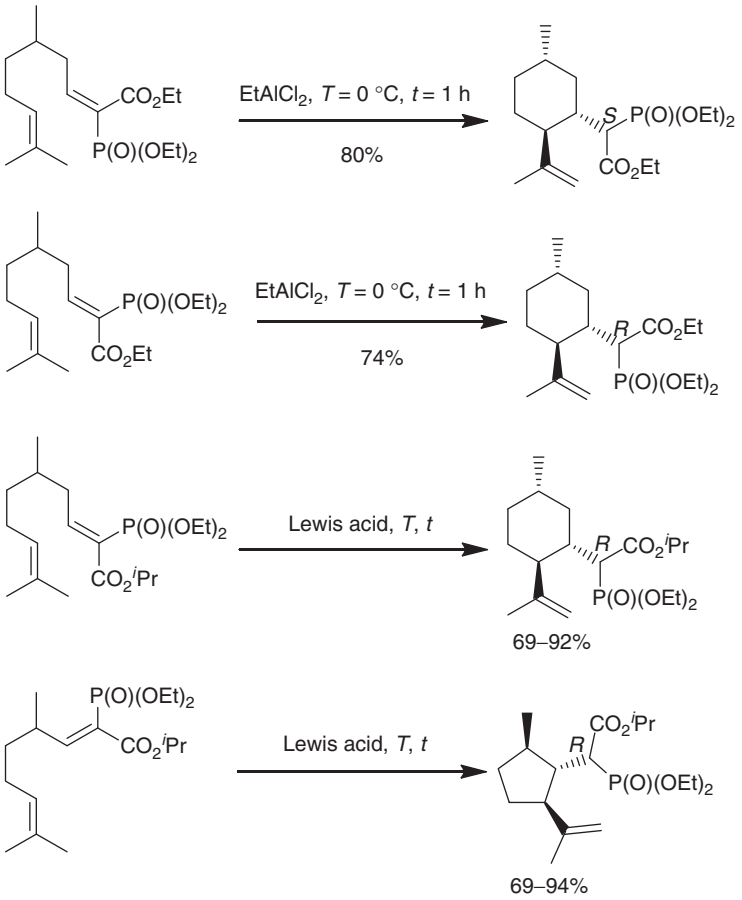
62% (*de* 97.3%)

Scheme 52 A chiral α-cyanovinyl sulfoxide as an efficient chiral enophile for Lewis acid-catalyzed intramolecular ene reactions.

Vinylphosphonates are also well suited as enophile moiety in intramolecular ene reactions. Minami et al.[107] presented a study where vinyl phosphonates, readily generated from citronellal or 2,6-dimethyl-5-heptenal, efficiently underwent an intramolecular Alder-ene reaction (Scheme 53). This key step was successfully applied to the synthesis of cadalane and valerenic acid sesquiterpenoids.

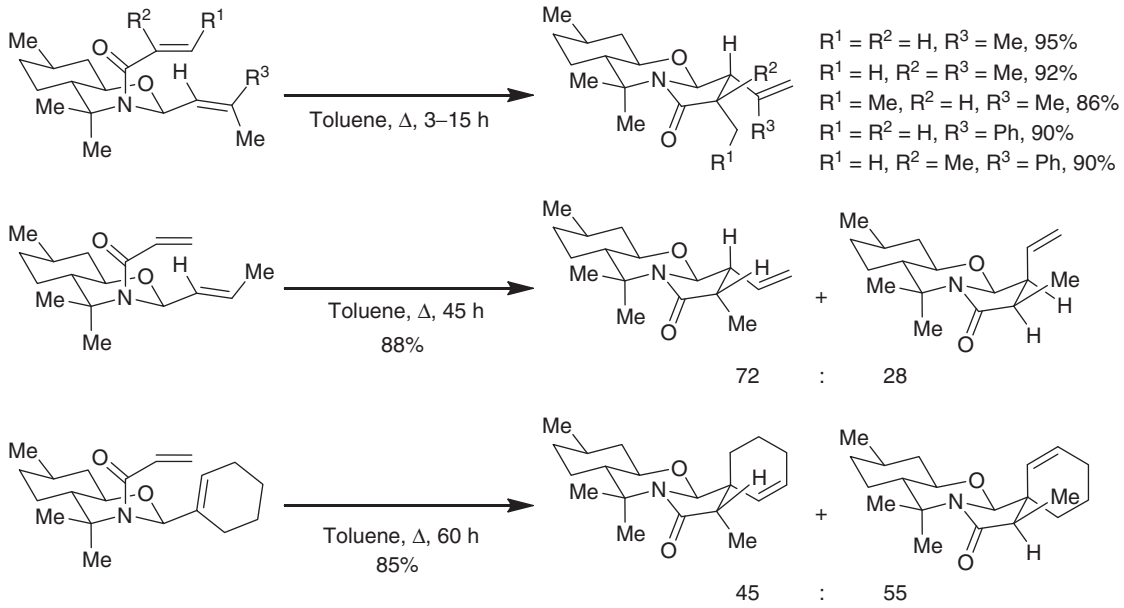
Likewise, heteroatoms in the tether of the enophile and the ene component open accesses to heterocycles via ene reactions. Based on an amide tether incorporated into a chiral aminal auxiliary, Pedrosa et al.[108] have disclosed a thermal intramolecular ene reaction furnishing 3,4-disubstituted pyrrolidinone derivates with excellent levels of diastereoselectivity (Scheme 54).



Noguchi et al.[109] found that *N*-allyl or *N*-crotyl substituted 2-amino vinylpyrido[1,2-*a*]pyrimidin-4(4*H*)-ones give annelated azepine derivatives as a consequence of an intramolecular Alder-ene reaction (Scheme 55).

The group of Sammes found that steric buttressing by bulky substituents, such as trityl, on the nitrogen atom of diallyl amine derivatives enables uncatalyzed ene reactions under remarkably mild conditions, which can be even implemented in a domino-Diels–Alder/ene sequence (Scheme 56).[110] *N*-Isoprenyl-*N*-γ-crotonates, i.e., the allyl amines bearing an electron-withdrawing ester group, react under kinetic control to give vinyl pyrrolidines with good levels of diastereoselectivity.[111]

α-Kainic acid is a biologically highly active molecule with a broad pharmaceutical potential, in particular, as it causes neuro-excitatory activity in several neurological disorders.[112] As a consequence, even up to very recently,[113] α-kainic acid and analogs[114] have received considerable attention by the synthetic community. The retrosynthetic analysis suggests an intramolecular ene reaction for the stereoselective formation of the pyrrolidine ring. Several enantioselective syntheses of (–)-α-kainic acid are based on this approach.



Xia and Ganem[115] reported an elegant application of a Lewis acid mediated enantioselective ene reaction with $Mg(ClO_4)_2$ and a (*R*,*R*)-4,4′-diphenyl bisoxazoline as a chiral ligand on the way to the kainic acid ring system (Scheme 57).

Majik et al.[116] have disclosed very recently the first example of a domino Wittig/intramolecular ene reaction in the synthesis of racemic kainic acid (Scheme 58). In that approach a stabilized phosphorus ylide with a tethered prenyl moiety undergoes a Wittig olefination with glyoxalic acid; the resulting product is subsequently transformed to give the *cis*-fused pyrrolidine skeleton of kainic acid in a one-pot fashion.

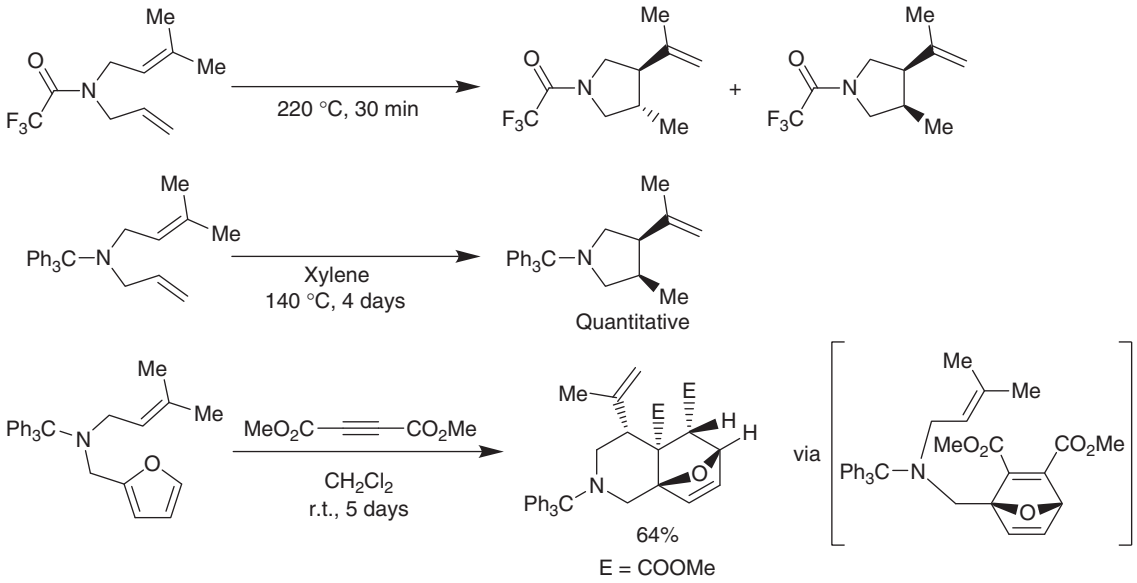
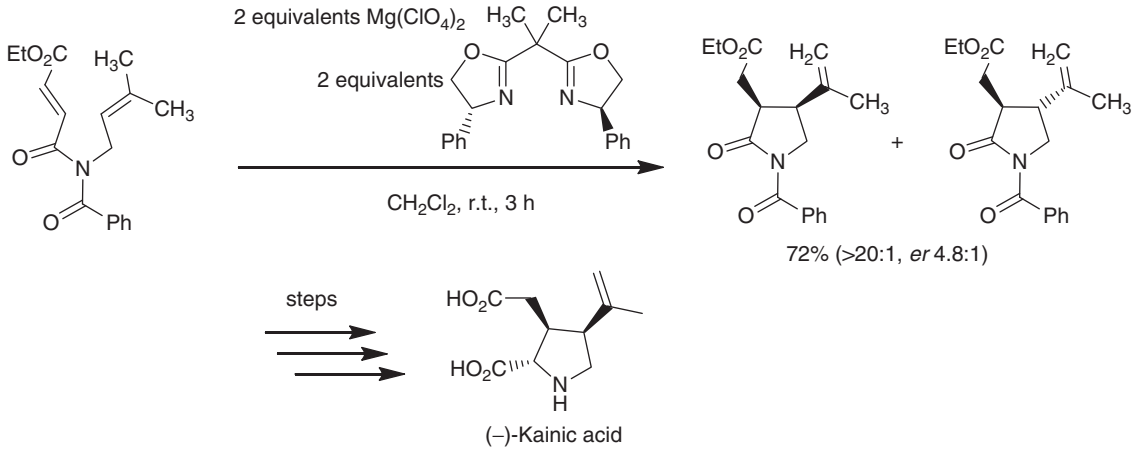
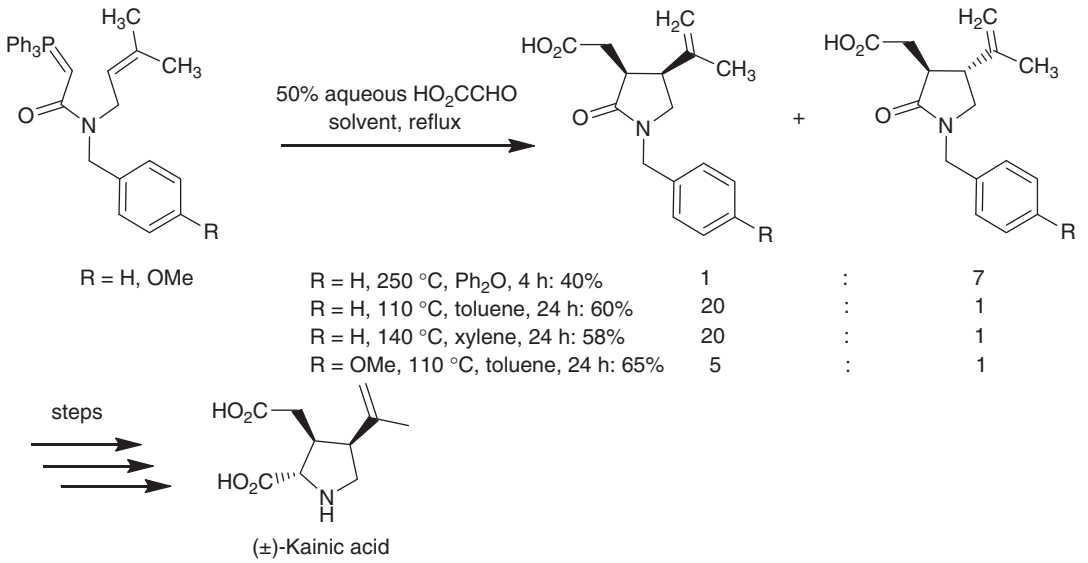


Scheme 53 Intramolecular ene reaction of vinylphosphonates.

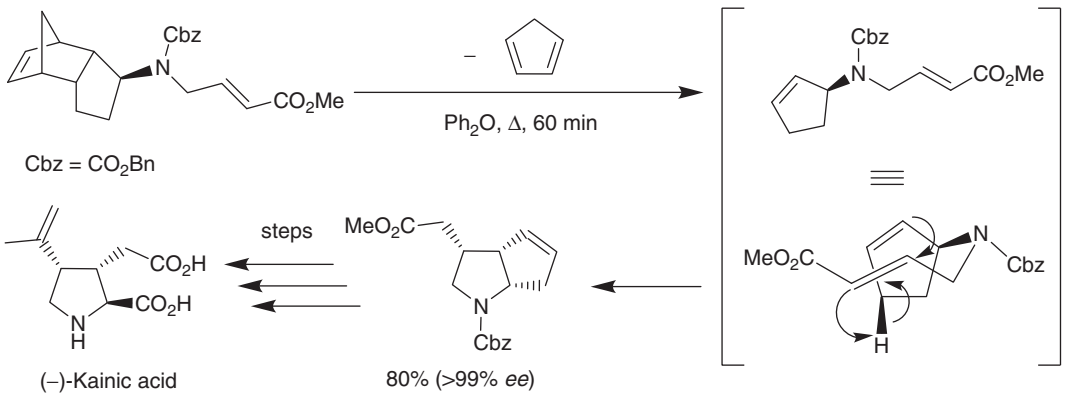


Scheme 54 Chiral auxiliary controlled diastereoselective intramolecular ene reactions.

Scheme 55 Intramolecular ene cycloisomerization with an allyl amine as ene component.



Scheme 56 Trityl steric buttress in intramolecular uncatalyzed ene reactions (for the first entry, no yield is reported).



Scheme 57 Lewis acid catalyzed enantioselective ene reaction as a key step in the synthesis of (–)-kainic acid.

Nakada et al.[117] chose a highly enantioconvergent route to (–)-kainic acid by setting the correct stereochemistry of the stereocenter next to the amino group on a tricyclic scaffold (Scheme 59). A retro-Diels–Alder reaction liberates the ene fragment in a very elegant fashion, which undergoes a concomitant intramolecular ene reaction in good yield and with excellent enantioselectivity.

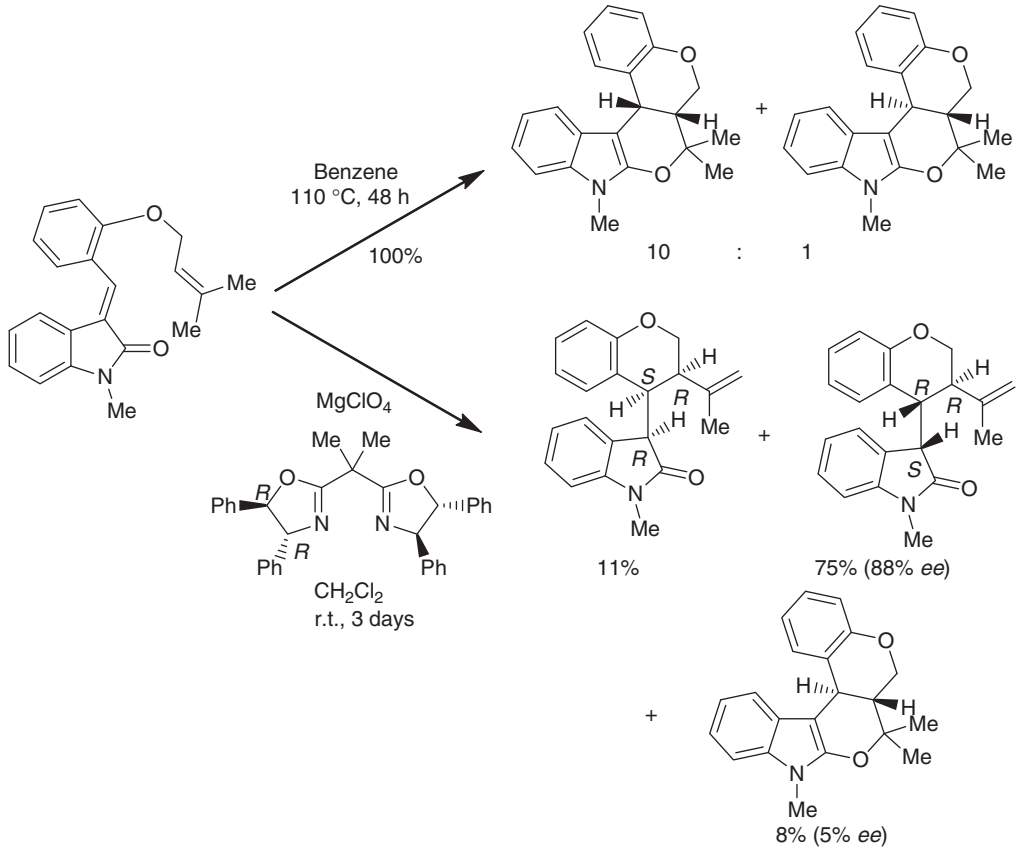
In several systematic contributions the group of Righetti and Desimoni has studied the effect of inorganic cations as Lewis acid catalysts on intramolecular Diels–Alder and ene reactions with several substrates.[118] In these studies α,β-unsaturated enophile

Scheme 58 A domino Wittig/ene reaction as a key step in the synthesis of (±)-kainic acid.

Scheme 59 A retro-Diels–Alder/ene reaction as a key step in the enantioselective synthesis of (–)-kainic acid.

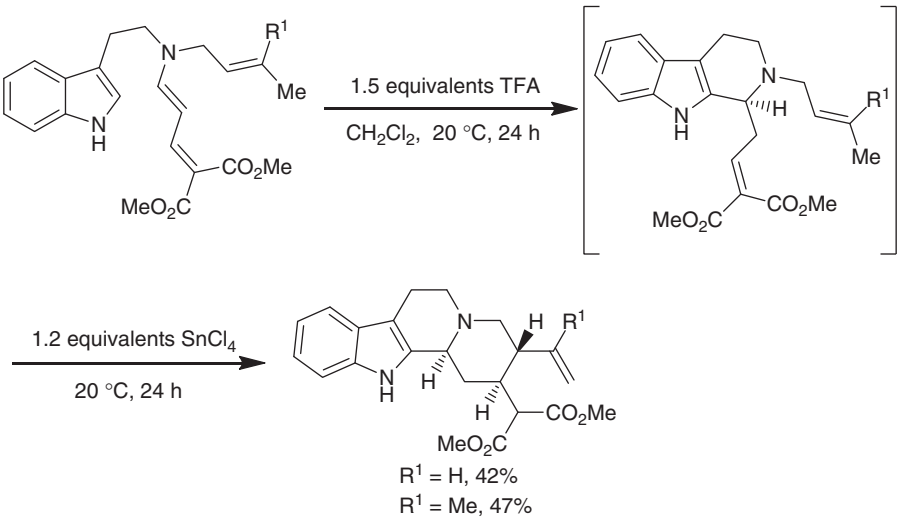
moieties and tethered allyl or crotyl ethers as ene fragments on various aromatic scaffolds were selected. Although under thermal conditions, the formation of hetero-Diels–Alder products is often favored for enone and enoate enophiles,[118a] magnesium perchlorate as a Lewis acid catalyst with bisoxazoline ligands is able to shift the selectivity toward the intramolecular ene reaction; using chiral ligands, good yields and remarkable levels of enantioselectivity were eventually attained (Scheme 60).[118b]

Several applications of intramolecular ene reactions in the past decades have impressively underlined the methodological versatility of this transformation.



Tietze and Wichmann[119] implemented a sequence comprising a Pictet–Spengler cyclization followed by an intramolecular ene reaction as the diastereoselective key step in the synthesis of derivatives of indole alkaloids of the corynantheine type (Scheme 61).

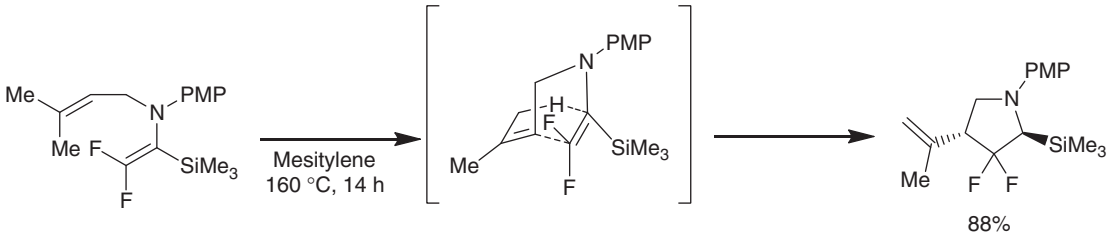
Difluoroeneamines are peculiar types of enophiles, being neither electron-rich nor electron-deficient. Amii et al.[120] observed that *N*-prenyl difluoroalkenamine undergoes a diastereoselective ene reaction, giving rise to the formation of the pyrrolidine by a 5-*exo* ring closure, obviously through a strained transition state (Scheme 62).



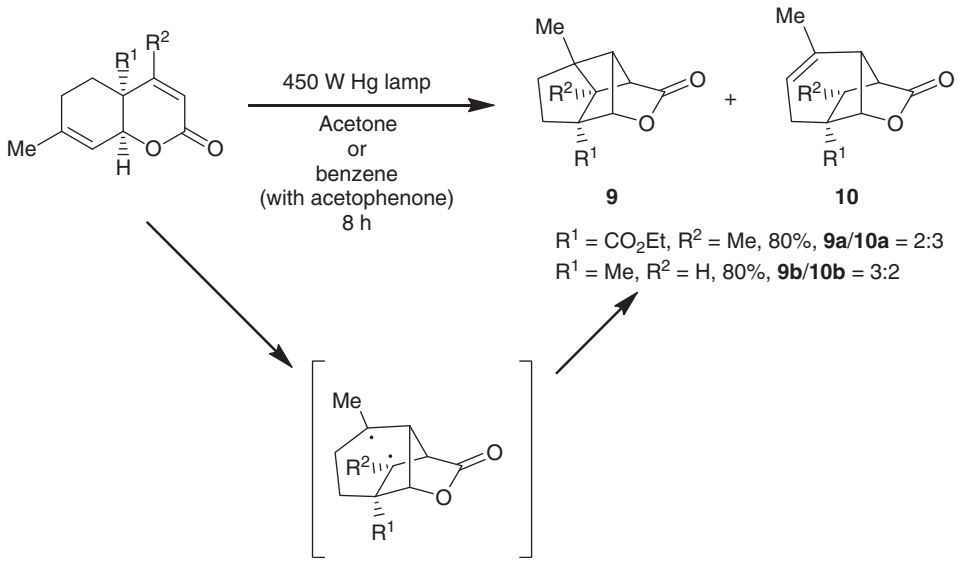
The group of Venkateswaran has reported photolysis experiments with *cis*-tetrahydrobenzopyran-2-ones giving rise to a mixture of the expected [2 + 2]-photoadducts and products of a photo-ene reaction (Scheme 63).[121] Based on the substituent R^2, the product ratio of the cycloadduct **9** and the ene product **10** is apparently correlated to the stability of an intermediate diradical species, which favors the photo-ene reaction.

5.01.3.1.2 Electroneutral alkenes as enophile moieties

Electroneutral alkene fragments as enophile moiety participate relatively sluggishly in ene reactions. Only if bulky substituents, steric strain, or conformational fixation are present in the alkene enophile or if the electronic nature of the ene component allows it, unactivated electroneutral alkene can participate in ene reactions.

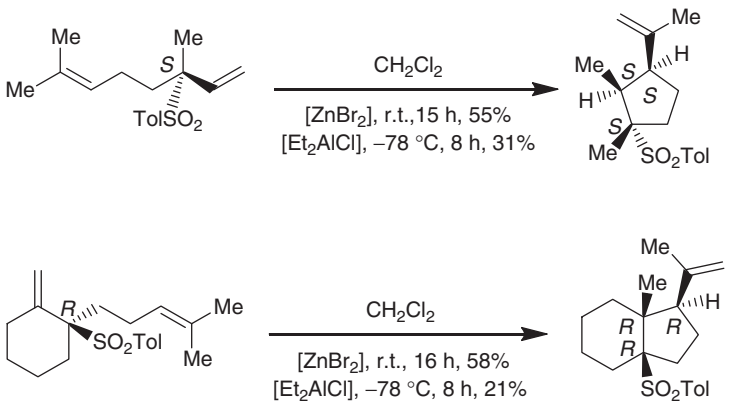


Scheme 60 Thermal hetero-Diels–Alder reaction versus $MgClO_4$-catalyzed ene reaction at room temperature.



Scheme 61 Pictet–Spengler/ene reaction sequence toward corynantheine alkaloid derivatives.

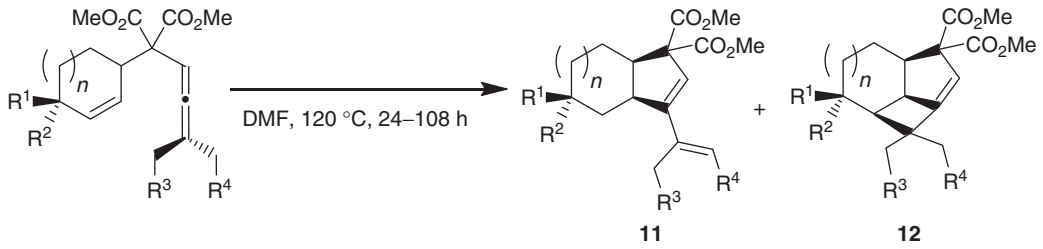
Hiroi et al.[122] found that the Lewis-acid catalyzed ene reaction of chiral allylic sulfones, obtained by thermal or Pd-catalyzed allylic sulfinate-sulfone rearrangement of optically active allylic sulfinates, gave rise to chiral cyclopentanes with an excellent stereocontrol over three contiguous stereogenic centers (Scheme 64).



Närhi et al. discovered that enallenes undergo the thermal Alder-ene reaction under fairly mild conditions, whereby the enophile is an electroneutral cycloolefinic fragment and the allenyl moiety acts as the ene component. The reaction gives rise to

Scheme 62 Unusual ene reaction of an *N*-prenyl difluoroalkenamine.

Scheme 63 Intramolecular photo-ene reaction.



Scheme 64 Asymmetric intramolecular ene reactions of chiral allylic sulfones.

the formation of [n.3.0] bicyclic systems **11** ($n=3$–5) in good yields (Scheme 65, Table 7). The minor byproduct **12** arises from a thermal [2 + 2] cycloaddition.[123]

In a concise total synthesis of (–)-kainic acid starting from enantiopure (+)-*cis*-4-(benzyloxycarbonylamino)-2-cyclopentenol, a Chugaev *syn*-elimination followed by an intramolecular ene reaction via an *exo* transition state were successfully applied as key steps by Nakagawa et al. (Scheme 66).[124]

The same key step was used in a stereocontrolled route to acromelic acids, which are neuroexitatory amino acids isolated from the mushroom *Clitocybe acromelalga*.[125]

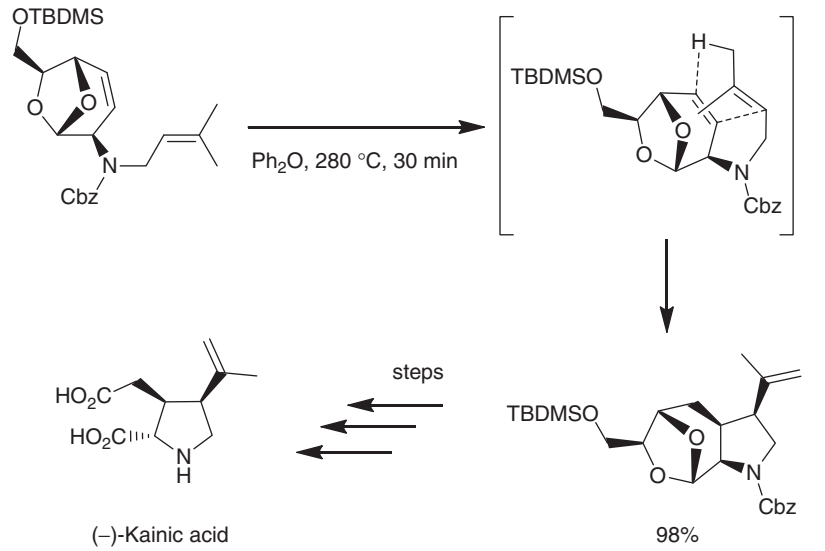
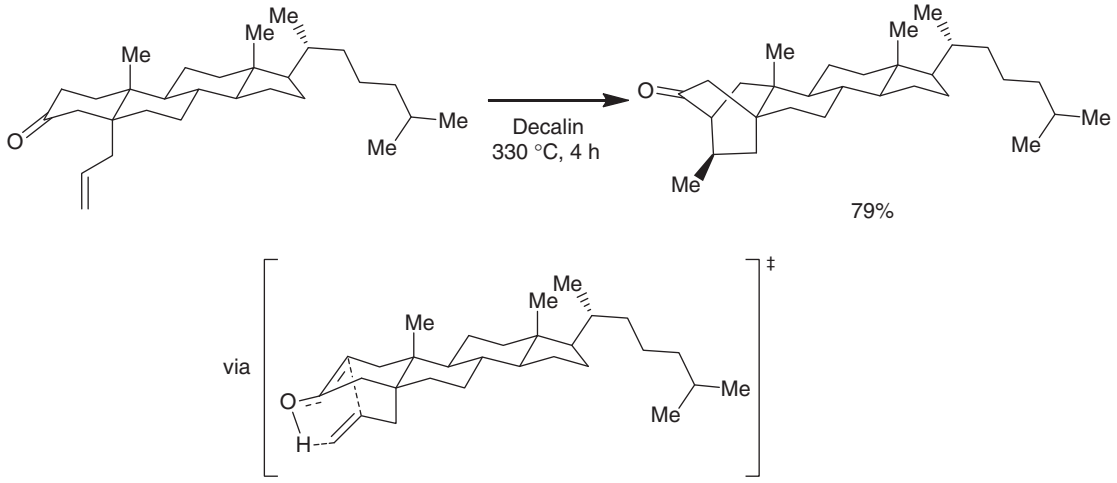
[b]The *cis*/*trans* ratio of the alkenyl substituent of **11** is 30:70.



Scheme 66 A retro-Chugaev-ene reaction as a key step in the enantioselective synthesis of (–)-kainic acid.

In the course of yet another enantioselective synthesis of (–)-kainic acid, Hirasawa et al. reported an intramolecular ene reaction of a 1,6-diene embedded and attached on a bicyclo[3.2.1]octane framework, which diastereoselectively formed a tri-substituted pyrrolidine annelated to a pyran ring (**Scheme 67**).[126]



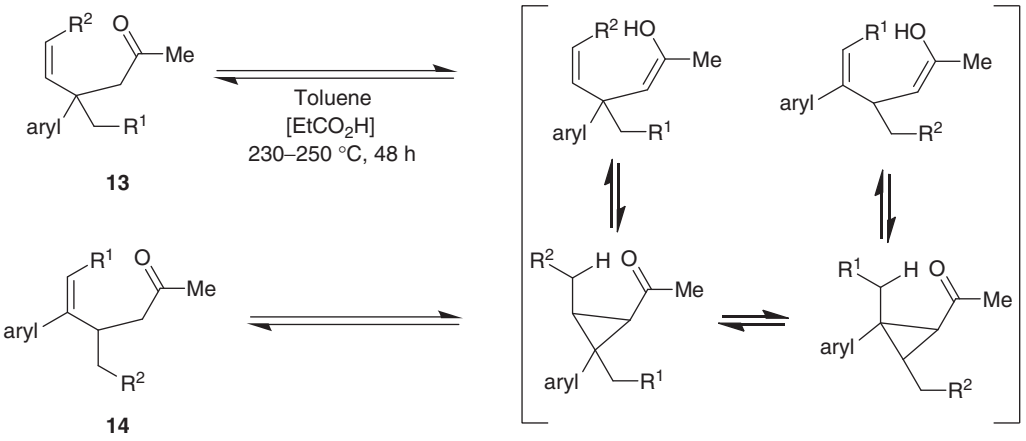
Although electroneutral alkenes remain fairly scarce as enophiles in intermolecular ene processes, they have become increasingly important functionalities in intramolecular ene reactions. This is also correlated to the occurrence of Conia-type ene reactions that proceed via enol tautomers as the hetero-ene components.[2]

Marples and Spilling[127] demonstrated that 5-(prop-2-enyl)-5α-cholestan-3-one, as well as acyloin analogs, smoothly underwent a thermal intramolecular ene reaction via the enol intermediate as an ene moiety to give 2 α,5-(1′-methylethano-5α)-cholestan-3-one in good yield (**Scheme 68**).

Srikrishna et al.[128] discovered an unusual acid-catalyzed rearrangement of γ,δ-unsaturated ketones **13**, which are typical Claisen products. The transformation obviously proceeds via a sequence of an intramolecular ene reaction followed by a retro-ene

Scheme 67 An intramolecular ene reaction on a bicyclo[3.2.1]octane system as a key step in an enantioselective synthesis of (–)-kainic acid.

Scheme 68 Intramolecular ene reaction via an enol as the ene component.



reaction via the intermediacy of an enol, and gives rise to the formation of regioisomeric γ,δ-unsaturated ketones **14** (Scheme 69). The ene intermediates are cyclopropyl methyl ketones, which remain elusive under the reaction conditions.

Enamines are the nitrogen analogs of enols and also well suited for implementation as ene partners into intramolecular ene reactions. This peculiar transformation was developed by Cossy et al.[129] for the synthesis of spirolactams, eventually also in a stereo- and enantioselective fashion. The thermal rearrangement of tertiary and secondary enamino carboxamides with an *N*-allyl substituent as the electroneutral enophile moiety can be successfully involved. The ene reaction furnish enamino or imino spirolactams (Scheme 70) via aza-ene (secondary enamino carboxamides) or carba-ene (tertiary enamino carboxamides) *exo*-transition states, both favoring the formation of *cis*-spirolactams.[129a] The enamino and imino spirolactam diastereomers **15**/**16** and **17**/**18** are separable and can be quantitatively hydrolyzed to the ketone derivatives.

5.01.3.2 Alkynes as Enophile Moieties

5.01.3.2.1 Electron-deficient alkynes as enophile moieties

Mikami et al.[130] found in the studies on the diastereoselectivity of thermal ene cyclizations of propargyl allyl ethers, which contain a methoxycarbonyl group as enophile-activating functionality and an allylic stereocenter, that the cycloisomerization proceeds with excellent yield and very good 1,2-asymmetric induction (Scheme 71, Table 8).

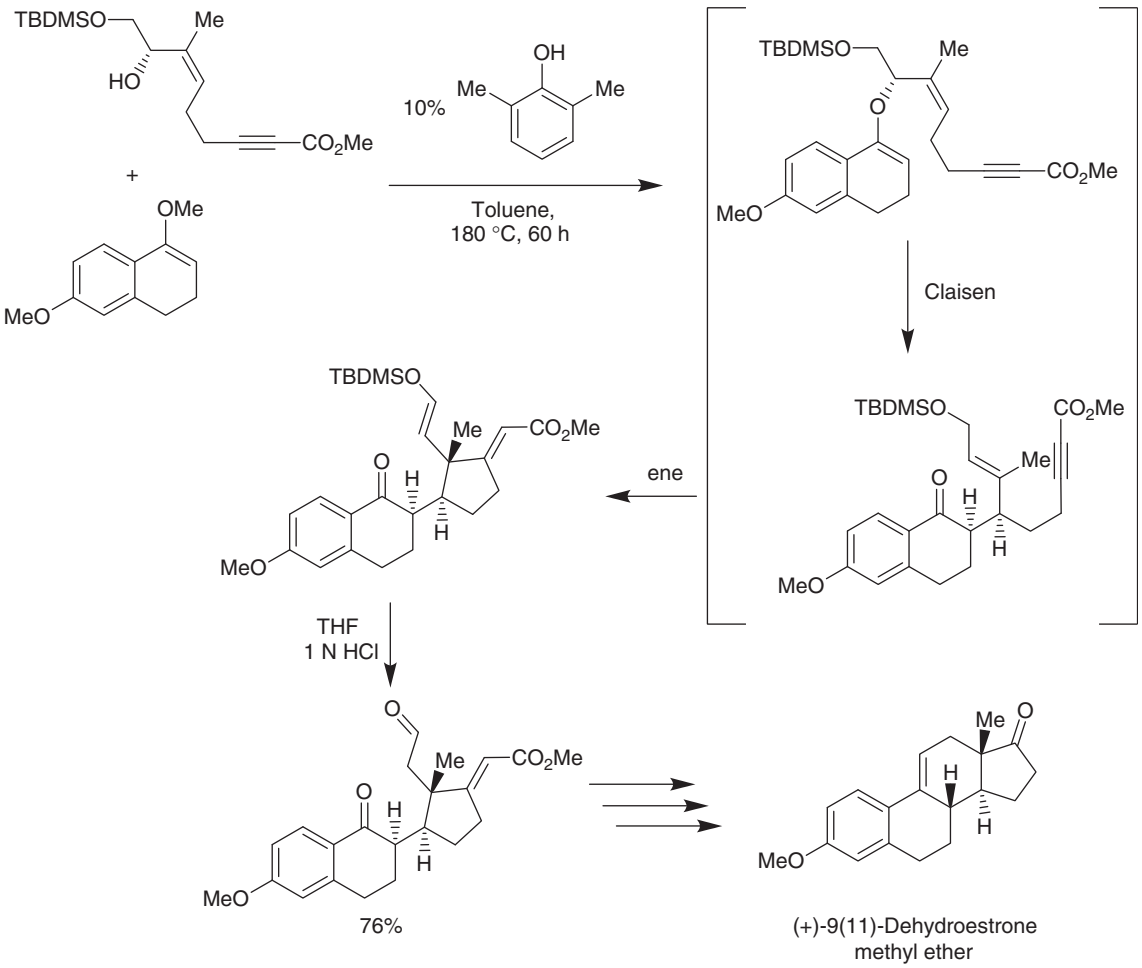
In an elegant combination with a preceding Claisen rearrangement, this methodology was applied in a domino reaction as a highly convergent key step to the asymmetric synthesis of (+)-9(11)-dehydroestrone methyl ether (**Scheme 72**). The same strategy was reported by Groen–Piotrowska and Groen for the synthesis of the progestagens desogestrel and 3-ketodesogestrel.[131]

5.01.3.2.2 Electroneutral alkynes as enophile moieties

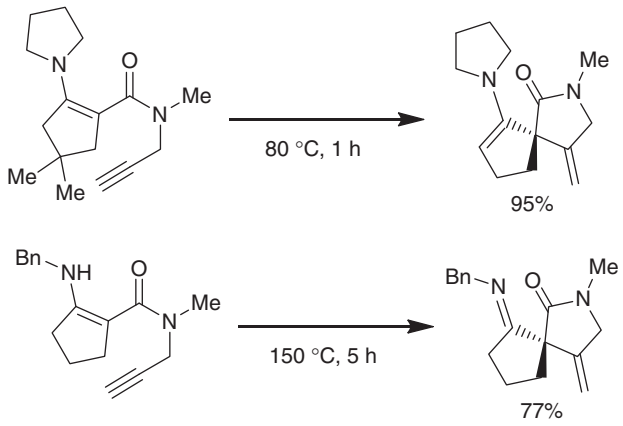
Electroneutral alkyne enophiles are also relatively unreactive substrates in intramolecular ene reactions within the framework of pericyclic reactivity. Alkenes substituted by heteroelements, such as enols, are particularly reactive in cycloisomerizations with the alkyne enophiles. In addition, the change of mechanism from pericyclic to transition metal-catalyzed processes has paved the way for highly efficient intramolecular Alder-ene-type reactions over the past three decades. Besides primordial palladium complexes, many other transition metal complexes have opened a whole new world of transition metal catalyzed Alder-ene-type reactions.

As already discussed in Chapter 3.1.2, enamines are particularly well suited as ene partners in intramolecular ene reactions with unactivated alkene enophiles. This aspect also holds true for unactivated alkynes. Cossy et al.[129] also used a tertiary and a secondary enamino carboxamide with an *N*-propargyl substituent as the electroneutral enophile moiety to obtain the corresponding enamino or imino exomethylene spirolactams in good to excellent yield (**Scheme 73**).



Desai et al.[132] have found an unusual formation of 3,7,7-trimethyl-2,4,7,7a-tetrahydrobenzofuran-4-one starting from 2-formyl-4,4-dimethyl-cyclohexa-2,5-dien-1-one in the sense of a domino Michael/ene/decarbonylation reaction (**Scheme 74**), where the initial Michael addition of propargyl alcohol triggers a subsequent enol-alkyne ene reaction. The fragmentation of the β,γ-enal might occur as a [4 + 1] cheletropic decarbonylation under the given reaction conditions.

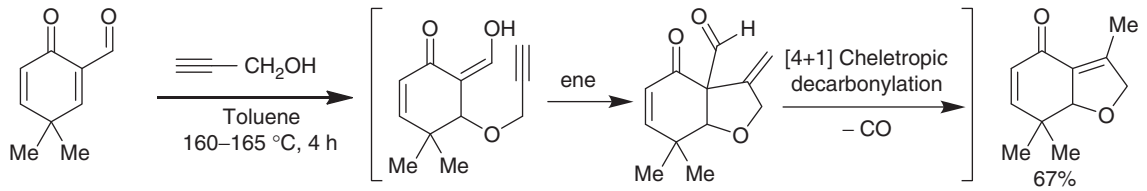
Just recently, the groups of Roglans[133] and of Danheiser[134] reported uncatalyzed formal [2 + 2 + 2] cycloadditions of triynes to tricyclic aromatic derivatives, which can be rationalized by a sequence of propargyl ene reaction and subsequent Diels–Alder reaction with concomitant aromatization by hydrogen shift. Macrocyclic triynes and enediynes were found to undergo a thermally induced [2 + 2 + 2] cycloisomerization through the intermediacy of an intramolecular ene reaction with exclusion of diradical intermediates (**Scheme 75**).[133]



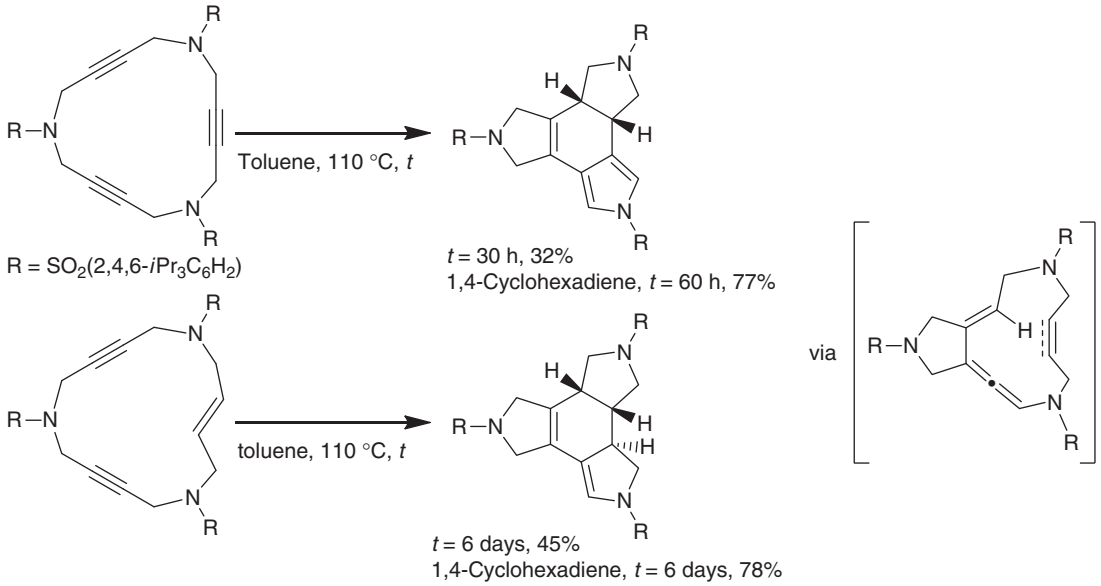
By participation of unactivated cyano groups, several examples of formal intramolecular [2 + 2 + 2] cycloisomerization and cycloadditions via propargylic ene/cyano Diels–Alder reactions were shown (**Scheme 76**).[134a] In addition, this propargylic ene/Diels–Alder reaction was also conducted in an intermolecular fashion with alkene and alkyne dienophiles (**Scheme 77**).[134b]

According to DFT calculations, uncatalyzed [2 + 2 + 2] cycloisomerizations of triynes to tricyclic benzene derivatives bearing a propargyl hydrogen atom proceed through energetically most favorable initial ene transition state.[135] In intramolecular ene reactions, such as Schmittel-ene cyclizations of enyne-allenes, alkyl substituted allenes can well serve as ene components, whereas the alkynyl moiety serves as the electroneutral enophile. As experimentally and computationally demonstrated by Schmittel et al.,[136] these cycloisomerizations rather occur via the intermediacy of very short lived diradical intermediates, as supported by stereochemical evidence and indicated by the lack of cyclopropyl methyl radical ring opening (**Scheme 78**).

Mechanistic investigations based on the determination of kinetic isotope effects as well as theoretical calculations suggest a highly asynchronous transition state, located near the boundary between concerted and stepwise processes.[137] However, in the case of bulky substituents on the alkyne enophile, diradical intermediates have been suggested by computations.[138] Recent isotope-labeling and radical clock experiments could further support the diradical intermediates in enyne-allene

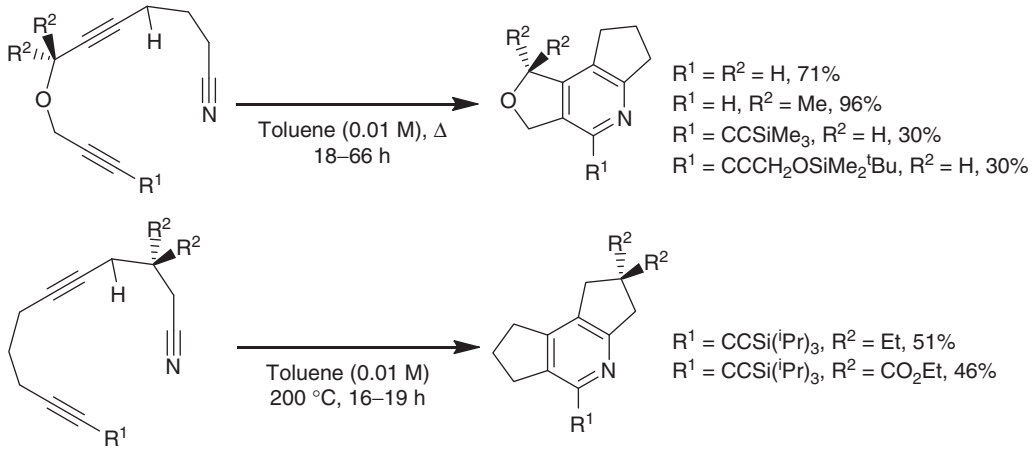


Scheme 72 Domino Claisen/ene reaction sequence as key step in the asymmetric synthesis of (+)-9(11)-dehydroestrone methyl ether.



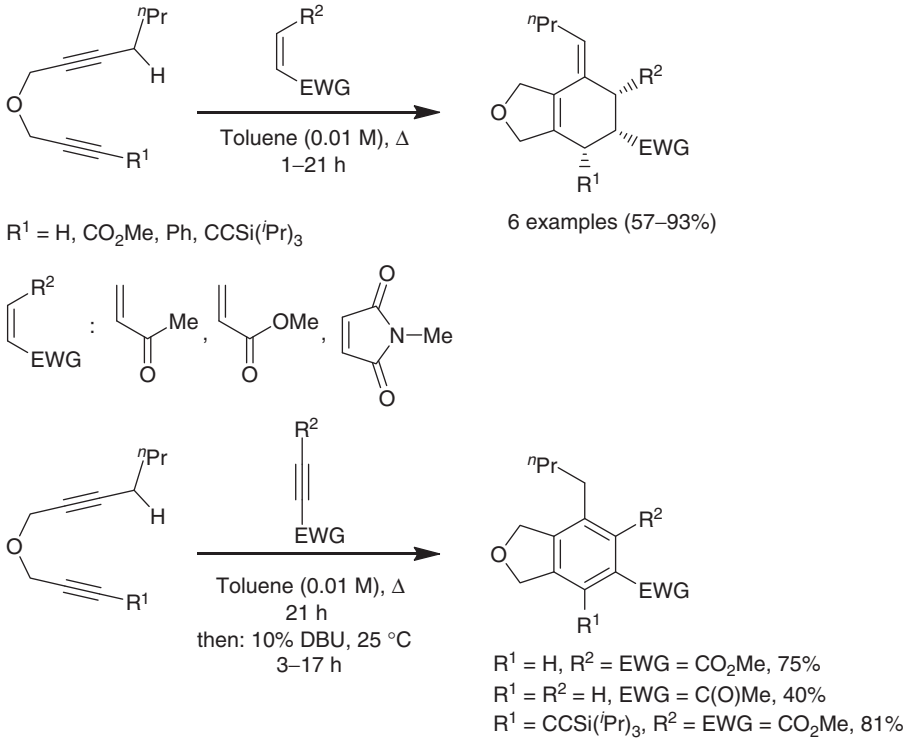
Scheme 73 Synthesis of exomethylene spirolactams by intramolecular ene reactions.

ene-cycloisomerizations.[139] Furthermore, comparable results were obtained under photochemical conditions and spectroscopic evidence of a fulvene triplet diradical intermediate was garnered by laser flash photolysis.[140]

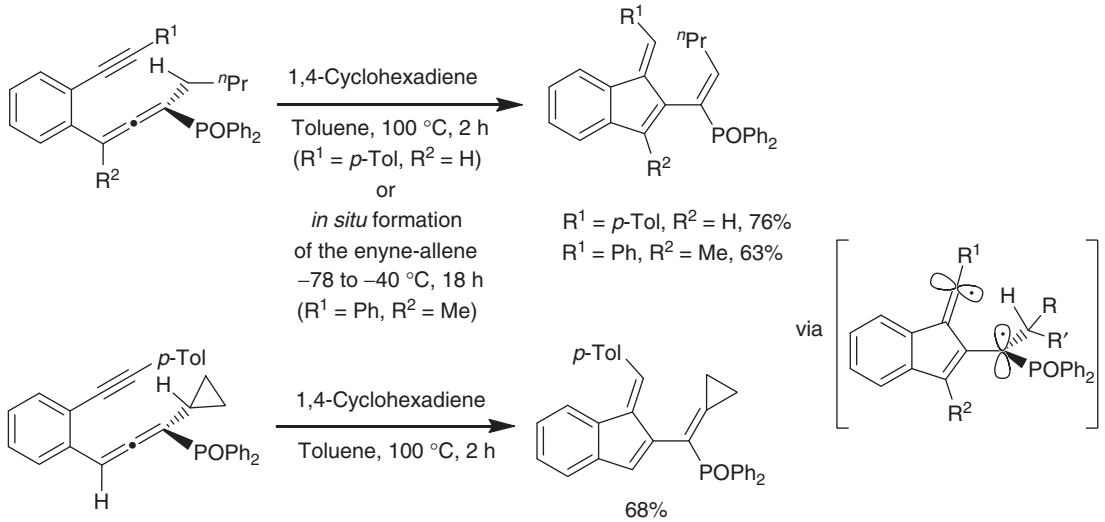


Buisine et al.[141] demonstrated Alder-ene cycloisomerizations of 1,6-allenynes without catalysts in boiling xylenes that provide 6-methylene-1-vinylcyclohexene derivatives in good to excellent yields (Scheme 79, Table 9).

Scheme 74 Domino Michael/ene/decarbonylation sequence for the synthesis of 3,7,7-trimethyl-2,4,7,7a-tetrahydrobenzofuran-4-one.



Scheme 75 Thermally induced [2 + 2 + 2] cycloisomerization and cycloadditions of macrocyclic triynes and enediynes.

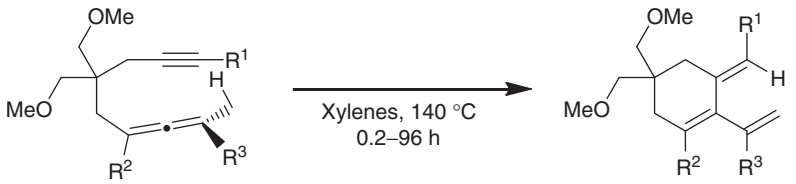


Scheme 76 Formal intramolecular [2 + 2 + 2] cycloadditions via propargylic ene/cyano Diels–Alder reactions.

Intramolecular palladium-catalyzed Alder-ene reactions have been discovered and developed in the 1980s Trost et al.[142] Changing the mechanism from pericyclic to organometallic intermediates has not only contributed a new paradigm, but also enriched the conceptual understanding and realization of the concept of atom economic processes.[143] The cycloisomerization of 1,n-enynes has remained an intensively pursued field of synthetic methodologies ever since.[144] Major advances of enantioselective transition metal catalyzed cycloisomerizations of enynes have also been covered in reviews.[145]

In 1999 Trost et al. disclosed the conditions for the palladium-catalyzed ene cyclizations of 1,6-enynes. Systematic variation of the substitution pattern on the tether and on the enophile and ene termini as well as of the Pd(II)-catalyst system were described

Scheme 77 Formal intermolecular [2 + 2 + 2] cycloadditions via propargylic ene/cyano Diels–Alder reactions with alkene and alkyne dienophiles.



Scheme 78 Formal ene cyclization of enyne-allenes.

(Schemes 80 and 81).[146] The reaction produces both 1,4-dienes **19**/**21** (Alder-ene-type products) (Scheme 80, Table 10) and 1,3-dienes **20**/**22** (Scheme 81, Table 11). Although either the absence of ligands or the use of the diimino ligand *N*,*N*-bis(benzylidene)ethylenediamine (BBEDA) or the soft triphenylarsane ligand favor the 1,4-diene products **19**/**21**, the bulkier tri-*o*-tolylphosphine ligand favors the formation of the 1,3-dienes **20**/**22**.

Most important for the synthesis of polycyclic frameworks, Alder-ene reactions lead to *cis*-annulated ring systems in a stereocontrolled fashion (Scheme 82).

The conditions for the formation of 1,3-dienes, which are excellent substrates for Diels–Alder reactions, were studied in detail by Trost et al.[147] A remote substituent effect of coordinating functionalities additionally enables an asymmetric induction in palladium-catalyzed enyne cycloisomerizations.[148]

Knierzinger et al.[149] have performed palladium(II)-catalyzed ene-type cyclizations of terpenoid 1,6-enynes with variable alkynyl substitution pattern in good yield (Scheme 83, Table 12). The diastereoselectivity with respect to the 2- and 5-position of the alkylidene-cyclopentane framework depends on the employed substituent.

Trost and Shi have also developed the Alder-ene-type cycloisomerization into domino processes, where, in the absence of *syn*-β-hydrogen atoms, the alkyl-Pd species is forced to continue inserting into another (even up to six additional) alkenyl

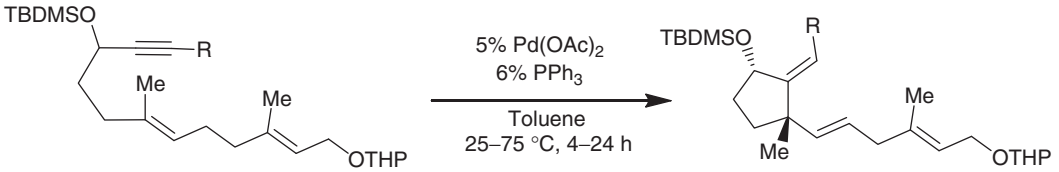
fragment(s).[150] Besides the formation of triquinane frameworks, the Pd(0)-catalyzed Alder-ene reaction could be used for the rapid formation of a polyspirocyclic rope-like molecule in a zipper-fashion (**Scheme 84**).

The groups of Trost and Banwell have contributed some remarkable applications of palladium-catalyzed Alder-ene-type cycloisomerizations to the synthesis of biologically active natural products, such as the antiulcerogenic aglycone (+)-cassiol,[151] the antifungal sesquiterpene (±)-chokol C,[152] the γ-aminobutyric acid antagonist picrotoxanes,[153] the crinine alkaloid (±)-hamayne,[154] and precursors to the *Amaryllidaceae* alkaloid tazettine[155] (**Table 13**).



Kressierer and Müller showed in several cases that the palladium(0)-catalyzed Alder-ene reaction of alkynyl allyl alcohols, which furnish cyclic γ,δ-enals as a consequence of the *in situ* enol-aldehyde tautomerism, is excellently suited as an entry into consecutive one-pot transformations (**Scheme 85**).[156] As a consequence, consecutive and sequential cycloisomerization/Wittig,[156] cycloisomerization/reductive amination,[157] and cycloisomerization/Knoevenagel condensation sequences[158] were readily established in a one-pot fashion, giving rise to five-membered carbo- and heterocycles with densely functionalized sidechains (**Scheme 86**).

Strübing et al.[159] illustrated that the enyne products arising from the three-component coupling of aldehydes, amides, and dienophiles are perfectly suited for catalytic postcondensation Alder-ene cyclizations (**Scheme 87**).

The success of the enantioselective rhodium catalyzed hydrogenation has considerably stimulated the development of intramolecular rhodium-catalyzed Alder-ene reactions by taking advantage of a plethora of chiral chelating diphosphane ligands. In 2002, the group of Zhang was the first to report an efficient and highly enantioselective synthesis of functionalized α-methylene-γ-butyrolactones via a rhodium(I)-catalyzed intramolecular Alder-ene reaction (**Schemes 88** and **89**).[160] *S*-2,2′–Bis(diphenylphosphano)–1,1′–binaphthyl) (*S*-BINAP) as a chiral chelating ligand furnishes the *S*-configured butyrolacton (**Table 14**), whereas *R*-BINAP delivers the *R*-enantiomer (**Table 15**). In contrast to palladium-catalyzed cycloisomerizations, the 1,4-diene isomer is formed exclusively. The reaction works equally well with allyl ethers (R^2=OR), allyl acetates (R^2=OAc), and allyl alcohols (R^2=OH). However, in the latter case the elusive enol immediately tautomerizes to give the corresponding aldehyde. An excellent formal synthesis of (+)-pilocarpine was achieved based on this methodology.

[a]The diastereoselectivity arising from the 2- and 5-substituents was determined after deprotection.
[b]A 1:2 diasteromeric mixture was found.
[c]A single diastereomer was found.
[d]Upon deprotection an anellated furan arising from a cyclocondensation was found.

With the same efficacy and efficiency, chiral α-substituted γ-butyrolactams,[161] tetrahydrofurans,[162] and also 3,4,5-trisubstituted γ-lactones[163] were obtained. In the latter case, the excellent enantioselectivity was applied for kinetic resolutions of racemic substrates and the cyclized enantiomerically enriched γ-lactones were used in formal asymmetric syntheses of (–)-blastmycinolactol and (+)-blastmycinone. Nicolaou et al.[164] have implemented the enantioselective rhodium-catalyzed Alder-ene cycloisomerization of 1,6-enynes as an asymmetric key step into the total synthesis of antibiotic platensimycin, which proceeded with excellent enantiomeric excess.

Based on the Rh-BINAP catalyst system for intramolecular Alder-ene cycloisomerizations sequences were conceived that take advantage of this unique and efficient enantioselective generation of five-membered carbo- and heterocycles. Körber et al.[165] have employed the enantioselective rhodium-catalyzed cycloisomerization of alkyl and (hetero)aryl alkynyl allyl alcohols for the generation of aldehyde-bearing chiral 4-alkyl 3-alkylidene tetrahydrofurans and tetrahydrofuranones, which were converted into α,β-unsaturated carbonyl side chains in a one-pot fashion via a concluding Wittig olefination in good yields (Scheme 90).

Furthermore, based on the initial Alder-ene cycloisomerization of alkyl and (hetero)aryl-substituted alkynyl allyl alcohols, the rhodium(I)-BINAP complex enables a subsequent reduction of the primary products with hydrogen and the transformation into 2,7- dioxabicyclo[3.2.1]octanes in the sense of a sequential rhodium catalyzed process (Scheme 91).[166]

Just recently, Okamoto et al.[167] reported an enantioselective rhodium(I)-BINAP-catalyzed allyl ether isomerization/cycloisomerization domino sequence of phenol- or naphthol-linked 1,7-enynes, giving rise to the formation of dihydrobenzofurans and dihydronaphthofurans (Scheme 92).

Scheme 84 Palladium(0)-catalyzed domino Alder-ene cycloisomerizations.

Also iridium complexes such as $[IrCl(COD)]_2$ have been shown to catalyze the intramolecular Alder-ene reaction of 1,6-enynes to give cyclic 1,4-dienes. Shibata et al.[168] demonstrated the increased efficiency of this catalyst system in an ionic liquid over toluene (Scheme 93). The iridium(I)-catalyzed Alder-ene cycloisomerization of an alkynoyl cyclohexadienyl ester or *N*-tosyl amide have been shown to furnish spirocyclic products (Scheme 94).[169]

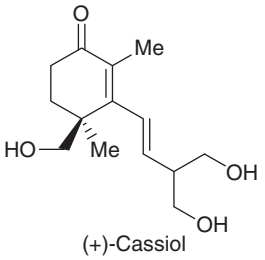
Kummeter et al.[170] employed this type of Alder-ene cycloisomerization as an entry into a sequential iridium(I)-catalyzed cycloisomerization/Murahashi reaction sequence in a one-pot fashion, where the intermediate aldehyde arising from the Alder-ene tautomerization step was condensed with cyano acetic esters without addition of acids or bases (Scheme 95).

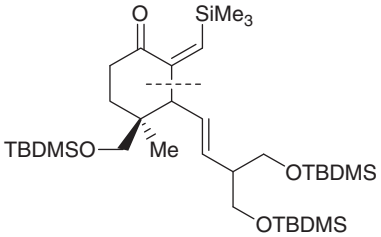
Fürstner et al.[171] disclosed iron(0)-ate complex catalyzed Alder-ene cycloisomerizations of linear and cycloalkene based enynes in good to excellent yields (Scheme 96).

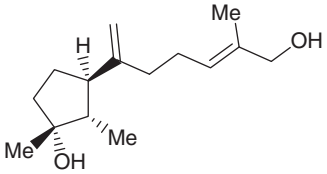
As the first example of an early transition metal-based catalyst Sturla et al.[172] reported a titanocene catalyzed intramolecular Alder-ene cycloisomerization of enynes and dienynes (Scheme 97).

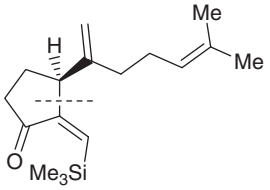
Cycloisomerizations of enynes with gold and platinum catalysts have received great attention in the past two decades in particular for their rich organometallic chemistry and mechanistic versatility.[173] Muñoz et al.[174] found that platinum and cationic gold complexes are able to catalyze the cycloisomerization of enynes with concomitant methoxylation in the presence of phosphane ligands (Scheme 98). The reactions are thought to proceed via cationic organometallic species and carbenium ion intermediates. Dinuclear gold complexes with BINAP ligands enable enantioselective cycloisomerizations of this type.

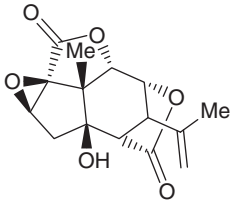
The cobalt(I)-catalyzed Conia-ene cycloisomerization of simple cyclic β-ketoester ω-ynes was reported by Renaud to give the corresponding bicyclic products in very good yields (Scheme 99).[175]

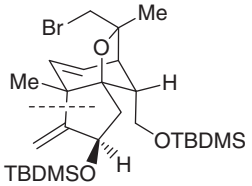


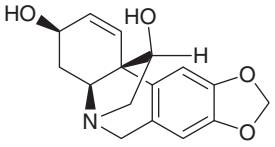


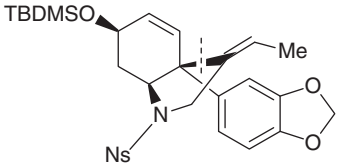


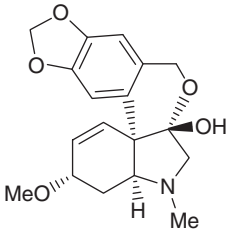


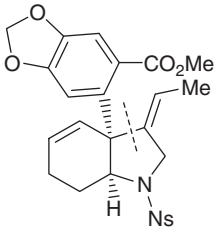




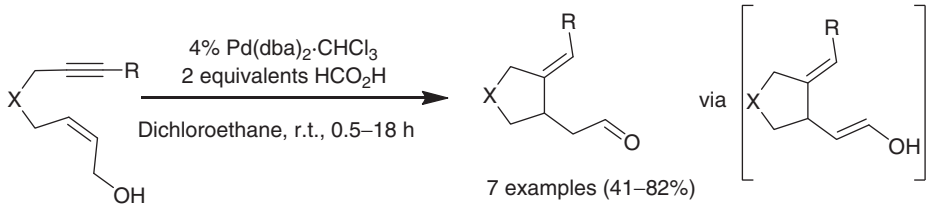








As discussed above, allenynes are suitable substrates for thermal Alder-ene-type cycloisomerizations, where, in the presence of an available hydrogen atom, the allenyl moiety serves as the ene partner and the triple bond adopts the enophile function. These highly unsaturated molecules are excellent ligands for the formation of transition organometallic complexes and, hence, also good substrates for metal-mediated or -catalyzed ene-type reactions.



Llerena et al.[176] first reported on cobalt-mediated formal Alder-ene reactions of allenynes on reacting allenynes with a stoichiometric amount of $CpCo(CO)_2$ under irradiation in refluxing xylenes. The reaction furnished 2:3 mixtures of the Alder-ene products **23** and η^4-cyclohexadiene-CpCo complexes **24** (Scheme 100). On their way to the 11-aryl steroid skeleton, the group of Malacria found that *trans*-allenediynes cycloisomerize in the sense of cobalt-mediated $[2+2+2]$ trimerization, whereas the *cis*-allenediyne efficiently undergoes the formal Alder-ene reaction.[177]

Brummond's group[178] and the group of Shibata[179] discovered simultaneously that rhodium(I) complexes are excellent catalysts in the formal Alder-ene cycloisomerization of allenynes to give cross-conjugated trienes under mild conditions and in good yields (Scheme 101).

In the past decade, Brummond and her group have considerably developed and extended this Alder-ene-type cycloisomerization of allenynes. It was expanded to the formation of δ- and ε-lactams,[180] to yne-allenamides as substrates;[181] moreover, it was applied as a key reaction to the synthesis of the angiogenesis inhibitor ovalicin.[182] The obtained cross-conjugated trienes[183] are excellent building blocks for complex molecular frameworks. Therefore, consecutive one-pot transformations initiated by the

rhodium(I)-catalyzed Alder-ene reactions were devised, such as Alder-ene/Diels–Alder,[184] and Alder-ene/Diels–Alder/Diels–Alder sequences,[185] furnishing complex polycyclic products **25** and **26** (**Scheme 102**). Interestingly, another rhodium(I) complex catalyzes an intramolecular Diels–Alder reaction with the triene moiety to give a diene, ready for an intermolecular [4 + 2] cycloaddition.

Lemiere et al.[186] found that cationic gold(I) and platinum(II) complexes are able to catalyze the Alder-ene cycloisomerization of allenynes as an optional outcome among other cycloisomerizations. DFT computations with extended basis sets and polarization functionals also supported the bifurcations in the cycloisomerization pathways of platinum(II) complexes.[187] Cheong et al.[188] identified the trinuclear cationic gold complex, $[(Ph_3PAu)_3O]BF_4$ as catalyst for the cycloisomerization of 1,5-allenynes,

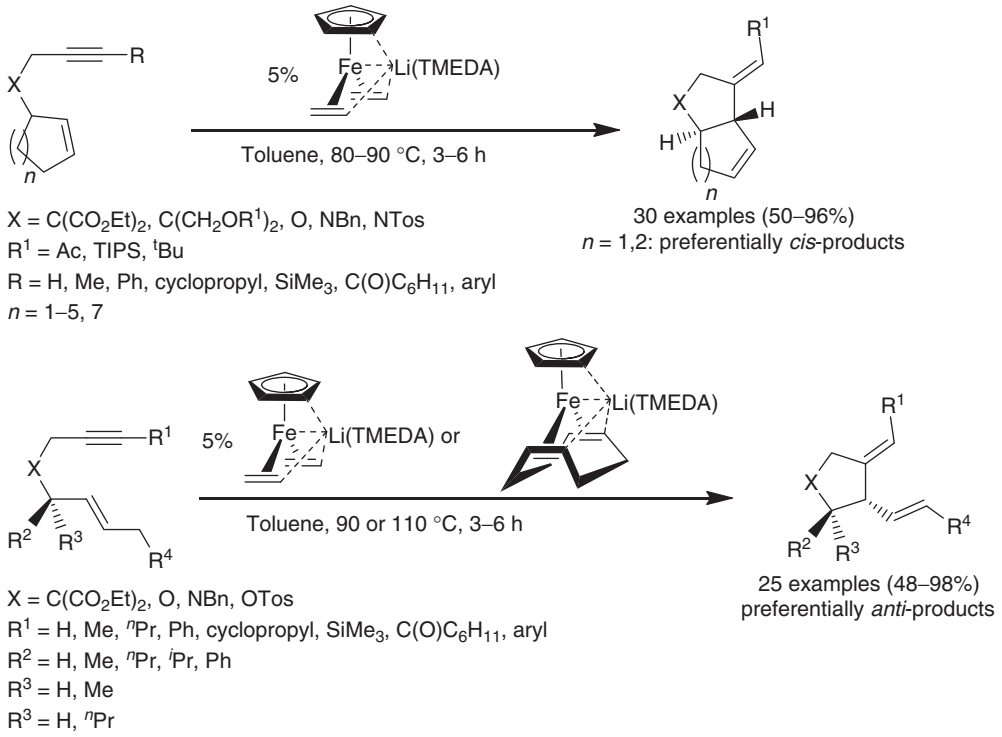
Scheme 93 Iridium(I)-catalyzed Alder-ene-type cycloisomerization in an ionic liquid.

Scheme 94 Iridium(I)-catalyzed Alder-ene-type cycloisomerization of an alkynoyl cyclohexadienyl ester and *N*-tosyl amide.

Scheme 95 One-pot iridium(I)-catalyzed Alder-ene/Murahashi reaction sequence.

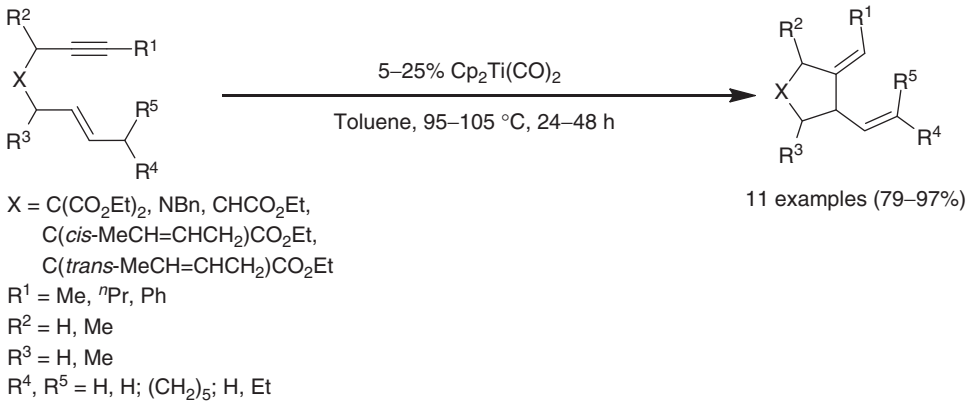
which lead to the formation of cross-conjugated trienes (Scheme 103, Table 16). Experimental and computational studies revealed that the ene reaction proceeds through a unique nucleophilic addition of the allene double bond to the cationic gold(I) acetylide species, concluded by a 1,5-hydrogen shift.

Zriba et al.[189] discovered that 3-hydroxy-1,5-allenynes are transformed by $PtCl_4$ or $PtCl_2$ as catalysts via an Alder-ene-type cycloisomerization followed by allyl alcohol-enone isomerization into 3-vinylcyclopent-2-enones with remarkable chemoselectivity.



5.01.3.3 Allenes as Enophile Moieties

Allenes can also participate as enophiles in thermal cycloisomerizations. In particular, if the allene bears an electron-deficient substituent, the prerequisites for Alder-ene cycloisomerizations with normal electron demand are fulfilled.

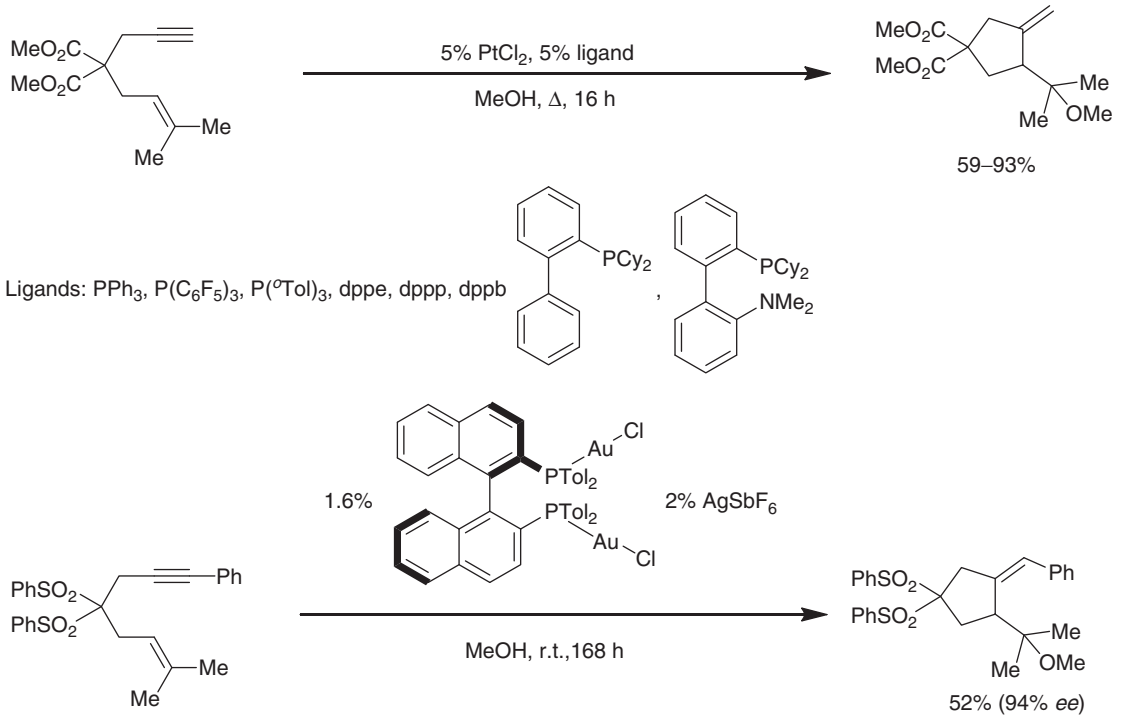


Bintz-Giudicelli and Uguen[190] revealed that, on thermal [2,3]-sigmatropic rearrangement of propargylic toluenesulfinates containing a homoallylic side chain, allenylsulfonyl ene partners are generated, which undergo the Alder-ene cycloisomerization to furnish aryl (cyclopentenyl)methyl sulfones in good yields (Scheme 104). In the case of cycloalkenyl groups as the ene-moieties, the allenyl sulfones give rise to the formation of the spirocycles **27** whereas the propargylic sulfinates form the spirocycles **28**.

Particularly intriguing is an *in situ* generation of alkoxyallenes from propargyl ethers via Müller's coupling/isomerization reaction.[191] Shen et al.[192] reported a domino sequence on the basis of the coupling/isomerization reaction, which concludes the sequence by an intramolecular Alder-ene reaction enabled by the tethered allylether ene moiety (Scheme 105).

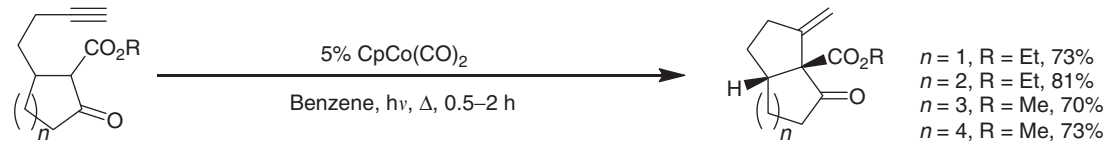
Hashmi and Szeimies[193] used the *in situ* generation and subsequent Alder-ene cycloisomerization of an ethano-bridged bis-allenylbicyclo[1.1.0]butane via $Fe(acac)_3$-catalyzed coupling of the corresponding vicinal di-organomagnesium bromides for the first synthesis of a [4.1.1]propella-2,4-diene (Scheme 106).

Scheme 96 Iron(0)-ate complex catalyzed Alder-ene cycloisomerization of enynes.



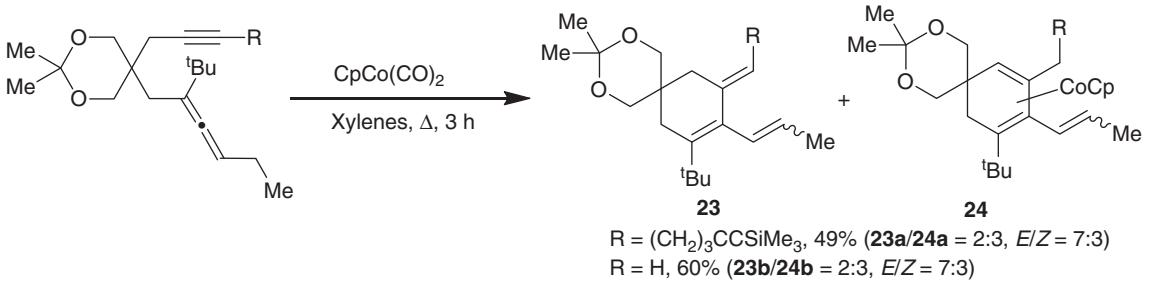
Scheme 97 Titanocene catalyzed Alder-ene cycloisomerization of enynes and dienynes.

Vinylidenecyclopropanes are peculiar allene substrates for transition metal-catalyzed transformations. Li et al.[194] reported that rhodium(I)-catalyzed Alder-ene cycloisomerizations of diarylvinylidenecyclopropanes with a but-3-en-1-yl substituent furnished bicyclo[5.1.0]-octylenes in good to excellent yields (Scheme 107). Mechanistically, the reaction is very likely to proceed through a η^3-allyl-rhodium intermediate.



5.01.3.4 Miscellaneous Enophile Moieties in Intramolecular Ene Reactions

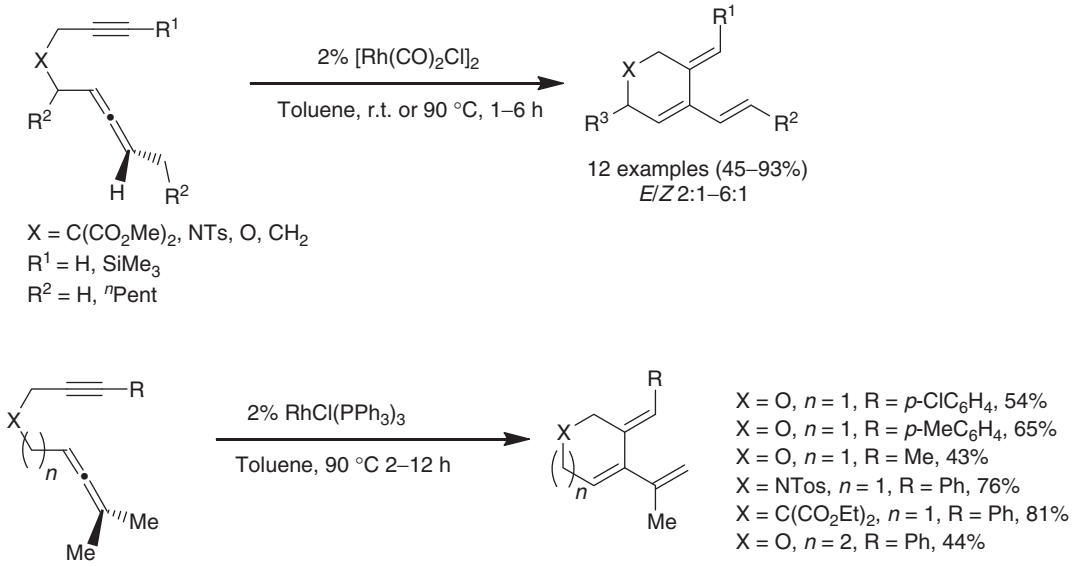
Arynes are also well-suited as enophile moieties in intramolecular ene reactions. Just recently, Candito et al.[195] showed in synthetic and mechanistic studies that the intramolecular aryne-ene reaction opens a general, high yielding and selective access to benzo-fused carbo- and heterocycles (Scheme 108, Table 17).



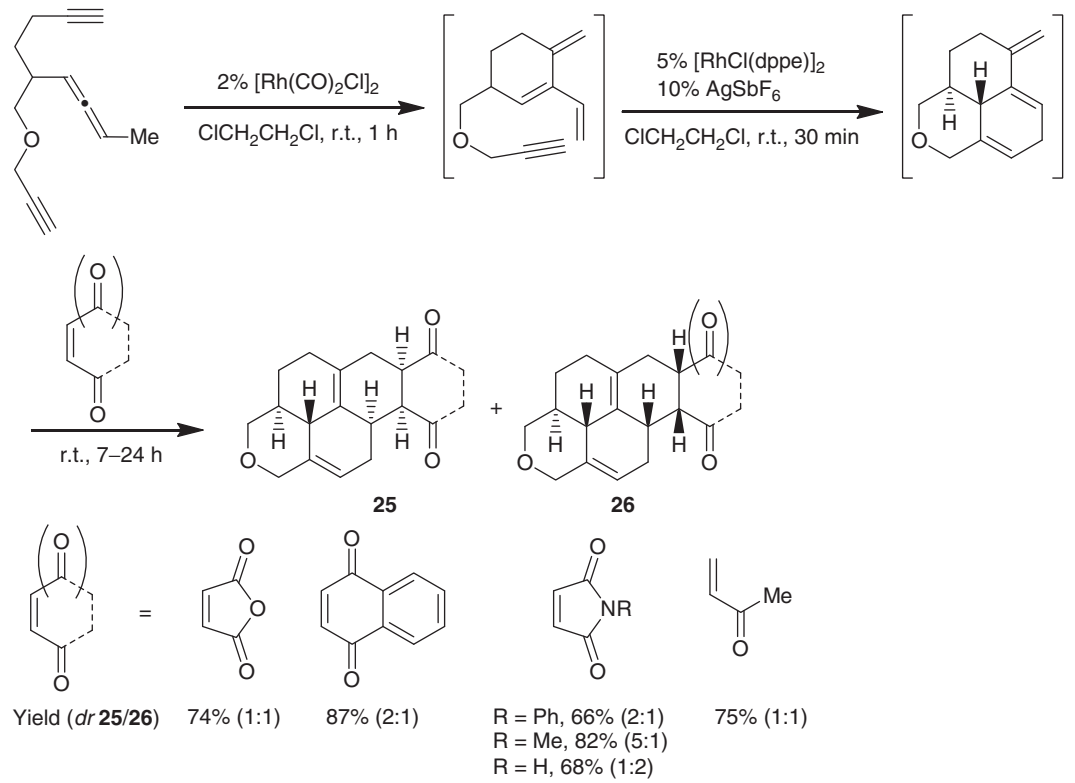
Alkynes bound to fullerenes also represent systems that are able to undergo an Alder-ene-type cycloisomerization, wherein the fullerene serves as an enophile and the alkynyl moiety as the ene component. Altable et al.[196] reported that the thermal reaction of 1,6-fullerenynes bearing an alkyl group on the alkyne terminus furnishes allenes through an intramolecular ene process

Scheme 98 Ligand effects in gold and platinum catalyzed cyclizations of enynes with concomitant methoxylation.

Scheme 99 Cobalt(I)-catalyzed Conia-ene cycloisomerization of cyclic β-ketoester ω-ynes.



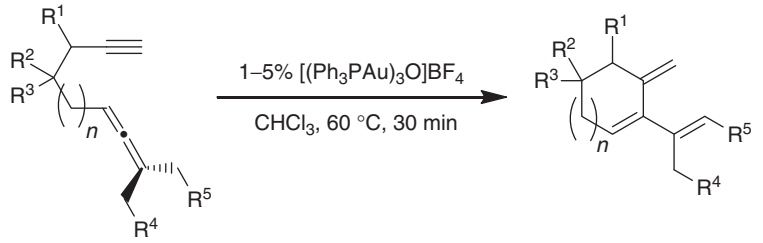
Scheme 100 Cobalt(I)-mediated ene cycloisomerization of allenynes.



(Scheme 109). Theoretical calculations revealed that the concerted ene reaction is favored over a diradical pathway for methyl terminated 1,6-fullerenynes, which preferentially lead to cyclobutenes in the case of terminal alkynes.[197]

5.01.4 Metallo-Ene Reactions

The concept of metallo-ene reactions, which can be formally considered as substitution of the migrating hydrogen atom by a metal, was introduced by Oppolzer and can be mechanistically understood as a carbometallation of an enophile.[4] As already pointed out in the introduction, the initial stoichiometric version of alkaline and earth alkaline allyl organometallics was



Scheme 101 Rhodium(I)-catalyzed ene cycloisomerization of allenynes.

Scheme 102 One-pot Alder-ene/Diels–Alder/Diels–Alder reactions initiated by rhodium(I)-catalyzed ene cycloisomerization of an allenyne.

transposed in the past two decades to several transition metals. The catalytic generation of allyl metal complexes as intermediates has paved the way to important expansions in the tool set of metallo-ene based reactions. First new contributions to metallo-ene additions, i.e., the intermolecular variation shall be discussed and the chapter shall conclude with intramolecular metallo-ene cycloisomerizations.

5.01.4.1 Metallo-Ene Additions

The fundamental metallo-ene process was theoretically studied for allyl lithium and allyl sodium with ethylene on the level of *ab initio* calculations, revealing that the reaction proceeds without intermediates, i.e., on a concerted pathway.[198]

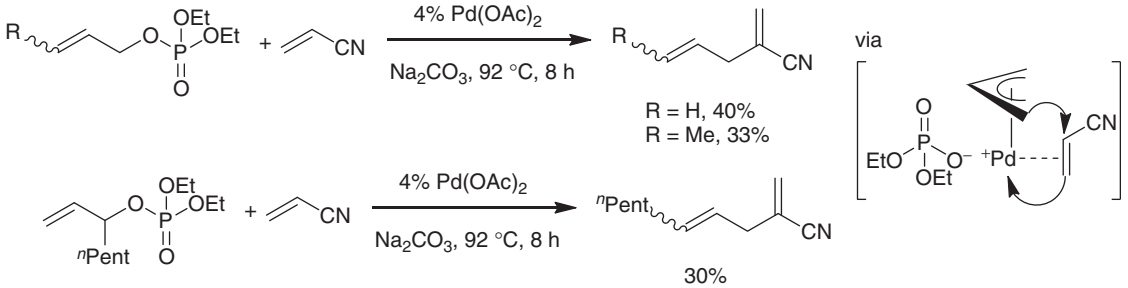
Scheme 109 Intramolecular fullerene-ene cycloisomerization.

Computationally, the same results were obtained for metallo-ene reactions with allyl magnesium hydride or allyl magnesium chloride as ene compound and ethylene as enophile.[199]

Experimentally, Nakamura et al.[200] reported a regioselective allylzincation of alkenylboronates furnishing geminal zincio-boryl intermediates, which give rise to the formation of δ,ε-alkenyl boronates on hydrolytic workup (Scheme 110,



Scheme 110

Table 18). The zincio-boryl intermediates can also be elaborated by trapping with electrophiles or by transmetallation. The mechanistic dichotomy between metallo-ene and Lewis-acid assisted metalla-Claisen reactions was previously studied by DFT calculations for various allyl metal–vinyl metal combinations. Such partners give rise to 1,1-dimetallic organometallic species, indicating that the endothermic key stage of the reaction has both metalla-Claisen and metallo-ene character.[201]

Shvo and Arisha[202] found that allyl di-ethyl phosphates and acrylonitrile react in the presence of $Pd(OAc)_2$ as a catalyst via an allyl-Pd species and insertion, i.e., in the sense of a metallo-ene reaction. A subsequent β-hydride elimination furnishes α-allylated acrylonitrile derivatives (Scheme 111).

Scheme 111 Palladium-catalyzed intermolecular metallo-ene reaction of allyl phosphates and acrylonitrile.

Propargylic alcohols and α-methyl styrenes react in a ruthenium-catalyzed allenylidene-ene reaction with formation of 1,5-enynes in moderate to good yield (Scheme 112, Table 19).[203] This transformation is an unusual ene reaction with metal participation, since the ruthenium-allenylidene species serves as an enophile, which is converted into a ruthenium-vinylidene via the classical ene pathway according to mechanistic investigations. An intramolecular version of this specific nonclassical metallo-ene reaction was illustrated by several synthetic examples.

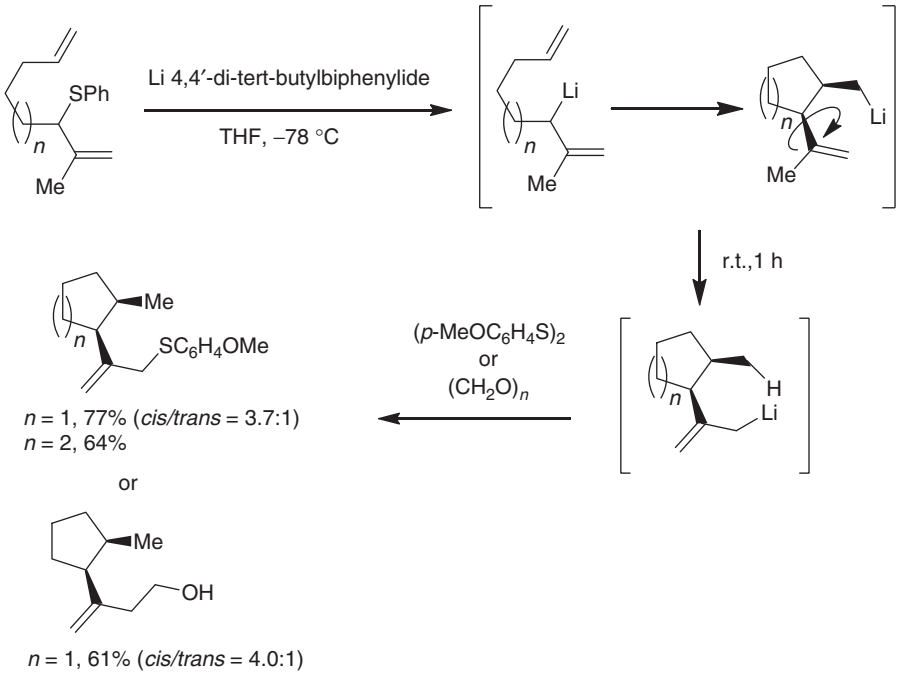
5.01.4.2 Metallo-Ene Cyclizations

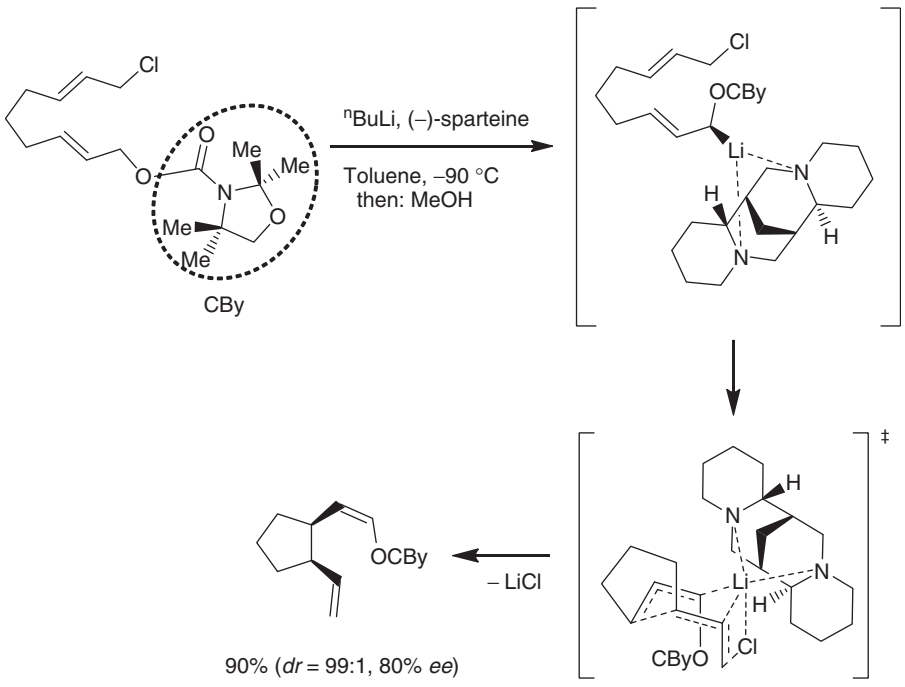
Metallo-ene cyclizations were pioneered by Oppolzer. As a consequence of higher rates of unimolecular reactions, many aspects of reactivity and selectivity can be more efficiently controlled than in intermolecular processes. Therefore, many examples ranging from stoichiometric to catalytic intramolecular metallo-ene have been disclosed in the past 20 years.

Cheng et al.[204] discovered that the lithium-ene cycloisomerization occurs at significantly lower temperatures than the magnesium analog; however, the initial ene product undergoes intramolecular proton transfer, if feasible, to generate an allyllithium species, which was identified by electrophilic trapping (**Scheme 113**).



Deiters and Hoppe[205] reported the first asymmetric lithium-ene reaction on the basis of an enantioselective deprotonation induced by (–)-sparteine and butyllithium (**Scheme 114**). This sequence was successfully applied in the synthesis of (+)-(3*R*,4*R*)-1,2-dihydromultifidene.

The 1:2 mixture of $Ti(O^iPr)_4$ and ^{i}PrMgBr forms (η^2-propene)$Ti(O^iPr)_2$,[206] which is an excellent reagent for mediating metallo-ene reactions. Sato and coworkers developed an efficient synthesis of cycloalkanes by titanium(II)-mediated metallo-ene cyclizations of 2,7- and 2,8-bis-unsaturated carbonates and acetate (**Scheme 115**, **Table 20**).[207] The reaction was then extended to the asymmetric cyclizations of chiral ethynyl acetals to optically active polysubstituted cyclopentanes and cyclohexanes.[208] Interestingly, the Ti(II)-mediated metallo-ene reaction works equally well in the intermolecular case.[207]

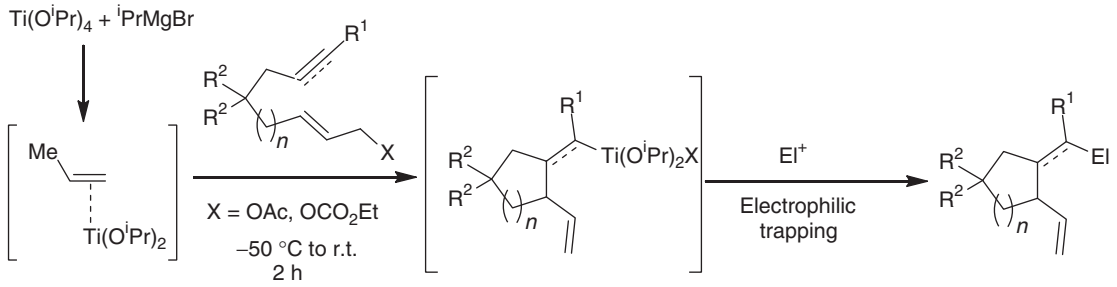


Korotvička et al.[209] reported a zirconocene-mediated metallo-ene reaction followed by trapping with allyl or homoallyl halides to furnish functionalized cyclopentane derivatives for the synthesis of *trans*-fused sesquiterpenoid analogs (**Scheme 116**). Starting from styrene derivatives, Kotora's group applied this zirconoceno-ene/allylation reaction several times to pave an elegant organometallic access to estrone precursors.[210]

Van der Louw et al.[211] found that 3-(alkynyl)-2-(methoxymethyl)-2-propenylzinc bromides are well suited for the preparation of 1,5-annulated 4-methylenecyclopentenes via zinc-ene cycloisomerization and subsequent Pd-catalyzed intramolecular allylic substitution of the zinc intermediates (**Scheme 117**). The products of the intramolecular zinc-ene reaction were unambiguously identified by quenching the reaction mixture with aqueous ammonium chloride solution instead of the addition of the palladium catalyst.

Propargyl/allenyl zinc derivatives with alkenyl or alkynyl substituents can undergo zinc-ene-allene[212] or zinc-yne-allene carbocyclizations[213] to carbocycles in excellent yields. On this basis, Marek's group disclosed new domino reactions that are

Scheme 113 Lithium-ene cyclization with subsequent intermolecular proton transfer.



Scheme 114 First asymmetric lithium-ene cyclization.

initiated by zinc-promoted Brook rearrangement followed by instantaneous ene-allene carbocyclization and terminated by addition of electrophiles (Scheme 118).[214]

Starting from enantioenriched propargyl silanols, Marek and coworkers showed that the domino sequences leads to the enantio- and diastereoselective formation of carbocycles in a one-pot operation.[215]

The Oppolzer group discovered that the combination of palladium(0) complexes and alkylzinc compounds enables unique cyclizations of 1-acetoxy-2,7-dienes and 1-acetoxy-2-ene-7-ynes under mild conditions. The workup of the alkyl zinc cyclization

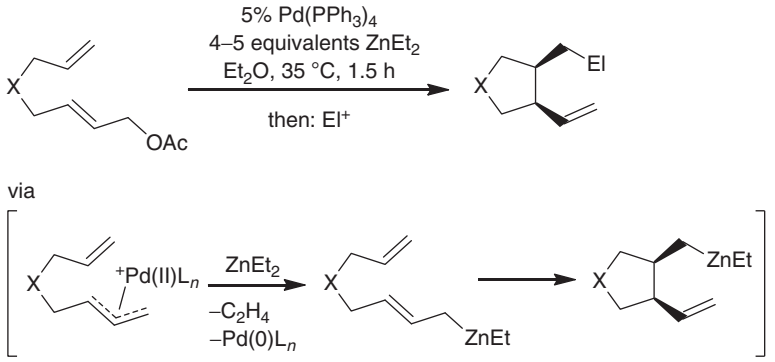
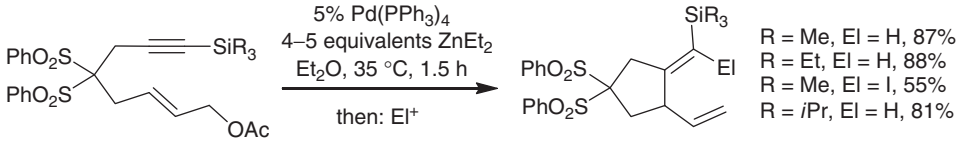
products with electrophiles furnishes *cis*-disubstituted cyclopentanes and pyrrolidines with excellent regio- and stereocontrol (Schemes 119 and 120, Table 21).[216]

Oppolzer and Flachsmann[217] reported a highly diastereoselective synthesis of the marine sesquiterpenoid (–)-erythrodiene applying an intramolecular Pd-catalyzed zinc-ene reaction as the key step. Furthermore, enantioselectivities of up to 47% could be achieved with a chiral C_2-symmetric cyclohexenyl bridged diphosphane ligands.[218]

The cyclization of 1-acetoxy-2,7-dienes[219] to five-membered carbo- and heterocycles was efficiently achieved with several easily prepared catalyst systems, such as $PdCl_2$, $RhCl_2(COD)_2$, $NiCl_2$ $6H_2O$, or $Ni(COD)_2/P(m\text{-}C_6H_4SO_3Na)_3$, and aqueous organic phases (Scheme 121, Table 22).[220]



Scheme 117 Intramolecular zinc-ene reaction and intramolecular zinc-ene/allylic substitution sequence.



Scheme 118 Domino zinc-promoted Brook rearrangement/ene-allene carbocyclization.

Expectedly, the cyclization concludes with a β-hydride elimination leading to cyclic diene products. Mechanistically, it was corroborated by DFT computations for cationic η^1-allyl palladium(II) complexes that an insertion pathway is strongly favored over a concerted classical metallo-ene pathway.[221]

Hiroi and Hirasawa[222] successfully developed palladium-catalyzed intramolecular metallo-ene reactions of allylic acetates and methyl carbonates bearing allylic sulfones as enophile moiety at appropriate sites. With chiral allylic sulfones derivatives as substrates, obtained by thermal rearrangement of an optically active allylic sulfinate, asymmetric palladium-catalyzed metallo-ene cyclizations were reported to proceed with modest yield but excellent diastereomeric ratios.[223]

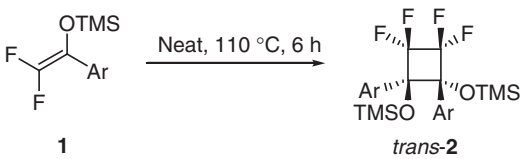
Glossary



Allenes Hydrocarbons (and by extension, derivatives formed by substitution) having two double bonds from one carbon atom to two others ($R_2C{=}C{=}CR_2$).
Diradical/Biradical Molecular species that have two unpaired electrons, in which at least two different electronic states with different multiplicities (electron-paired (singlet state) or electron-unpaired (triplet state)) can be identified.
Electrocyclization A molecular rearrangement that involves the formation of a σ-bond between the termini of a fully conjugated linear π-electron system (or a linear fragment of a π-electron system) and a decrease by one in the number of π-bonds, or the reverse of that process.
Ketenes The compounds in which a carbonyl group is connected by a double bond to an alkylidene group ($R_2C{=}C{=}O$).
Zwitterion The neutral compounds that have formal unit electrical charges of the opposite sign.

5.02.1 Introduction

The importance of the cyclobutane skeleton originates from its presence in natural products of diverse origin,[1,2] its importance in pharmaceutical and medicinal chemistry,[3] as well as its usefulness as a molecular building block in organic synthesis primarily due to the inherent ring strain.[4–6] The aim of this chapter is to update the current state of the thermal [2 + 2] cyclobutane ring formation since 1991–2011. In contrast to the previous edition,[7] thermal [2 + 2] cycloadditions of other π components such as ketenes and keteniminium salts are included. In addition, due to the increasing use of allenes during recent years, dimerizations and intermolecular and intramolecular [2 + 2] cycloadditions of allenes are also discussed. In some cases, classical papers reported before 1990, not contained in the previous edition, have been included to support the studies published more recently.

5.02.2 Dimerization of Alkenes, Alkynes, and Allenes

The [2 + 2] dimerization of alkenes under thermal conditions is one of the simplest ways to obtain the cyclobutane skeleton. Usually, a biradical intermediate has been proposed. This radical pathway has been proved recently by radical scavenging reactions and electron paramagnetic resonance.[8,9] The same biradical intermediates have also been postulated for the thermal rearrangement of the fused cyclobutane 3,4-dicyanotricyclo[4.2.2.0]decane.[10] In addition, several works have discussed the [2 + 2] cycloreversion of the cyclobutane nucleus with formation of 1,4-butanediyl or tetramethylene radical cation intermediates.[11–14]

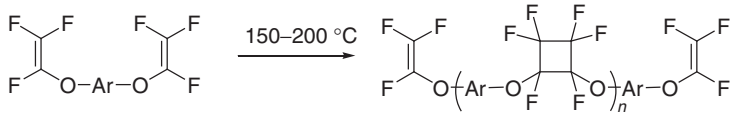
(1)

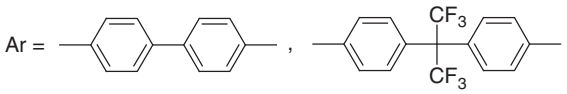
The thermal [2 + 2] cycloaddition of α,α-difluoro-olefins **1** is one of the well-known methods of obtaining fluorinated cyclobutanes **2** (equation 1). For example, the thermal dimerization of 2,2-difluoro enol silyl ethers gives mixtures of *trans*:*cis* 3,3,4,4-tetrafluorocyclobutanes in a head-to-head fashion.[15] This preference is explained by assuming that the open-chain

 doi:10.1016/B978-0-08-097742-3.00502-4



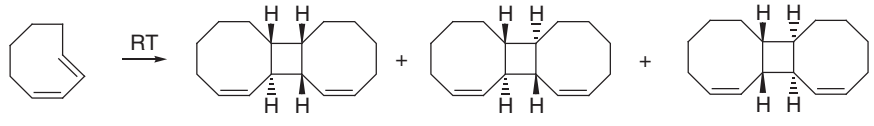
biradical intermediates, generated by radical coupling at the 2-position (head-to-head coupling), are much more stable than those formed by head-to-tail coupling, because of the stabilization of both radical centers by the aromatic and silyloxy groups.

Coumarin and thiocoumarin molecules are usually thermally unreactive for dimerization; however the [2 + 2] dimerization of **3** takes place in crystalline inclusion complexes, under high vacuum conditions (3.0×10^{-4} Pa) at 85 °C, with regio- and enantioselective ionformat of dimer **4** (equation 2).[16] High vacuum may decrease the concentration of O_2 wrapped in the solid and adsorbed on the surface, thus giving the radical intermediate a long enough lifetime for ring closure. The enantioselectivity has been explained by taking the chiral crystal environment and the presence of a rigid pyrone ring into account. Thermal [2 + 2] cycloadditions have also been applied to the dimerization of aryl bis-trifluorovinyl ethers **5** at 150–200 °C to give products of type **6** via a diradical intermediate (equation 3).[17]



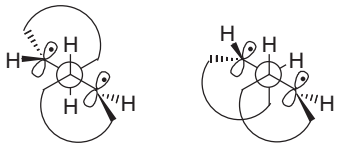
(2)

3 **4**



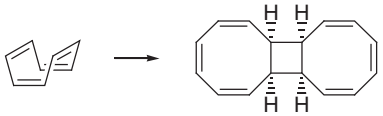
(3)

5 **6**



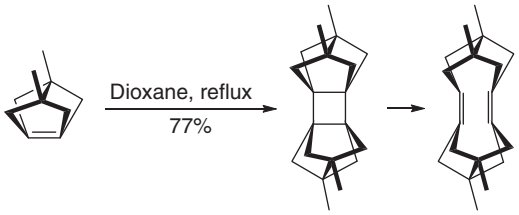
Bridgehead alkenes usually dimerize affording mixtures of different isomers. The thermal dimerization of bicyclo[2.2.0]hex-1(4)-ene has been studied previously[18]; however, its perfluorinated analog was found to be less reactive toward dimerization on prolonged heating, but rather undergoes electrocyclic ring opening.[19] B3LYP calculations have shown that bicyclo[2.2.0]hex-1(4)-ene dimerization is an exothermic process, whereas dimerization of perfluorobicyclo[2.2.0]hex-1(4)-ene is an endothermic process.[20]

The thermal [2 + 2] cyclodimerization of (*E*,*Z*)-cycloocta-1,3-diene **7** has been revisited in the presence of trapping agents for carbon-centered free radicals.[21] Obtention of cyclobutanes **8**, **9**, and **10** has been justified by assuming the formation of the *anti*-configured singlet 1,4-diradicals **11** and **12**, followed by an *anti*-to-*gauche* conformational change of these intermediates (equation 4). The thermal [2 + 2] cycloaddition of a related strained alkene, (5*Z*, 11*E*)-dibenzo[*a*,*e*]cyclooctatetraene, has been carried out in the presence of Ni(0), which facilitates the formation of the corresponding cyclobutane product.[22]



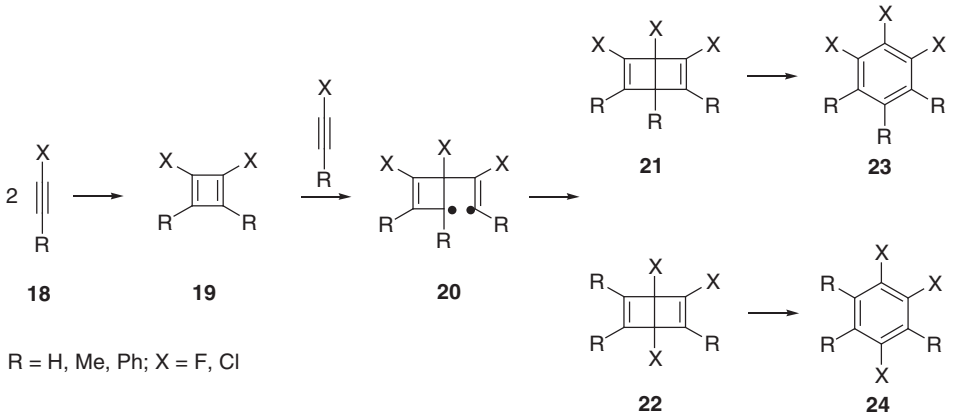
7 **8** **9** **10**

(4)



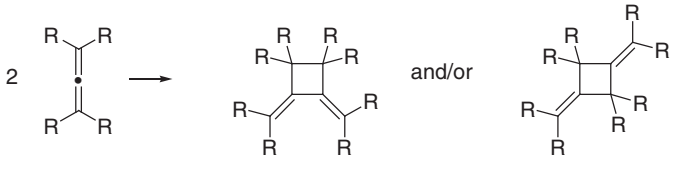
11 **12**

The thermal dimerization of cyclooctatetraene **13** was studied some time ago; however, the structure of the dimer has been discussed controversially.[23] Recently, the *syn* configuration of dimer **14** has been confirmed by X-ray diffraction (equation 5).[24]



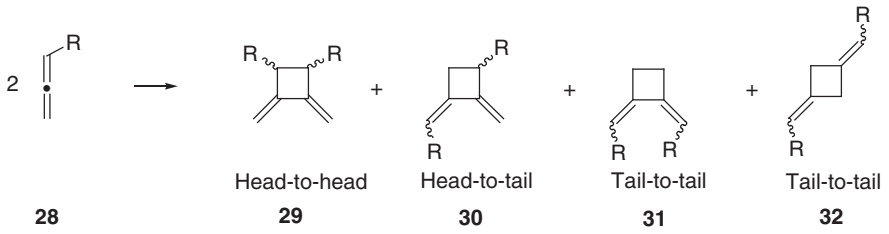
13 **14** (5)

Highly pyramidalized alkenes dimerize through [2 + 2] cycloaddition reactions in the absence of nucleophiles and dienes. 3,7-Dimethyltricyclo[3.3.0.03,7]oct-1(5)-ene **15** dimerizes to the cyclobutane derivative **16**, which undergoes retrocycloaddition to give diene **17** as shown in equation 6.[25] A similar behavior has been observed with other highly pyramidalized alkenes, obtaining the corresponding retrocycloaddition dienes.[26–28] The thermal reversion of the obtained cyclobutanes has been studied by ^{1}H nuclear magnetic resonance (NMR) and ab initio calculations. Strained 7-methylenebicylo[3.2.0]hepta-1,3-diene also affords cyclobutane dimers.[29]



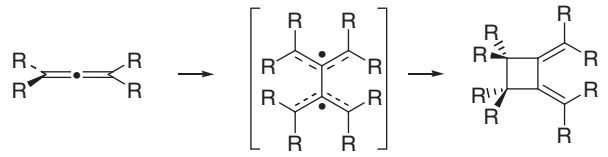
15 **16** **17** (6)

Cyclotrimerization of alkynes to form benzenes via a stepwise mechanism is a very well studied reaction, which first involves the formation of cyclobutadienes through a [2 + 2] cycloaddition.[30] Recently, theoretical studies of the mechanism of the thermal cyclotrimerization of fluoro- and chloroacetylenes **18** have been reported. A third molecule of alkyne would react with cyclobutadiene intermediates of type **19** to form species **21** and **22**, which finally afford benzene derivatives **23** and **24** (**Scheme 1**).[31]

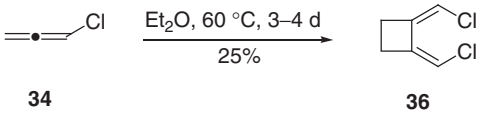


Scheme 1 Reproduced from Yao, Z-K.; Yu, Z.-X. *J. Am. Chem. Soc.* **2011**, *133*(28), 10864–10877, with permission from American Chemical Society.

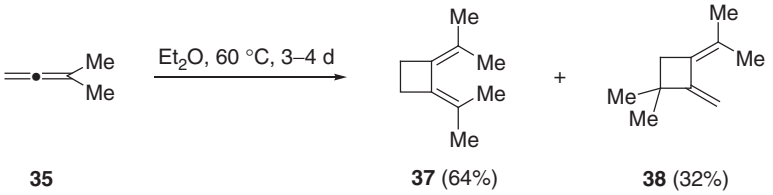
Allenes are reactive species with cumulated double bonds, which are widely used as intermediates for organic synthesis.[32] [2 + 2] Homodimerization of allenes has been studied in a large number of systems.[33] However, it is important to consider the substitution of the allene, because it is possible to obtain different regioisomers. Thus, when the allene is symmetrically substituted as in **25**, two regioisomers, **26** and **27**, are obtained (equation 7). However, when the allene substrate is not symmetrically substituted such as **28**, several regioisomers can be isolated: the head-to-head adduct **29**, the head-to-tail adduct **30** and the tail-to-tail adducts **31** and **32**, in the form of the corresponding *cis*-, *trans*-, *Z*-, and *E*-isomers (equation 8).



25 **26** **27** (7)

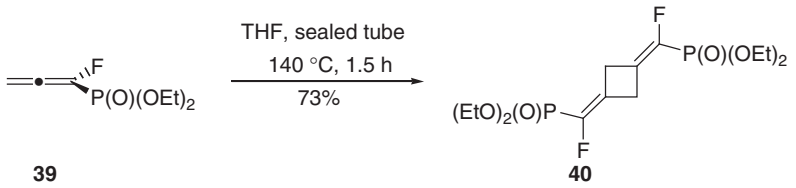


(8)

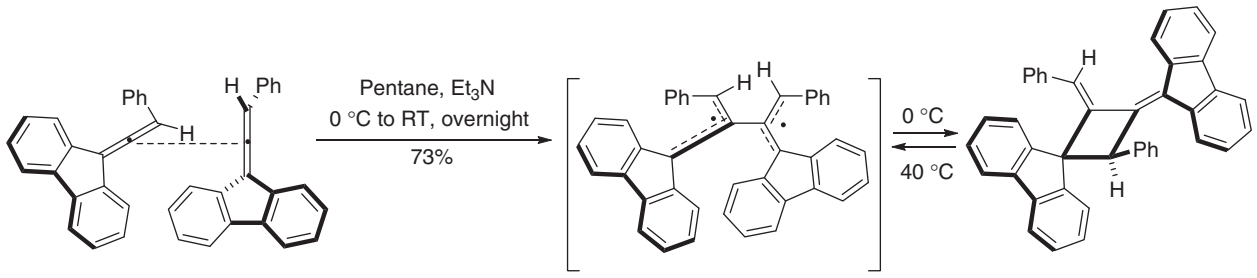


The high stereoselectivity observed in some [2 + 2] cycloadditions has pointed out the possibility that these transformations were concerted reactions. However, other studies have indicated that the [2 + 2] dimerization of allenes is not a synchronous process, and the intermediacy of a 1,1′-bis-allyl diradical intermediate **33** has been proposed to afford the corresponding cyclobutane **26** (equation 9).[34] As an example, chloroallene **34** and 1,1-dimethylallene **35** dimerize mainly in a head-to-head manner to afford the corresponding cyclobutanes **36**, **37**, and **38** respectively (equations 10 and 11).[35,36]

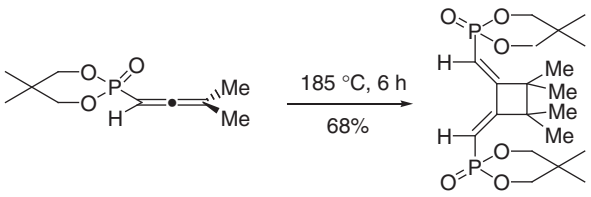
(9)



(10)



(11)



In general, it is important to consider the influence of the nature of the substituents attached to the allene moiety on the regiochemistry of the [2 + 2] cycloaddition. α-Fluoroallenylphosphonate **39** dimerizes under thermal conditions to afford product **40** exclusively as shown in equation 12.[37] This result contrasts with the mechanistic scenario accounting for a concerted [2 + 2] process in the allene dimerization. Probably, the bulky phosphorous substituent on the allene moiety allows rotation in the bis-allyl diradical intermediate yielding the corresponding tail-to-tail dimer **40**. The fluorenylidene-derived allene **41** reacts at room temperature to afford the [2 + 2] head-to-tail dimer **42** (equation 13).[38] Again, a stepwise process involving a diallyl diradical intermediate **43** has been proposed. The orthogonal arrangement of the substituents in allene **41**, together with the preference of large groups to minimize steric hindrance, suggests that the two molecules of **41** approach each other along a C_2-symmetric trajectory. Thus, at the moment of generation, the most favorably oriented *p* orbitals, through which radical coupling can occur, are located on unlike termini, and a least-motion rotation about the central bond suffices to bring these centers close enough for bond formation to occur, which leads to dimer **42**. The entire sequence of intermediates has been elucidated by NMR and X-ray crystallography.[39] In a similar work, ferrocenyl- and fluorenylidenallene dimerizations were studied as well.[40] Dimerization of allene **44** afforded the head-to-head dimer **45** in 68% yield, pointing to a concerted mechanism (equation 14).[41] However, in some cases a mixture of several regioisomers was isolated.[42] A very recent report has studied the dimerization of chlorotriphenylallenes to form rubrene analogs or bis(alkylidene)cyclobutanes depending on the substituents present on the chloroallene.[43]

5.02.3 Intermolecular [2 + 2] Cycloadditions

Reaction of (*Z*)-[6]paracycloph-3-ene **46** with tetracyanoethylene **47** gives the [2 + 2] cycloadduct **48** in 80% yield.[44] This thermal cycloaddition has been subject to theoretical studies, assuming the formation of a zwitterion intermediate **49** as shown in equation 15.

46 47 49 48 (15)

The [2 + 2] cycloaddition reaction of enol ethers **50** to *exo*-methylene-2-oxacyclopentylidene complexes of chromium and tungsten **51** provides a novel access to spirocyclobutane skeletons **52** at room temperature or 50 °C (equation 16).[45] Single diastereoisomers were obtained in all cases, consistent with either a concerted mechanism or a two-step process in which ring closure is fast in comparison with rotation around the new C–C bond formed in the first step.

The reaction of (benzyloxymethylene)cyclopropanes **53** with alkylidenemalononitriles **54** at ambient pressure gives the spirocyclopropanated cyclobutane derivatives **55** in good to high yields (equation 17).[46] The formation of compounds **55** has been explained by initial attack of the carbon–carbon double bond in **53** on the β-position of the alkylidenemalononitrile to afford the *anti*-oriented zwitterion *anti*-**56**, which after initial rotation to **57**, cyclizes to the cyclobutanes *trans*-**58** or *cis*-**58** (Scheme 2). The cyclopropyl group adjacent to the cationic center is essential to stabilize the zwitterionic intermediate **57**.

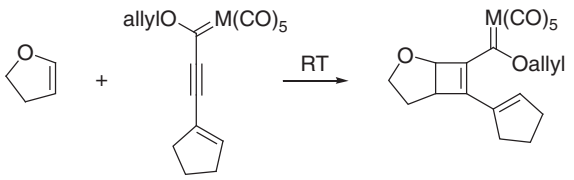

Scheme 2 Reproduced from Nakamura, I.; Nagata, R.; Nemoto, T.; *et al. Eur. J. Org. Chem.* **2007**, *27*, 4479–4482.

The competition between [2 + 2] and [4 + 2] cycloadditions in reactions of electron-rich alkenes with electron poor alkenes is dependent on the energy levels of the participating highest occupied molecular orbital–lowest unoccupied molecular orbitals, and on the chosen reaction conditions. To test the ability of the zwitterionic intermediate to react with an internal double bond, the reaction of electron-rich bifunctional vinyl ethers with electrophilic alkenes has been studied.[47] Thus, reaction of tetracyanoethylene **47** with the divinyl ether **59** afforded the cyclobutane adduct **60**, which, in a polar solvent, is in equilibrium with the zwitterionic intermediate **61** (Scheme 3). This species does not react with the other C–C double bond of the vinyl ether molecule, but does react with the solvent acetonitrile to give compound **62**, instead of an intramolecular reaction to give a [3.1.1]bicyclic adduct **63**. This experiment indicates that under these reaction conditions, the anionic end of the zwitterion **61** reacts faster than the cationic end; and, consequently, that the anionic end is less-stabilized than the cationic one. In contrast, in the reaction of **64** with vinyl ether **59**, only cyclobutane adduct **65** is obtained, because the two ester substituents in the β-positions provide less stabilization to the anionic charge. Thus, the ester moieties stabilize the cyclobutane structure, making it unreactive to tetrahydropyridine formation on prolonged exposure to acetonitrile.

Cyclobutenes **66** containing a 1,3,5-metallahexatriene moiety have been obtained by [2 + 2] cycloaddition of cyclic enol ethers **67** and chromium or tungsten alkynyl carbene complexes **68** at room temperature (equation 18).[48,49]

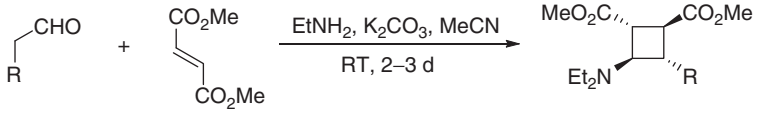
Thermal [2 + 2] cycloadditions of morpholinoenamines **69** have been studied with C_{60} (**70**), yielding the corresponding adducts **71** in high yields (equation 19).[50] This cycloaddition takes place via a single electron transfer, radical coupling, and subsequent ionic cyclization.



(19)

The highly functionalized cyclobutane serine analog **72** has been obtained in moderate yield by thermal [2 + 2] cycloaddition involving 2-acylaminoacrylate **73** as electron poor acceptor alkene, and ketene diethyl acetal **74** as electron-rich olefin (equation 20).[51–53] The mechanism proposed for the thermal [2 + 2] cycloaddition reaction involves zwitterionic intermediates. The first addition of one molecule of ketene diethyl acetal **74** onto amidoacrylate **73** by Michael reaction leads to zwitterion **75**, which after ring closure gives the cyclobutane core **72**. [2 + 2] Cycloaddition of enamines to electron-deficient alkenes under thermal

conditions has been studied some time ago[54]; however, this reaction has been reevaluated as a multicomponent process of enamines, generated *in situ* from aldehydes **76** and diethylamine, with dimethyl fumarate **77**, which afforded functionalized cyclobutanes **78** with moderate yields (equation 21).[55]

Ketenes are suitable substrates for the [2 + 2] cycloaddition with different π components. The mechanism has been a subject of much interest and controversy. Although a concerted $[_{\pi}2_a + _{\pi}2_s]$ mechanism, as proposed by Woodward and Hoffmann, is widely accepted, an asynchronous $[_{\pi}2_s + (_{\pi}2_s + _{\pi}2_s)]$ pathway involving a dipolar process may operate in certain such reactions. The synthesis of fused cyclobutanes **79** through [2 + 2] cycloaddition of the five-membered endocyclic enecarbamate **80** with ketene **81** is a good example (equation 22).[56] The synthesis of spiranic cyclobutanes **82** has also been reported from olefin **83** and ketene **84** (equation 23).[57,58] In a recent work studying the thermal cyclopropanation of aryldiazoketones **85** and alkenes **86**, cyclobutanones **87** were formed instead. The formation of the four-membered carbocycles **87** may be explained by thermal [2 + 2] cycloaddition of the ketene generated by Wolff rearrangement of the starting aryldiazoketone **85** with alkenes **86** (equation 24).[59] Interestingly, vinyl ketene **88**, formed by thermal [1,5]-H shift of 3-ethoxycarbonyl-2,4-dienal **89**, reacts with butylvinyl ether **90** under thermal conditions to afford the corresponding cyclobutanones **91** (equation 25).[60]

The [2 + 2] cycloaddition of keteniminium salts under thermal conditions was discovered in 1908,[61,62] but its importance was recognized only in the early 1970s.[63,64] Since then, many examples have been reported to prepare the cyclobutane ring.[65] Furthermore, in contrast to alkenes, alkynes, and allenes, keteniminium salts do not dimerize or polymerize. Although in 1972, Marchand-Brynaert and Ghosez proposed a [$\sigma_2^* + \sigma_2^*$] concerted mechanism,[66] Saimoto et al. later showed that this cycloaddition proceeds in a stepwise manner through cationic intermediates.[67] This methodology has been applied to the synthesis of cyclobutanones of type **92** from compound **93** and alkenes **94** (equation 26)[68]; more recently it has been used for the synthesis of the helical hydrocarbon **95** from **96** and **97** (equation 27).[69] However, different reactivity profiles toward dienes have been observed; in most cases [4 + 2] cycloadducts involving the C=N bond as dienophile component are obtained.[70]

In a series of classic papers, Pasto studied in detail the synthesis of cyclobutanes by intermolecular thermal [2 + 2] cycloaddition of allenes with alkenes or alkynes. A high number of experiments were reported in order to get a better understanding of the mechanism, the stereo- and chemoselectivity, the relative reactivities and kinetic isotope effects.[71–73] For example, mono- and 1,1-disubstituted allenes **98** react with 1,1-dichloro-2,2-difluoroethene **99** to give mixtures of the adducts **100**, **101**, and **102** via the formation of stereoisomeric diradical intermediates **103** and **104** (Scheme 4).[74] In addition, the reversibility of the formation of the biradical intermediates has been investigated as well in the reaction of allenes with diethyl fumarate and maleate.[75] The reactivity of

More recently, the reactivity of allene carboxylate **114** with diene **115** to give cyclobutanes **116** (equation 31),[79] and the synthesis of methylene-cyclobutanes **117** and -cyclobutenes **118** by reaction of vinylideneoxazolidin-2-ones **119** with alkenes **120** or alkynes **121** (Scheme 5),[80] respectively, have been described. Formation of cyclobutenes **117** and **118** has been rationalized via a concerted mechanism. However, the [2+2] cycloaddition of C_{60} (fullerene, **70**) with allenamides **122** to afford the cyclobutane annulated fullerene derivatives **123** in moderate yields has been explained via the formation of an iminium intermediate **124** (Scheme 6).[81]

5.02.4 Intramolecular [2 + 2] Cycloadditions

The intramolecular thermal [2+2] cycloaddition of unsaturated systems is a very useful strategy for the preparation of polycyclic structures in a single step. In addition, some problems found in the intermolecular version have been solved when the reaction was carried out in an intramolecular fashion. For example, stilbene does not give concerted thermal cycloadditions because the required orthogonality is not accessible due to steric hindrance and angle strain.[82] However, recently the intramolecular [2+2] cycloaddition, at room temperature, of 2,5,2′,5′-tetra(4-*N*,*N*-diphenylaminostyryl)biphenyl **125** has been reported; its central biphenyl motif is responsible for the relatively free rotation of the molecule (equation 32).[83] These characteristics allow a swivel-cruciform conformation to be reached in which the biphenyl core places two of the 1,2-disubstituted double bonds in **125** in the orientation required for thermal [2+2] cycloaddition: an orthogonal rearrangement of π orbitals at a short distance. Furthermore, the high electron density of the double bonds in the starting material enhances the reactivity. According to the geometry, the head-to-tail cyclobutane **126** is the product obtained.

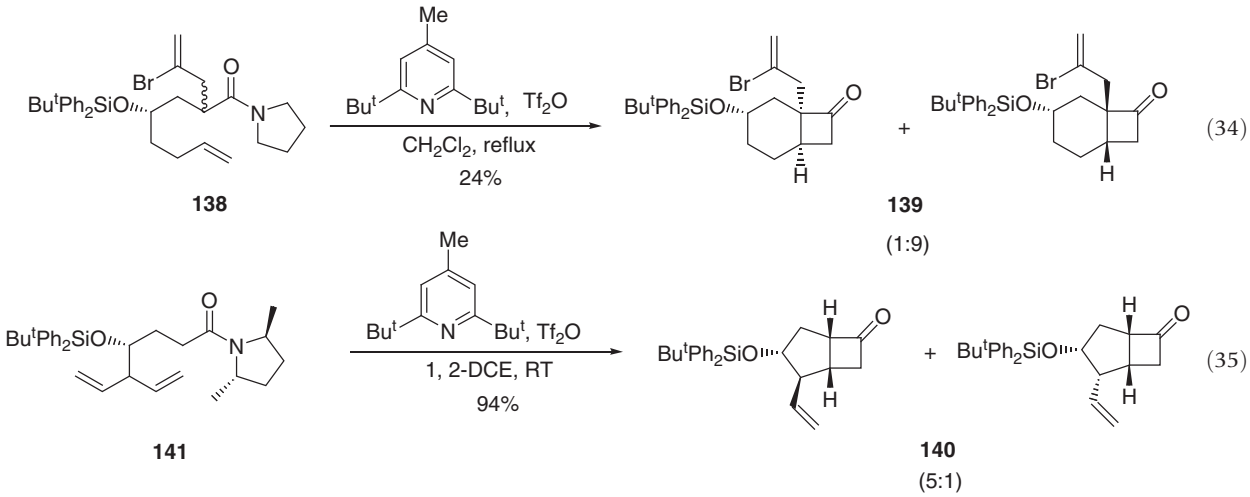
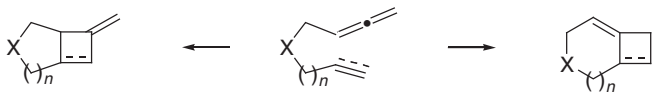
During the synthesis of the natural product pre-kingianin A, cyclooctatriene conformers **129** and **130** have afforded bicyclooctadienes **131** and **132**, respectively through a rapid 6π-electrocyclization (**Scheme 7**).[85]



The intramolecular [2 + 2] cycloaddition of alkenes has been studied with ketenes and keteniminium salts as well.[86] Reaction of acid chloride **133** with triethylamine leads to *in situ* formation of the ketene **134**, which then undergoes intramolecular cycloaddition with the olefin to form the fused cyclobutanone **135** (**Scheme 8**). The same skeleton has also been prepared by intramolecular [2 + 2] cycloaddition of alkynyl ketenes.[87] An alternative method for the preparation of cyclobutanones is the hydrolysis of [2 + 2] cycloadducts from keteniminium salts. The keteniminium salt **136** is generated by treatment of an amide **137** with trifluoromethanesulfonic anhydride and 2,4,6-collidine (**Scheme 8**). In general, cycloadditions of keteniminium salts give better yields than the analogous cycloadditions of ketenes. Other examples have been reported in the literature, such as the synthesis of a key intermediate of (+)-gibberellic acid by intramolecular [2 + 2] cycloaddition of **138** to give cyclobutanes **139** (equation 34),[88] and the asymmetric synthesis of the prostanoid scaffolds **140** by employing an asymmetric intramolecular [2 + 2] cycloaddition of keteniminium salts derived from **141** as a key step (equation 35).[89]



Scheme 7 Reproduced from Sharma, P.; Ritson, D. J.; Burnley, J.; Moses, J. E. *Chem. Commun.* **2011**, *47*(38), 10605–10607, with permission from Royal Society of Chemistry.

The intramolecular [2 + 2] cycloaddition of allenes is an interesting strategy to prepare polycyclic fused structures. However, it is necessary to consider that two regioisomers can be formed in the reaction of allene-enes and allene-ynes **142**; the proximal cycloadduct **143** is formed by reaction with the internal 2π component, whereas the distal cycloadduct **144** is formed by reaction with the external 2π component of the allene moiety (Scheme 9).

143 **142** **144**

Scheme 9 Reproduced from Alcaide, B.; Almendros, P.; Aragoncillo, C. *Chem. Soc. Rev.* **2010**, *39*(2), 783–816, with permission from Royal Society of Chemistry.

Initial works were focused on the study of the regioselectivity depending on the substitution on the alkene moiety. Allene-enes **145** and **146** as starting materials afforded different regioisomers **147** and **148** in excellent yields via biradical intermediates **149** and **150** (equations 36 and 37).[90,91] More recently, an analogous behavior has been observed in β-lactam-based allene-enes **151** and **152**. Once again, the presence of an internal substituent on the alkene moiety controls the regiochemistry of the [2 + 2] cycloaddition, affording cyclobutanes **153** and **154** as single regioisomers with moderate yields.[92,93] In both examples, biradical intermediates have been proposed (equations 38 and 39).

However, the presence of a nonterminal alkyne moiety is essential for the [2 + 2] cycloaddition of allene-ynes, affording in most of the cases distal adducts with complete regioselectivity. Recently, allene-ynes **155** were shown to give the corresponding cycloadducts **156** in excellent yields (equation 40) under thermal conditions.[94] In addition, this method has been applied to the construction of both bicyclo[6.2.0]deca-1,8-dienes **157** from allene-ynes **158** (equation 41),[95] as well as to the synthesis of 3-oxabicyclo[4.2.0]octa-1(8),5-dien-4-ones **159** via intramolecular [2 + 2] cycloaddition of propargylic 2,3-allenoates **160** under conventional heating conditions (equation 42).[96]

The thermal [2 + 2] cycloaddition reaction of the cyclic 1,3-bis-(alkylthio)allene **167** gave the fused tricyclic cyclobutane **168** quantitatively via the biradical intermediate **169** as shown in equation 46.[99,100] Bispropargylic alcohols are excellent precursors to bis-allenes. For example, the reaction of bis(propargylic alcohols) **170** with chlorodiphenylphosphine **171** has been reported to afford 3,8-bis(diphenylphosphynyl)naphtho[*b*]cyclobutanes **172** via the corresponding 1,2-bis(α-phosphinylallenyl)benzenes **173**.[101] Formation of compounds **172** has been rationalized via the intermediacy of biradical intermediates **174**. The aromaticity of the final products is probably the driving force to obtain compounds **172** as sole isomers (**Scheme 10**).

A competitive reaction involving a [2 + 2] cycloaddition of allene-ynes was presented in 2003. During the attempted synthesis of a dicyclopenta[*a*,*e*]pentalene via a Pauson–Khand reaction, the monocyclized [5.4] system **175** was obtained instead on heating the diyne-diallene **176** in toluene at 100 °C (equation 47).[102]

176 175 (47)

5.02.5 Summary

In summary, a high number of different examples have been reported concerning the thermal cyclobutane synthesis, with different π components such as alkenes, alkynes, allenes, ketenes, and iminium salts. In most cases, a biradical intermediate has been proposed to explain the mechanism, although in a few examples zwitterionic intermediates have been postulated. The regiochemistry, which is usually controlled by the nature of the substituents in the starting material, has been discussed in detail for reactions which can lead to several isomers.

A huge amount of work has already been published, but seems to be only the starting point for the preparation of more complex structures, probably focusing on the preparation of biologically active cyclobutane-containing compounds or the synthesis of macrocyclic and polymeric structures with interesting physical properties.

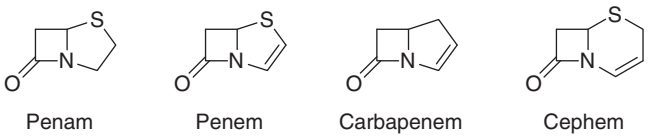
Glossary

Allene Compounds having two double bonds from one atom to two others. It can be a hydrocarbon ($R_2C{=}C{=}CR_2$) or a derivative formed by substitution ($R_2X{=}Y{=}ZR_2$).
Hünig's base *N*,*N*-diisopropylethylamine (DIPEA). It is used as a sterically hindered, hence poorly nucleophilic base in organic chemistry.
Ketene Organic compound in which a carbonyl group is connected by a double bond to an alkylidene group, $R_2C{=}C{=}O$.
β-Lactam A four-membered cyclic amide having a 1-azacyclobutan-2-one (2-azetidinone) structure.
β-Lactone A four-membered cyclic ester having a 1-oxacyclobutan-2-one (oxetan-2-one) structure.
Mukaiyama reagent 2-Chloro-1-methylpyridinium iodide.
Zwitterion Neutral compound having formal unit electrical charges of opposite sign at different locations within that compound, sometimes referred to as inner salts or dipolar anion.

5.03.1 Introduction

This section is devoted to the formation of four-membered cycles containing at least one heteroatom, and obtained by combining π-systems through formal [2 + 2] cycloaddition reactions. Heat-activated and metal-, acid-, or base-catalyzed reactions will be considered here, whereas the photochemical cycloadditions are discussed in Chapter 5.04.

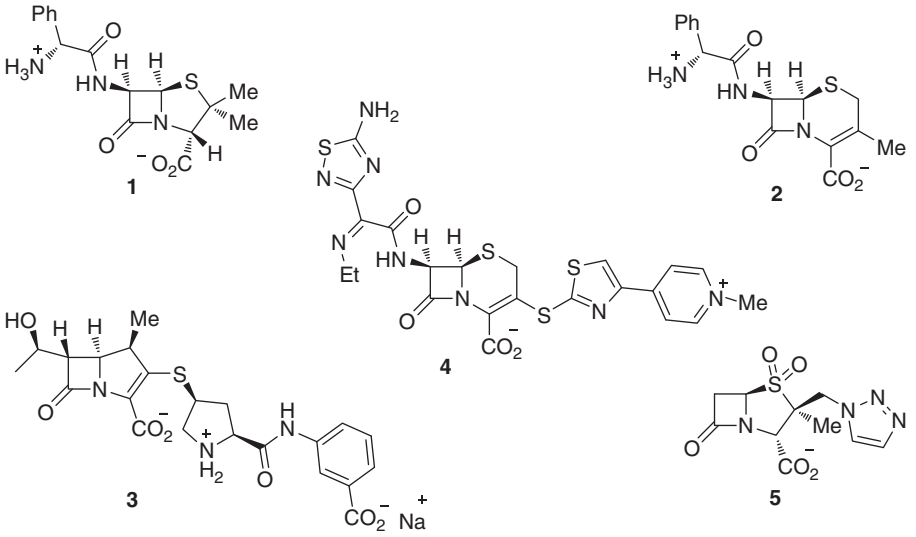
There are several classes of four-membered heterocycles (Scheme 1).[1–8] The considerable attention focused on these heterocycles originates from the discovery of penicillins,[9] cephalosporins,[10] and related antibiotics[11] which feature a β-lactam (azetidin-2-one) ring in their core structures. The β-lactone (oxetan-2-one) ring is also found as an important structural characteristic in several biologically active compounds.



Scheme 1

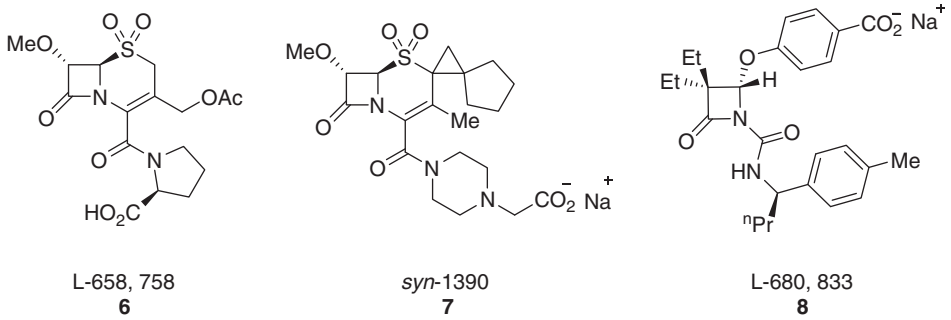
The functionalities involved in four-membered heterocycles are endowed with increased reactivity resulting from the ring strain. Accordingly, these molecules can be exploited as building blocks in organic synthesis, in particular when regio, stereo, and enantioselectivities have to be controlled.[12–16]

A brief survey of the above mentioned important aspects, lying outside the scope of this section, is presented as Introduction.



5.03.1.1 Four-Membered Heterocycles as Biologically Active Compounds

The antibiotics belonging to the so-called β-lactam class are still the most prescribed ones against bacterial infections.[17] Several subclasses exist depending on the nature of the fused five- or six-membered rings (Scheme 2).[9–11] Due to the increasing bacterial resistance to early drugs such as ampicillin **1** and cephalexin **2**, increasingly sophisticated derivatives have been developed as illustrated with ertapenam **3**[18] and ceftarolin **4**.[19] These β-lactams are active against methicillin resistant *Staphylococcus aureus* (MRSA) responsible for nosocomial infections in hospitals (Scheme 3). Another way to fight resistant bacteria is the administration of a traditional penicillin (ampicillin for instance) together with an inhibitor of β-lactamases (i.e., bacterial defense enzymes), such as tazobactam **5**.[20]

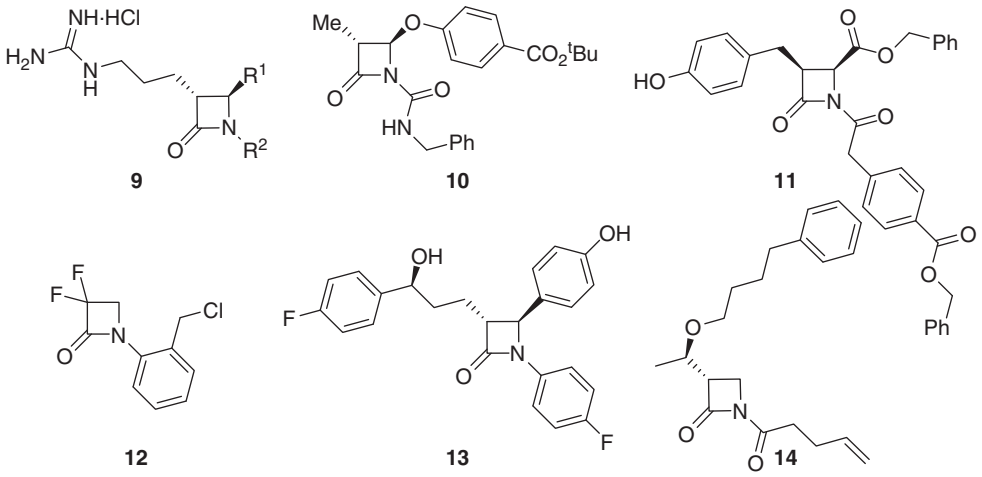


Scheme 2

The mode-of-action of the β-lactam antibiotics as well as the resistance mechanisms have been intensively studied.[17] The structures of several bacterial target enzymes are known at the atomic level, thus allowing the rational design of novel β-lactams

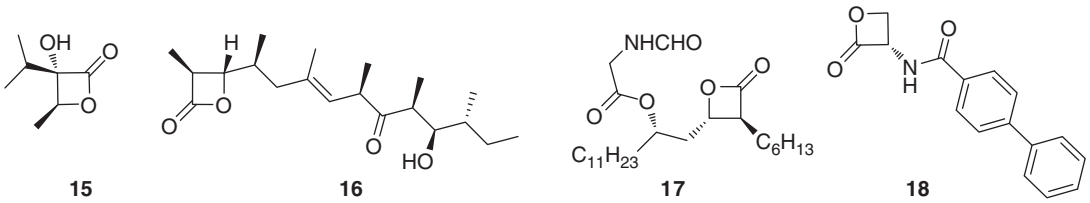
Scheme 3

acting as inhibitors of the so-called penicillin-binding proteins (PBPs).[21,22] Since these enzymes are serine proteases (DD, transpeptidases–carboxypeptidases involved in the bacterial cell-wall biosynthesis), the β-lactam motif was considered by the medicinal chemists as a common pharmacophore for the inhibition of other serine enzymes playing a key role in numerous diseases. For instance, human leukocyte elastase inhibitors L-658758 (**6**)[23] and SYN-1390 (**7**),[24] used in aerosols for the treatment of allergy, are structurally related to the cephem antibiotics (Scheme 4). Orally bioavailable antiinflammatory drugs, such as L-680833 (**8**) are simple monocyclic β-lactams.[25]



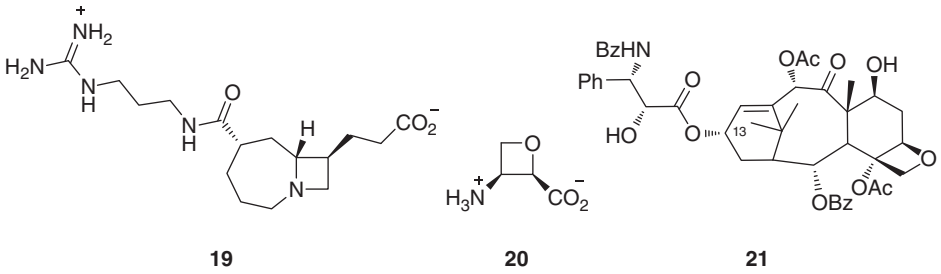
Scheme 4

A lot of monocyclic β-lactams[26–30] have been disclosed for the inhibition of thrombin (e.g, **9**),[31] human cytomegalovirus protease (e.g.,, **10**),[32] prostate specific antigen (e.g., **11**),[33] β-lactamases (e.g., **12**),[34] cholesterol absorption (e.g., **13**),[35] and fatty acid amide hydrolase (e.g., **14**),[36,37] among others (Scheme 5).

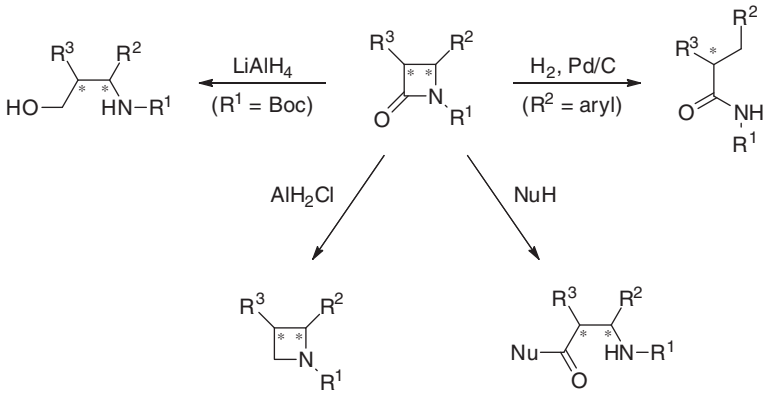


β-Lactones found in nature are pheromones (**15**),[38] esterase inhibitors (**16**),[39] etc. Synthetic derivatives have been designed for the inhibition of pancreatic lipase,[40] monoacylglycerol lipase (MAGL) (**17**),[41] and *N*-acylethanolamine-hydrolyzing acid amidase (NAAA) (**18**),[42] as examples (Scheme 6). β-Turn mimics for the construction of Arg–Gly–Asp (RGD) peptidomimetics are based on bicyclic azetines **19**.[43] Antimicrobial (**20**)[44] and anticancer drugs (**21**, paclitaxel)[45] feature an oxetane ring. The synthetic analog with a thietane ring (Taxol-thietane) has also been prepared (Scheme 7).[46]

5.03.1.2 Four-Membered Heterocycles as Reactive Intermediates

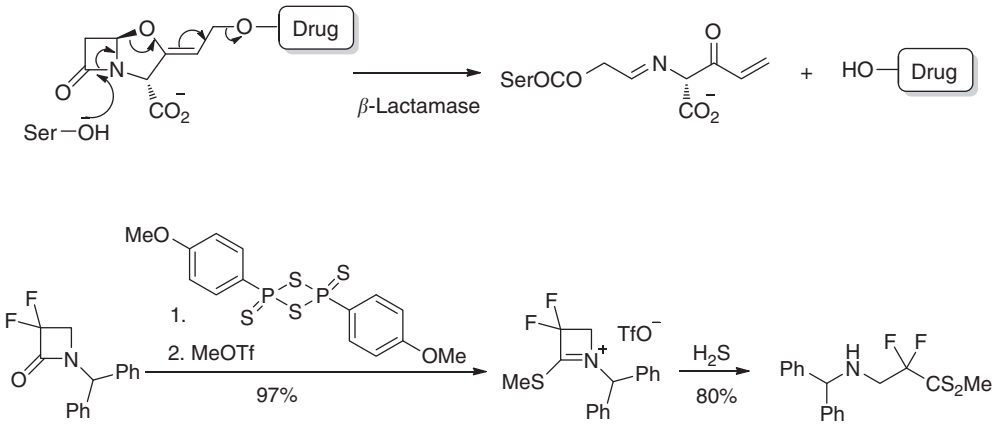


Chiral β-lactams are useful precursors of azetines, amides, and 1,3-aminoalcohols, with preserved chirality, by selective reduction of the C_2 carbonyl, N_1–C_4 bond (R^2 = aryl) and C_2–N_1 bond (R^1 = Boc), respectively (Scheme 8). Nevertheless, the main applications concern the nucleophilic addition on the C_2 carbonyl group accompanied by the C_2–N_1 bond cleavage, leading to chiral β-aminoacid derivatives (Scheme 8).[1,12] The β-lactam function can also be broken by basic or acidic hydrolysis. A general strategy to produce enantiopure, nonproteogenic α,β-diaminoacids makes use of β-lactam precursors.[47]



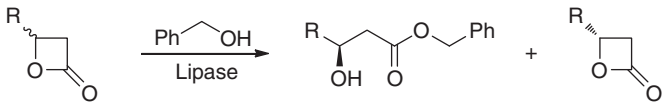
Scheme 5

Scheme 6

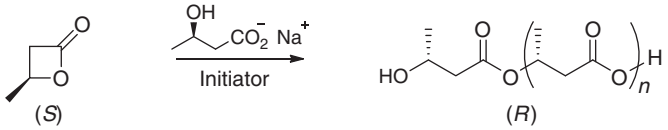


Scheme 7

Scheme 8

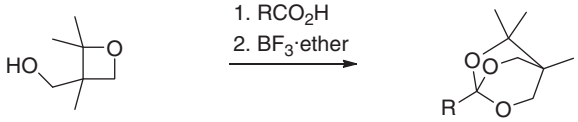


The processing of β-lactams by serine enzymes has been used for the design of pro-drugs. The drug of interest is coupled to a bicyclic β-lactam that is sensitive to β-lactamases; this conjugate is inactive. The enzymatic hydrolysis of the β-lactam core liberates the active drug on the site of infection. Equation 1 illustrates one example of drug delivery based on this strategy.[48,49] β-Lactam ring opening can also proceed via an azetine (or azetinium) intermediate as shown in the synthesis of fluorinated β-amino dithioesters (Scheme 9).[50]



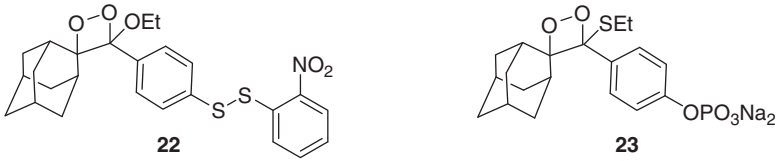
(1)

Scheme 9



β-Lactones are very sensitive to nucleophilic attack and ring opening. An interesting kinetic resolution has been achieved via a lipase-promoted asymmetric transesterification with benzyl alcohol (O_1–C_2 bond cleavage) (equation 2).[51] Anionic polymerization of β-lactones occurs via the O_1–C_4 bond cleavage. The nucleophilic attack on C_4 (S_N2 reaction) has been established by the inversion of configuration at this center: (*S*)-β-butyrolactone leads to the formation of poly-(*R*)-3-hydroxybutyrate (equation 3).[52] The most commonly used method to synthesize polyethers is the cationic ring-opening polymerization of oxetanes; the living polymerization has been demonstrated.[53] Another example of acid-catalyzed ring opening of oxetanes is given by the synthesis of *ortho*-esters as the protection of carboxylic acids (equation 4).[54,55]

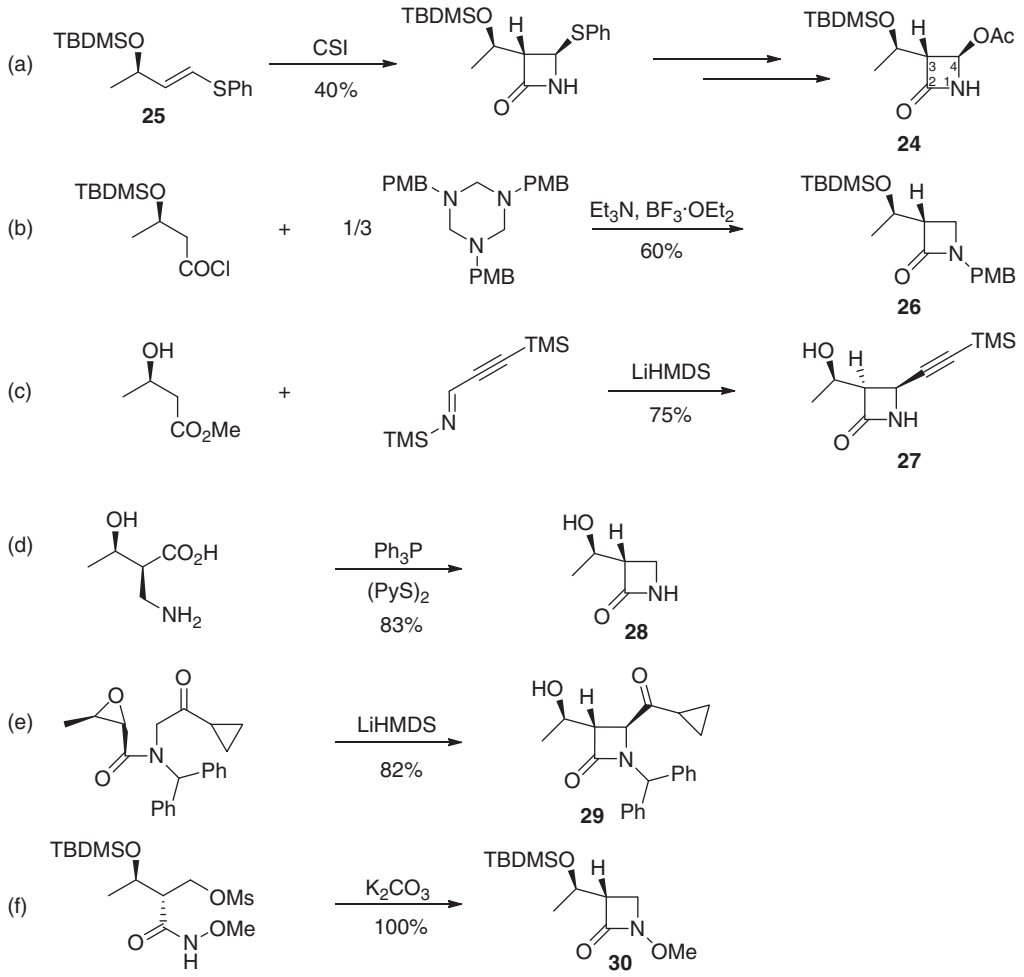
(2)



(3)

(4)

Chemiluminescent probes based on the dioxetane moiety are commonly used in molecular biology.[56] The simultaneous O_1–O_2 and C_3–C_4 bond cleavages give carbonyl species at the excited state, the deactivation of which produces light. Scheme 10 depicts the molecules **22** and **23** behind the bioassays for detection of cholin esterase and alkaline phosphatase activities,



Scheme 10

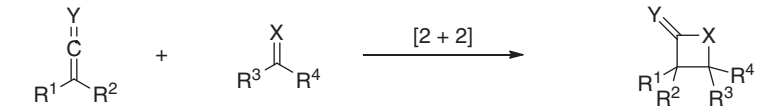
respectively.[57,58] Bioluminescent assays using a luciferase substrate are based on the *in situ* formation of a dioxetanone, which decomposes into CO_2 and an excited carbonyl species emitting light under decay.[59]

5.03.1.3 Strategies for the Preparation of Four-Membered Heterocycles

The various strategies exploited for the synthesis of four-membered heterocycles are exemplified here with the preparation of acetoxy-azetidinone **24**, the industrial starting material of all the (carba)penem antibiotics (Scheme 11).[60–62] Usually, the chirality is introduced by using enantiomerically pure reagents and controlled reaction mechanisms. A first route (a) is based on the [2 + 2] cycloaddition of chlorosulfonyl isocyanate (CSI) onto the *trans*-phenylthio-alkene **25**,[63] thus forming concomitantly the C_2–C_3 and N_1–C_4 bonds. The [2 + 2] cycloaddition of ketenes or enolates to Schiff bases constitutes other main routes (b)[64] and (c),[65] leading to the simultaneous formation of C_3–C_4 and C_2–N_1 bonds. The cyclization reactions cover the C_2–N_1 bond formation from β-aminoacid precursors[66] (route (d)), the C_3–C_4 bond formation by intramolecular S_N2 reactions[67] (route (e)), and the Miller process for creating the N_1–C_4 bond (route (f)) from hydroxylamide derivatives.[68] All the chiral β-lactams **26** to **30** are precursors of the key building block **24**: the process (a) and (d) have been developed at pharmaceutical production scale.

Scheme 11

Besides these three [2 + 2] cycloaddition strategies and three cyclization appoaches, the carbonylation of aziridines offers a practical access to β-lactams,[69–71] via a ring-expansion reaction. Rearrangement of isoxazolidines (obtained by 1,3-dipolar cycloaddition of nitrones to alkynes, see Section 5.03.7) leads to β-lactams by a ring-contraction known as the Kinugasa reaction.[72,73]



Similarly, β-lactones are prepared by [2 + 2] cycloadditions of aldehydes to ketenes[74,75] or enolates,[76,77] and by lactonization, i.e., O_1–C_2 cyclization from adequately β-substituted carboxylic derivatives,[78,79] as the principal strategies.

5.03.1.4 Aim of the Review

A recent volume of the CHC series (Comprehensive Heterocyclic Chemistry III, 2008) edited by Katritzky covers extensively the chemistry of four-membered heterocycles and all fused systems with a four-membered heterocyclic ring. The synthetic strategies other than the cycloadditions, namely various cyclization methods, ring-expansion, and ring-contraction methods, are discussed in an exhaustive manner for each class of compounds. The present review, which has been written in continuation of the previous one in the first edition of this series (Comprehensive Organic Synthesis 1991, Vol. 5), focuses on new developments in [2 + 2] cycloadditions leading to four-membered heterocycles which appeared in between 1992 and 2012. A special attention is drawn to the mechanistic aspects of the reactions and their consequences on the stereochemical outcome of the cycloaddition processes. Accordingly, the subdivision in sections reflects this point of view: the entries are related to reactions of various reagents (ketenes, enolates, ynolates, isocyanates, etc) with C═X bonds instead of a list of types of heterocycles. New sections have been introduced dealing with cycloaddition of alkenes, allenes, and alkynes with C═N bonds, as well as of alkynes with nitrones and of sulfenes with C═X bonds. The accent is also put on asymmetric catalysis which is of particular interest for the enantioselective synthesis of biologically active compounds or their precursors

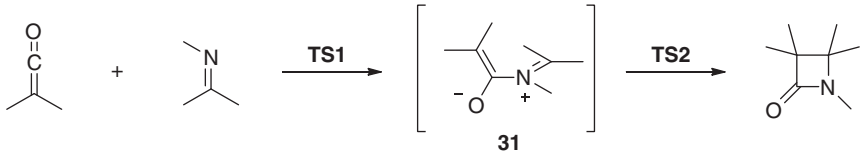
5.03.2 Reaction of Ketenes, Ketenimines, and Thioketenes with C═X bonds

Heteroallenes of the type $R_2C{=}C{=}Y$ (Y=O, NR, or S) are reactive intermediates which undergo [2 + 2] cycloaddition with C═X bonds to lead to the corresponding four-membered heterocycles (equation 5).[80–83] Among these reactions, the most important is the [2 + 2] cycloaddition reaction between ketenes and imines, known as the Staudinger cycloaddition (Y=O; X=NR).[84,85] Ketenes are also reported to react with carbonyls and thiocarbonyls, leading to corresponding 2-oxetanones and 2-thietanones.[82]

Y = O, NR, S X = O, NR, S (5)

However, ketenimines and thioketenes (Y=NR and S) have received only little attention.[86–88] In the former case, the reason is the low reactivity of such heteroallenes; for thioketenes, it is their instability and the difficulty to prepare them, which explain the dearth of examples.

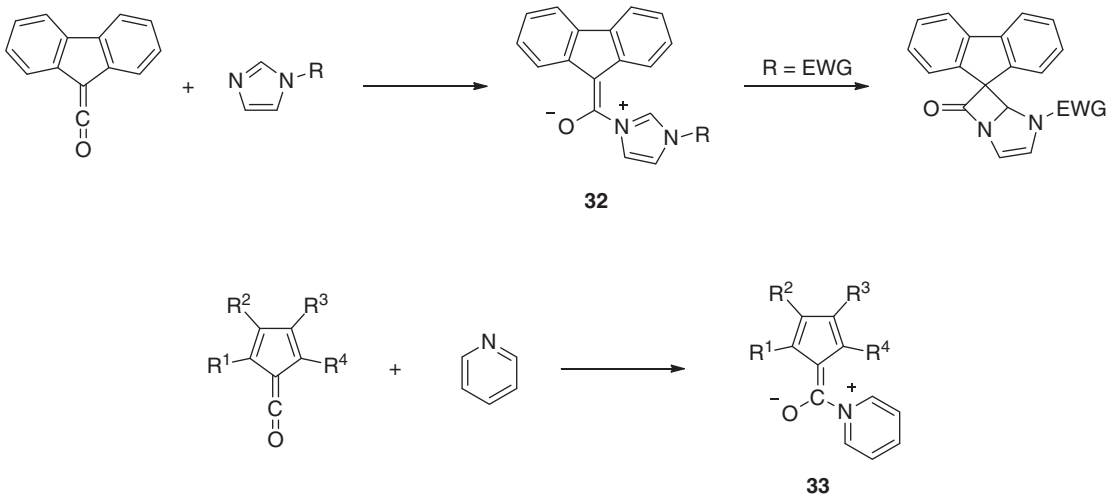
Most disubstituted ketenes are stable intermediates which can be isolated. Monosubstituted and heterosubstituted ketenes on the contrary have limited stability (prone to polymerize).[89] Accordingly, ketenes are usually generated *in situ*, from the corresponding acyl chlorides or related derivatives in the presence of a base, by photolysis of metal–carbene complexes, or by rearrangement of α-diazocarbonyl compounds.[90] It is important to note however that the conditions for generating ketenes may have an influence on the mechanism and the stereochemical outcome of the reaction (*vide infra*).



5.03.2.1 Reaction with Imines

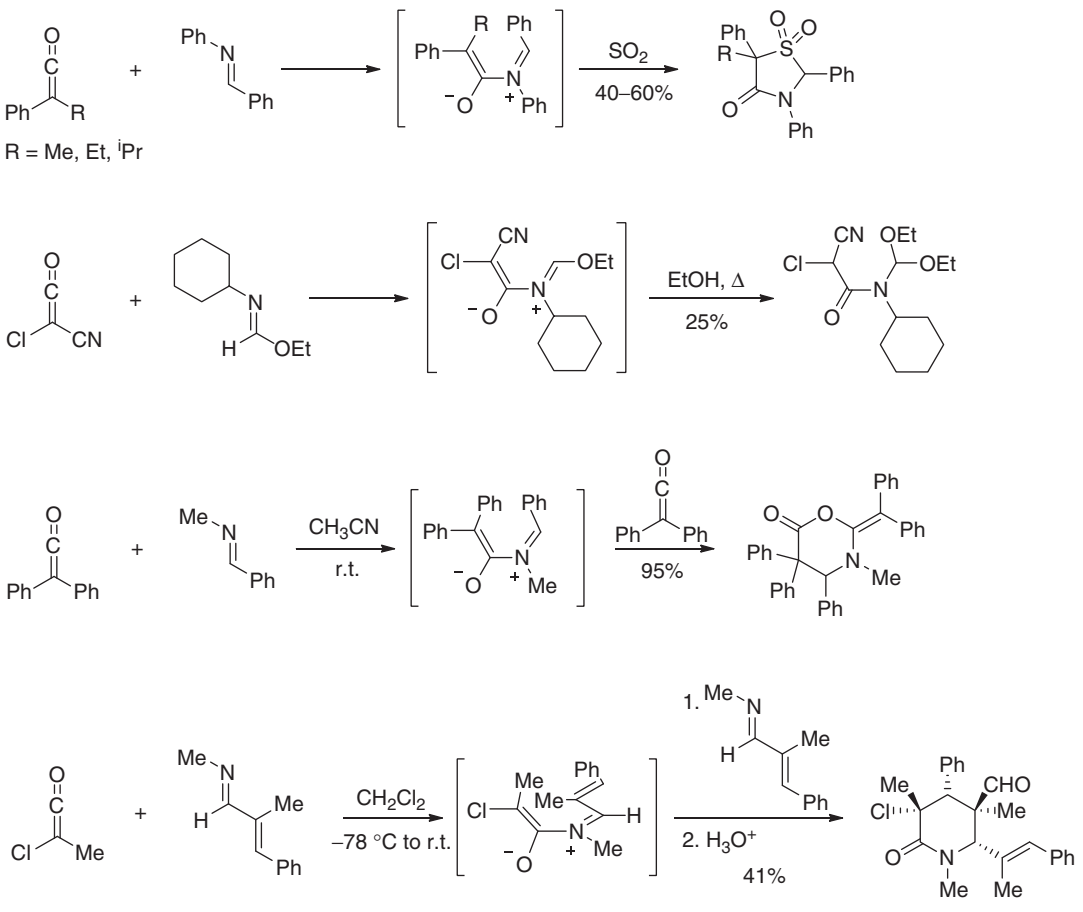
The most developed reaction of ketenes is their [2 + 2] cycloaddition with imines, known as the Staudinger cycloaddition.[84,85] This reaction is the most widely used strategy for the preparation of *β*-lactams.[91–94] The relevance of this method is due to its convergent nature and ready access to reagents, and thus a wide range of *β*-lactams are available.

5.03.2.1.1 Mechanism



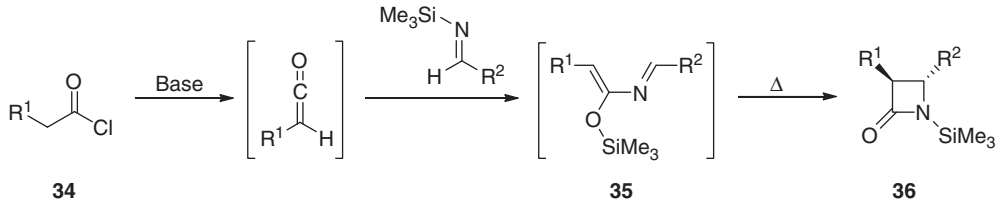
The ketene–imine Staudinger reaction is a [2 + 2] cycloaddition. These cycloadditions are allowed by the Woodward–Hoffmann rules, provided that the approach of the π-systems occurs in a *supra–antara* mode ($[{}_{\pi}2_s + {}_{\pi}2_a]$).[95] There are, however, abundant experimental evidences showing that the mechanism in solution is not concerted but is instead a stepwise process.[93,94]

The accepted mechanism for these reactions involves initial formation of a zwitterionic intermediate (**31**) by addition of the imine nitrogen atom to the central sp-hybridized carbon atom of the ketene (Scheme 12).[91,96] Subsequent conrotatory electrocyclic ring closure ($[{}_{\pi}4_c]$) then leads to the *β*-lactam.



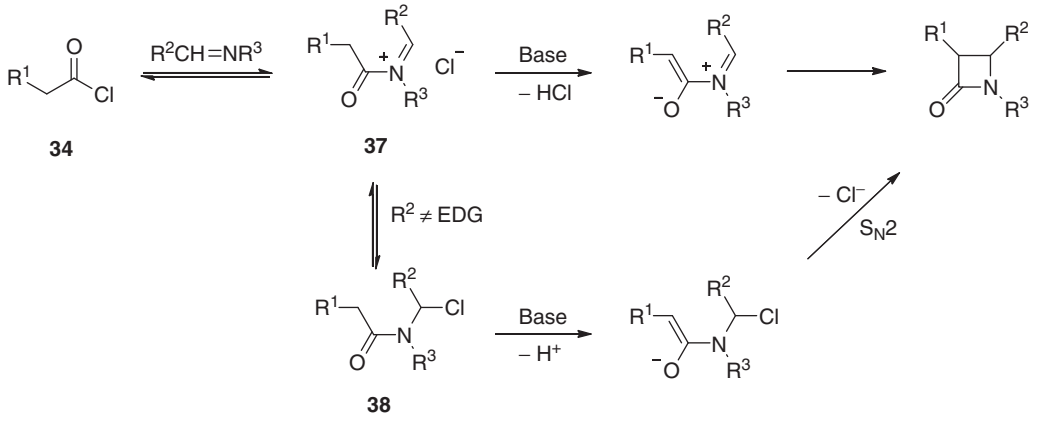
Scheme 12

This mechanism has been confirmed by isolation and characterization of the zwitterionic intermediates of type **32** and **33** in the reaction of stabilized ketenes with imidazoles and pyridine, respectively (Scheme 13).[97,98] In several cases, the zwitterionic intermediate could also be trapped by sulfur dioxide,[99] ethanol,[100] a second equivalent of ketene,[101] or a dienophile[102] (Scheme 14).



Scheme 13

Scheme 14



Additionally, in the reaction of monosubstituted ketenes and *N*-silylimines, the unambiguous formation of 3-aza-1,3-dienes **35** has been reported.[103–106] These intermediates were completely characterized and found to yield the corresponding *N*-silyl-*β*-lactams **36** on heating (Scheme 15).

Scheme 15

The two-step mechanism is also supported by computational results. Computational studies on the synthesis of *β*-lactams via [2 + 2] thermal cycloadditions have recently been reviewed by Cossio.[91] It is important to note that inclusion of solvent effects in the calculations of the mechanism was found to be crucial; calculations in the gas phase point to a concerted mechanism. It is also worth mentioning that calculations indicate that addition of the imine onto the ketene is reversible, with electrocyclization being the rate-determining step of the process.[107,108]

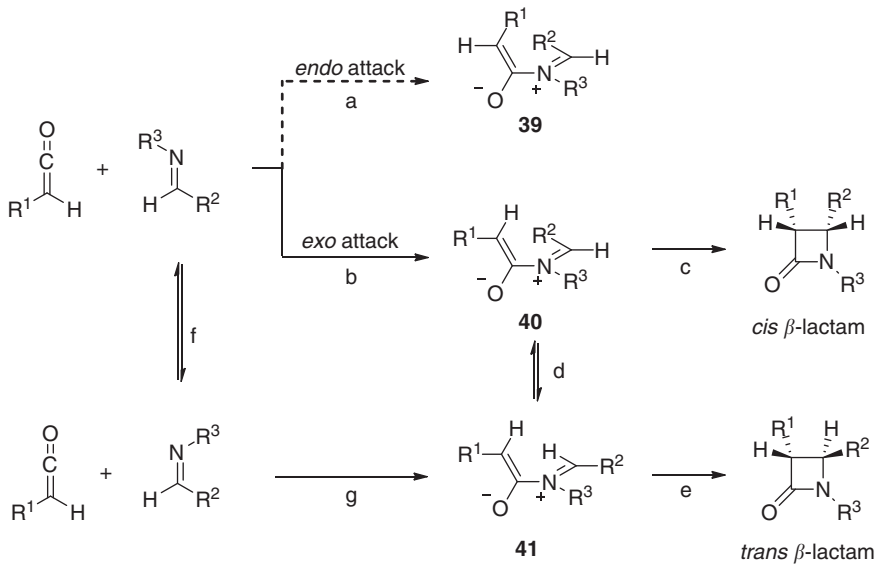
Xu et al. have shown that in some cases (when the acyl chloride is used as starting reactant), depending on the mode of addition of reagents, the mechanism may vary.[90,109] Indeed, when the acyl chloride is added to a solution of imine and a base, the ketene is directly formed and the reaction pathway follows the one described in Scheme 12. However, when the base is added to a solution of an imine and an acyl chloride, direct addition of the imine onto the acyl chloride (before ketene formation) produces an acyl iminium chloride **37** (Scheme 16). In most cases, this acyl iminium chloride undergoes a hydrogen abstraction to lead to the zwitterionic intermediate which further produces the *β*-lactam as in the general mechanism. In some specific cases (when the solution of the imine and the acyl chloride is stirred for several hours before the addition of the base, and the imine is not substituted by a strong electron-donating substituent, EDG) addition of chloride has been shown to occur, producing the corresponding chloro amide (**38**). Subsequent deprotonation and intramolecular alkylation (via a S_N2 mechanism) then leads to the *β*-lactam.

Scheme 16

The mechanism thus depends on the substitution of the reactants and on the reaction conditions. This is of particular importance since the nature of the pathway has an impact on the stereochemical outcome of the reaction (*vide infra*).

The reaction can also be catalyzed by Lewis acids (LAs) or nucleophiles (tertiary amines). In the former case, mechanistic studies indicate that activation occurs through complexation of the ketene (see Section 5.03.2.2.3).[110] In nucleophile-catalyzed reactions, the nucleophile adds first to the ketene to form an enolate which then reacts with the imine.[111] The imine-enolate condensation will be discussed in Section 5.03.4.

Reactions of ketenimines and thioketenes have been less studied.[112–117] However, mechanistic studies indicate that the [2 + 2] cycloaddition of these intermediates occurs via the same mechanism as for ketenes.[91]



5.03.2.1.2 Cis–trans selectivity

As the four-membered heterocycles formed by [2 + 2] cycloaddition of unsymmetrically substituted ketenes, ketenimines, or thioketenes with imines possess two stereogenic centers, four different stereoisomers can be produced. In order to obtain

selectively one of these isomers, one needs to control both the relative (*cis*/*trans*) and the absolute stereochemistries of these two stereogenic centers.

The relative selectivity has been shown to depend on several factors such as the solvent used, the temperature, and the sequence of addition of the reactants.[91,107,109] Indeed, despite its formal simplicity, the stepwise mechanism of the reaction of ketenes and imines raises a complex stereochemical situation.

First, the initial nucleophilic attack of the nitrogen atom of the imine can occur either via the *endo* or the *exo* side of the ketene, leading to zwitterionic intermediate **39** or **40**, respectively (**Scheme 17**; pathway 'a' or 'b').[118,96,91] Experimental studies showed, however, the exclusive formation of zwitterion **40**, resulting from an *exo* approach. This can be accounted for by steric considerations.[118]

Scheme 17

Next, intermediate **40** can evolve in two ways: it can cyclize directly to form the corresponding β-lactam, or isomerize via rotation around the C=N bond (pathway 'd') before cyclizing to the β-lactam. Ring closure of the zwitterionic intermediate via a stereospecific conrotatory electrocyclization converts the *E*-isomer (**40**) into a *cis*-β-lactam (pathway 'c') whereas the *Z*-isomer (**41**) produces a *trans*-β-lactam (pathway 'e'). Accordingly, variations in the selectivity can be accounted for by the relative rate of cyclization/isomerization of the iminium in the zwitterions (k_c/k_d).[90,118]

In a series of systematic experimental studies, Xu et al. investigated the influence of several factors on the *cis*/*trans* selectivity in the reaction of ketenes with imines.[109,118,119] These results showed that the nature of the substituents of the ketenes and imines (R^1, R^2, and R^3) is the crucial factor that determines the *cis*/*trans* selectivity of this reaction through their influence on the rate of the direct ring closure (k_c). Indeed, electron-donating groups on the ketene (R^1 = EDG) and electron-withdrawing imine substituents (R^2, R^3 = electron-withdrawing group (EWG)) increase the nucleophilicity of the enolate moiety and the electrophilicity of the acyl-iminium group, respectively. This pattern of substitution thus accelerates the direct ring closure (increase k_c), and hence leads to a preference for *cis*-β-lactam formation (**Figure 1**). Conversely, electron-withdrawing ketene substituents and EDGs on the imine lower the rate of the ring closure (decrease k_c), thus allowing isomerization (k_d) to take place before cyclization. In these

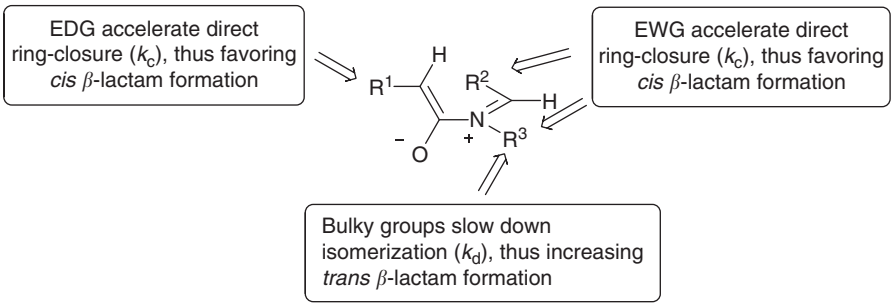


Figure 1 Influence of substitution on the *cis/trans* selectivity in the reaction of ketenes with imines.

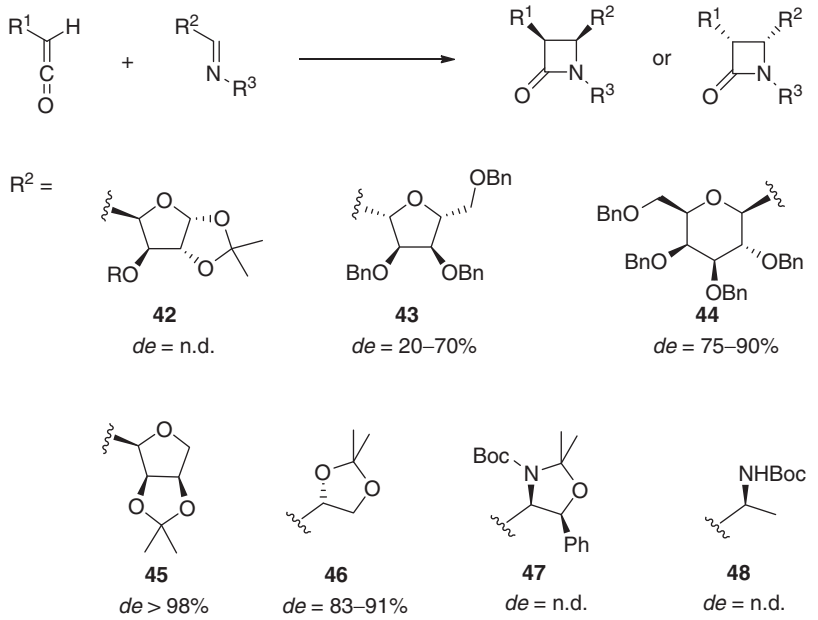
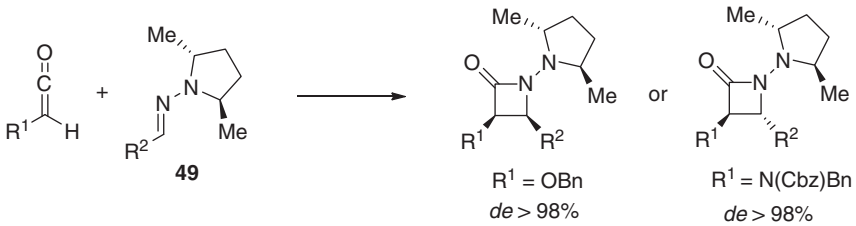
cases, formation of the more stable *trans*-β-lactam is therefore observed (via pathway 'e'). The electronic effect of the substituents on the rate of isomarization has been shown to be a minor factor in the stereoselectivity. On the contrary, the presence of a bulky group on the imine nitrogen (R^3) has a significant decelerating effect on the rate of isomerization.



In some specific cases (when R^3 = anthracenyl), calculations have shown that the *E*/*Z* isomerization of the imine (pathway 'f') is faster than the addition ($k_f > k_b$, k_g). In these cases, the observed selective formation of *trans* isomer is thus accounted for by the addition of the more nucleophilic *Z*-imine onto the ketene yielding directly intermediate **41** (pathway *g*).[96,108]

Besides the main factor, which is the nature of the substituents, Xu et al. have shown that the reaction conditions (solvent, temperature, addition order of reagents, base, etc.) could also affect the stereochemical outcome of the Staudinger cycloaddition reaction.[90,109]

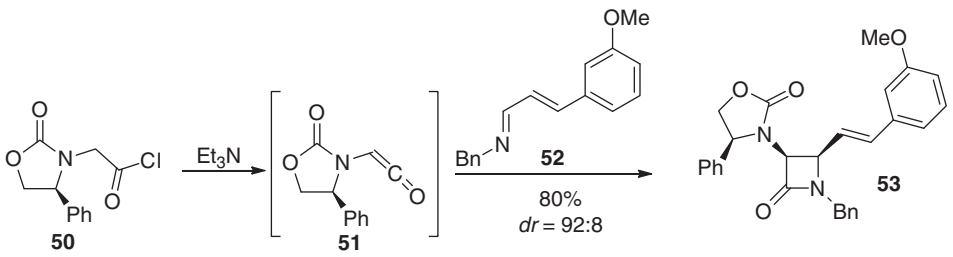
5.03.2.1.3 Reaction of chiral imines



One of the strategies for controlling the absolute stereochemistry of the two chiral centers which are created in the reaction of unsymmetrically substituted ketenes and imines makes use of chiral imines. In this context, the reaction of chiral imines either derived from chiral aldehydes or from chiral amines has been reported.

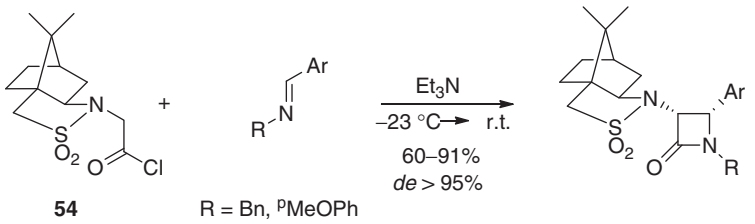
In the former case, a common approach uses sugar aldehyde-derived imines such as **42**, **43**, and **44** (Scheme 18).[120,121] Other α-oxyimines, **45** and **46**, have also been used successfully.[107,122–124] Similarly, a wide variety of *N*-Boc-α-amino imines (such as **47** and **48**) have been reported to yield the corresponding *cis*-β-lactams with high diastereoselectivity.[94,125,126] The corresponding β-lactams are obtained in most cases as a single *cis* diastereoisomer after purification by column chromatography.

Scheme 18



Imines bearing a chiral group on nitrogen have also been used for the asymmetric synthesis of chiral β-lactams (equation 6). Enantiopure *N*,*N*-dialkylhydrazones **49** react with ketenes to yield the corresponding 3,4-disubstituted β-lactams as single diastereoisomers.[127,128] The *cis*/*trans* selectivity depends on the substitution of the ketene: alkoxyketenes lead to *cis* β-lactams with a very high selectivity, whereas cycloaddition of ketenes derived from *N*,*N*-disubstituted glycine occurs *trans*-selectively. Subsequent N–N bond cleavage under oxidative conditions allows the chiral auxiliary to be removed with formation of the corresponding NH β-lactams in high yields.

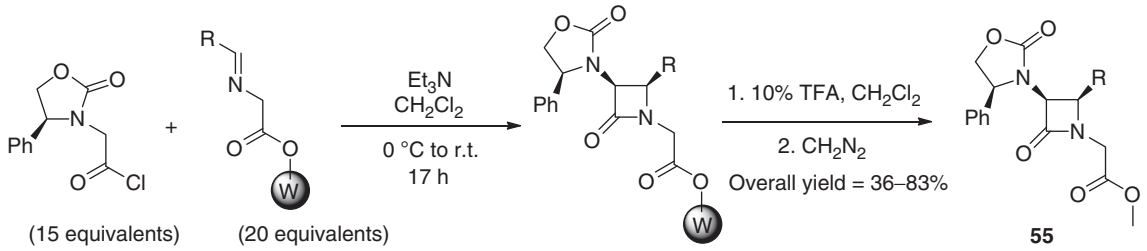
(6)



5.03.2.1.4 Reaction of chiral ketenes

Another strategy for the asymmetric synthesis of β-lactams is the [2 + 2] cycloaddition of imines with chiral ketenes.[92,94] The most widely used chiral ketene is 4-phenyloxazolidinylketene (**51**) (Evans–Sjögren ketene), generated from the corresponding oxazolidinylacetyl chloride (**50**) and triethylamine. As an example, the asymmetric synthesis of a carbacephem precursor from chiral ketene **51** and imine **52** has been described by Evans and coworker (Scheme 19).[129,130] After cycloaddition, the oxazolidinone auxiliary of β-lactam **53** can be reductively removed to give the unprotected 3-amino-β-lactam with a high *ee*.

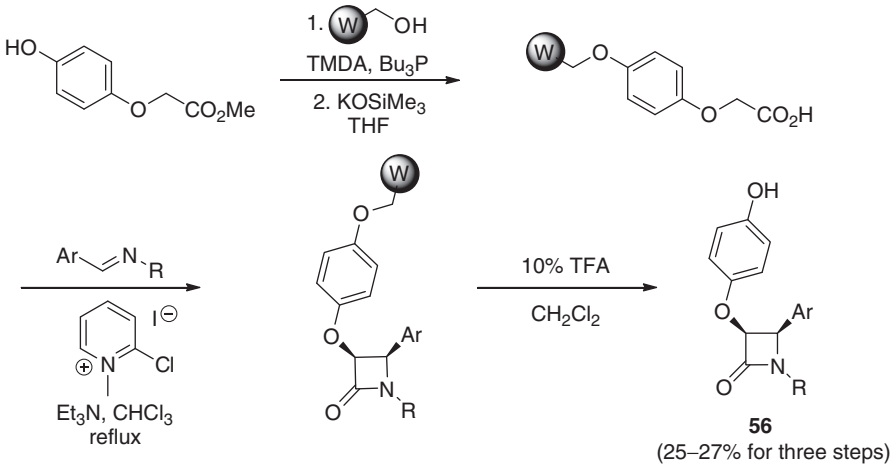
Scheme 19



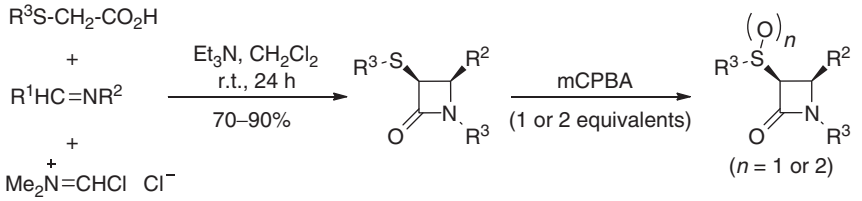
The ketene generated from acid chloride **54** has also been found to allow the formation of β-lactams with excellent diastereoselectivities (equation 7).[131] Nonetheless, all attempts to remove the camphorsultam moiety failed.

(7)

5.03.2.1.5 Applications



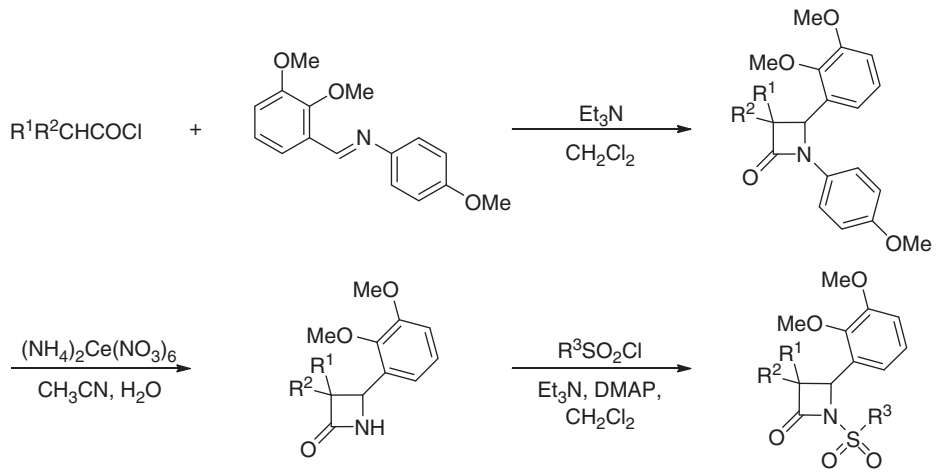
The large-scale production of β-lactams has required the development of solid-phase techniques and polymer-supported synthesis. This has been recently reviewed,[132] with a special topic dedicated to the Staudinger reaction. Most often Wang resins are used and the imine partner is bound to the resin via its *N*-substituent (Scheme 20).[133] Inversely, in few cases, the ketene precursor is linked to the resin (Scheme 21).[134,135] The *cis* (chiral) β-lactams **55** and **56** are precursors of carbapenems and cholesterol absorption inhibitors, respectively.



Scheme 20

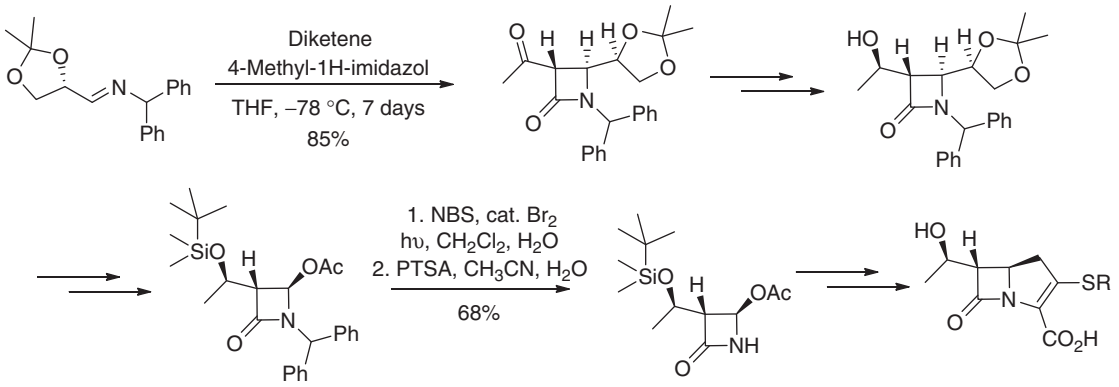
Methods for the *in situ* activation of carboxylic acids worked efficiently, thus avoiding the isolation of acid chlorides as the ketene precursors. Beside the very popular Mukaiyama reagent (2-chloro-1-methylpyridinium iodide),[136] the Vilsmeier reagent (i.e., (chloromethylene)dimethylammonium chloride) was recently disclosed as a versatile activator of the [2 + 2] cycloaddition, directly from substituted acetic acids and imines.[137,138] 3-Thiolated-2-azetidinones endowed with antibacterial and antifungal activities have been prepared via this one-pot process for the cycloaddition step (Scheme 22).[139]

N-Unsubstituted β-lactams are often desirable as key-intermediates in the synthesis of more elaborated antibiotics. For that purpose, imines bearing *N*-protecting groups are used. The deprotection conditions of *p*-methoxyphenyl and benzhydryl groups are compatible with the β-lactam ring. The former can be cleaved by oxidation with cerium ammonium nitrate on solid phase[140] and the latter by photoactivated bromination followed by smooth aqueous acid treatment.[141] Applications of the above methods

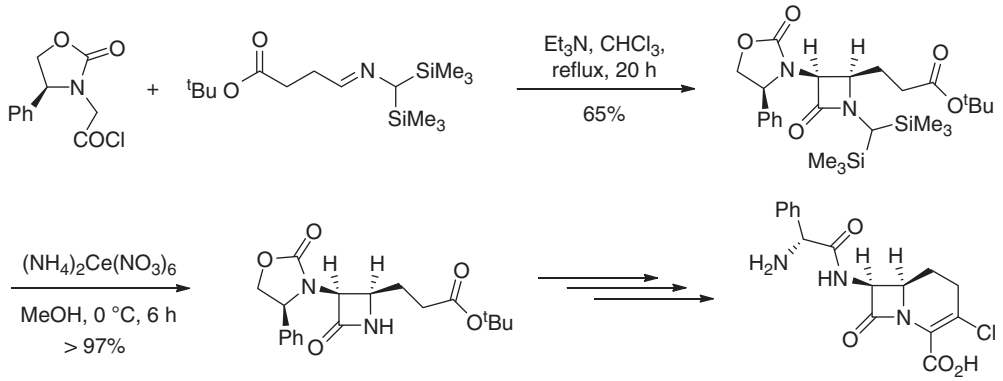


Scheme 21

Scheme 22

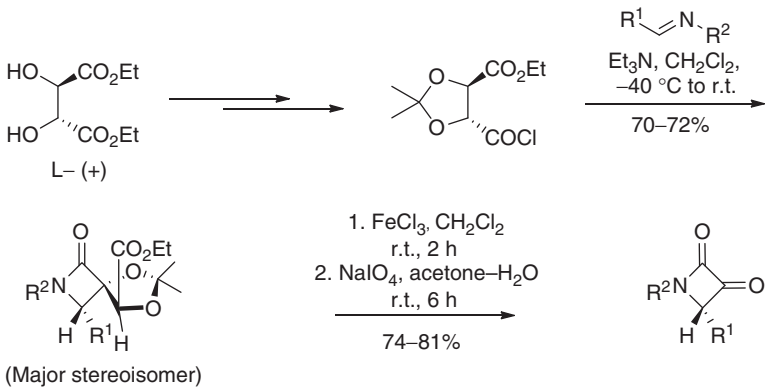


to the synthesis of monobactams (i.e., *N*-sulfonyl monocyclic *β*-lactams)[142] and carbapenems[143] are described in Schemes 23 and 24 respectively.



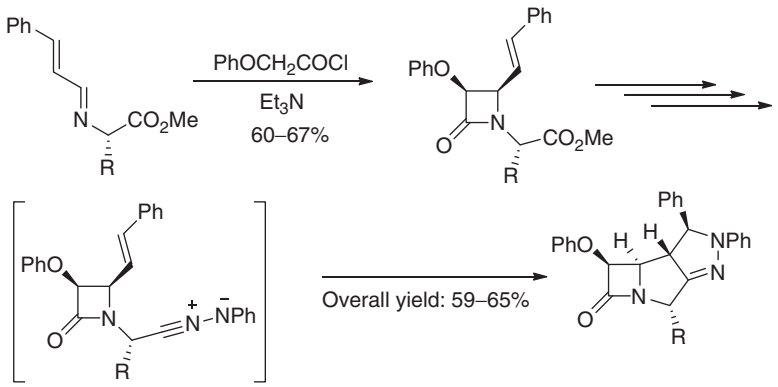
Scheme 23

Virtually all investigations about the Staudinger reaction have dealt with nonenolizable aldimines. Because of the instability of the corresponding imines, 4-alkyl-2-azetidinones were not readily accessible via the [2 + 2] cycloaddition strategy before the work of Palomo et al.[144] who designed α-(trimethylsilyl)methyl imines as stable reagents, due to the ability of the silyl groups to stabilize electron-poor centers in the *β*- or *γ*-position. Deprotection of the *N-bis*(trimethylsilyl)methyl group from the cycloaddition products could be easily performed with cerium ammonium nitrate in methanol. The Loracarbef precursor **57** was prepared according to this strategy as a single enantiomer (Scheme 25).

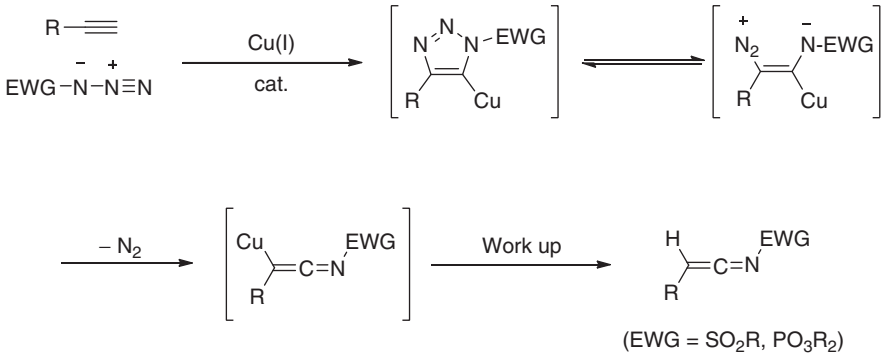


Azetidine 2,3-diones constitute a useful class of synthons. Enantiopure derivatives were obtained by the Staudinger cycloaddition of the ketene derived from L-(+)-diethyl tartrate, giving spiro-*β*-lactams intermediates (Scheme 26).[145]

Scheme 24

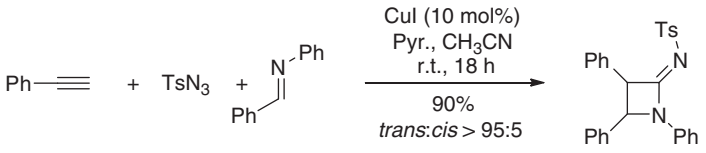


Scheme 25



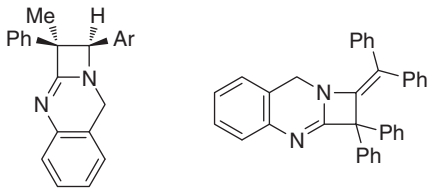
Scheme 26

Numerous polycyclic *β*-lactams of potential interest in medicinal chemistry resulted from reaction sequences including the Staudinger cycloaddition as the first step. Indeed, the *β*-lactam ring could play the role of a scaffold favoring the intramolecular reactions of functionalized chains on its backbone (Scheme 27).[146,147]



Applications of ketenimine [2 + 2] cycloadditions are less abundant than the ketene analogues. A novel method for *in situ* generation of *N*-sulfonyl- (or *N*-phosphoryl-) ketenimines appears worthy of note because it allowed the development of inter- and intramolecular cycloadditions with imines.[88] The well-known Cu(I)-catalyzed 'click' reaction of aryl- or alkyl-azides with 1-alkynes, affording 1,4-disubstituted triazole adducts, gave a different outcome when using sulfonyl- (or phosphoryl-) azides: a ring-opening rearrangement of the initially formed *N*-sulfonyl- (or phosphoryl-) copper triazole species occurs rapidly (Scheme 28). Thus, *N*-sulfonyl ketenimines could be easily produced and quenched with a range of imines (equation 8),[148,149] enlarging the scope of the initial reaction.[150]

Scheme 27

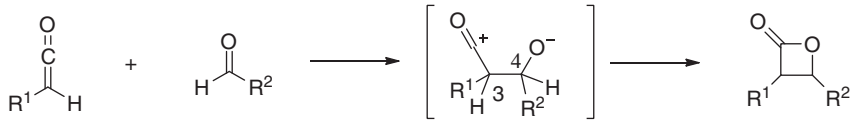


Scheme 28

(8)

Intramolecular ketenimine–imine [2 + 2] cycloadditions led to polycyclic systems such as **58**[151] and **59**.[152]

58



59

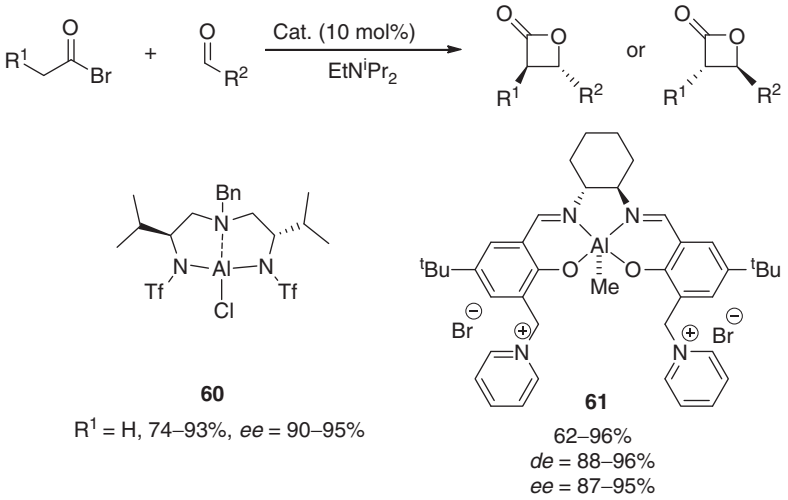
5.03.2.2 Reaction with Carbonyl Compounds

The carbonyl π-bond has been found to add also across the alkenic π-bond of ketenes to produce oxetan-2-ones (β-lactones).[83] Unlike in the Staudinger ketene–imine cycloaddition, only highly activated systems (bearing strongly electron-withdrawing substituents) react readily with ketenes in the absence of catalyst (adducts decompose at the high temperatures necessary for their cycloaddition to occur). This lower reactivity can however be compensated by using either a LA or a nucleophile (or both) as catalysts (see Sections 5.03.2.2.3 and 5.03.4.2.2).

5.03.2.2.1 Mechanism

Lecea and Cossio have extensively explored the mechanism of uncatalyzed and LA-catalyzed cycloadditions of ketene onto carbonyl compounds by computational means (*ab initio* and DFT).[153–155] These studies indicate that this cycloaddition occurs in fact via a two-step mechanism (Scheme 29). First, the ketene adds onto the carbonyl double bond, forming the C_3–C_4 bond and leading to a zwitterionic intermediate. Next, this intermediate undergoes cyclization to afford the β-lactones. This mechanism has been supported by kinetic isotope effect measurements.[156]

Scheme 29



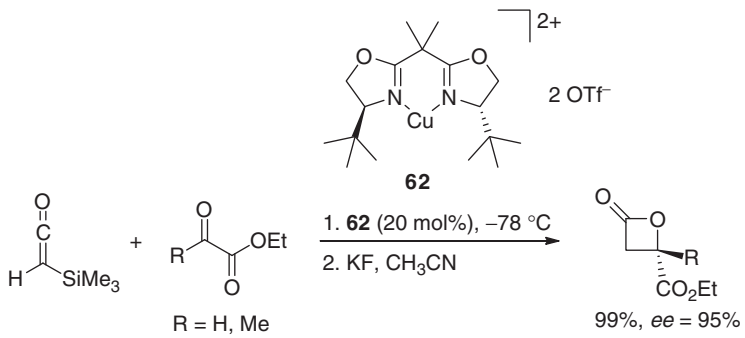
Alternatively, in the presence of a nucleophilic catalyst (an amine or a phosphine), the reaction occurs through formation of an enolate (by addition of the nucleophile onto the ketene) followed by addition of this later onto the carbonyl compound.[111] These reactions will be discussed in Section 5.03.4.

5.03.2.2.2 Cis–trans selectivity

In aldehyde cycloadditions with unsymmetrically substituted ketenes, mixtures of *cis* and *trans* isomers are generally obtained. In most cases, the ratio varies from 1:1 to 2:1.[83] Some LA-catalyzed cycloadditions are however described to afford β-lactones with good diastereoselectivities (see Section 5.03.2.2.3).

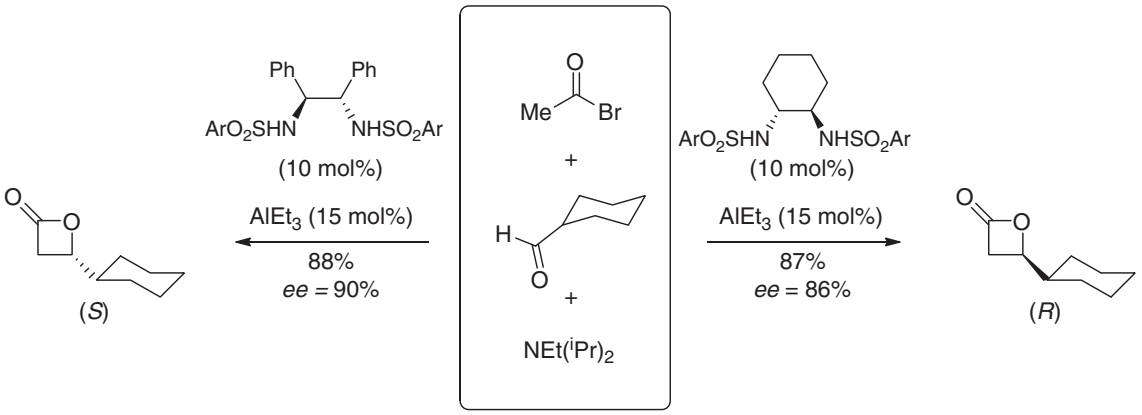
5.03.2.2.3 Enantioselectivity with chiral Lewis acids

Nelson and Peters developed the chiral C_2-symmetric aluminum complexes **60** and **61**, respectively, for the cycloaddition of monosubstituted ketenes with aldehydes (Scheme 30).[157,158] The corresponding *trans*-2-azetidinones are obtained with good *ee*'s. The proposed mechanism is based on a contact ion pair-directed Lewis acid catalysis.[156]



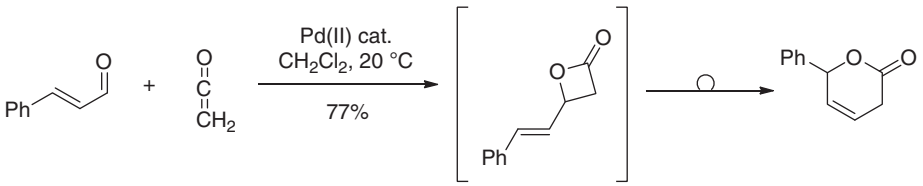
Scheme 30

The asymmetric [2 + 2] cycloaddition of the more stable trimethylsilyl ketene has also been developed using different chiral LA catalysts (Scheme 31).[159–162] The best enantioselectivities have been obtained with the C_2-symmetric copper(II)–bisoxazoline complex **62** of Evans and coworker and glyoxylate derivatives.[163]



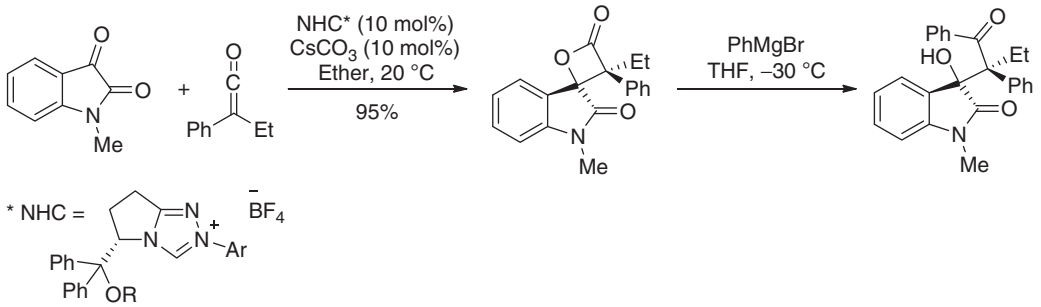
5.03.2.2.4 Applications

Ketene, generated *in situ* from acetyl bromide and Hünig's base, reacts with various α-unbranched and α-branched aliphatic aldehydes to give chiral β-lactones under catalysis by aluminum bis-sulfonamide complexes[164] formed *in situ* from (*R*, *R*)- or (*S*, *S*)-1,2-diamine derivatives and triethylaminium in toluene at $-85\ ^\circ C$ (Scheme 32).



3,6-Dihydro-2*H*-pyran-2-ones are obtained via tandem [2 + 2] cycloaddition-allylic rearrangement of ketene with α,β-unsaturated aldehydes and ketones; both reactions are catalyzed by the cationic palladium (II) complex $[Pd(dppb)(PhCN)_2]BF_4$ (dppb = 1,4-*bis*-(diphenylphosphino)butane) (Scheme 33).[165]

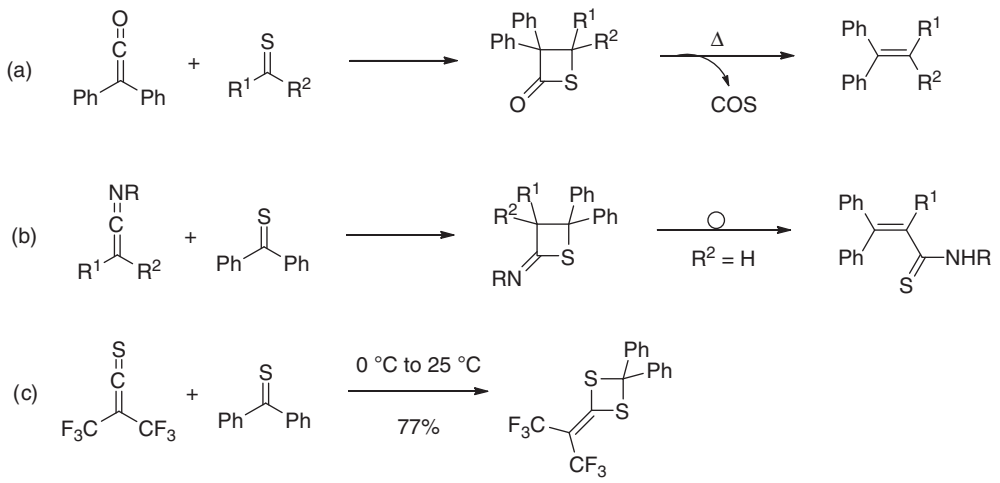
Scheme 31



Scheme 32

Scheme 33

Chiral spirocyclic oxindole-β-lactones result from the cycloaddition of ketenes and isatins, catalyzed by *N*-heterocyclic carbenes (NHC).[166] Subsequent ring opening with Grignard reagents leads to 3-hydroxy-oxindoles with high enantionselectivity (Scheme 34).

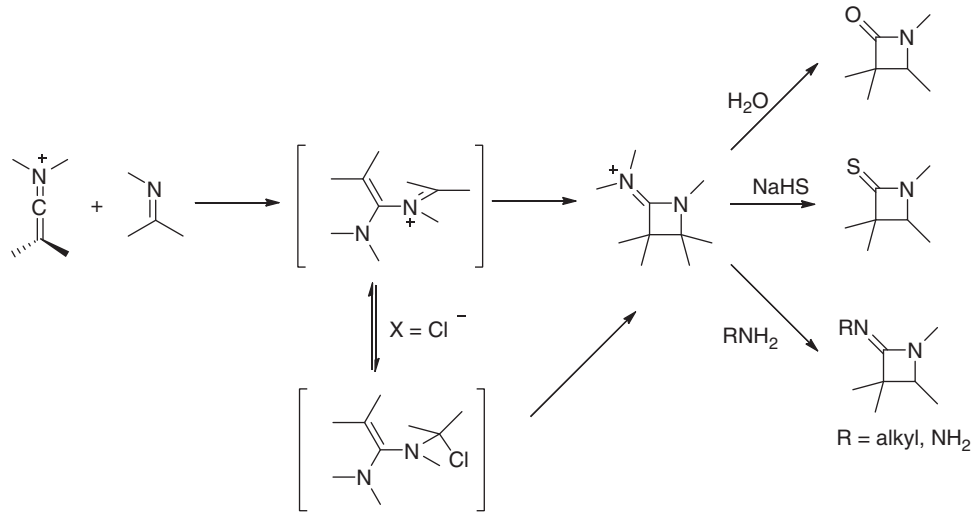


Scheme 34

5.03.2.3 Reaction with Thiocarbonyl Derivatives

Cycloadditions of heteroallenes onto C═S bond are scarcely described, most probably because the corresponding cycloadducts have no real synthetic usefulness and are prone to decompose or rearrange.

Diphenylketene reacts with thiones, thioesters, and thioamides to furnish thietane-2-ones (β-thiolactones), which lead to alkenes on heating (Scheme 35 (a)).[167–169]

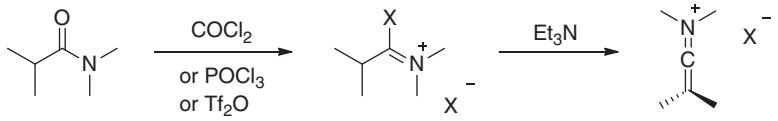


Scheme 35

The reaction of ketenimines with thiobenzophenone leads to thietane-2-imines; enolizable cycloadducts suffer a ring-opening rearrangement into α,β-unsaturated thioamides (Scheme 35(b)).[170,171]

Addition across the C═S bond of bis(trifluoromethyl)thioketene has been observed (Scheme 35(c)) as a curiosity.[172]

5.03.3 Reaction of Keteniminium Salts with C═X Bonds

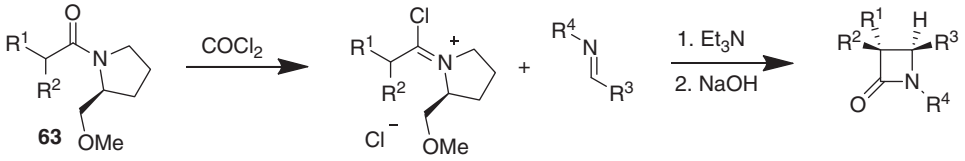


The [2 + 2] cycloaddition reaction of keteniminium salts with imines has been discovered by Ghosez in 1974.[113] It leads to the formation of 2-azetidinium salts which can be easily converted to azetidin-2-ones, -thiones, or -imines (Scheme 36).[114,173,174] No example of cycloaddition of keteniminium salts with (thio)carbonyl compounds can be found in the literature.

Scheme 36

One advantage of keteniminiums salts is that they are highly reactive and can undergo cycloaddition reactions with imines which are unreactive with ketenes.

Due to their high reactivity, keteniminium salts are usually generated *in situ* by treatment of tertiary carboxamides with phosgene or triflic anhydride and a base (Scheme 37).[114]



Scheme 37

Similar to the Staudinger reaction, the reaction between keteniminium salts and imines involves a two-step mechanism.[115] First, the imine adds onto the keteniminium to form the N_1–C_2 bond (Scheme 36). Next, this adduct undergoes an electrocyclic ring closure to form the C_3–C_4 bond leading to the 2-azetidinium salts.

The *cis*/*trans* stereoselectivity of the reaction is determined at the second step, when the C_3–C_4 bond is formed. It was found that the stereochemical outcome depends on the nature of the anion, which in turn is related to the method used for generating the keteniminium intermediate. Indeed, the reaction is generally *cis*-selective, but if the anion is nucleophilic, such as chloride, the ring closure preferentially takes place via intramolecular S_N2 reaction (similarly to the mechanism described in Scheme 16 for the Staudinger reaction) and *trans* selectivity is observed.[115]

An important advantage of the reaction of keteniminium salts, as compared with that of ketenes, is that they provide yet another position for the incorporation of chirality. Indeed, starting from the chiral amide **63**, the corresponding chiral *β*-lactams can be obtained after hydrolysis with excellent *ee*'s (Scheme 38).[175] The nature of the keteniminium substituents R^1 and R^2 plays a

R^1	R^2	R^3	R^4	Yield (%)	*cis/trans*	*ee* (%)

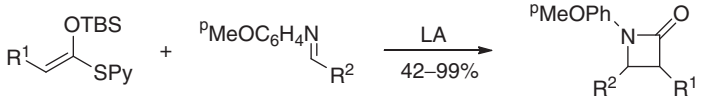
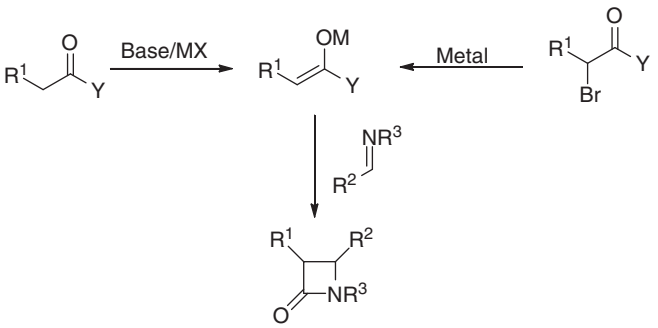
Scheme 38



decisive role in determining the stereoselectivity. When R^1 and R^2 are different from hydrogen, the stereoselectivity is very high, but it drops dramatically when R^1 and/or R^2 are hydrogen atoms.[175]

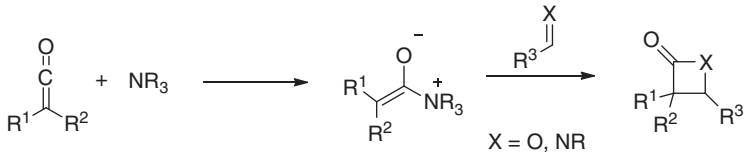
5.03.4 Reaction of Enols and Enolates with C═X Bonds



5.03.4.1 Scope and Mechanism

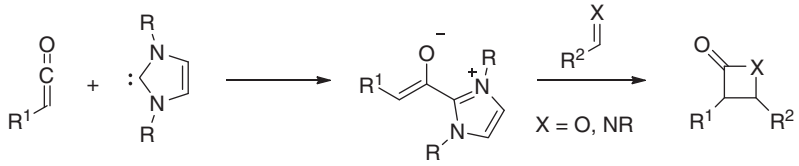
Metal enolates derived from carboxylic acid derivatives have been reported to condense with imines to yield directly *β*-lactams (Scheme 39).[92] In this context, *S*-thioester enolates (Y═SR) serve particularly well.[176] Indeed, thiolates are more readily displaced from the carbonyl carbon than alkoxides. They are also more easily formed because of the enhanced acidity of the CH-α position as compared with that of simple esters. Several metals (MX) have been investigated for these transformations. Best results were obtained with titanium, aluminum, zinc, boron, and tin.[176] Experiments demonstrated however that tin, aluminum, and boron enolates had a more limited application to *β*-lactam synthesis than titanium enolates, and thus their chemistry was less developed.

Although less studied, the reaction of silylketene thioacetals with imines in the presence of a LA has also been reported to yield *β*-lactams (equation 9).[176,177]



(9)

Scheme 39

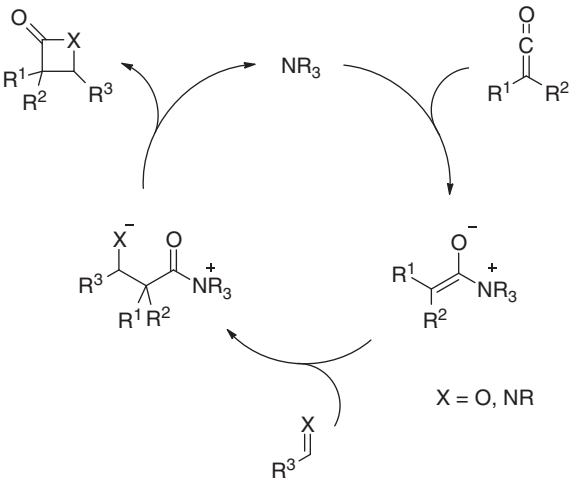


Inspired by early studies on the amine-catalyzed dimerization of ketenes,[178] many groups have worked on the generation of zwitterionic ammonium enolates from ketenes and amines and their reaction with aldehydes and imines to give *β*-lactones and *β*-lactams, respectively (Scheme 40).[81] In the case of imines, the overall process consists of the amine-catalyzed Staudinger reaction.

Scheme 40

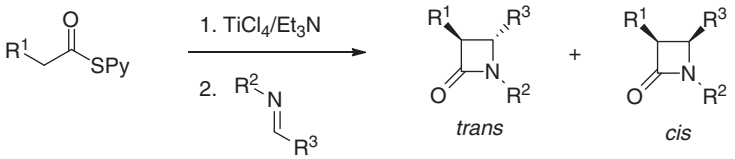
Cinchona alkaloids have rapidly emerged as prominent catalysts for these transformations.[111] One drawback associated with this strategy, however, was the need for highly reactive aldehydes or imines, presumably to compete with ketene dimerization. It was shown that the low reactivity of ammonium enolates could be overcome and the scope of the reaction improved by using LA cocatalysts ($In(OTf)_3$, $LiClO_4$).[179–181] Later, Wilson and Fu showed that ammonium enolates derived from planar chiral DMAP derivatives (see Section 5.03.4.2) display increased reactivity as compared with cinchona derivatives.[182] These intermediates react with a large range of aldehydes and imines, allowing for the preparation of highly substituted *β*-lactones and *β*-lactams, respectively.

It was reported that NHCs are also efficient catalysts for the cycloaddition of ketenes with aldehydes and imines (Scheme 41).[183,184]



Scheme 41

The mechanism of the [2 + 2] cycloaddition of ketene with aldehydes or imines catalyzed by amines involves three steps: addition of the amine to the ketene to form an ammonium enolate, its addition onto the aldehyde or imine electrophile, followed by cyclization of the newly formed alkoxide or amide onto the acylammonium species (Scheme 42).[81] NHC-catalyzed cycloadditions and metal enolates of (thio)ester reactions have been shown to follow a similar mechanism.[176,184,185]



5.03.4.2 Stereoselectivity

5.03.4.2.1 Reaction of metal enolates

Systematic studies on titanium enolates have shown that the *cis*/*trans* selectivity depends highly on the substitution of the two partners (Scheme 43).[176] A few rules can however be drawn from the collected data: (1) large and nonchelating groups at the C_2-position of the *S*-thioester (R^1) and at the imine carbon (R^3) result in the formation of a *trans*-azetidinone; (2) the presence of a chelating substituent at either one of these positions results in a *cis*-selective reaction; and (3) enolizable imines are more prone to produce a *cis*-*β*-lactam than conjugated imines.

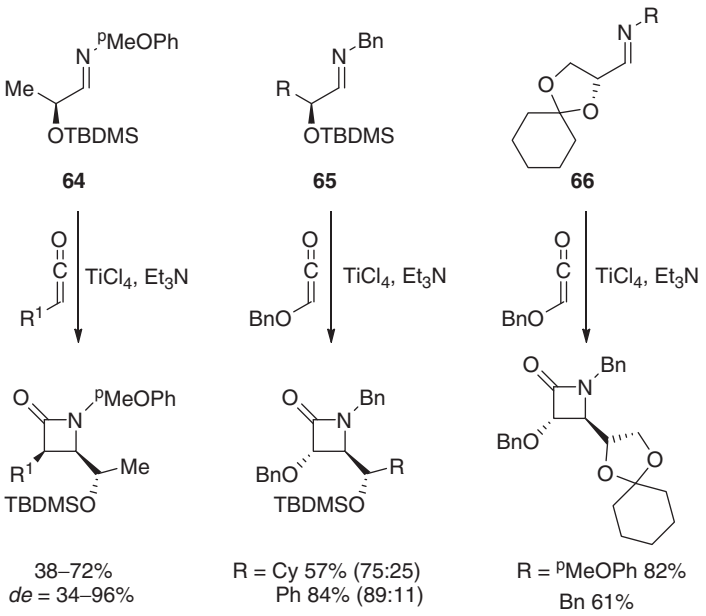
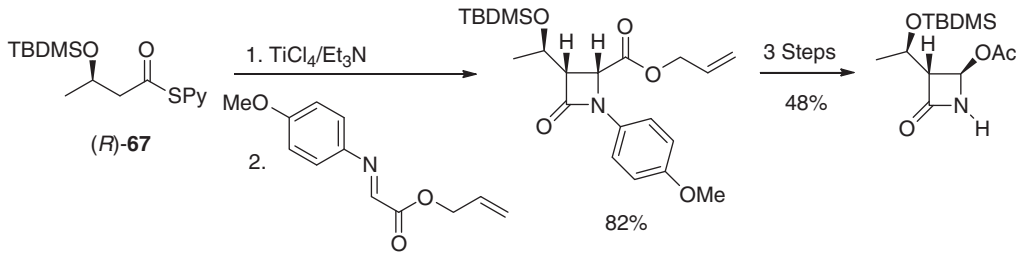
Scheme 43



The proposed model to account for the observed *trans* selectivity involves a chair-like six-membered transition state (A) for the addition step in which the steric clash between the bulky R^1 and R^2 groups is minimized (Scheme 44).[176] In the case of small R^1 and R^2 groups, *cis*-*β*-lactams may be formed via similar transition structures involving either an (*E*)-enolate or a (*Z*)-imine. The *E*/*Z* imine equilibrium is also believed to be the origin of the tendency of alkyl-substituted imines to give more *cis*-azetidinones. Indeed, ^{1}H NMR experiments showed that conjugated imines exist predominantly in and are likely to react from their (*E*)-configuration, whereas aliphatic imines consist of almost equal mixtures of (*E*) and (*Z*) isomers.

Scheme 44

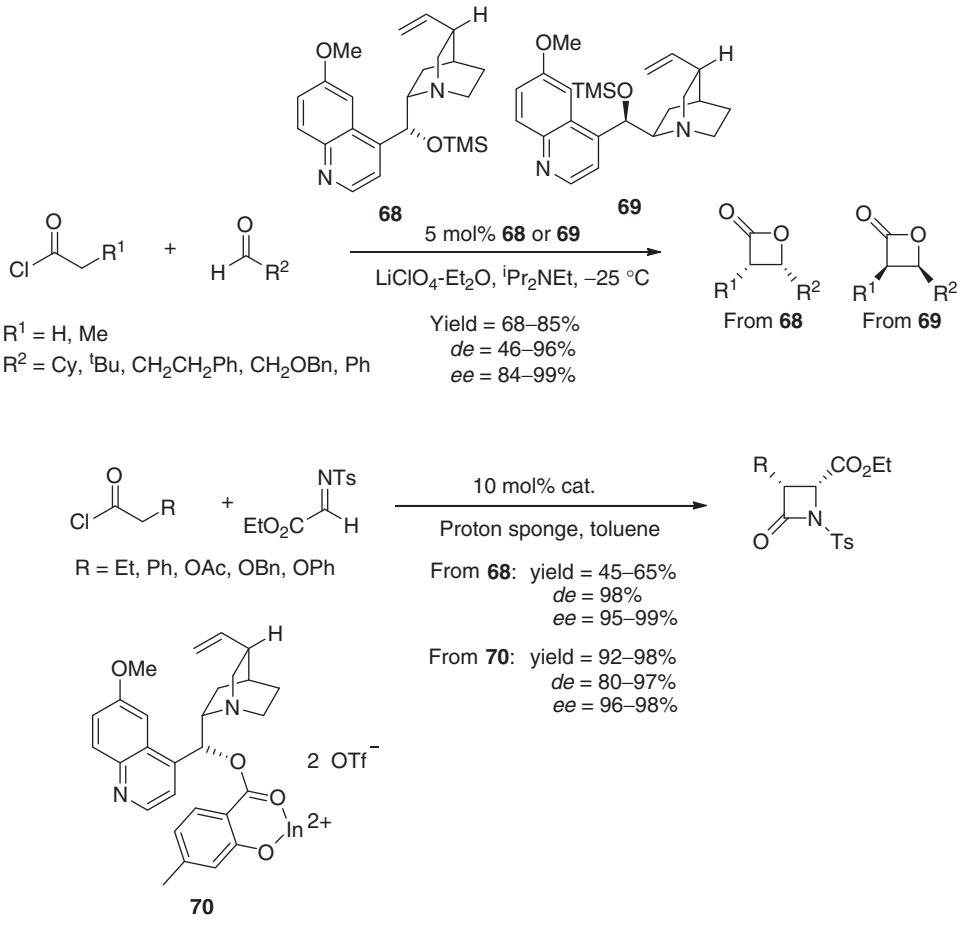


The formation of *cis*-*β*-lactams in the presence of a chelating substituent at either R^1 or R^2 position can be explained by the boat-like transition state models B and C, respectively (Scheme 44).

The absolute stereochemistry of the two chiral centers generated during the [2 + 2] cycloaddition is determined as at the addition step and can be controlled by using either chiral imines or chiral enolates. The first of these strategies has been explored by several groups with α-alkoxy and α,β-dialkoxyimines such as **64**, **65**, and **66** (Scheme 45).[186,187] When these imines were treated with the titanium enolates of 2-pyridyl thioesters, very high levels of stereocontrol were observed in the formation of β-lactams. Several imines bearing a chiral substituent on the nitrogen atom have also been studied but the obtained results were less satisfactory.[176]

Scheme 45

Cozzi investigated the reaction of the chiral 2-pyridyl thioester (*R*)-**67**.[188] Cycloaddition of the derived enolate with imines led to the corresponding β-lactams bearing the (*R*)-1-hydroxyethyl side chain at C_3 present in the penem antibiotics with high diastereoselectivities (Scheme 46).

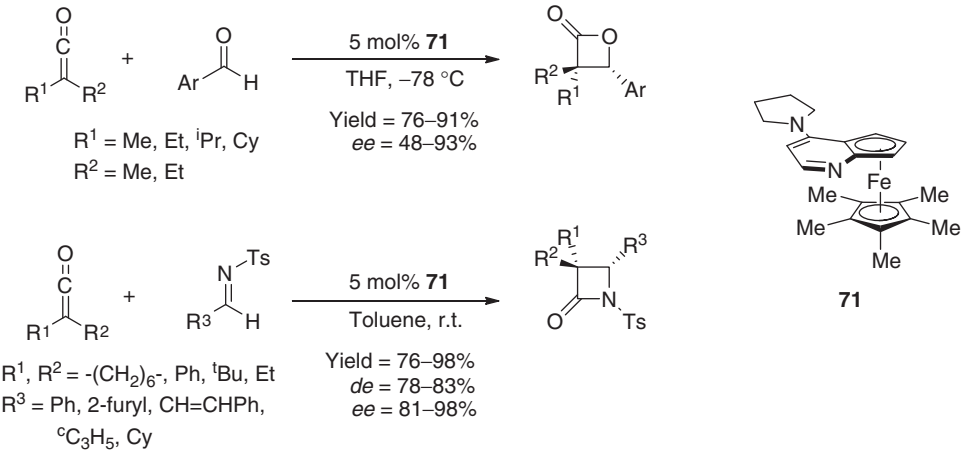


Scheme 46

The possibility of using chiral metal complexes has also been investigated (with boron as metal), but the *ee*'s never exceeded 78%.[189]

5.03.4.2.2 Reaction of ketenes

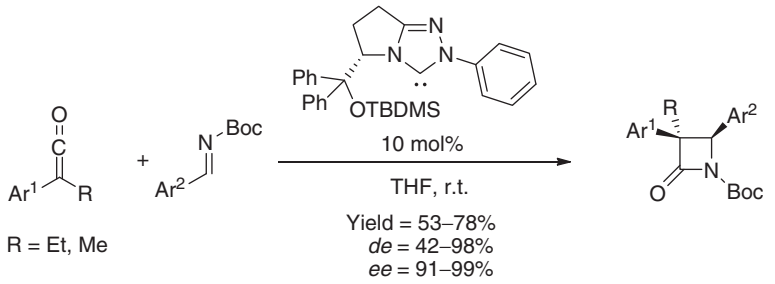
Both chiral carbene and amine catalysts have been applied to the enantioselective synthesis of β-lactones and β-lactams from ketenes. The first chiral amines to be used in this context were cinchona alkaloids (equation 10).[111] *cis*-β-Lactones and *cis*-β-lactams are obtained in moderate to good yields with excellent diastereo- and enantioselectivity (Scheme 47). Interestingly, by employing the diastereomeric alkaloids quinine (**68**) and quinidine (**69**) as catalysts one can access either enantiomer of a given product.



(10)

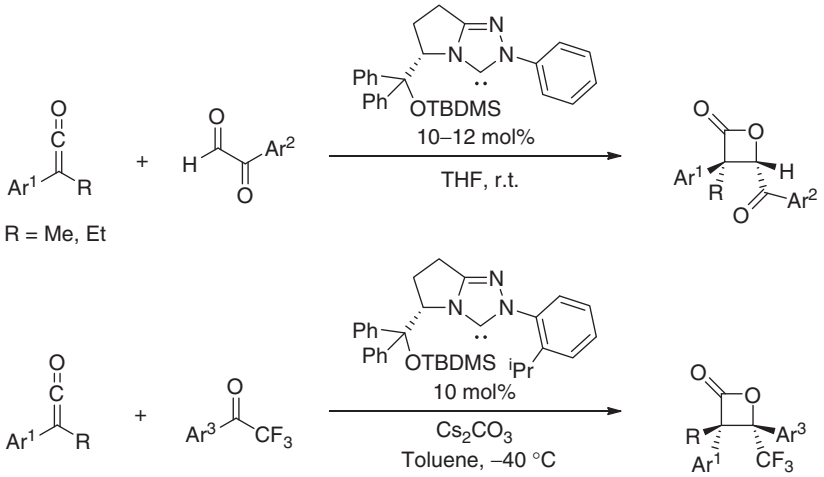
Scheme 47

Bifunctional catalysts in which the nucleophilic chiral amine is paired with a LA have also been developed (**70**; Scheme 47).[190–194]



The limited scope of the reaction catalyzed by cinchona alkaloids prompted Fu and Wilson to investigate the application of planar chiral DMAP to these reactions. In the presence of 5 mol% of the chiral catalyst **71**, ketenes react with aldehydes and imines to yield [2 + 2] cycloadducts with excellent yields and stereoselectivities (Scheme 48).[182]

Scheme 48

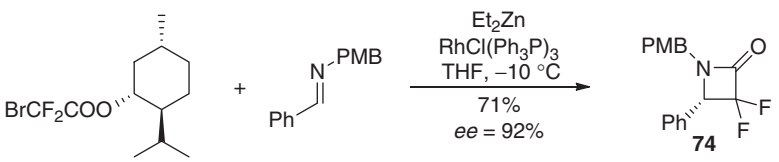


An interesting reversal in diastereoselectivity was observed by employing *N*-Tf-imines instead of *N*-Ts-imines.[132] The switch in selectivity is attributed to a change in mechanism.

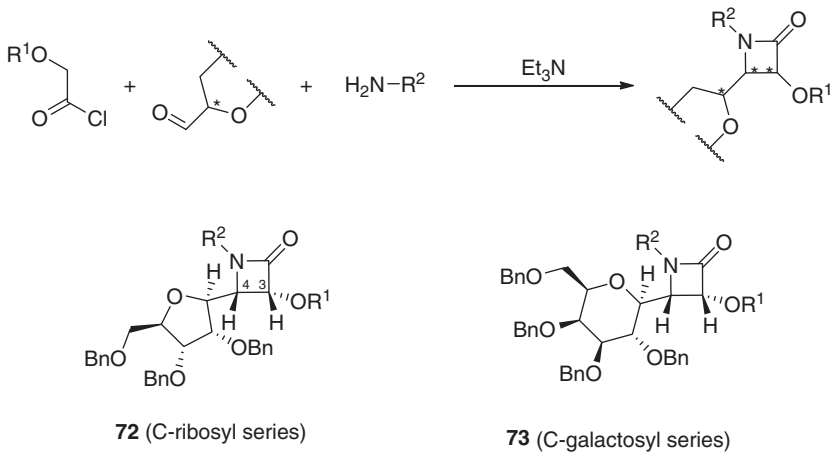
More recently, Smith and Ye showed that enantioselective β-lactam formation can also be accomplished by chiral NHC catalysis (Scheme 49).[195,196] The catalytic cycle is similar to the one described for tertiary amine catalysts.[184,185]

Scheme 49

Later, this enantioselective strategy has been applied to the reaction of ketene with carbonyl compounds to form β-lactones bearing two contiguous stereocenters. Indeed, reaction of alkyl(aryl)ketenes with 2-oxoaldehydes or trifluoromethyl ketones leads to the corresponding β-lactones in high yields with good diastereoselectivities and excellent enantioselectivities (Scheme 50).[166,183,197] One drawback of this methodology, however, is the fact that it is limited to activated carbonyl compounds.



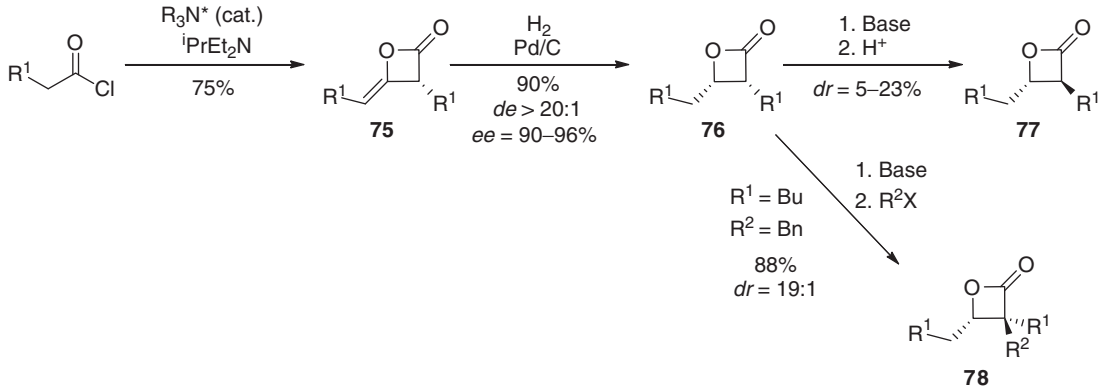
Scheme 50



5.03.4.3 Selected Applications

With the aim of simultaneously locking the transglycosidase and transpeptidase domains in PBP2a of resistant bacteria, Dondoni and Massi have synthesized sugar-decorated β-lactams. The C_4-glycoconjugate β-lactams **72** and **73** are obtained by a 3CR-based methodology, i.e., the two-step/one-pot amine-catalyzed Staudinger reaction, combined with the polymer-assisted solution-phase technique (Scheme 51).[121,198]

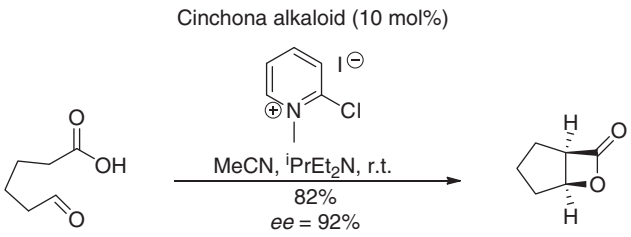
The Reformatzky-type reaction of imines and α-bromoesters with zinc dust[199,200] is the method of choice for the preparation of 3,3-difluoro-β-lactams,[201] and derivatives thereof such as α,α-difluoro-β-aminoacids. An asymmetric version using (–)-menthyl bromodifluoroacetate has been developed for the preparation of the chiral β-lactam **74** which was further reacted with taxane alcohol to give the 2,2′-difluoro analog of the anticancer drug docetaxel (equation 11).[202]



(11)

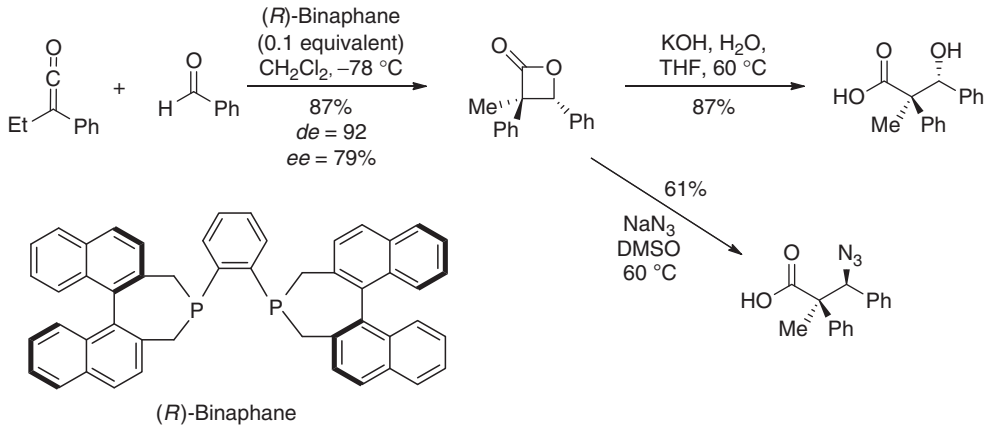
Scheme 51

3,3-Dichloro β-lactones were obtained from trichloroacetyl chloride, α-oxyaldehydes or α-aminoaldehydes and zinc, and used as precursors of 1,2-diols or 1,2-amino alcohols subunits with predictable stereochemistry.[203]



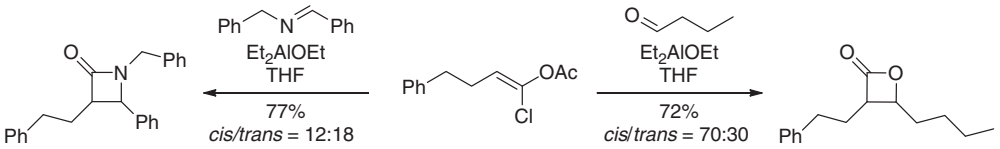
The catalytic asymmetric synthesis of β-lactones via a sequential ketene dimerization/hydrogenation process opens efficient access to inhibitors of the thio-esterase domain of fatty acid synthase (Scheme 52).[204] The facial-selective hydrogenation of the dimer **75** leads to the *cis*-substituted β-lactone **76**. The subsequent epimerization at C_3 under basic treatment gives the *trans* isomer **77** as the major compound. Alkylation of the enolate derived from **76** furnishes the β-lactone **78** with a C_4 quaternary center of controlled configuration.

Scheme 52



Chiral β-lactones with a C_4 quaternary center can be directly obtained from disubstituted ketenes that cycloadd to aldehydes in the presence of a chiral phosphine catalyst. Further basic hydrolysis and nucleophilic opening of the cycloadducts afford β-hydroxy- and β-amino acid precursors featuring a controlled quaternary asymmetric carbon atom at the α-position (Scheme 53).[205] This reaction sequence illustrates well the use of chiral β-lactones as versatile building blocks.[161]

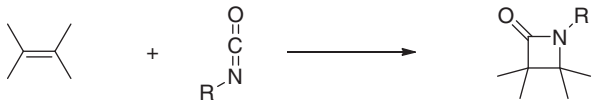
An intramolecular version of the Wynberg synthesis of β-lactones is proposed by Romo and coworkers (equation 12).[204,206]



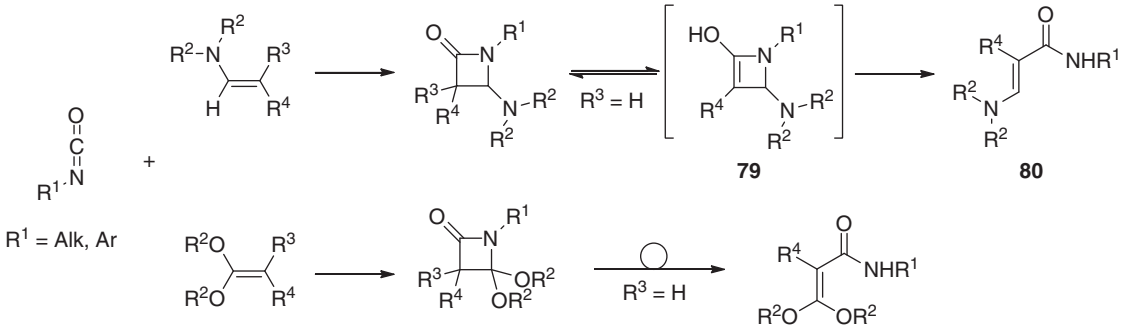
(12)

Mioskowski has disclosed new ketene equivalents, namely α-haloenol acetates, for the practical synthesis of β-lactones and β-lactams. The [2 + 2] cycloaddition occurs readily in the presence of diethylaluminum ethoxide (Scheme 54).[207]

Scheme 53



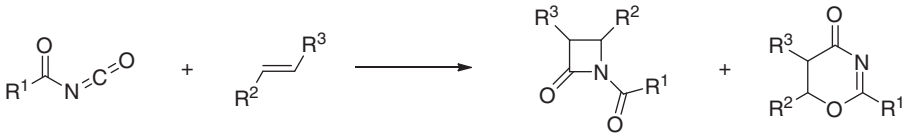
Scheme 54



5.03.5 Reaction of Isocyanates with Alkenes

5.03.5.1 Scope

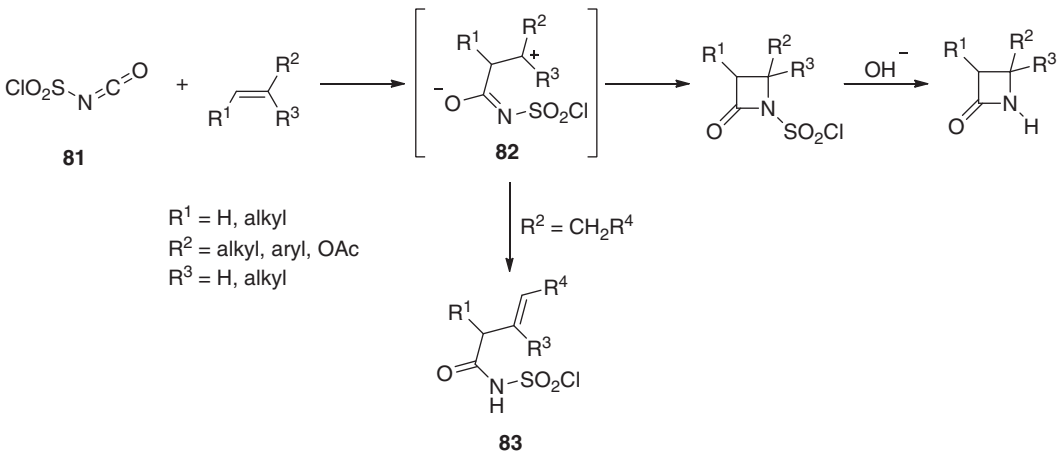
The cycloaddition of alkenes across the C═N bond of an isocyanate is a useful method for synthesizing β-lactams (equation 13).[208] The reaction requires either activation of the alkene by electron-releasing substituents or activation of the isocyanate by EWGs. Nonactivated (alkyl or aryl) isocyanates react with enamines and ketene acetals (Scheme 55). The initial product is a β-lactam. However, when R^3═H, enolization occurs and a fast electrocyclic rearrangement of the enol form (**79**) gives the open-chain isomer (**80**). In both cases, the rearrangement is driven by the release of strain and the presence of an EDG at C_4.



(13)

Scheme 55

Acyl isocyanates are more activated and can react with nonactivated alkenes (equation 14).[209–211] However, the presence of an additional π-bond conjugated to the C═N unit of the isocyanate opens the possibility for [4 + 2] cycloadditions to compete with



normal [2 + 2] additions. The chemoselectivity varies with subtle changes in the structures of the reactants as well as the experimental conditions.

R^1 = Ph, CCl_3
R^2 = Me, Ph, CH=CH_2
R^3 = H, Me

(14)

A more general and practical approach toward β-lactams from isocyanates uses the cheap chlorosulfonyl isocyante (CSI; **81**; Scheme 56).[212] This derivative, first described by Graf[213] offers several advantages: (1) it has a strong activating effect on the cyanate function; (2) it does not lead to competing [4 + 2] cycloadditions; and (3) it can be smoothly removed by simple basic hydrolysis or reductive treatment. CSI reacts with a wide range of alkenes under mild conditions to produce β-lactams together with variable but usually minor amount of open-chain adducts (**83**).

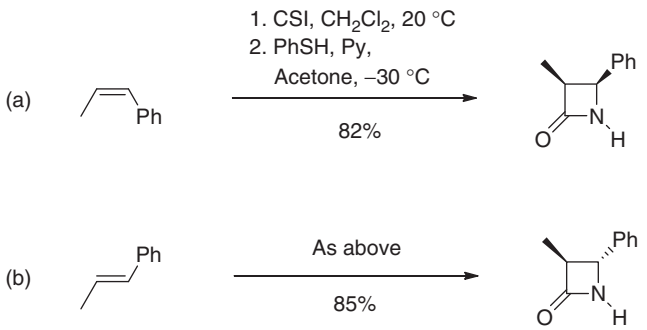
81

82

83

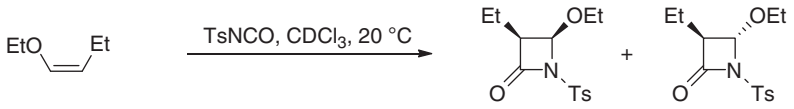
R^1 = H, alkyl
R^2 = alkyl, aryl, OAc
R^3 = H, alkyl

R^2 = CH_2R^4



Scheme 56

Based on experimental results and computational studies, a stepwise mechanism via formation of a 1,4-dipolar intermediate (**82**) has been proposed for these reactions (Scheme 56).[214] In some specific cases, however, a concerted mechanism was shown to be preferred.[215] The reaction rates are markedly increased in polar solvents. The cycloadditions of isocyanates to alkenes are always regiospecific, the reaction taking place so as to form the most stable 1,4-dipole.

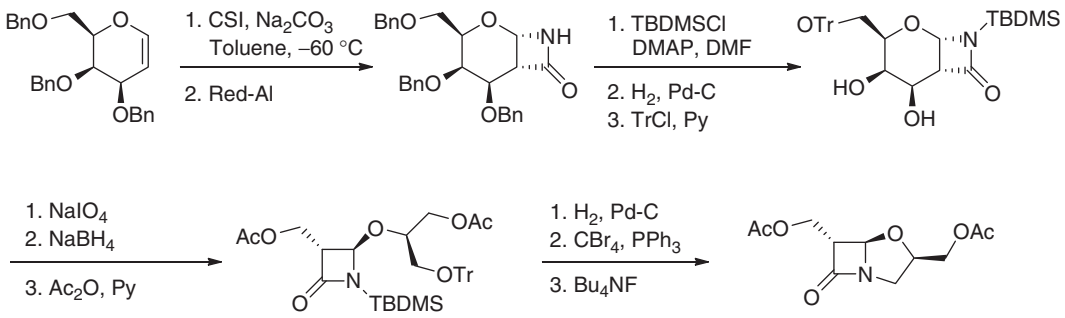


5.03.5.2 Stereochemical Aspects

Reaction of activated isocyanates with alkenes are generally highly stereospecific (Scheme 57).[209,216,217]

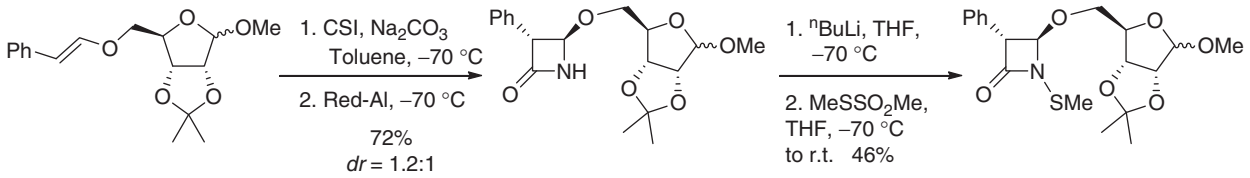
In a few cases, it was found that the primary adduct epimerizes under the reaction conditions (Scheme 58).[218]

Scheme 57



Reaction time	*cis*	*trans*
1 min	> 95%	< 5%
18 min	65	35
24 h	27	73

Scheme 58

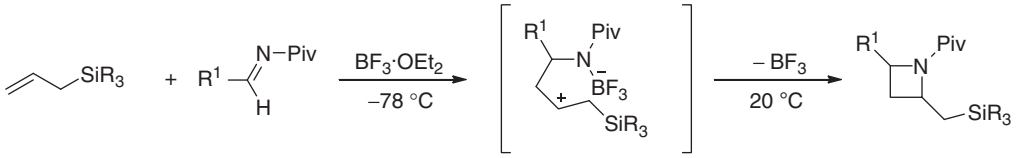


5.03.5.3 Selected Applications

The main applications of the [2 + 2] cycloaddition of isocyanates with alkenes are related to the chemistry of antibiotics. A stereocontrolled synthesis of 1-oxabicyclic β-lactam antibiotics, using the cycloaddition of chlorosulfonyl (or trichloroacetyl) isocyanate to sugar vinyl ethers as the key step, has been developed by Chmielewski et al. (Scheme 59, yields not specified).[219]

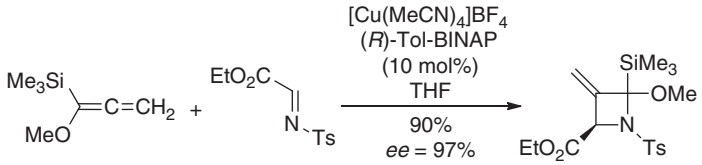
Scheme 59

Pyridinyl sulfones bearing carbohydrate moieties at the α-position have been used in the Julia–Lythgoe–Kocienski olefination with aldehydes, in a one-pot protocol affording glycosidic enol ethers with (*E*)-stereoselectivity. Their [2 + 2] cycloaddition reaction with CSI provides glycosylated β-lactams regioselectively and with an exclusive *trans*-stereochemistry (Scheme 60).[220] After conversion into *N*-methylthio derivatives, these β-lactams showed antibacterial activity toward MRSA.



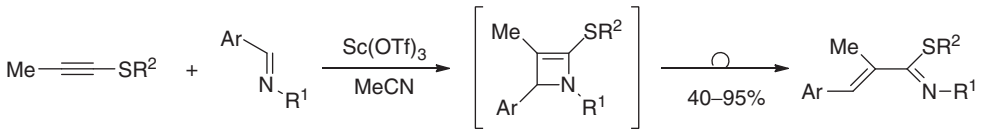
Scheme 60

5.03.6 Reaction of Alkenes, Allenes, and Alkynes with C═N Bonds



5.03.6.1 Lewis Acid-Catalyzed Reactions

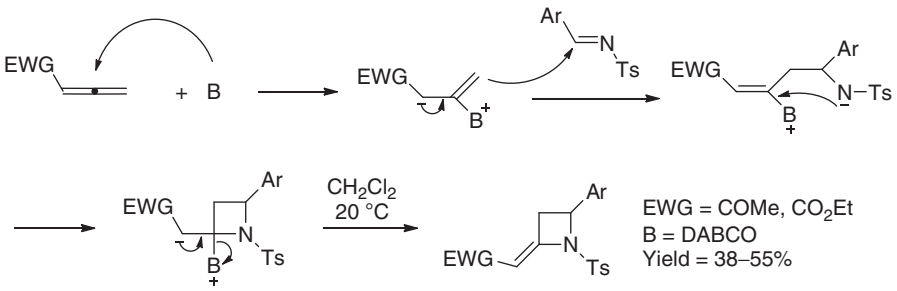
N-Pivaloyl aldimines react with allylsilanes in the presence of boron trifluoride etherate or zinc chloride to give azetidines (Scheme 61). This formal [2 + 2] cycloaddition most probably proceeds in two steps, via a β-silyl cation intermediate.[221]



Scheme 61

The reaction of allenylsilanes with *N*-tosyl aldimines has been carried out in the presence of a chiral copper catalyst[222]; 3-*exo*-methylene azetidines were obtained with good *ee*'s (equation 15). An application to allenyl germanes is also described.[222]

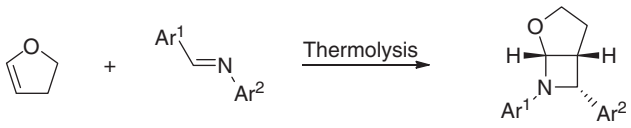
(15)



2-Azetine intermediates have been obtained by [2 + 2] cycloaddition of Schiff bases with alkynyl sulfides (or selenides), catalyzed by scandium triflate, ytterbium triflate, or boron trifluoride. The initially formed cycloadducts rearrange rapidly into α,β-unsaturated thioimidates (or selenoimidates) (Scheme 62).[223,224]

Scheme 62

5.03.6.2 Lewis Base-Catalyzed Reactions

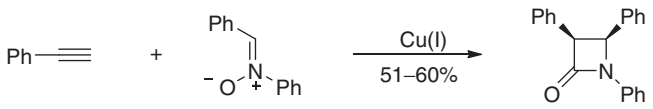


The cycloaddition of allenes substituted with an EWG to *N*-tosyl aldimines is catalyzed by 1,4-diazabicyclo[2.2.2]octane. 2-*Exo*-methylene azetidines are formed via a zwitterionic intermediate undergoing an intramolecular Michael addition (Scheme 63).[225]

Scheme 63

5.03.6.3 Thermic Reactions

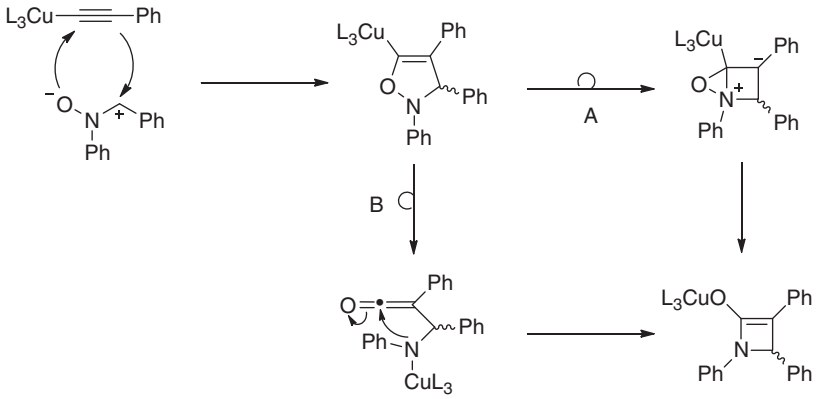
On heating under pressure, 2,3-dihydrofuran cycloadds onto (E)-benzylideneanilines to furnish bicyclic azetidines with high stereoselectivity (equation 16).[226]



(16)

5.03.7 Reaction of Alkynes with Nitrones

5.03.7.1 The Kinugasa Reaction

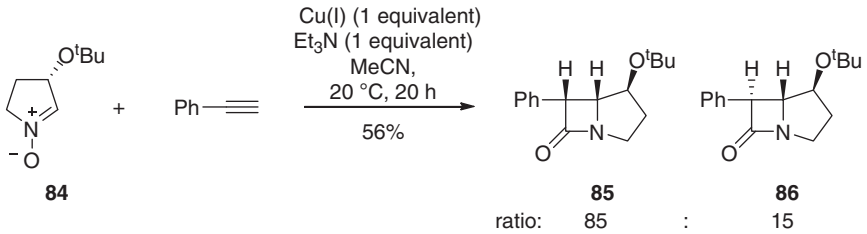


The reaction of C,*N*-diphenylnitrone, phenylacetylene and a stoichiometric amount of a Cu(I) salt in dry pyridine was initially reported in 1972 by Kinugasa and Hashimito (equation 17).[227] Later on, various terminal alkynes and substituted nitrones, both

readily available starting materials, were used for the stereoselective synthesis of *cis*-*β*-lactams.[228] The Kinugasa reaction offers a high functional group tolerance and an atom-economical character since the catalytic version (substoichiometric Cu(I)) could be developed by Miura et al.,[229] and further optimized by Fu and Lo[230] with appropriate metal ligands.

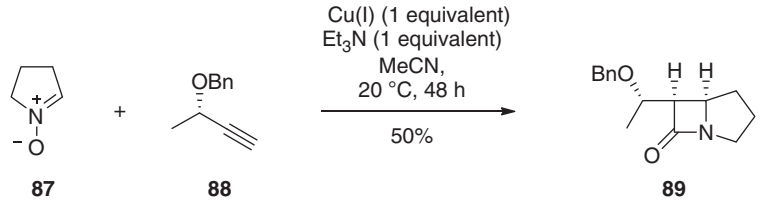
(17)

The proposed mechanism of *β*-lactam formation is outlined in **Scheme 64**: the reactive intermediate is the Cu(I) phenylacetylide which gives a 1,3-dipolar cycloaddition with the nitrone. The five-membered heterocyclic intermediate suffers a rearrangement, via the path A or, most probably, the path B, leading to a *β*-lactam Cu(I) enolate. Protonation of this species occurs from the less shielded side of the skeleton, and consequently the major diastereoisomer displays the relative *cis*-orientation of the *β*-lactam C_3/C_4 protons.[231]



Scheme 64

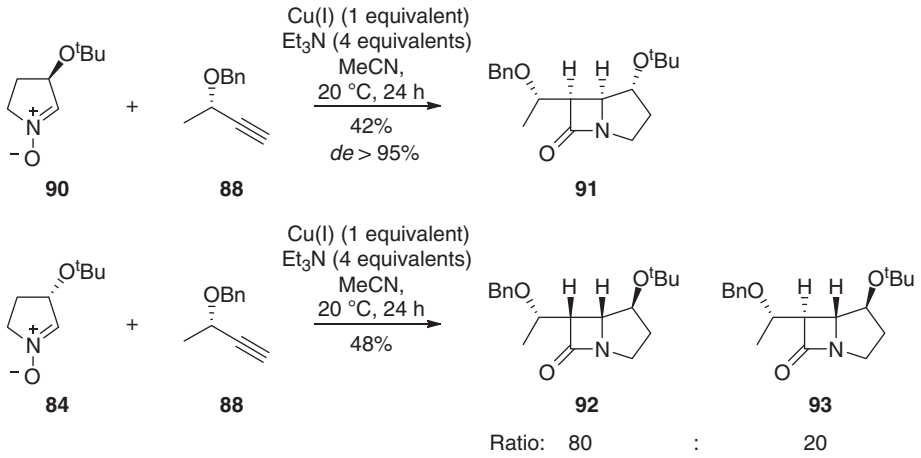
Recently, Tang et al.[232] found that the Cu(I) salt can be replaced with $Cu(ClO_4)_2 \cdot 6H_2O$ to catalyze the Kinugasa reaction. The advantage of the Cu(II) source is that the reaction does not have to be performed under strictly inert atmosphere and with anhydrous solvents.



5.03.7.2 Asymmetric Synthesis

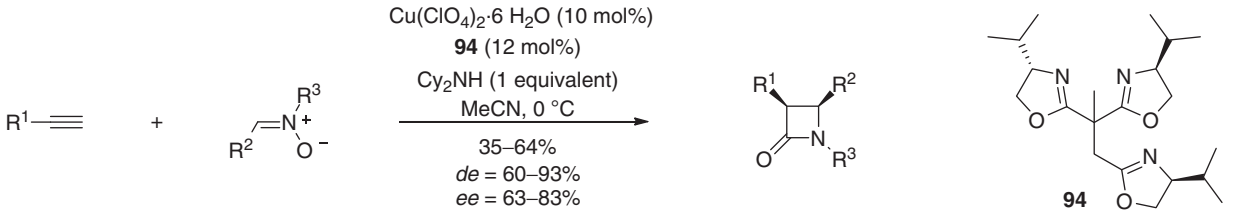
The use of chiral nonracemic nitrones as partners of the Kinugasa reaction was explored by Chmielewski et al.[233] For instance, the cyclic nitrone **84** (available from (*S*)-malic acid) reacts with phenylacetylene in the presence of one equivalent of copper iodide and one equivalent of triethylamine to yield a 85:15 mixture of diastereoisomers **85** and **86** (equation 18). The stereochemical outcome is controlled by the initial 1,3-cycloaddition step which determines the configuration of the bridgehead carbon atom. The approach of acetylide to the *Si* face of **84** (i.e., *syn* to the O*t*Bu substituent) is strongly disfavored by steric interactions.

(18)



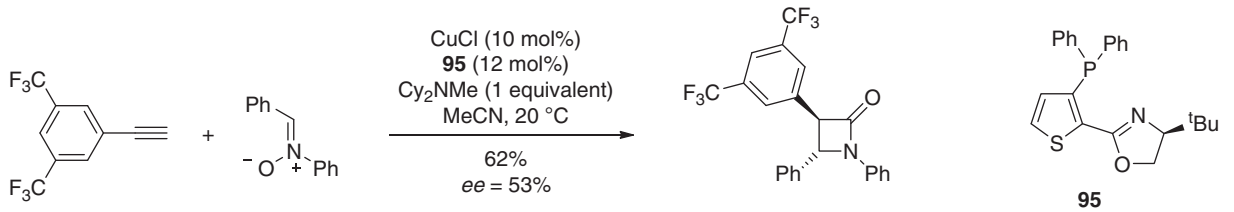
The copper(I)-mediated reaction between nitrones and chiral, nonracemic terminal acetylenes was also studied by Chmielewski et al.[234] As shown in equation 19, the reaction of cyclic nitrone **87** with alkyne **88** proceeds with excellent diastereoselectivity (*de* > 95%), affording the *cis* *β*-lactam **89**.

(19)



The use of (4*S*)-benzyl-3-propargyl oxazolidinone as acetylenic partner has been reported by Basak et al.[1,3,235]

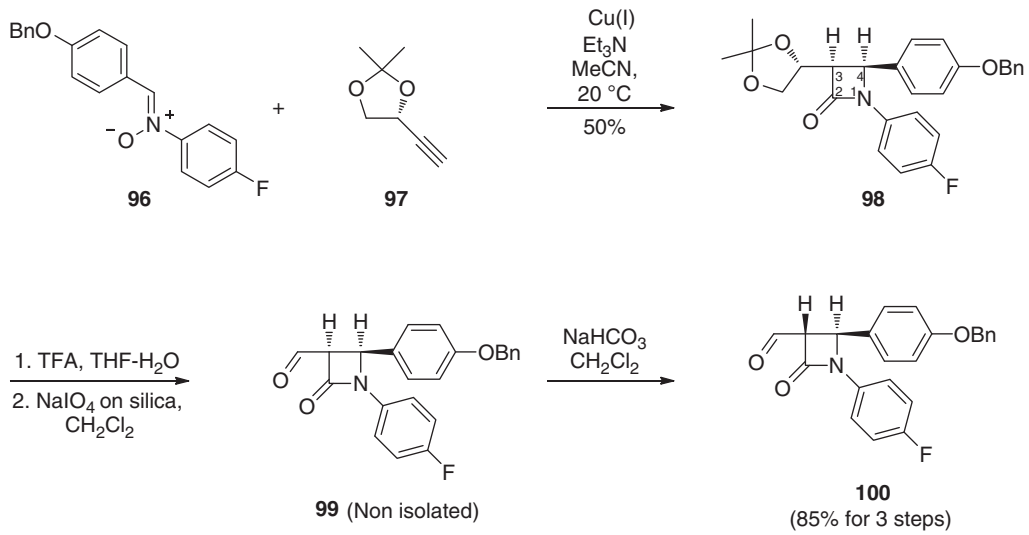
Using both enantiomerically pure reagents, i.e., nitrone and acetylene, matched and mismatched pairs have been identified (Scheme 65). Specifically, in reactions with acetylene **88**, the nitrone **90** leads to a quasi total diastereoselectivity, whereas its enantiomer **84** gives a 80:20 mixture of diastereoisomers.



Scheme 65

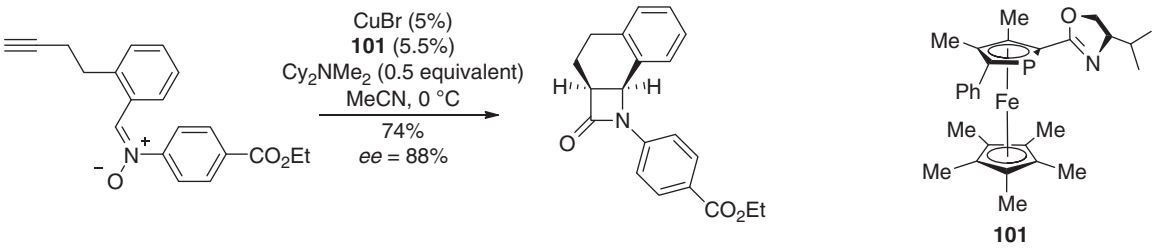
Pioneering work[229] on the catalytic asymmetric synthesis of *β*-lactams made use of *bis*-oxazolines as chiral ligands. More recently, *bis*-azaferrocenyl ligands allowed the enantioselectivities to be increased from 30% *ee* to approximately 90% *ee*.[230] Tang et al.[73] have designed a pseudo-C_3-symmetric *tris*-oxazoline ligand (**94**) by a 'side-arm approach' and found that the combination of **94**/Cu(II) efficiently catalyzed asymmetric Kinugasa reactions in air (equation 20).[232] The presence of a base was essential to control the dia- and enantio-selectivities; compared with tertiary and primary amines, secondary amines gave the best results.

(20)



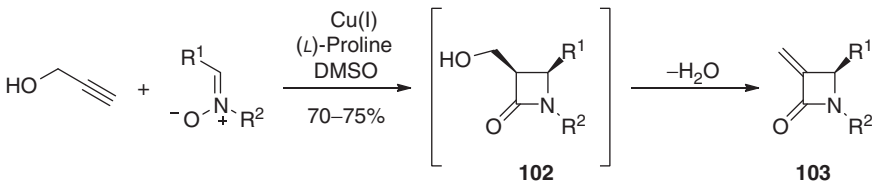
Beside the usual *N*,*N*-ligands, *P*,*N*-ligands, such as **95**, have been applied to the Kinugasa reaction by Guiry et al.[236] High levels of diastereoselectivity are obtained, but with moderate enantioselectivity, approximately 50%. An unexpected reversal of the diastereoselectivity is observed for 3,5-(trifluoromethyl)phenylacetylene (equation 21).

(21)



5.03.7.3 Selected Applications

The key-intermediate **100** toward the cholesterol absorption inhibitor Ezetimibe® has been synthesized from the nitrone **96** and the enantiomerically pure acetylene **97** (Scheme 66).[237] Under standard conditions (2 equivalents of **96** with respect to **97**, 1 equivalent of CuI, and 4 equivalents of triethylamine), the Kinugasa reaction provides the desired *cis*-configured *β*-lactam **98** with the (4*S*)-configuration as the major diastereoisomer (separable from the (4*S*)-*trans*, (4*S*)-*cis*, and (4*R*)-*trans* isomers). Acetonide deprotection, followed by oxidation to aldehyde **99** and C_3 epimerization lead to the (4*S*)-*trans* *β*-lactam **100** in 85% overall yield.

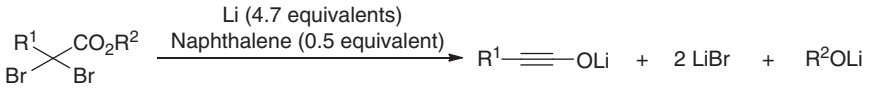


Scheme 66

The intramolecular version of the Kinugasa reaction has been applied to efficiently construct fused tricyclic ring systems with good enantioselectivities when using the chiral ferrocenyl derivative **101** as catalyst (equation 22).[238]

(22)

3-*Exo*-methylene *β*-lactams can be obtained by a one-pot process via Cu(I)-mediated cycloaddition between propargyl alcohol and nitrones in the presence of (L)-proline.[239] In DMSO as solvent (instead of acetonitrile), the intermediate **102** led directly to the dehydration product **103** (equation 23).

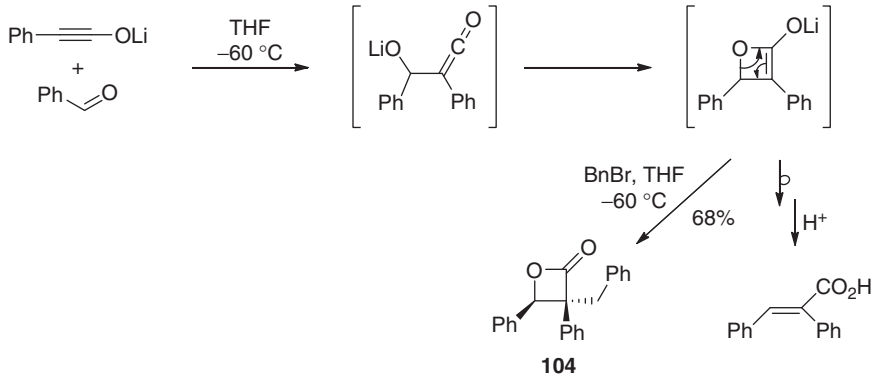


(23)

5.03.8 Reaction of Ynolates with C═X Bonds

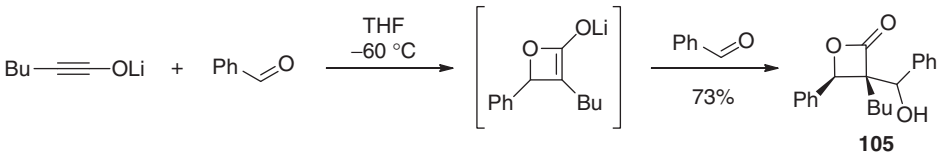
5.03.8.1 Synthesis of Ynolates

Contrary to enolates, which are well-established carbanions in synthetic organic chemistry, ynolates have attracted much less attention due to the lack of general and convenient methods[240] for their synthesis, until the work of Shindo et al. was



published.[241] They developed a safe and economical preparation of lithium ynolates by reductive lithiation of α,α′-dibromoesters in the presence of naphthalene (equation 24).[242] Ynolates can be stored for a few days at room temperature.

(24)

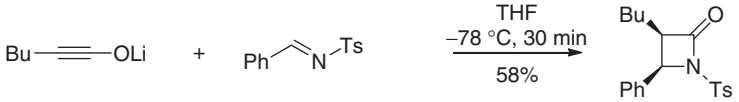


5.03.8.2 Reaction with Aldehydes and Ketones

Lithium phenylynolate reacts with benzaldehyde to give a β-hydroxy lithiated intermediate which cyclizes into a β-lactone enolate; it can be quenched at low temperature with an electrophile such as benzyl bromide to afford the stable β-lactone **104** with high stereocontrol (Scheme 67).[243]

Scheme 67

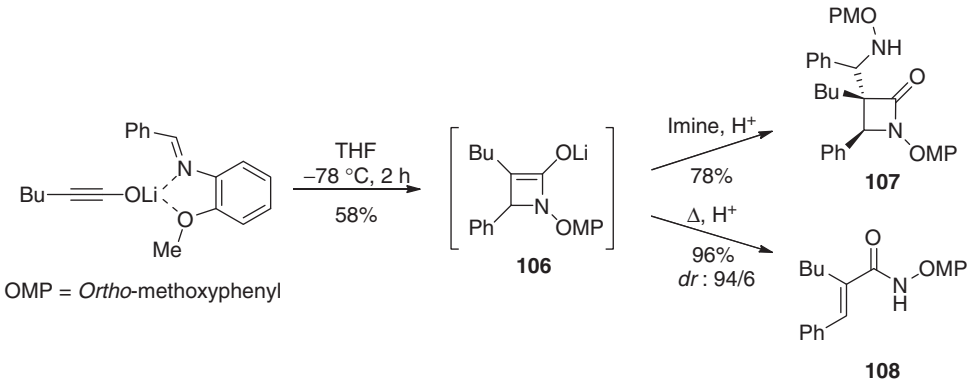
Lithium butylynolate and 2 equivalents of benzaldehyde yield the β-lactone **105** resulting from the quenching of the enolate intermediate with the aldehyde itself (Scheme 68).[244]



Scheme 68

In the absence of an electrophile, the β-lactone enolate intermediates are transformed on heating into olefins with high stereoselectivity. Tri- and tetrasubstituted alkenes have been prepared; their configuration is controlled by the torquoselectivity of the electrocyclic ring-opening reaction (Scheme 67).[241]

The ynolate chemistry has been successfully applied to the synthesis of furanes, pyrroles, and thiophenes via a cascade of reactions, namely cycloaddition, intramolecular cyclization, decarboxylation, and dehydration.[245]



5.03.8.3 Reaction with Imines

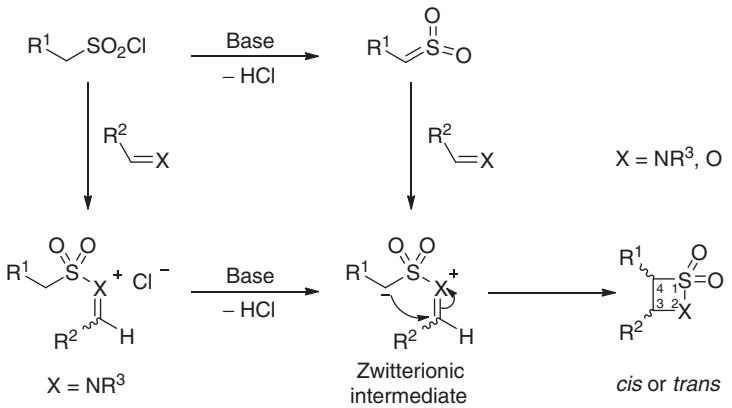
Barrett et al.[246] and Murai et al.[240] reported that phenyl- and silylynolates add to aldimines bearing an electron-withdrawing substituent to provide, respectively, β-lactams (2:1 adducts) at low temperature (− 60 °C) and α,β-unsaturated amides at room temperature. Reaction of ynolates with *N*-sulfonyl imines leads to β-lactams (1:1 adducts) at − 78 °C (equation 25).[247]

(25)

Unactivated imines are not reactive, even in the presence of LAs.[248] One exception is worthy of note: *N*-2-methoxyphenyl imine cycloadds to lithium ynolates as shown in Scheme 69. The authors propose an activation of the imino group by double

Scheme 69

chelation of the lithium ynolate. The isolated β-lactam **107** corresponds to the 2:1 adduct, because the nucleophilicity of the enolate intermediate **106** is higher than that of the ynolate. As a matter of fact, 1:1 adducts are obtained with the less nucleophilic *N*-tosyl imines (equation 25). When heated to room temperature before aqueous work-up, the β-lactam enolate **106** suffers a ring-opening reaction leading to the α,β-unsaturated amide **108** with excellent *E*-selectivity.[249]

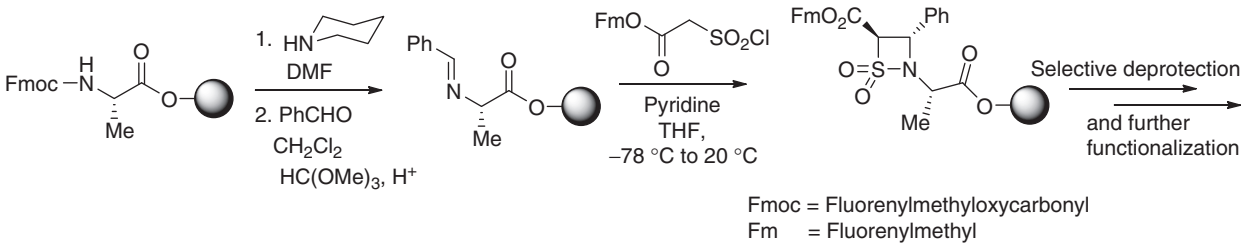


5.03.9 Reaction of Sulfenes with C=X bonds

5.03.9.1 Analogy with the Ketene Chemistry

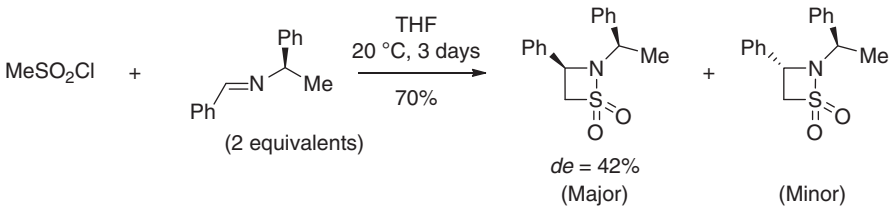
Similarly to β-lactams and β-lactones, β-sultams (1,2-thiazetidine-1,1-dioxides), and β-sultones (1,2-oxathietane-1,1-dioxides) have been studied for their potential properties in medicinal chemistry[250,251] and synthetic organic chemistry.[252,253]

In particular, β-sultams are exploited for the discovery of active site directed inhibitors of serine enzymes such as elastases,[254] β-lactamases,[255] and D,D-peptidases.[256] However, the high reactivity of β-sultams toward nucleophiles, leading to S–N bond cleavage, opens the route to taurine derivatives.[257]



Most often, β-sultams are obtained by cyclization reactions, mainly the formation of the N–S bond[258,259] or the C–C bond.[260] Another general route toward β-sultams is based on the formal [2 + 2] cycloaddition of sulfenes to imines.[250] Sulfenes are formed *in situ* by the dehydrochlorination of alkylsulfonylchlorides with a base at low temperature (**Scheme 70**).[261] Their existence was spectroscopically demonstrated,[262] but in contrast to ketenes, sulfenes cannot be isolated. The reaction with imines (**Scheme 70**, X=NR^3) has been described as a multistep process with a zwitterionic intermediate.[263] Depending on the nature of the R^1, R^2, and R^3 substituents, formation of a zwitterionic intermediate via the initial reaction of the alkylsulfonyl chloride with the imine is also possible.

Scheme 70

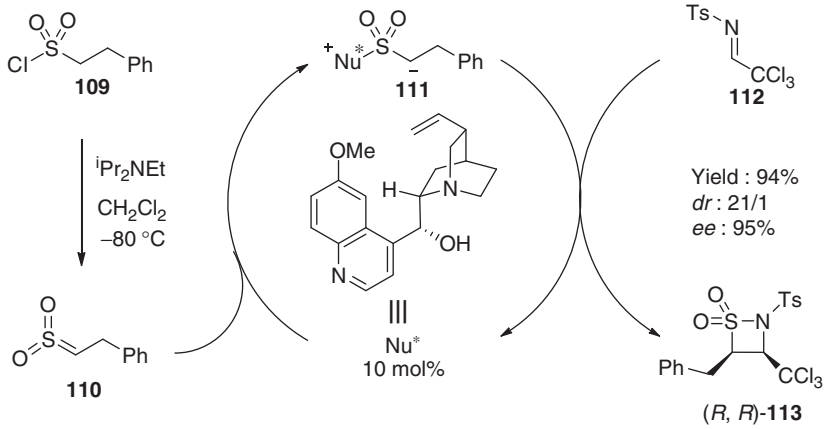


The diastereoselectivity of the reaction is variable and depends mainly on the nature of R^1. Production of *trans* β-sultams has been reported for the reactions of benzoylmethanesulfonyl chloride (R^1=PhCO); [264] mixtures of *cis* and *trans* isomers have been obtained with benzylsulfonyl chloride (R^1=PhCH$_2$).[265] Combinatorial chemistry on solid phase allowed for the synthesis of β-sultams libraries with a broad structural diversity.[250] In this application, the imine partner is produced *in situ* from a TentaGel

resin derivatized with an amino acid; the sulfene partner arises from chlorosulfonyl acetates as exemplified in Scheme 71 with the fluorenylmethyl ester (Fm).

Scheme 71

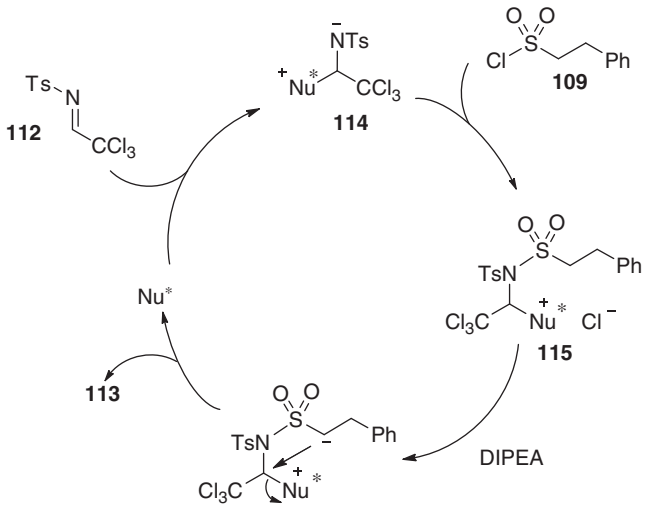
The 1,3-asymmetric induction in solution phase has been studied using chiral imines derived from (*R*)- or (*S*)-α-methylbenzylamine.[266] The diastereoslectivities are moderate, in favor of the *syn*-stereoisomer, for the [2 + 2] cycloaddition of unsubstituted sulfene produced *in situ* from mesylchloride and 2 equivalents of imine (equation 26).[267]



(26)

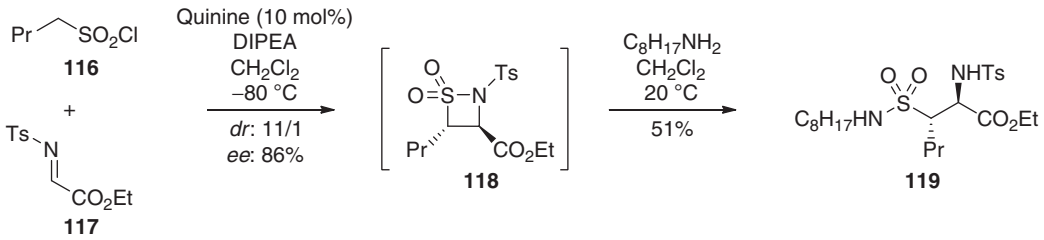
The number of accessible β-sultones, according to the strategy of Scheme 70 with aldehydes (X=O) as nucleophilic partners of the [2 + 2] cycloaddition, is rather limited because most β-sultones are unstable at room temperature; the occurrence of proton shift, elimination and rearrangement reactions has been reported.[268,269] Derivatives holding an EWG and sterically demanding group at the C_4 atom are the most stable ones (stabilization of the labile C–O bond).[251] For that reason, chloral is the privileged aldehyde for [2 + 2] additions to sulfenes (see Section 5.03.9.2).

5.03.9.2 Catalytic Asymmetric Synthesis of β-Sultams and β-Sultones



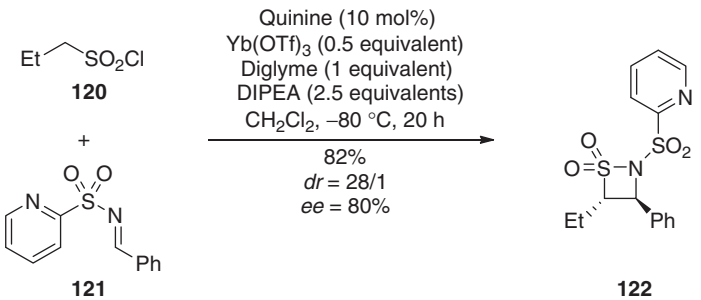
In contrast to ketenes, the use of sulfenes in asymmetric catalysis is scarcely described and the major contribution in this field is from Peters et al.[251,257,270,271] The main problem relies on the instability of sulfenes which have to be produced *in situ* at very low temperature. Nevertheless, reproducible protocols could be validated for the catalytic asymmetric synthesis of β-sultams and β-sultones, using electron-poor imines and aldehydes as highly activated partners of the [2 + 2] cycloadditions, and employing cinchona alkaloid derivatives as nucleophilic organocatalysts.

The sulfene **110**, produced *in situ* by dehydrochlorination of the corresponding sulfonyl chloride **109** by diisopropylethyl amine (DIPEA), reacts with the chiral nucleophilic catalyst (Nu∗) to form the zwitterionic intermediate **111** capable of initiating the asymmetric [2 + 2] cycloaddition with the electron-poor *N*-tosyl imine (**112**) (Scheme 72). Indeed, **112** has to be



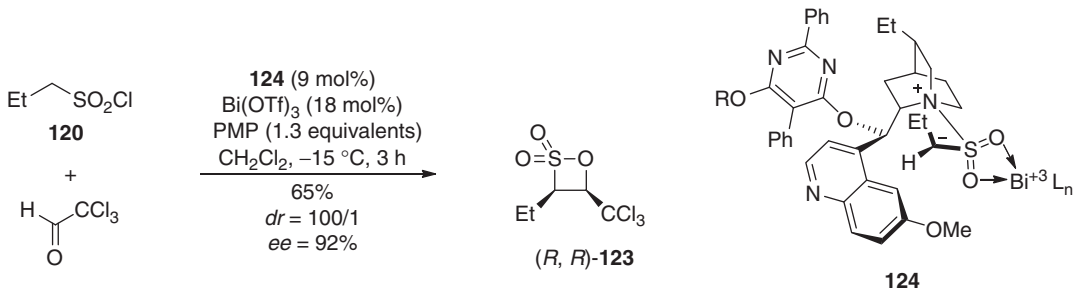
Scheme 72

nonnucleophilic to avoid the noncatalyzed competitive reaction between **112** and **110**. Using the cinchona alkaloid quinine as the catalyst, the *cis* β-sultam **112** was obtained in 94% yield with 95% of *ee*. Depending on the temperature and the order of addition of the reagents, another catalytic cycle has been proposed, involving the intermediate formation of an adduct (**114**) of the catalyst (Nu∗) with the highly electrophilic imine **112**. The negatively charged N-Ts atom of **114** attacks the sulfonyl chloride (without prior formation of a sulfene) to give the intermediate **115** which suffers deprotonation by DIPEA. Lastly, an intramolecular nucleophilic substitution leads to the β-sultam **113** and the release of the catalyst (Scheme 73).



Scheme 73

The methodology has been extended to α-iminoesters. Because these imines are prone to polymerize, the reagent **117** is added very slowly to a solution of catalyst (quinine), DIPEA and sulfonyl chloride **116** at $-80\ ^{\circ}C$ to furnish the *trans*-β-sultam **118** with 86% *ee*. The tandem one-pot cycloaddition/nucleophilic ring-opening sequence with octylamine leads to **119** in 51% yield (Scheme 74).

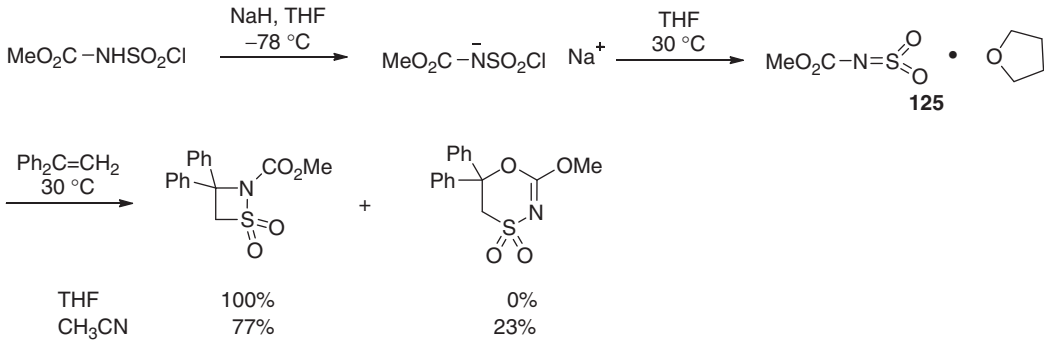


Scheme 74

Arylaldimines are less reactive toward sulfenes and therefore require the replacement of the tosyl group with the 2-pyridylsulfonyl group. Indeed, this moiety offers the possibility of bidentate coordination to a LA cocatalyst, giving an additional activation. For instance, the reaction of sulfonyl chloride **120** with imine **121** in the presence of DIPEA, quinine (10 mol%), ytterbium triflate as cocatalyst and diglyme as additive yielded the *trans*-β-sultam **122** in 82% yield and 80% *ee* (equation 27).

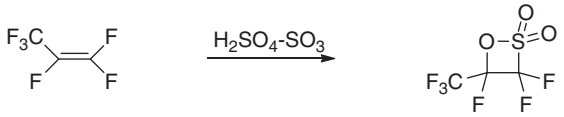
(27)

The catalytic system developed for the asymmetric synthesis of β-sultams (Scheme 73) is not similarly efficient for the preparation of enantiomerically pure β-sultones (replacement of imine **112** with chloral).[251] The addition of a LA cocatalyst is required to enhance the performance. As the result of a large screening of reagents and experimental conditions, the selected catalytic system involves: (1) dihydroquinine 2,5-diphenyl-4,6-pyrimidinediyl diether ($(DHQ)_2PYR$) as the chiral nucleophilic catalyst; (2) bismuth triflate as the LA cocatalyst; (3) 1,2,2,6,6-pentamethylpiperidine as the stoechiometric nonnucleophilic base; and (4) an excess of chloral (2.75 equivalents) (equation 28). Under these conditions, the cycloaddition of ethyl sulfene to chloral (trichloroacetaldehyde) affords the *cis*-β-sultone **123** with the *R*,*R*-configuration (established by X-ray diffraction analysis).[251] This result can be rationalized by the formation of a sulfene-$(DHQ)_2PYR$ adduct **124** coordinated to the Bi^{3+} salt, which is the reactive species for the addition to chloral. Another role attributed to the bismuth salt was the coordination of the aldehyde; the coordination of both reactants may lead to a highly organized transition state and consequently to high enantioselectivity.



(28)

5.03.10 Miscellaneous

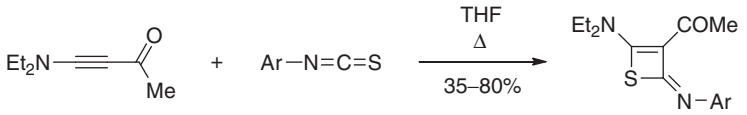


5.03.10.1 Four-Membered Rings Containing One Sulfur Atom (and Another Heteroatom)

N-Sulfonylamines ($RN{=}SO_2$) are able to react with strained or nucleophilic alkenes to furnish β-sultams.[272] Methyl *N*-sulfonylurethan **125** cycloadds to nonactivated alkenes, due to its high electrophilicity (Scheme 75).[273] This species is produced *in situ* from carbomethoxysulfamoyl chloride and is stabilized by complexation with tetrahydrofuran. A solvent dependent competition between [2 + 2] and [4 + 2] cycloadditions has been reported.[273]

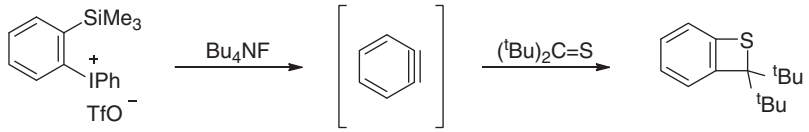
Scheme 75

The similar [2 + 2] cycloaddition of sulfur trioxide with alkenes generates β-sultones, a method especially dedicated to the synthesis of perfluorinated derivatives (equation 29). Perfluorinated β-sultones are used for the preparation of hybrid organic–inorganic mesoporous materials featuring terminal sulfonic acid groups; such materials are better catalysts than Nafion-silica® for the esterification of fatty acids.[274,275]



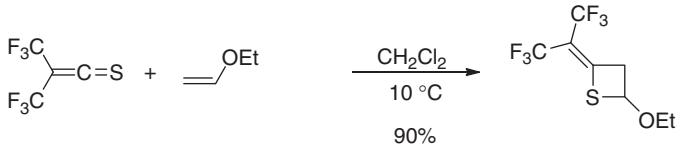
(29)

Oleum (fuming sulphuric acid) can be used as a source of SO_3.[276] Otherwise, the SO_3–pyridine complex is the usual source of SO_3. An alternative way to produce SO_3 *in situ* is based on the reaction of trimethylsilylsulfonyl chloride with iodosobenzene at



low temperature, performed in the presence of alkenes; this method allows β-sultones to be isolated in moderate to good yields.[277]

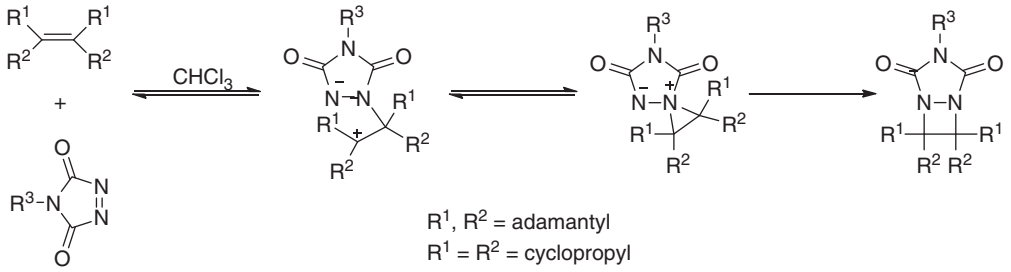
The [2 + 2] cycloaddition of 4-diethylamino-3-butyn-2-one (ynamine) with aryl isothiocyanates leads to thietimine derivatives (equation 30).[278]



(30)

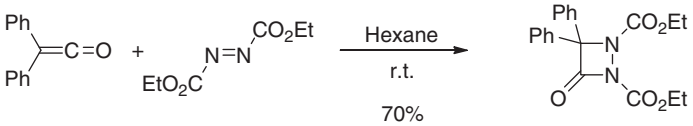
Fused thietes are obtained by the reaction of benzyne with thioketones (Scheme 76).[279]

Scheme 76



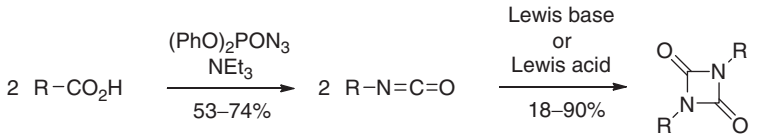
Since thioketenes are usually difficult to prepare, only reactions of bis(trifluoromethyl)thioketene as a stable representative with a range of C=C bonds have been studied. Unlike the other heterocumulenes, [2 + 2] cycloadditions occur across the cumulene C=X bond, leading to 2-*exo*-methylene-thietane derivatives (equation 31).[172]

(31)



5.03.10.2 Four-Membered Rings Containing Two Nitrogen Atoms

The formation of two C–N bonds by [2 + 2] cycloaddition between alkenes and azo compounds constitutes the general route toward 1,2-diazetidines.[280] Reactions between highly substituted alkenes and 1,2,4-triazoline-3,5-diones lead to bicyclic, N–N fused, diazetidine derivatives, most probably via zwitterionic intermediates (Scheme 77).[281–283]

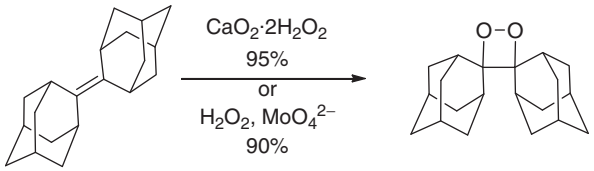


Scheme 77

1,2-Diazetines, accessible from adequately substituted 1,2-diazetidines, behave as excellent dienophiles in [4 + 2] cycloadditions.[284] 1,2-Diazetidin-3-ones are obtained by [2 + 2] cycloaddition of ketenes to azobenzenes. Since only the *cis* stereoisomers are reactive, these reactions require light activation to isomerize the azobenzenes *in situ*.[285] In contrast, azodicarboxylates and azoketones react without irraditation (equation 32).[286,287]

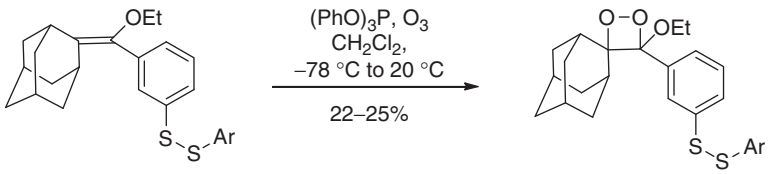
(32)

1,3-Azetidin-2,4-diones are classically obtained by dimerization of isocyanates under either Lewis base or LA catalysis. Non-commercially available isocyanates can be readily obtained from carboxylic acids by the Curtius rearrangement (Scheme 78).[288,289]



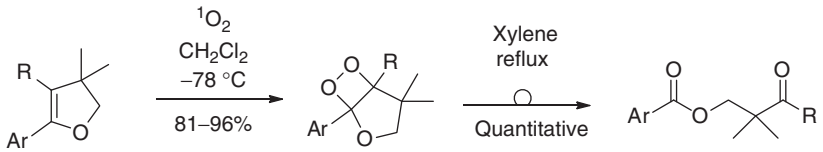
Scheme 78

Carbodiimide dimerization[290] and cross-dimerization between isocyanates and carbodiimides[291] have also been reported.



5.03.10.3 Four-Membered Rings Containing Two Oxygen Atoms

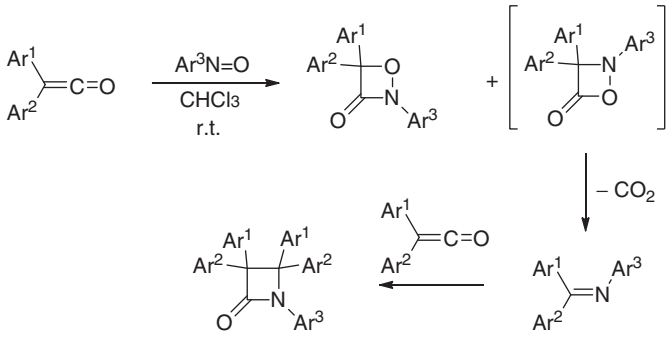
In the past, 1,2-dioxetanes were prepared by cyclization methods, from β-halo hydroperoxides or from β-epoxy hydroperoxides. Presently, the cycloaddition of singlet oxygen to electron-rich alkenes is the most useful method, exemplified with a large number of compounds and employing a range of singlet oxygen sensitizers.[292–296] Environmentally friendly sources of singlet oxygen have been described, such as calcium peroxide diperoxohydrate[58,297] and hydrogen peroxide with molybdate ions in a reverse microemulsion (equation 33).[298]



(33)

Beside the above general method, enol ethers could be transformed into 1,2-dioxetanes with triphenylphosphite and ozone (equation 34);[57] this protocol is compatible with the sensitive disulfide function which is not oxidized.

(34)



Singlet oxygen oxidation of cyclic enol ethers leads to the fused bicyclic 1,2-dioxetanes prone to rearrange into keto-esters when R=H (Scheme 79).[299]

Scheme 79

5.03.10.4 Four-Membered Rings Containing One Nitrogen and One Oxygen Atom

The cycloaddition of diarylketenes onto arylnitroso derivatives occurs with poor regioselectivity: mixtures of 1,2-oxazetidin-3-ones and 1,2-oxazetidin-4-ones are obtained, the latter being unstable (Scheme 80). Their decomposition leads to imines which are trapped by the ketene reagent to form β-lactams.

Scheme 80

Glossary

Alkene photocycloaddition Photochemical process leading to the formation of a cyclobutane on addition of an electronically excited alkene to another ground-state alkene, or of an electronically excited α,β-unsaturated carbonyl compound to a ground-state alkene.

Electron transfer Transfer of an electron from one molecular entity to another or between two localized sites in the same molecular entity.

Energy transfer Process by which a molecular entity is excited by absorption of radiation and is deactivated to a lower-lying state by transferring energy to a second molecular entity which is thereby raised to a higher energy state. The excitation may be electronic, vibrational, rotational, or translational.

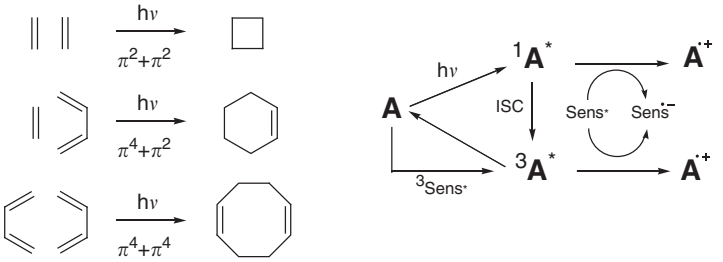
Intersystem crossing Isoenergetic radiationless transition between two electronic states having different multiplicities.

Photocatalysis Change in the rate of a chemical reaction or its initiation under the action of ultraviolet, visible, or infrared radiation in the presence of a substrate – the photocatalyst – that absorbs light and is involved in the chemical transformation of the reaction partners.

Photocycloaddition Photochemical process leading to carbo- or heterocyclic systems by formation of two new single bonds, either by concerted or multistep processes.

Photosensitization Photochemical or photophysical alteration occurring in one molecular entity as a result of initial absorption of radiation by another molecular entity called a photosensitizer.

Triplet-triplet energy transfer Energy transfer from an electronically excited triplet donor to produce an electronically excited acceptor in its triplet state.

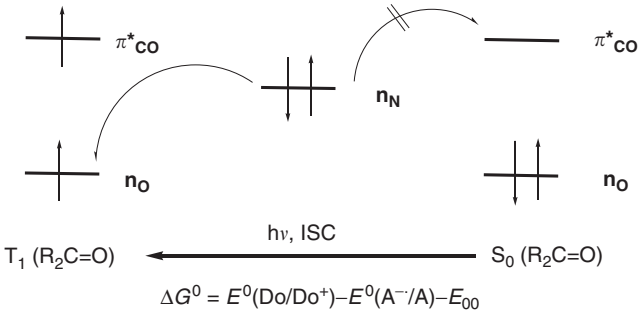


Ultraviolet Region of the electromagnetic spectrum extending from approximately 100 to 400 nm. The region is divided into four subbands as follows: Vacuum ultraviolet (VUV): 100–200 nm; UV-C: 200–280 nm; UV-B: 280–315 nm; UV-A: 315–400 nm.

5.04.1 Introduction

Photocycloadditions are concerted or stepwise photochemical processes that lead to the formation of cyclic products from acyclic or cyclic substrates.[1,2] Stepwise processes often involve 1,*n*-biradicals or radical ion pairs that are formed by photoinduced electron transfer (PET) steps. For initiation of these primary processes, one substrate has to be activated by electronic excitation. There are three major routes that can be used for activation: (a) direct absorption by the substrate in the ultraviolet (UV) or visible region, (b) energy transfer sensitization using appropriate catalysts (sensitizers), and (c) electron transfer sensitization using PET catalysts.

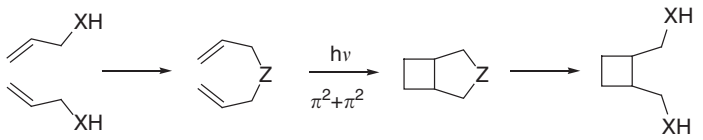
Direct excitation requires appropriate lamp and filter technology to irradiate into the relevant absorption bands of the chromophore in the substrate. These experimental conditions are crucial for selective photochemistry. Before any photochemical experiment, the absorption spectra of substrates as well as that of reagents and the solvents have to be compared in order to



examine and match the irradiation windows. The relevant excited singlet states in organic photochemistry are nπ* and ππ* states of mono- or polyalkenes, alkynes, aromatic substrates, carbonyl, and carbonyl analog groups. The generation of the initial singlet is followed by several deactivation steps that are unproductive with respect to product formation: fluorescence, intersystem-crossing, radiationless decay to the ground state, energy or electron transfer to appropriate acceptor groups either in intra- or intermolecular fashion (Scheme 1). Fluorescence can be measured independently and the singlet lifetimes, determined by time-resolved techniques, are crucial for the application of reagents in intermolecular photoreactions, for example, if reagents can be used in stoichiometric ratios or have to be used in large excess. Efficient intersystem crossing (ISC) generates the excited triplets, which generally have much longer lifetimes but are sensitive against energy transfer to triplet oxygen. From the reaction of excited nπ* and ππ* singlet states, concerted photochemical addition processes can be expected, whereas the corresponding nπ* and ππ* triplets generally react in multistep pathways due to spin restrictions. The electronic spin properties are crucial for the reaction progress, i.e., concerted versus two-step process – influencing regio- and stereoselectivity as well as reaction and quantum yields, respectively.[3]

Scheme 1

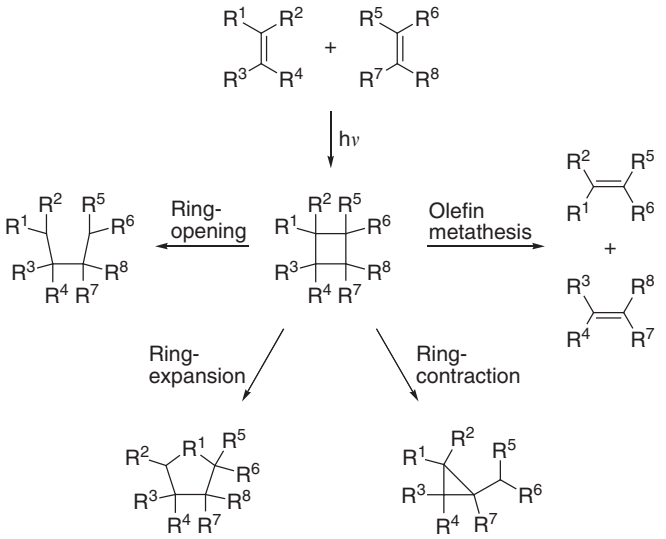
As a competing side reaction, singlet excited nπ* and ππ* states can undergo efficient group transfer reactions. Intermolecular hydrogen transfer to excited singlet states can compete with intersystem crossing; however, in many cases this is not synthetically useful because large excess of hydrogen-donor must be used. Addition of nucleophiles to ππ* singlets is an alternative group transfer process. If alcohols are used in excess (e.g., as solvent), efficient ether formation is possible, which is also studied in enantioselective fashion.[4] Triplet excited ππ* and nπ* states can be selectively generated by energy transfer from appropriate energy donors. Prerequisites for triplet energy donors is a proper triplet energy and high intersystem crossing quantum yields as well as low chemical reactivity of singlet and triplet states. Benzophenone is a typical triplet sensitizer for alkene or polyene ππ* triplets, however, with a strong tendency for hydrogen transfer reactions.



Electronically excited states feature, at the same time, significantly increased reduction and oxidation properties, as compared to ground states. The investigation of PET as a key step in many photochemical reactions was further stimulated by the Nobel Prize awarded work of Marcus[5] and has, in the past few decades, not only led to new synthetic applications,[6] but also to a general paradigm change in photochemistry. As has been described in detail in several reviews,[7] the energetics of light-induced electron transfer can be estimated using a simplified version of the Rehm–Weller equation (Scheme 2; ΔG° = free enthalpy of electron transfer; $E^\circ(\mathrm{Do/Do^+})$ = first oxidation potential of the donor; $E^\circ(\mathrm{A^-/A})$ = first reduction potential of the acceptor; E_{00} = energy difference between ground state and first excited state).[8] Unlike many other physical equations, this relationship immediately shows its chemical relevance: electronically excited states are concurrently much better reductants and oxidants; the actual redox behavior depends on the reaction partner. This concept can be easily explained for the carbonyl–amine system (Scheme 2): the high-lying lone-pair at N and the low-lying antibonding π^*_{CO} render the amine–carbonyl combination suitable for Frontier molecular orbital (FMO)-controlled nucleophile–electrophile ground-state interaction. But only after electronic excitation to the n→π* carbonyl state, an exergonic electron transfer becomes feasible. The same is true for less active electron donors like alkyl carboxylates, unsaturated or strained hydrocarbons, aromatic compounds, and many more.

Scheme 2

To perform an efficient photocycloaddition reaction, the light-absorbing substrate has to be designed carefully: (a) photoexcitation has to be limited to the substrate and neither the product(s) nor potential long-lived reaction intermediates must absorb light in the region applied. This can be achieved by the use of monochromatic light sources or by appropriate filters. Alternatively, triplet sensitizers are advisable that selectively transfer energy to the substrate and absorb in the red-shifted part of the UV–vis region; (b) nondesired electron transfer reactivity of the substrate can be suppressed by introducing electron-withdrawing groups to reduce the donor-capability or electron-donating groups to reduce the acceptor-capability; (c) spin-selectivity has to be investigated for intermolecular photoreactions by variation of the reagent concentration; (d) oxygen sensitivity is often observed for triplet photocyclization reactions where the long-lived substrate donors can transfer energy (or an electron) to triplet oxygen to generate singlet oxygen (or the superoxide radical anion).

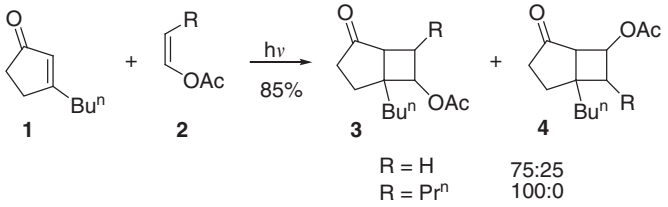


From an orbital symmetry point of view, photocycloadditions of the $\pi^2+\pi^2$- and $\pi^4+\pi^4$-types can be applied for organic synthesis. The $\pi^2+\pi^2$-cycloadditions have been described in recent reviews and can be characterized by the relevant substrates as ene–ene,[9] ene–enone,[10] as well as enone–enone cycloadditions (and carbonyl analogs).[11] The combination of two dienes under photolysis conditions can result in $\pi^2+\pi^2$-(cyclobutanes), $\pi^4+\pi^2$-(cyclohexenes), and $\pi^4+\pi^4$-(cycloocta-1,5-dienes) products.[12] As a special variant of the ene–enone protocol, the photocycloaddition of alkenes to the β-hydroxy enone tautomers of 1,3-dicarbonyl compounds is described as de Mayo reaction. Also, aromatic substrates can be used as ene components, leading to different addition modes which are characterized with respect to the positions involved in the aromatic system as *ortho* (1,2)-, *meta* (1,3)-, and *para* (1,4) aromatic photocycloadditions.[13] Besides direct excitation of the π-chromophore or triplet sensitization, PET is a versatile method for activation of $\pi^n+\pi^m$-substrate combinations. Intermolecular reactions often suffer from the short lifetimes of the excited singlets and the tethering concept has been developed for this purpose. The spatial orientation of two allylic alcohols, for example, by silicon tethering, leads to excellent yields and selectivities in photocycloadditions (**Scheme 3**, $X=SiR_2$). The tether group is most convenient if a nonphotochemical cleavage follows the photocycloaddition.[14]

Scheme 3

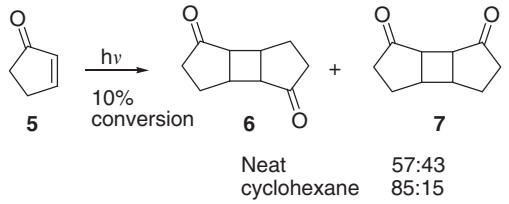
5.04.2 [2 + 2]-Photocycloadditions

[2 + 2]-Photocycloadditions are highly useful transformations in modern organic synthesis, since they provide a straight-forward approach to the strained cyclobutane ring system. In addition to that, up to four new stereogenic centers can be formed during the reaction. Various subsequent synthetic manipulations of the resulting cyclobutane give access to a multitude of products, making the [2 + 2]-photocycloaddition a highly versatile tool (**Scheme 4**).[15]



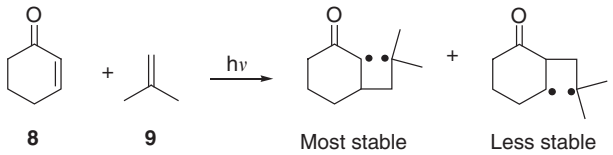
Scheme 4

Several variants of nonheteroatom [2 + 2]-photocycloadditions are known: the addition of one alkene to another (ene–ene), the addition of Michael systems or one Michael system to an alkene (ene–enone, enone–enone), the addition of a carbonyl compound to an alkene (Paternò–Büchi), and the addition of an alkene to an aromatic system (arene–alkene). Concerning [2 + 2]-photocycloadditions, this chapter emphazises ene–enone, ene–ene and enone–enone reactions.



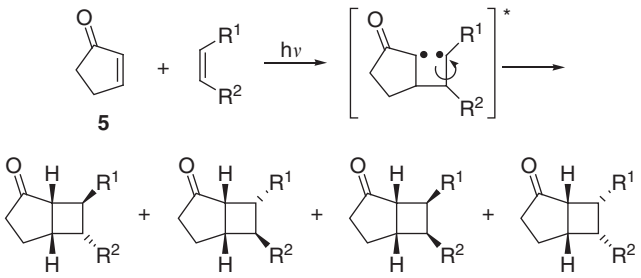
5.04.2.1 Ene–Enone [2 + 2]-Photocycloaddition

5.04.2.1.1 Intermolecular Processes



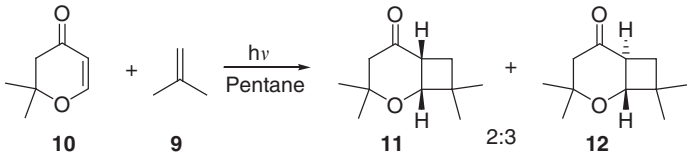
Ene–enone [2 + 2]-cycloadditions are the most widely known type of photocycloaddition forming cyclobutane ring systems. Therefore, extensive research was carried out considering chemo-, regio-, as well as stereoselectivity and application possibilities.[16] It was found that the regioselectivity is affected by steric interactions[17,18] (equation 1), solvent polarity[19,20] (equation 2), and diradical intermediate stability (equation 3).[21]

(1)



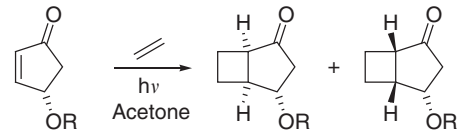
(2)

(3)



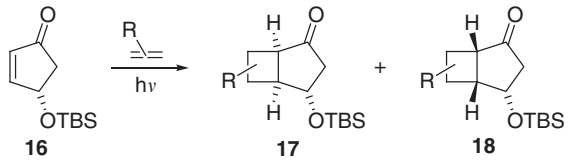
Prediction of the stereochemistry is of equal importance, since up to four new stereogenic centers can be formed of the cycloaddition. In numerous reactions, however, a sufficient control of stereoselectivity has proven to be quite difficult. For instance, the addition of acyclic alkenes to cyclopentenone **5** produces all four possible *cis*-fused bicyclic photoadducts as a result of rotational freedom during the long-lived 1,4-diradicals (equation 4).[22,23]

(4)



With unsaturated five-membered or smaller ring substrates, *cis-trans* isomerization of this reaction partner is inhibited. Larger rings, however, also show loss of cycloalkene stereochemistry. Cyclic enones with ring sizes of five members or less always retain *cis* configuration at the corresponding stereogenic centers of the resulting cyclobutane[18] (equation 4), whereas cyclohexenones often produce significant amounts of *trans*-fused photoadducts **12** (equation 5, no yield given).[24]

This is due to the fact that cyclohexenone triplets are considerably twisted, thus allowing sequential bond formation on opposite faces of the ring.[25]



10 **9** **11** **12** (5)

As expected, preexisting stereogenic centers on either the alkene or the enone can also influence the stereochemistry of the resulting products by steric or stereoelectronic interactions. For example, cyclopentenones **13** and **16** bearing a stereogenic center at C4 lead to an excess of the corresponding *anti* products after irradiation (equations 6 and 7).[26]

(7)

Chiral cyclohexenone **19** exhibits a similar behavior on irradiation, thus influencing the diastereomeric excess of the corresponding *cis* and *anti* products **20**–**22** (equation 8).[27] The application of stereogenic centers tethered to the cyclohexenone ring (e.g., in **23**) also led to a substantial increase in diastereoselectivity (equation 9).[28]

(9)

Solvent variation can also influence the stereochemistry of the photoadducts. Heterocyclic enones such as furanone show similar behavior regarding regio- and stereochemistry. Therefore, stereogenic centers at the furanone ring of **26** can be utilized to influence the resulting product distributions (equation 10).[29]

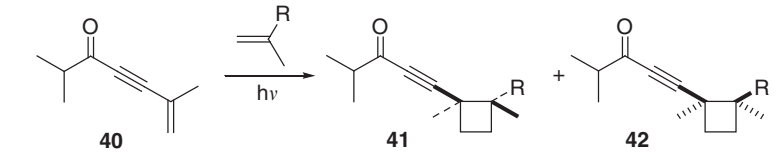
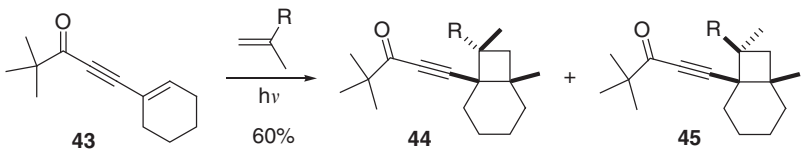
(10)

The reaction of 2(*5 H*)-furanone with ethylene was investigated by computational methods, thus developing reaction energy profiles for the corresponding excited states, biradical intermediates, and products.[30] Recently, the addition of pyrimidines to cyclopentene was also the subject of computational research.[31] Although there are various examples of [2 + 2]-photocycloadditions with excellent regio- and (relative) diastereoselectivities, absolute control of stereochemistry still remains difficult despite the advances in the field of asymmetric thermal syntheses. Only few enantioselective ene–enone [2 + 2]-photocycloadditions are known. The synthesis of grandisol (**34**) from a bicyclic lactam **32** (Scheme 5)[32] and the synthesis of meloscine (**39**) from the quinolone **35** (Scheme 6)[33] using a chiral complexing agent **37** are examples of highly selective asymmetric [2 + 2]-photocycloadditions. The first example involves intramolecular chirality transfer using a 'chiral pool' building block derived from valine as auxiliary. The second example utilizes a chiral sensitizer that transfers the excitation energy to the prochiral substrate in an intermediate hydrogen-bonded host–guest complex.



Scheme 5

Scheme 6



Since [2 + 2] ene–enone photocycloadditions are effective processes with easily available substrates, numerous synthetic applications have been developed for this type of reaction.[34,35] For example, the addition of enynones **40** or **43** to alkenes (equations 11 and 12)[36] proceed with perfect chemoselectivity as the alkyne is completely passive during the cycloaddition. The reaction of a *m*eta di-2-pyrone **46** with ethylene di(methylacrylates) **47** shows sequential inter- and intramolecular cycloadditions, resulting in macrocyclic compounds **48** and **49** with two cyclobutane rings (equation 13)[37] The formation of cyclobutanes was also utilized in the syntheses of natural products like sterpurene (**52**, Scheme 7),[38] bourbonene (**56**, Scheme 8),[39] and alphanamol (**60**, Scheme 9).[40]

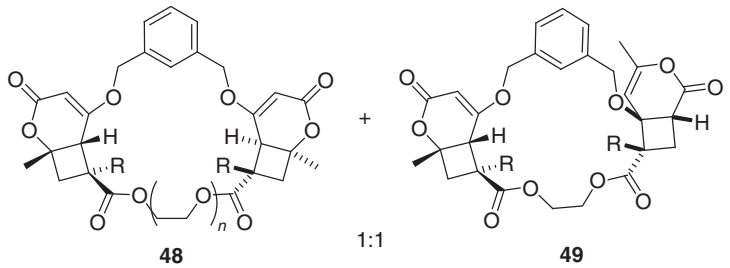
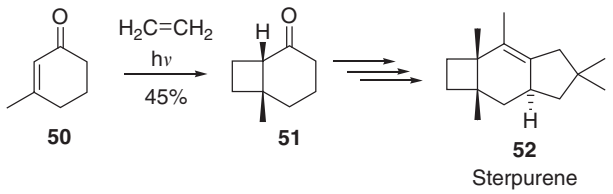
(11)

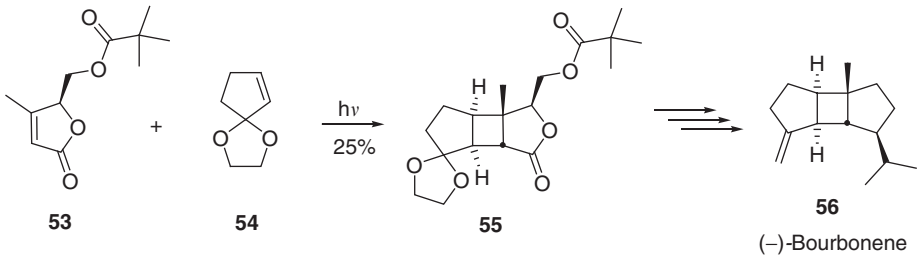


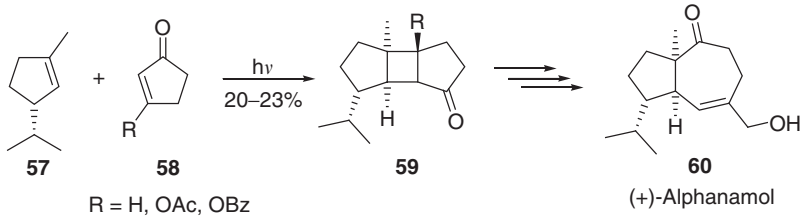
a R = —CN 17:3



b R = 100:0

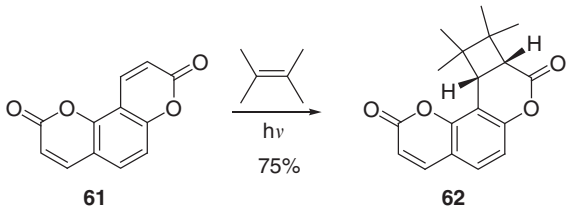
(12)





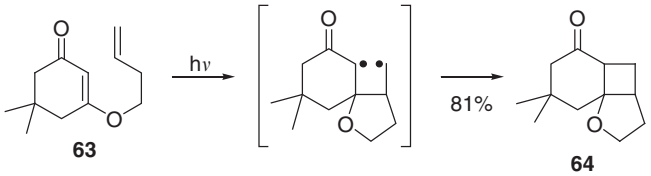
(13)

Scheme 7



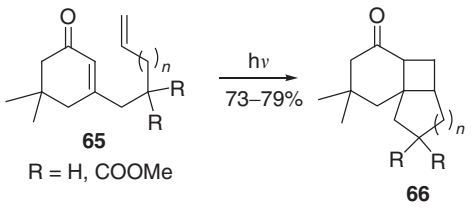
Scheme 8

Scheme 9



Additionally, synthetic applications can also make use of the locoselective addition of alkenes to one out of two enone groups in the same molecule, for example, the selective addition of 2,3-dimethylbut-2-ene to the benzodipyran **61** (equation 14).[41]

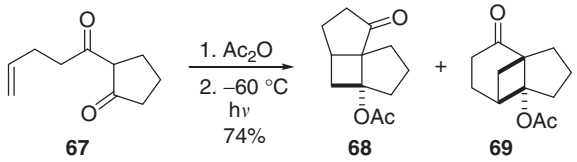
(14)



5.04.2.1.2 Intramolecular Processes

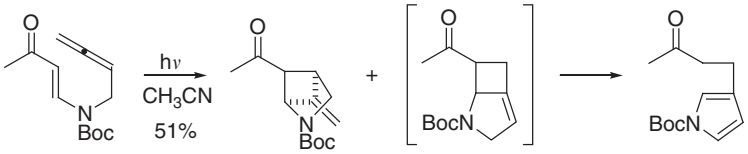
Although intermolecular ene–enone [2 + 2]-photocycloadditions are highly useful tools, the low stereoselectivity observed in many reactions limits the possible applications. An easy solution to this problem can be achieved by temporarily incorporating the two reaction sites in the same molecule, often leading to complex polycyclic compounds with high stereoselectivities. The regioselectivity of the intramolecular ene–enone [2 + 2]-photocycloaddition is generally more predictable due to the geometric constraints in the transition states during the ring formation steps. It is apparent that the formation of five-membered rings is favored in the initial attack of the excited-state enone on the ground-state alkene. This observation was termed the 'rule of five.'[42] For example, the cycloaddition of the β-substituted cyclohexenone **63** with a three-atom tether produces exclusively the straight adduct **64** (equation 15).[43]

(15)



Especially, cyclopentenones and cyclohexenones with linker chains of two or three atoms attached to C-2 or C-3 (**65**) show high regioselectivity. When the reaction sides are tethered with four or more atoms, the straight adducts **66** are formed in most cases albeit with lower regioselectivities (equation 16).[44]

65
R = H, COOMe



66 (16)

Although a multitude of compounds comply with the 'rule of five' during cycloaddition, there are some exceptions. For example, cyclopentenones with terminal alkene groups (e.g., **67**) sometimes show a mixture of straight (**68**) and crossed adducts (**69**) after irradiation (equation 17).[45] Systems bearing an allene as the alkene component also do not comply with the 'rule of five' (**Schemes 10**, **11** and equation 18).[46–49] The strained products with endocyclic double bond are unstable and rearrange to the heteroaromatic products **72** and **75**, respectively. In some cases, the formation of the straight or the crossed adduct is dependent on the tether length (**Scheme 12**)[50,51] or specific functional groups (**Scheme 13**).[52]

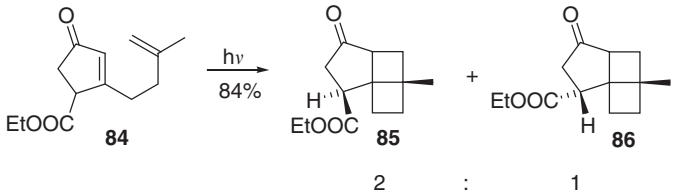
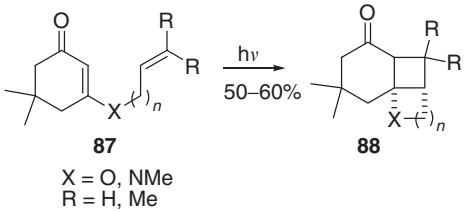
R = H, *n*-Bu

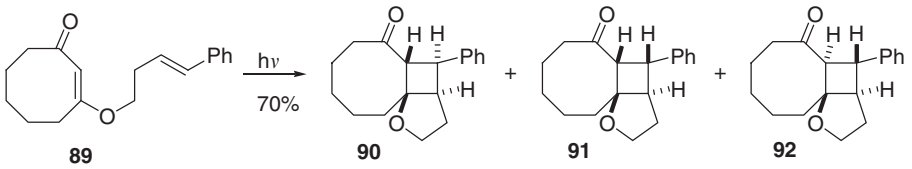


Scheme 12



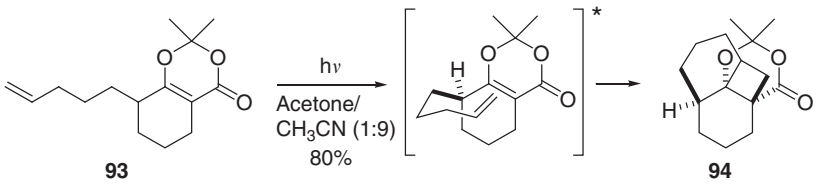
Scheme 13

The preferred formation of five-membered rings in intramolecular cycloadditions is rationalized by the relative orientation of the reaction sites during the initial attack. Unbranched reaction systems usually show 1,5-cyclization, whereas a substituent at C5 can retard the rate of cyclization. However, incorporation of the enone in a five-membered ring reduces the excited triplet twisting, thus altering the cyclization geometry. When both effects are combined as for **84**, 1,6-cyclization becomes predominant (equation 19).[53,54]



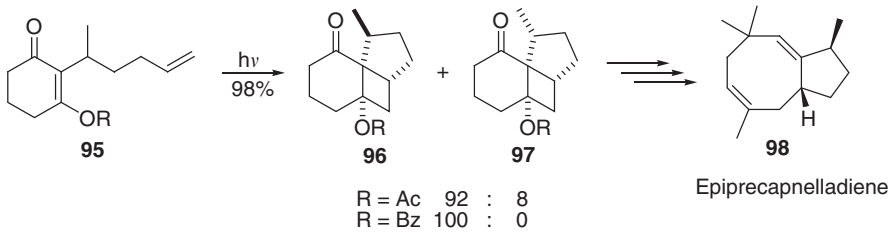
(19)

Similar to that for the regioselectivity, the control of stereochemistry in intramolecular ene–enone [2 + 2]-photocycloaddition is superior compared to intermolecular cycloadditions. The geometric constraints already mentioned before involved in the cyclization often yield to high stereoselectivities. The cyclobutane ring in the photoadducts **88** is *cis*-fused to the linker-chain derived ring in almost all cases (equation 20).[55]

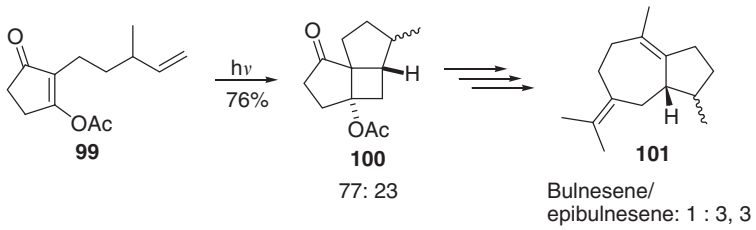


(20)

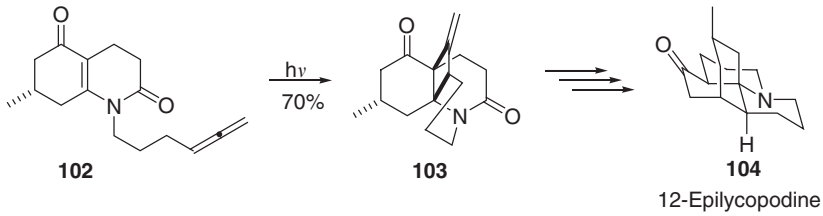
Exceptions to these trends are rare and result from substrates where either the cycloalkenone is larger than six members (equation 21)[56] or the tethering chain is easily able to stabilize the resulting ring junction (equation 22).[57]



(21)

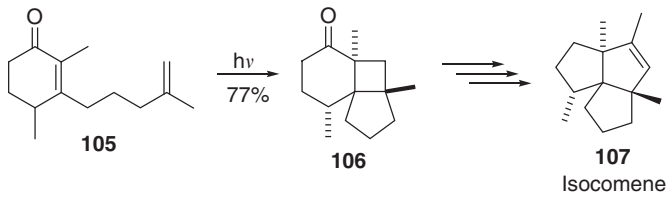


(22)

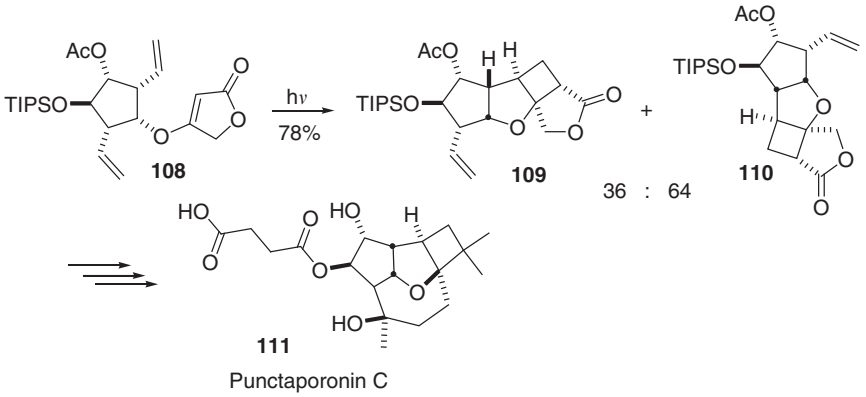


Preexisting stereogenic centers in the starting materials can also influence the stereochemistry in the resulting cycloadducts by steric and stereoelectronic interactions. This was used in the stereoselective synthesis of various natural products like epiprecapnelladiene (**98**, Scheme 14),[58] bulnesene and epibulnesene (**101**, Scheme 15),[59] 12-epilycopodine (**104**, Scheme 16),[60] isocomene (**107**, Scheme 17),[61] punctaporonin C (**111**, Scheme 18),[62] stoechospermol or spatol (**114**, **115**, Scheme 19),[63] and lactiflorin (**118**, Scheme 20).[64]

Scheme 14

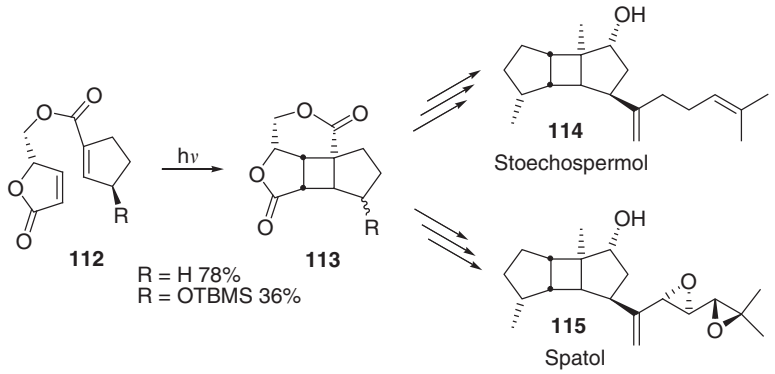


Scheme 15

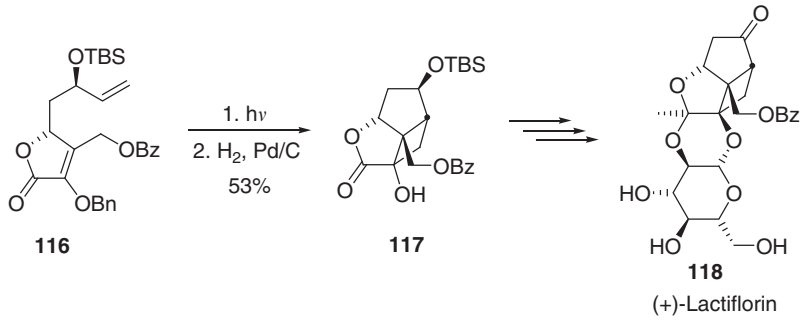


Scheme 16

Chiral substrates have also been used in photocycloadditions for the stereoselective syntheses of hydroxymethylated β-amino acids **121** (Scheme 21)[65] and diterpenoid compounds of the briarellin and asbestinin family **124** (Scheme 22).[52]

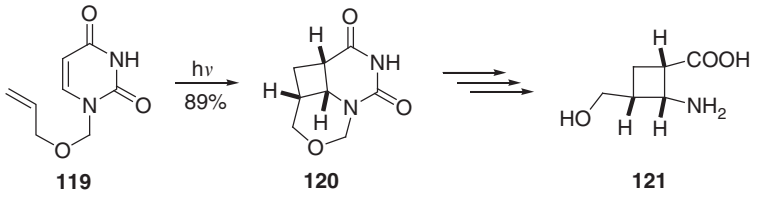


Although various dia- and enantioselective ene–enone cycloadditions have been accomplished with chiral photosubstrates, absolute control of stereochemistry with achiral photosubstrates is still a difficult task to achive. Chiral lactams based on the

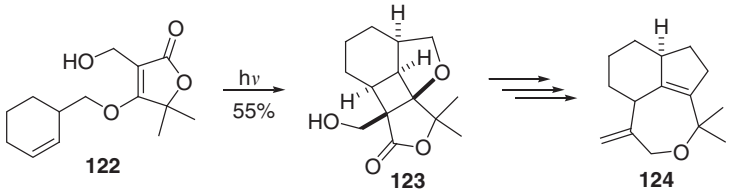


Scheme 17

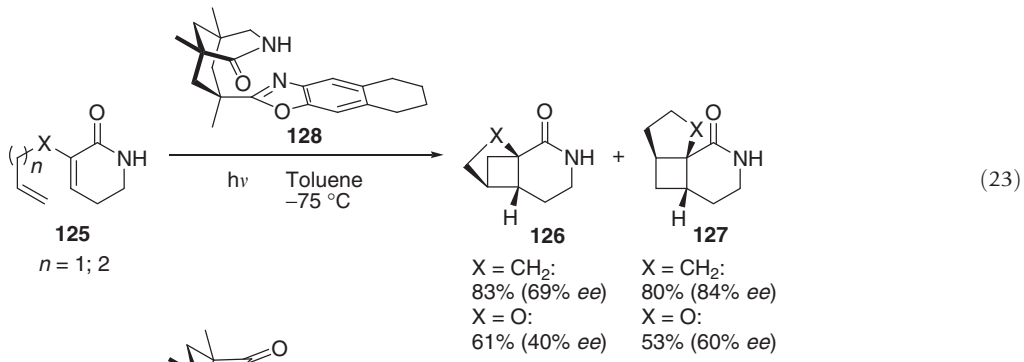
Scheme 18



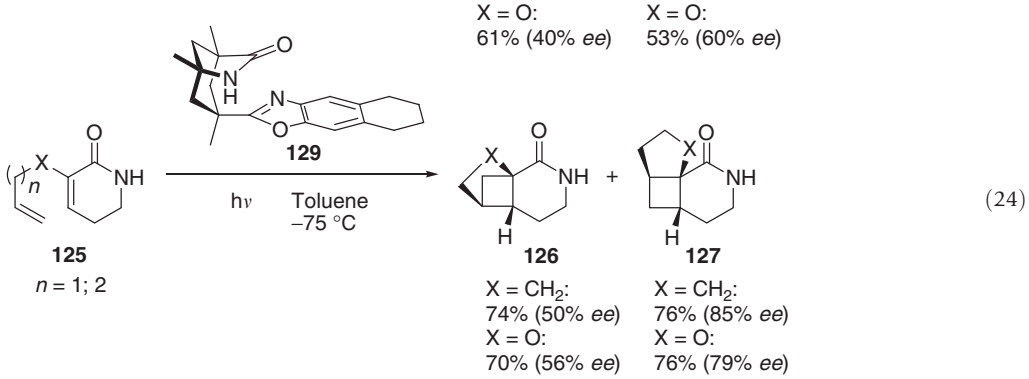
Scheme 19



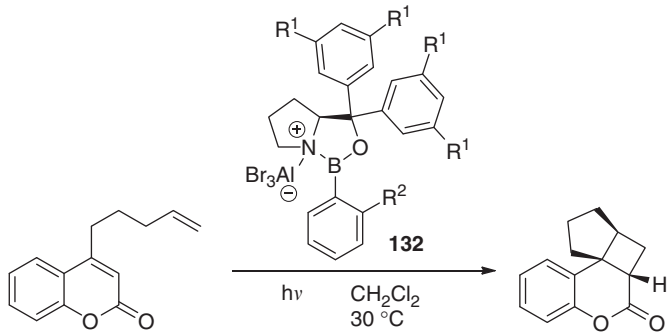
Scheme 20



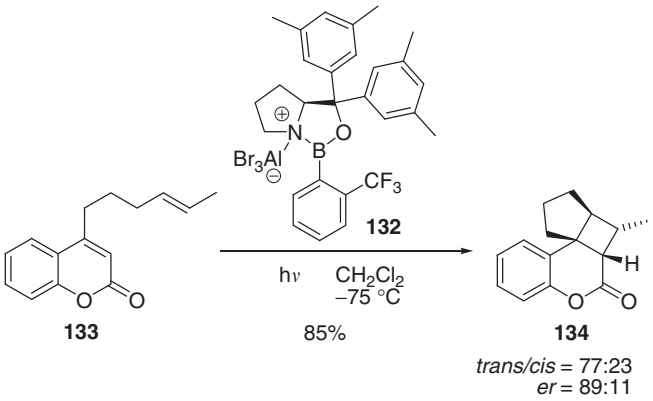
Kemp's triacid as light-absorbing and sensitizing catalysts, which interact with the photosubstrate via hydrogen bonding, have been successfully employed, yielding good to excellent enantiomeric excesses using the constitutional isomers of the catalyst **128** or **129** (equations 23 and 24).[66,67] Chiral Lewis-acids like oxazaborolidines **132** have also yielded moderate enantioselectivities as chiral hosts with catalytic properties (equations 25 and 26).[68]



Scheme 21



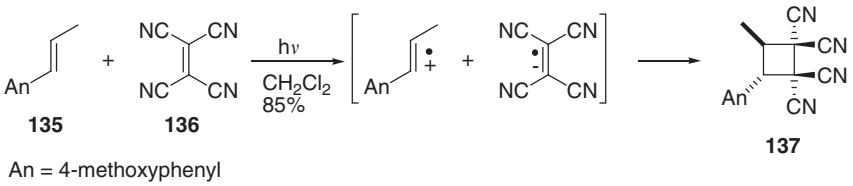
Scheme 22



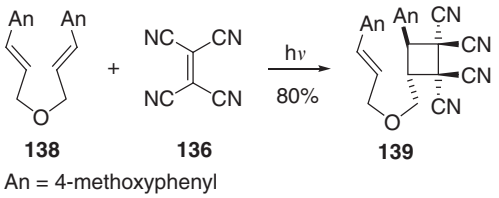
(23)

(24)

(25)



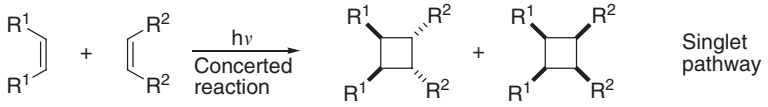
(26)



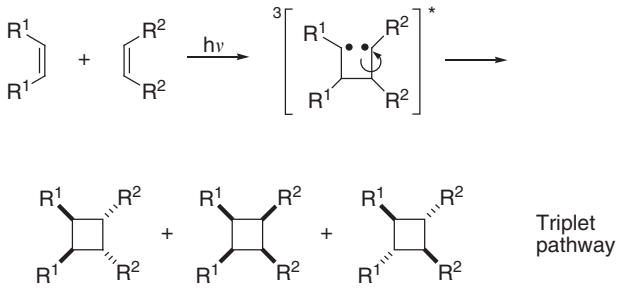
5.04.2.2 Ene–Ene [2 + 2]-Photocycloaddition

5.04.2.2.1 Intermolecular Processes

Compared to ene–enone photocycloadditions, there is a limited number of ene–ene reaction systems which are not tethered or constrained in close proximity. Since the short-lived singlet states[69] are predominant in most excited alkenes, the chance of productive collision is limited. An exception are cycloadditions between electron-rich and -poor alkenes such as methoxyphenyl-substituted alkenes **135** and tetracyanoethylene (**136**), indicating intermediate charge-transfer (equations 27 and 28).[70]

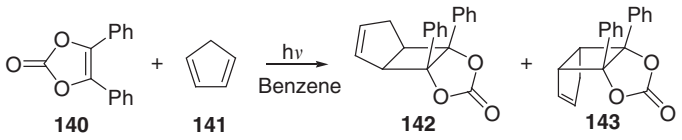


(27)

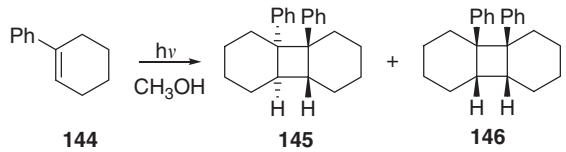


(28)

These matched pairs also benefit from ground state attraction, which leads to a preorientation enhancing the alkene orbital overlap and improving the reaction efficiency. As computational results indicate, photocycloaddition between two propene molecules favors a head-to-tail approach and a concerted reaction pathway via conical intersections.[71] Accordingly, cycloadditions between alkenes with electron-withdrawing groups should favor the formation of the corresponding *trans*-1,3-disubstituted cyclobutane. Although the singlet state is predominant in excited alkene reactions (equation 29), [2 + 2]-photocycloadditons including a triplet alkene excited state are known. Since the lifetime of the 1,4-biradical triplet intermediate formed after the initial attack allows bond rotation, a lower stereoselectivity is expected (equation 30).



(29)

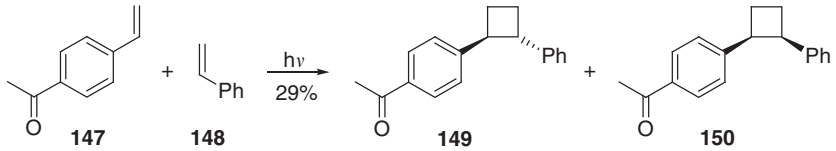


(30)

Therefore, stereochemical analysis of the cycloaddition products can provide direct information on the predominant electronic pathway in the corresponding cycloaddition. Since direct excitation of ene–ene reaction systems often does not lead to effective cycloadditions, triplet sensitizers have been employed in an attempt to facilitate those reactions through triplet sensitization. Although sensitizers like benzil or acetophenone indeed enhanced [2 + 2]-photocycloaddition processes, their application resulted in altered product ratios compared to the direct irradiation (equations 31 and 32, no yields given).[72–75]

Direct excitation	4	:	1
benzil sens.	1	:	9

(31)



Direct excitation	3	:	1
p-OMe-acetophenone sens.	4	:	1

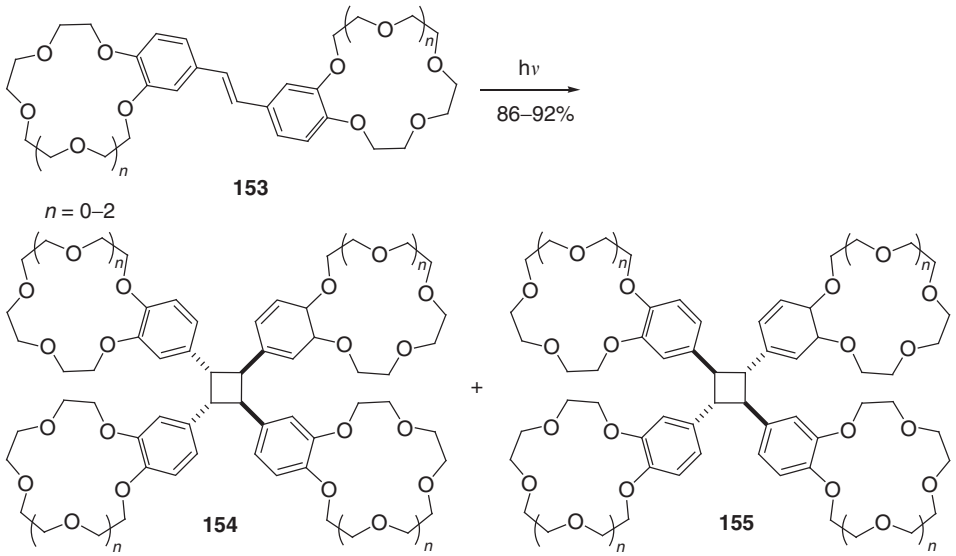
(32)

As triplet-sensitized photoreactions proceed via triplet pathways and long-lived excited states as well as intermediates, product formation often shows thermodynamic control. Singlet cycloadditions proceed from the transition state featuring the greatest frontier orbital overlap, thus affecting the reaction geometry by kinetic control. The product distributions also indicate that π-stacking plays an important role during the reaction by stabilizing the transition states. In addition to that, the product quantum yields suggest the formation of a loose exciplex in both reaction pathways.

In contrast to the computational results obtained on the dimerization of propene, arylsubstituted alkenes like 1-phenylcyclohexene **144** (equation 32) or styrene **148** (equation 33) preferentially give the corresponding head-to-head products.

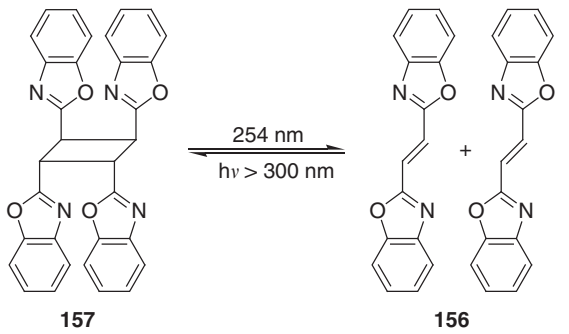
	11	:	1

(33)



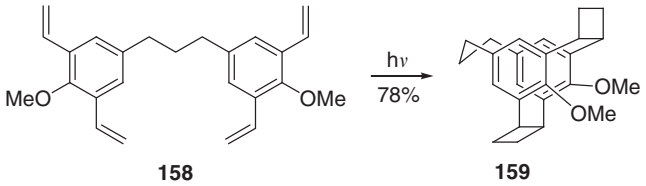
In both cases, preferentially the *trans*-1,2-products are formed. This selectivity can be rationalized for the triplet pathway as a result from steric interactions at the stage of the 1,4-triplet biradical intermediates.

As already discussed for ene–enone reactions, complete control of ene–ene photocycloaddition stereochemistry is a difficult task to achieve. So far, no reports of catalysts or complexing agents which were successfully employed to enhance enantioselectivities are known. Preexisting stereogenic centers on the reaction substrates (e.g., in **151**), however, are well capable of directing the product stereochemistry (equation 34).[76]

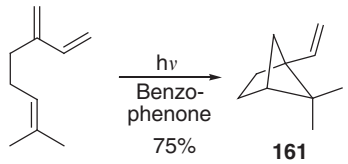


(34)

Useful applications of intermolecular ene–ene photocycloadditions are not as common as for ene–enone reactions, but still exhibit interesting possibilities. One example is the photodimerization of bis(crown)stilbenes **153** to yield unusual bis-sandwich complexes **154** and **155** (equation 35).[77] The reversible dimerization of 1,2-bis-benzoxazol-2-yl-ethene (**156**), forming a rewritable optical data storage material medium **157**, is another interesting example of ene–ene photocycloadditions (equation 36).[78]

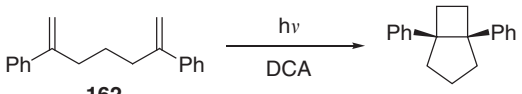


(35)



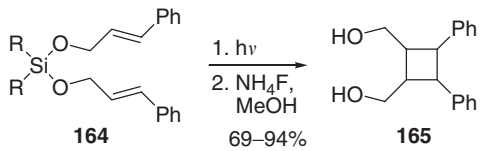
(36)

5.04.2.2.2 Intramolecular Processes

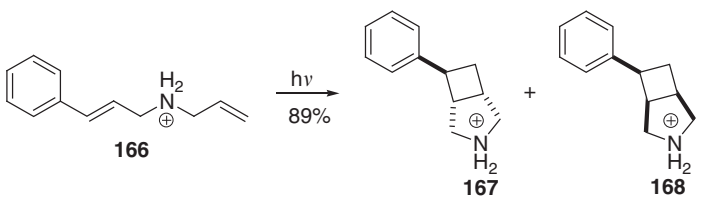


Compared to their intermolecular versions, intramolecular ene–ene photocycloadditions are applied more frequently. Since the two reaction sites are connected by a tether group, simple bond rotation allows productive interactions between the corresponding π-orbitals, thus raising the chance of reaction in the lifetime of the excited states. Also, there is evidence of π-stacking for closely held moieties, therefore improving the orbital interactions between the alkenes.[9] The most prominent examples of the tethering concept are alkyl linked styrenes **158**, which yield cyclophanes **159** on irradiation (equation 37).[79] The application of triplet sensitizers can furthermore enhance the photocycloaddition process (equations 38 and 39).[80,81]

158 159 (37)



160 161 (38)



162 163 (39)

Tethered alkenes show significantly higher reactivities and various temporarily usable tethers have been developed in order to facilitate cycloaddition in otherwise ineffective reaction systems. In this regard, the silyloxy tethers in **164** have been proven to be quite useful, giving rise to cyclobutane formation in good to excellent yields (equation 40).[82] Alkyl tethers bearing central amine functionalities have also been employed, yielding cycloadditions with high stereoselectivity (equation 41).[83] This concept was successfully applied for the synthesis of natural products like coerulescine (**171**) and horsfiline (**172**, Scheme 23).[84] Facilitated ene–ene reactions have also been observed for palladium-tethered complexes **173** (equation 42),[85] yielding photochromic systems. Platinum- (**175**, equation 43, no yields given)[86] and iridium- (**177**, equation 44)[87] tethered complexes show intramolecular cycloaddition as well, yielding highly symmetric cyclobutane compounds.

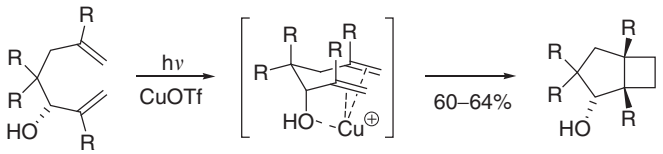
Copper(I)-organic compounds constitute another example for reversible noncovalent tethering reagents. Although there is still some discussion if the copper complex is the chromophore rather than the uncomplexed alkene substrate, copper(I)-compounds are capable of facilitating ene–ene reactions (equation 45).[88]

179 **180** (45)

R = H, n-Bu



In addition, copper(I)-catalyzed cycloadditions often proceed with high regioselectivity and impressive stereoselectivity due to intramolecular coordination effects (equation 46).[89] The photoreactions of hydroxysubstituted 1,6-heptadienyl compounds are excellent examples regarding these effects (equations 47 and 48),[69,90] providing a synthetic route to grandisol (**34**, Scheme 24) and *β*-panisene (**192**, Scheme 25)[91] among other possible target molecules.

Since intramolecular ene–ene reactions are capable of forming large multicyclic hydrocarbon cages, they can also be used for assembling structures like methylated cubane **194** (equation 49, no yields given)[92] or norbornene dimer structures **197** (equation 50).[93]

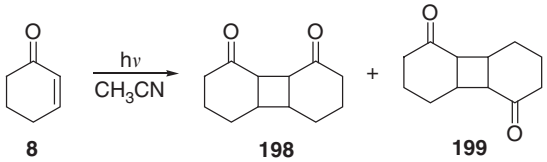
5.04.2.3 Enone–Enone [2 + 2]-Photocycloaddition

In contrast to the variety of examples and synthetic applications of the ene–enone cycloadditions, enone–enone cycloadditions have found little consideration. Until recently, only cyclic enones have shown enone–enone reactions with sufficient efficiency (equation 51).[94,95] Among those reactions, the dimerizations of cyclopentenones and cyclohexenones were intensively investigated.



(51)

The regiochemistry of these dimerisations (head to head or head to tail) is strongly affected by solvent polarity (e.g., equation 2) and, in case of nonpolar solvents, also affected by ketone concentrations (equation 52 and 53, product ratios after 10% conversions).[96]

5 6 7 (52)

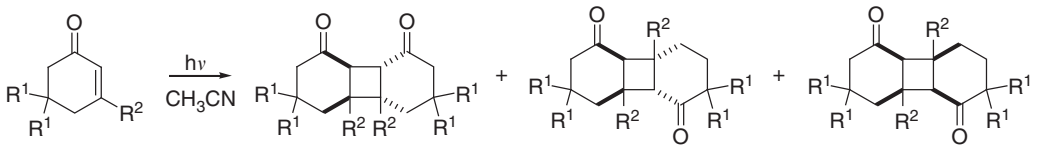
8 198 199 (53)



2 : 1

As already described for ene–enone reactions, the stereoselectivity of enone–enone cycloadditions can be influenced by various steric and stereoelectronic interactions between the substrates (equations 54 and 55, no yields reported).[97] Conducting these reactions in zeolites can also alter the ratio between the corresponding photoadducts, which can lead to high diastereomeric excesses.[98,99]

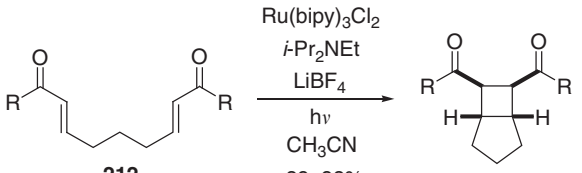
(55)



Acyclic enones usually show no enone–enone photocycloaddition reactivity upon direct excitation because of *E*/*Z* isomerization that leads to thermalization of the excitation energy. Recently, however, ruthenium–bispyridin complexes have been successfully employed as photocatalysts in various inter- (equation 56)[100] and intramolecular (equation 57);[101] enone–enone cycloadditions, yielding photoadducts with perfect regio- and high diastereoselectivity via a oxidative quenching cycle (**Scheme 26**).[102]

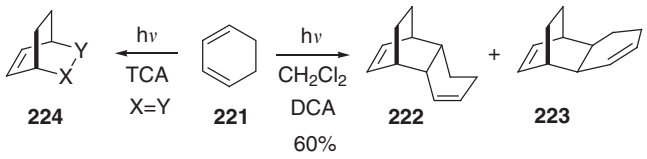
5.04.3 [4 + 2]-Photocycloaddition

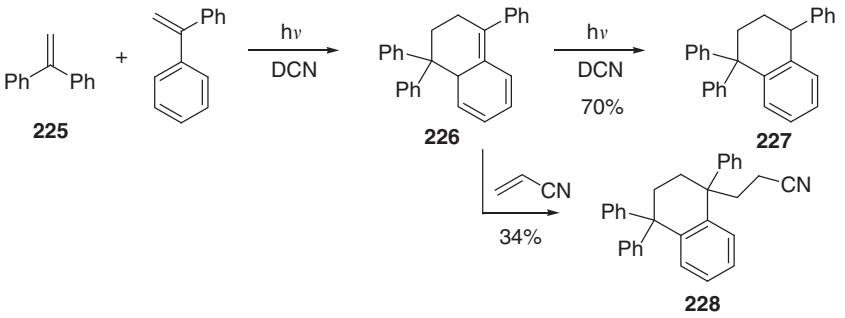
5.04.3.1 Intermolecular Processes



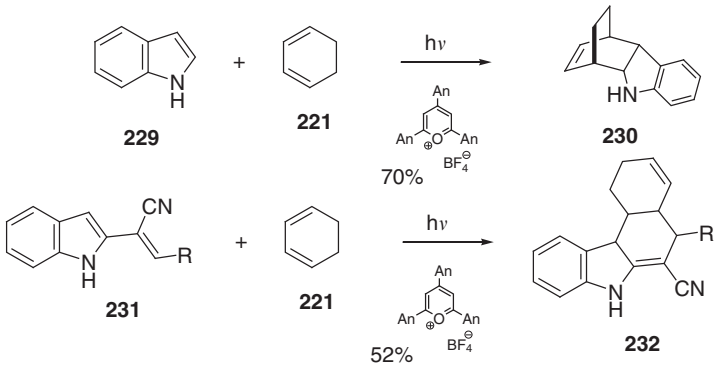
From the viewpoint of orbital symmetry, supra-supra [4 + 2]-cycloadditions (Diels–Alder reactions) are photochemically forbidden and thermally allowed.[103] Thus, the majority of these reactions are conducted either by thermal activation at higher

temperatures or by Broensted/Lewis acid catalysis at room temperature or at lower temperatures.[104] The (thermal) Diels–Alder reactions belong to the most relevant processes for organic synthesis of complex molecules.[105] In general, the majority of these reactions relate to the combination of electron-rich dienes and electron-poor dienophiles. Catalytic variants often increase the acceptor properties of the dienophiles by complexation with Broensted or Lewis acids. An analogous activation mode is the radical cation generation from dienophiles that are converted into superelectrophiles. This has been shown for numerous substrates using thermal one-electron oxidants (e.g., aminium radical cations).[106] Alternatively, PET can be used for generation of radical ions, albeit photochemical processes can also lead to competing [2 + 2]-cycloadditions. A good example for this interplay is the reaction of phellandrene (**214**) and 4-methoxystyrene **215**.[107] The reaction of these substrates in the presence of pyrylium salts as electron transfer catalysts leads to intermolecular [4 + 2] (**216**, **217**) as well as [2 + 2] cycloadducts (Scheme 27). At low substrate concentrations, the formation of the [4 + 2] product prevails with appreciable amounts of homodimers from diene and styrene. At higher concentrations, homodimers and [2 + 2] cycloadducts are formed in larger amounts. The results indicate that in both cases the substrates can be oxidized by the excited sensitizer to the corresponding radical cations.

Scheme 27



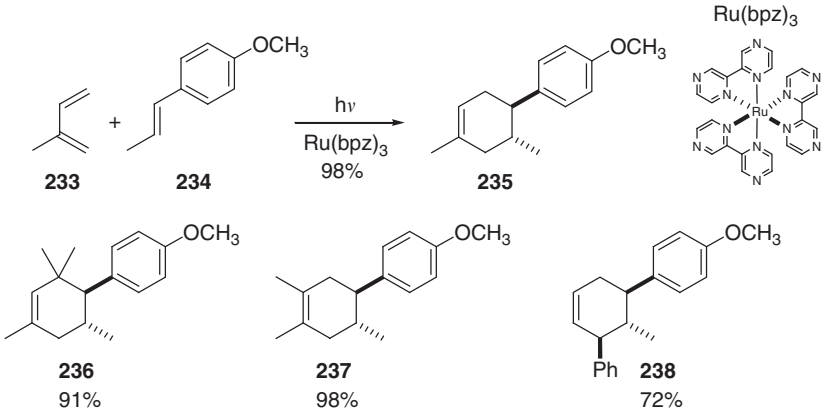
A key step in the synthesis of the natural sesquiterpene substrate *β*-selinene is the phenylvinyl sulfide (**218**) photocycloaddition to the limonene-derivative **219** catalyzed by the photosensitizer 1,4-dicyanobenzene (DCB) in 60% yield.[108] The photodimerization of 1,3-cyclohexadiene (**221**) is another exceedingly well studied process. As a typical photocatalyst, 9,10-dicyanoanthracene (DCA) was used and a 4:1 *endo*/*exo*-mixture of dimers **222**, **223** was isolated in a total yield of 60%.[109] In the presence of electron-rich dienophiles X=Y, the 1,3-cyclohexadiene radical cation can be trapped to give bicyclo[2.2.2]octane derivatives **224**, for example, with styrenes or indene as substrates and 2,6,9,10-tetracyanoanthracene (TCA) as PET-catalysts (Scheme 28).[110]



Scheme 28

Better control of chemoselectivity can be achieved by controlled one-electron oxidation of the dienophile. Careful evaluation of the correct sensitizer for rapid PET is thus necessary.[111] Besides organic sensitizers, covering an impressive range of excited state redox potentials, transitions metal complexes have been used for decades and were re-discovered in recent years especially in context with stereoselective photoredox catalysis.[112] Diene and dienophile can also be part of a single substrate molecule and the photochemical Diels–Alder reaction leads a homodimerization. This is analogous to the dimerization of isoprene as the archetypical thermal [4 + 2] homodimerization. 1,1-Diphenylethylene (**225**) is a PET-active substrate and sensitization by 1,4-dicyanonaphthalene (DCN) as PET catalyst leads to a nonaromatic product that isomerized to the tetrahydronaphthalene **227** or is trapped by enophiles, for example, acrylonitrile (Scheme 29).[113]

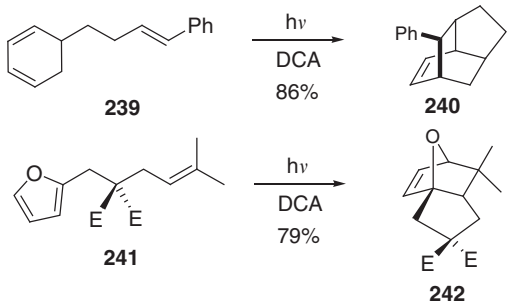
Using electron-rich dienophiles that can be easily oxidized by PET, the cycloaddition sequence can be reversed, i.e., the dienophile radical cation traps the diene. For indole and 1,3-cyclohexadiene (and other 1,3-dienes), this process leads to a tetracyclic dihydroindole derivative in high yields and with high *endo* selectivity. In this case, pyrylium salts were applied as PET catalysts.[114] When 2-vinylindoles were applied in the presence of 1,3-cyclohexadiene, the role of reagents is inverted and the acceptor diene is trapped by the donor cyclohexadiene (Scheme 30).[115]



Scheme 29

Scheme 30

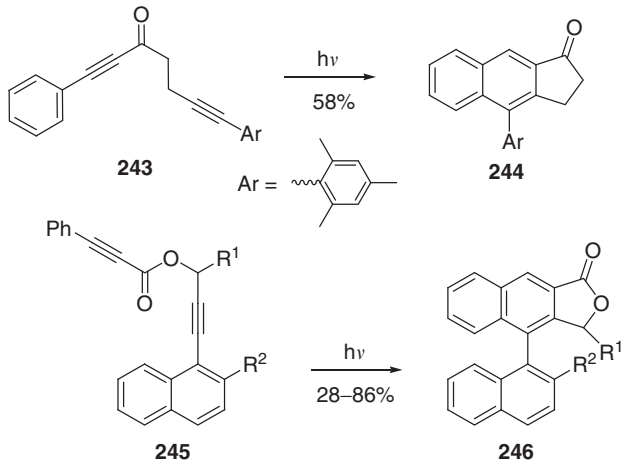
Acyclic reaction partners can also be activated for photochemical Diels–Alder reactions by means of PET catalysis. Analogous to the [2 + 2] PET-catalysis,[102] the [4 + 2] cycloaddition of isoprene (**233**) to a styrene derivative **234** is efficiently catalyzed by a ruthenium tris(bipyrazyl) PET sensitizer (equation 58).[116]



(58)

The reaction was subsequently expanded to radical anion hetero-Diels–Alder reactions[117] and evaluated on a theoretical basis.[118] As a sacrificial electron acceptor, oxygen was used in the optimized version instead of methyl viologen and less than 1 mol% of the PET catalyst was sufficient to convert a number of diene/alkene combinations into Diels–Alder products.

5.04.3.2 Intramolecular Processes

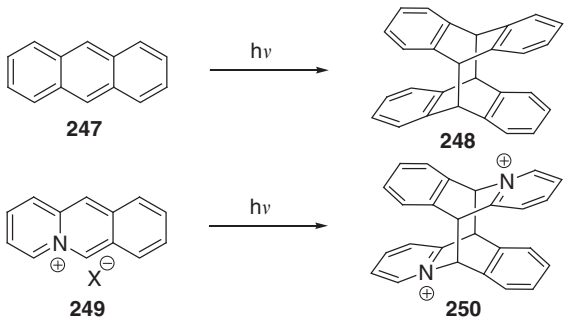


Transformation of the concepts for the intermolecular [4 + 2] photocycloaddition to substrates with tethered dienes and dienophiles leads to intramolecular photochemical Diels–Alder reactions, for example, the PET-DCA sensitized reaction of the cyclohexadiene/styrene pair[119] or the furan/alkene pair (**Scheme 31**).[120]

Intramolecular versions allow also for the generation of highly strained intermediates than can be stabilized by subsequent hydrogen transfer. The intramolecular photo-dehydro Diels–Alder (PDDA) reaction serves as a prominent example

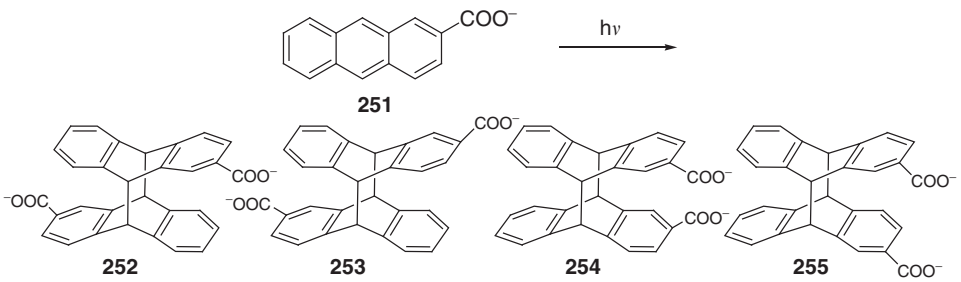
Scheme 31

(Scheme 32).[121] The intramolecular PDDA of propargyl ketone **243** leads to the mesityl-substituted naphthalene **244** after [4 + 2]-photocycloaddition and intramolecular hydrogen transfer.[122] Atropisomeric binaphthyls **246** can also be generated from chiral propargyl esters **245** by direct photolysis.[123]



Scheme 32

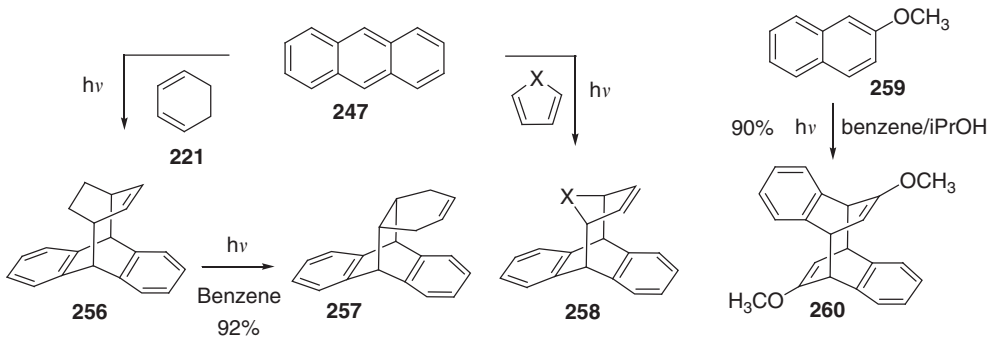
5.04.4 [4 + 4]-Photocycloadditions



5.04.4.1 Intermolecular Processes

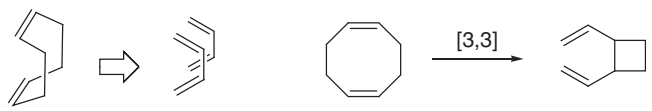
From the viewpoint of orbital symmetry, supra-supra [4 + 4]-cycloadditions are photochemically allowed and thermally forbidden.[103] The archetype of a photochemical [4 + 4]-cycloaddition reaction is the dimerization of anthracene **247**, reported already by J. Fritzsche in 1867.[124] The reaction pathways that originate from the electronic excitation of 1,3-dienes are summarized in numerous reviews.[12] The relevant reactive species in diene photochemistry are the singlet and triplet states (by direct excitation or by triplet sensitization), respectively, as well as radical ions originating from PET steps. After the early experiments that described the formation of a dimer by irradiation of anthracene in solution, this process disappeared from the chemical literature for a considerably long period of time. Only recently, the potential of anthracence photodimerization[125] was rediscovered and several applications of this reversible thermo/photochromic system were developed, for example, for photochemical upconversion[126] or molecular switches.[127] Other useful substrates for photodimerization are acridizinium salts **249** that give rise to the formation of *anti*, *trans*-type adducts (Scheme 33, general processes).[128] The regioselectivity of the reversible photodimerization of substituted acridizinium salts was investigated in solution and under solid-state reaction conditions.[129]

In the context of photochirogenesis, the photocyclodimerization of 2-anthracene carboxylates **251** constitutes highly relevant experiments. Under these conditions, two chiral and two achiral products are formed, the *syn*, *anti* head-to-tail (HT) and *syn*, *anti* head-to-head (HH) diastereoisomers (equation 59). The formation of these compounds is dependent on the reaction conditions, especially under chiral environment conditions; also enantioselectivity for the formation of the chiral photoproducts was obtained, for example, with amino acid derived organocatalysts,[130] in human serum albumin,[131] polysaccharide matrices,[132] with naphthalene-capped cyclodextrins,[133] or in ionic liquids.[134] Recently, also the wavelength dependence of the supramolecular photocyclodimerization in γ-cyclodextrins was observed.[135]



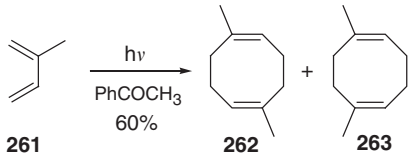
Scheme 33

(59)



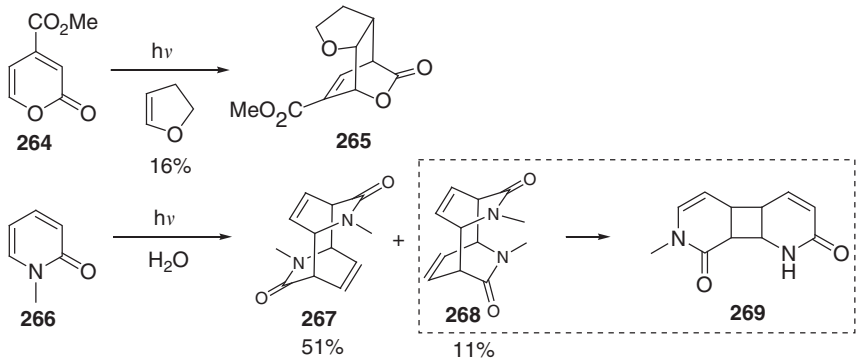
Anthracenes constitute an excellent scaffold for the [4 + 4]-cycloaddition of other dienes such as 1,3-cyclohexadiene or cyclopentadiene.[136] The [4 + 4] cycloadducts of 1,3-cyclohexadiene to anthracene (**256**) or tetracene can be rearranged to the corresponding [4 + 2] cycloadducts **257** by benzene-sensitized photolysis (Scheme 34).[137]

Scheme 34



Naphthalene photochemistry is less intensively explored. Irradiation of 2-methoxynaphthalene **259** results in an efficient regioselective photocyclo dimerization.[138] The cycloaddition of naphthalene to other cyclic dienes has also been reported. The corresponding reactions with benzene and benzene derivatives result in very low yields of [4 + 4] products and are synthetically less useful. Benzene derivatives prefer *ortho*- and *meta*-photocycloaddition chemistry. In analogy to substituted anthracences, the enantioselective photocyclodimerization of 3-methoxyl-2-naphthoate in γ-cyclodextrin[139] and other chiral auxiliaries was investigated.[140]

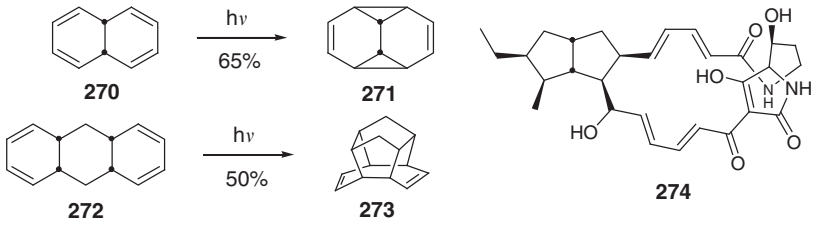
Open-chain and nonaromatic diene compounds are less controllable and more diverse in cycloaddition photochemistry. The photochemistry of the parent diene, 1,3-butadiene, is complex and results in a series of products from unimolecular and bimolecular reactions,[141] among them [2 + 2], [4 + 2], and [4 + 4] photocycloadducts. By use of electron transfer sensitization, the [4 + 4] path can be suppressed.[142] One fascinating property of the [4 + 4]-cycloadducts should be mentioned from the beginning: because the central ring systems is a double Cope system (1,5-cyclooctadiene), Cope-rearrangements can easily be induced either thermally or photochemically to give the formal [2 + 2] cycloadducts (Scheme 35).[143]



Scheme 35

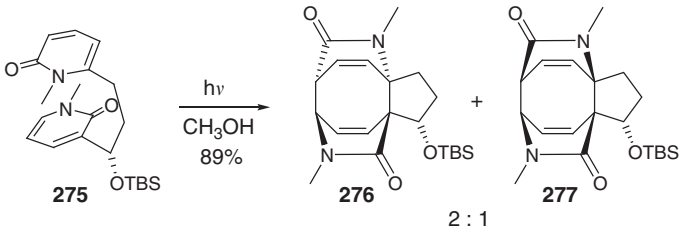
The simple model nonsymmetric 1,3-diene isoprene **261** gives a mixture of the [2 + 2], [4 + 2], and [4 + 4] cycloadducts (**262**, **263**) in sensitizer-dependent ratios.[144] When acetophenone was used as triplet sensitizer, 60% relative yield of isomeric 1,5-cyclooctadienes were formed (equation 60).

(60)



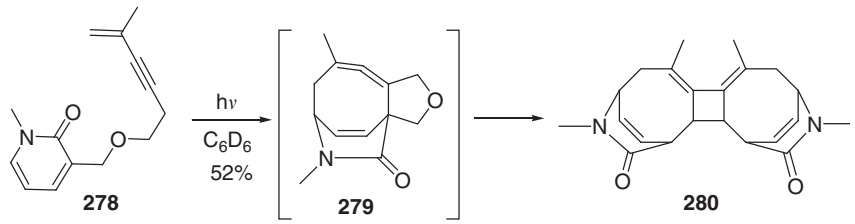
A combination of a conformationally fixed s-*cis* 1,3-diene subunit with activating functional groups, for example, heterocyclic cyclohexadiene analogs, serves as the blueprint for highly active substrates for intermolecular [4 + 4] photocycloadditions. 2-Pyrones are cyclic π^4 components that show [2 + 2] and [4 + 2] photochemical reactivity with alkenes, for example, the reaction of the 2-pyrone-5-carboxylate **264** with 2,3-dihydrofuran yields a mixture of [2 + 2] and the [4 + 2] cycloadduct **265** in 38% and 16% yield, respectively.[144] In contrast to that, 2-pyridones result in efficient formation of the [4 + 4]-cycloaddition products **267** and **268** that can Cope-rearrange to cyclobutanes (e.g., **269**) from the correct stereochemical precursor (**Scheme 36**).[145] 2-Pyridones show [4 + 4] photoreactivity with furan and naphthalene as π^4 reaction partners.[146]

Scheme 36



5.04.4.2 Intramolecular Processes

Anthracene can be tethered to other cyclic dienes by alkyl or ethylenglycol chains, for example, in dendrimers with anthracene cores.[147] The photolysis of these dendrimers leads to intramolecular [4 + 4] cycloadduct formation between the π^4 components anthracene and arenes in the side chain, a reaction that is seldomly observed in an intermolecular fashion.[148] A dihydronaphthalene **270** with a saturated central C–C bond constitutes a perfect model compound for the intramolecular $\pi^4 + \pi^4$ interaction and the corresponding tetracyclic product **271** is formed in good yields on irradiation.[149] The analogous hexahydroanthracene **272** results in the cage compound **273** in moderate yields.[150] Another illustrative example was reported for a cyclohexadiene-annulated fullerene.[151] Cyclooctane-based natural products are obvious target molecules for intramolecular [4 + 4] photocycloadditions as shown for alteramide A (**274**) that is quantitatively cyclized by visible light irradiation (**Scheme 37**).[152]



Scheme 37

The intensively studied photochemistry of 2-pyridones is applicable also for intermolecular versions. There are numerous cyclooctene-containing natural compounds that constitute potential targets for [4 + 4]-photocycloadditions. In an approach to the fusicoccin skeleton, a C_3-linked bis-pyridone **275** was used as substrate, leading to cyclopentano-annulated amide-bridged cyclooctadienes **276** and **277**, respectively (equation 61).[153,154]

(61)

The cycloaddition stereochemistry was studied with an additional cyclopentane ring annulated to one of the pyridines,[155] and several other applications in natural product synthesis were reported.[156] Intramolecular enyne/pyridione photocycloadditions lead to highly strained bridged 1,2,5-cyclooctatrienes **279** (cyclic allenes) that are substantially bent and thermal dimerize to give a series of the less strained dimers (e.g., **280**, Scheme 38).[157]

Scheme 38

5.04.5 Conclusions and Outlook

Harvesting solar radiation is one of the central challenges for mankind in the forthcoming decades. Photochemical reactions might be one solution out of many. Shifting the absorption window to the red is therefore crucial. Photochemical redox catalysis is a rediscovered field of activation for many reaction pathways and will probably replace many traditional photochemical routes that produced thermal waste and open new routes to synthetically valuable products of photocycloaddition reactions.

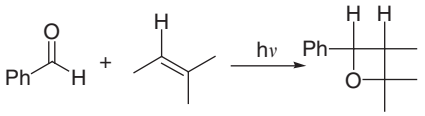
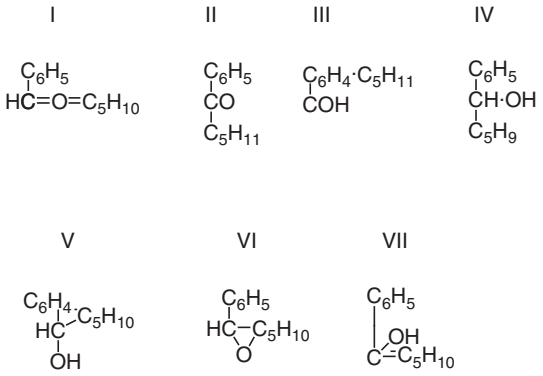
5.05.1 Introduction

The synthesis of oxetanes can have great importance in the development of compounds with relevant biological properties: an oxetane ring is present in the scaffold of Taxol® (**1**), an important drug used in the treatment of ovarian cancer[1]; merrilactone A (**2**), a sesquiterpene dilactone with neurotrophic activity[2]; and several antiviral oxetanes, such as **3**, **4**, and **5**, have been described in the literature (Scheme 1).[3–5]



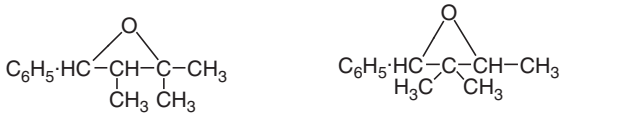
1 **2** **3** **4** **5**

Scheme 1



In 1909, Paternò studying the photochemical reaction of benzophenone with amylene showed the formation of the corresponding [2 + 2]cycloadduct (Scheme 2).[6] He started his first article in this field with these words: "In una prima esperienza abbiamo esposto un miscuglio equimolecolare di amilene (gr. 43) e di aldeide benzoica (gr. 67) in un tubo chiuso, dal 5 dicembre 1907 al 20 marzo 1908, cioè per circa tre mesi e mezzo della stagione invernale. Il contenuto del tubo leggermente colorato ed un poco ispessito fu sottoposto alla distillazione frazionata: conteneva ancora dell'amilene e dell'aldeide benzoica inalterata, e distillava da 180° fin sopra 300°, però la porzione maggiore, del peso di gr. 48, passava fra 200° e 250°.[7] (In a first experiment we exposed an equimolecular mixture of amylene (gr. 43) and benzaldehyde (gr. 67) in a sealed tube from 5 December 1907 until 20 March 1908, for almost three months and a half in the winter. The lightly colored and little thickened contents of the tube were fractionally distilled: they still contained amylene and unmodified benzaldehyde and distilled from 180° until over 300°; however, the main fraction, almost gr. 48 in weight, distilled between 200° and 250°)." Some pages later he wrote: "Per spiegare la formazione di un composto di amilene e benzaldeide sei ipotesi sono possibili che conducono a sei diverse

formole di struttura. E cioè: o che amilene bivalente si colleghi all'atomo di ossigeno, formando un composto di ossonio; o che l'amilene unendosi all'idrogeno del gruppo aldeidico formi il radicale amile, o che il radicale amile si formi a spese di un atomo di idrogeno del gruppo fenile al quale resterebbe congiunto, o che l'amilene trasformi l'ossigeno chetonico in ossidrile formando il gruppo amilenico, o che pur formandosi l'ossidrile l'amilene si mette a cavallo fra il carbonio aldeidico ed il fenilico, o ancora che l'ossigeno dell'aldeide si metta a cavallo fra l'amilene ed il benzilidene, o finalmente che l'amilene si unisca per le sue due valenze al carbonio del gruppo aldeidico.



Scheme 2

I composti che ne risultano avrebbero la seguente struttura.

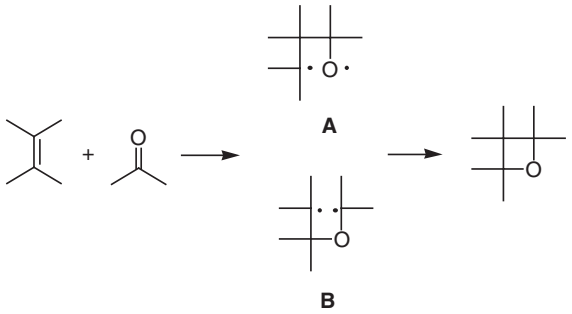
La prima di queste formole non ha alcun carattere di probabilità, avuto riguardo alla formazione ed alle proprietà dell'ossonio, la seconda e la terza dobbono escludersi mancando nel composto le proprietà aldeidiche o chetoniche, la quarta, la quinta e la settima debbono pure escludersi perché non abbiamo potuto riconoscere la presenza di un ossidrile nel composto, cosicché resta come maggiormente probabile la formola sesta. E tenuto presente che il nostro composto si forma dal trimetiletilene esso può corrispondere ad uno dei seguenti schemi:

Ossido di
1. Fenil-2.metil-3,3.dimetil-
trimetilene

Ossido di
1. Fenil-2,2.dimetil-3.metil-
trimetilene

La scelta fra queste due formole è per ora prematura. (To explain the formation of a compound of amylene and benzaldehyde six hypotheses are possible that lead to six different structure formulas. In the order: either the bivalent amylene joins to the oxygen atom to give an oxonium compound; or the amylene, joining to the hydrogen of the aldehydic group, gives the amyl radical, or the amyl radical is obtained at cost of the phenyl group which it is joined to, or the amylene transforms the ketonic oxygen in a hydroxyl giving the amylenic group, or, even if the hydroxyl group is formed, the amylene places itself as a bridge between the aldehydic carbon and phenylic one, or the oxygen atom of the aldehyde places itself as a bridge between the amylene and the benzylidene, or, finally, the amylene joins with its two valences to the carbon atom of the aldehydic group.

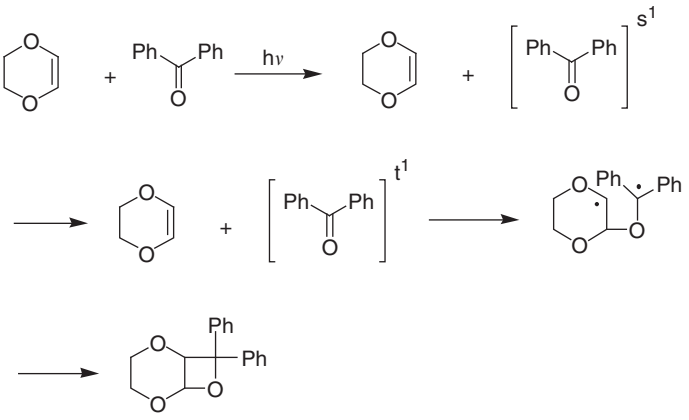
The compounds thus obtained should have the following structures.



The first of these formulas is not probable, considering the formation and the properties of the oxonium, the second and the third must be excluded considering that the compound has no aldehydic or ketonic properties, the fourth, the fifth, and the seventh formulas must be excluded because we cannot recognize the presence of a hydroxyl group in the compound, then the sixth formula is the most probable one. Furthermore, considering that our compound was obtained from trimethylethylene, it can correspond to one of the following structures.

The choice between these two formulas is not possible now.

Paternò and Chieffi could not distinguish between two possible regioisomers of the oxetane and, obviously, they could not distinguish between all the possible stereoisomers of the product. Only in 1953, Büchi reported the exact identification of the product, showing that this photochemical process could represent an interesting synthetic process.[8]



After these pioneering works, several reviews cover all the papers published in this field.[9–24]

The reaction is a photocycloaddition reaction of a carbonyl compound in the excited state with an alkene in the ground state. The carbonyl compound must possess an n,π^* S_1 or T_1 excited states. Frontier orbitals approach has been used to explain the formation of oxetanes. Highest single occupied molecular orbital (HSOMO)–lowest unoccupied molecular orbital (LUMO) interaction is the main process observed where the half-occupied π^* orbital of the carbonyl compound interacts with the unoccupied π^* molecular orbital of an electron deficient alkene: the results of this interaction is the formation of a C,O-biradical (**A** in Scheme 3). If the lowest single occupied molecular orbital (LSOMO)–highest occupied molecular orbital (HOMO) interaction is prevalent (interaction of the half-occupied n orbital of the carbonyl O atom with the π orbital of an electron-rich alkene), the formation of a C,C-biradical (**B** in Scheme 3) is the main process.[25,26]

Scheme 3

The majority of Paternò–Büchi reactions occur from the carbonyl triplet state, which is accessed by an intersystem crossing. The biradicals are the direct consequence of the precursor spin and their lifetimes are connected with the mode of spin inversion processes and the mechanism, thus leading to the formation of closed-shell products. 1,4-Biradicals derived from the addition of a carbonyl compound in its first excited triplet state and an alkene were studied spectroscopically[27–30] and they were trapped by radical quenchers.[31–34] The biradical intermediate in the reaction between benzophenone and an electron-rich alkene has been determined using laser flash photolysis. An absorption with λ_{max} 535 nm has been observed (Scheme 4).[27,29]

Scheme 4

In the reaction between 1,4-dioxene and benzaldehyde, theoretical calculations showed that the only transition able to give the observed transient absorption is that from LSOMO to LUMO (549 nm); the same result was obtained for the reaction between furan and benzaldehyde.[21]

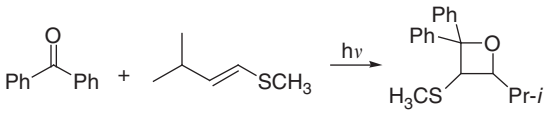
The regioselectivity of the reaction can be explained considering the hard–soft acids and bases theory. This approach gave results in agreement with the experimental results.[35] Another approach able to explain the regiochemistry of the Paternò–Büchi reaction appeared and considered that atoms arrange themselves so that the obtained molecule reaches the minimum electrophilicity.[36]

A theoretical study of the Paternò–Büchi reaction showed that there are two conical intersection points located near the C–C and C–O bonded biradical regions of the ground state. These two conical intersections support a mechanism where the decay

from the excited state is accompanied by a geometric rotation of the terminal group, in the case of C–O attack, and by an orbital rotation at the oxygen center, in the case of C–C attack. Furthermore, for C–O attack, the triplet surface must cross the singlet to reach a diradicaloid minimum. For C–C attack, the triplet biradical minimum is located at the same geometry as the conical intersection between the two singlet states, and the efficiency of the intersystem crossing will be determined by the nature of the spin–orbit coupling (SOC). Thus, for the triplet, the reaction path can be predicted by the most stable biradical rule.[37] A conformational analysis of the biradicals also appeared.[38,39]

A complete active space multiconfiguration self consistent field geometry optimization using triple zeta valence basis set of the intermediate biradicals showed that the diradical region corresponding to the C–C attack lies approximately 10 kcal mol^{-1} lower in energy than the C–O region.[40,41] Unfortunately, this result is not in agreement with the reported experimental results.

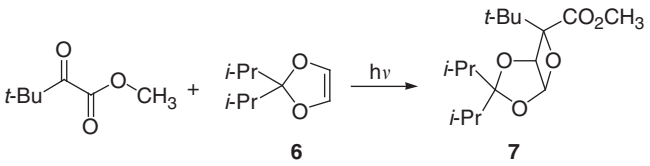
The formation of an exciplex is used to explain the reaction behavior of a simple alkene. However, evidence of monoelectron transfer processes is reported for electron-rich alkenes.[42]



5.05.2 Intermolecular Reactions

5.05.2.1 Reactions with Electron Rich Unsaturated Compounds

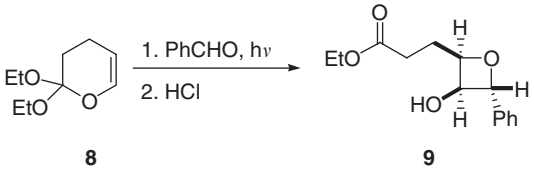
5.05.2.1.1 Reactions of carbonyl compounds with enolethers and enolthioethers



The first oxetane derived from ethyl vinyl ether and benzophenone was described by Paternò.[43] He described the formation of oxetane in the reaction of benzophenone with diethyl ether. He suggested the *in situ* formation of ethyl vinyl ether. The reaction between acetone and ethyl vinyl ether in the presence of ultrasounds gave a different mixture of regioisomers than that obtained without the use of ultrasound.[44]

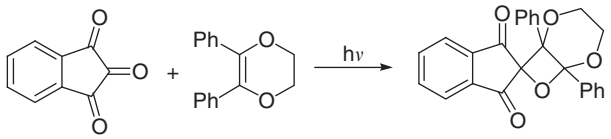
A high regioselectivity was obtained when ethyl vinyl ether was used as an alkene with benzaldehyde and benzophenone.[45] The reaction of benzophenone with alkenyl sulfide also showed a high regioselectivity (Scheme 5).[46]

Scheme 5



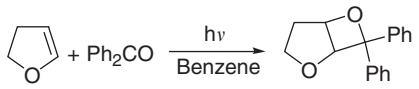
Substituted pyruvates reacted with 1,3-dioxol **6** and this reaction allowed one to obtain the *endo* isomer **7** (Scheme 6).[47–49] The analysis of the conformations of the biradical intermediate was used in order to explain the observed stereochemical behavior.[50]

Scheme 6



Unsubstituted cyclopropyl enol ethers gave, when reacted with a carbonyl compound, the corresponding oxetane rings. When a substituent is introduced on the cyclopropyl ring, the formation of oxepanes was observed being derived from cyclopropyl ring opening at the level of the biradical intermediate.[51]

When enol ether **8** was irradiated in the presence of benzaldehyde, and the reaction mixture was purified after an acid hydrolysis, oxetane **9** was isolated in good yield with a good diastereoselectivity (Scheme 7).[52]



Scheme 7

1,2,3-Indanetrione reacted with 2,3-diphenyl-1,4-dioxene to give the oxetane on the carbonyl in 2 position (Scheme 8).[53] On the contrary, when the less electron rich 2,3-dimethyl-2-butene is used as an alkene, a complex mixture of products is obtained.[54]

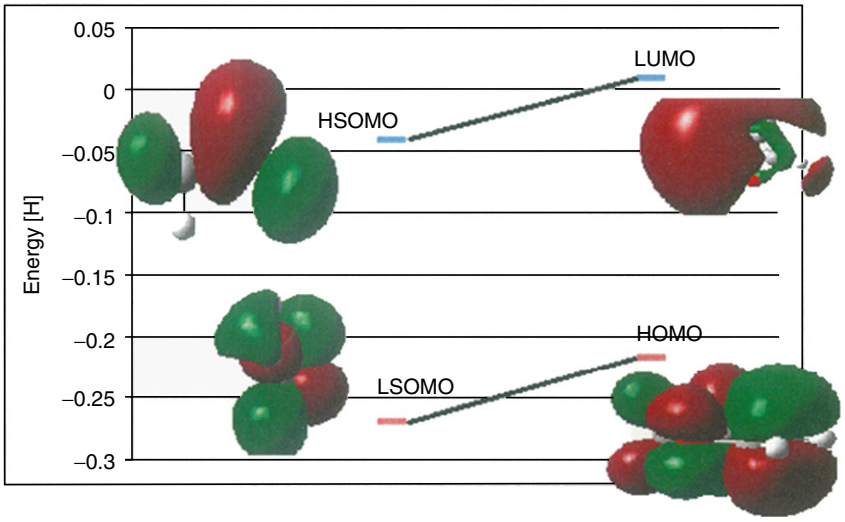
Scheme 8

The irradiation of 2,3-dihydrofuran with benzophenone in benzene gave adduct **10** (Scheme 9).[55]

10

Scheme 9

When acetone was used as the carbonyl compound, the adduct was obtained in 52% yield: It was a mixture of two regioisomers in a 200:1 isomeric ratio.[56] Also, the reaction of 5,5-dimethyl-2,3-dihydrofuran with both aromatic and aliphatic aldehydes gave the corresponding oxetanes with high *endo* selectivity.[57] When acetaldehyde was used as the carbonyl compound, the adduct was obtained in 63% yield as a mixture of stereoisomers. The selectivity depended on 2,3-dihydrofuran concentration: This behavior was explained with a switch from a triplet mechanism to a singlet mechanism at higher concentration.[58–62] This behavior can be explained.[63] It can be seen that the best interaction between the frontier orbitals is that from the LSOMO of acetaldehyde and the HOMO of 2,3-dihydrofuran (Figure 1). The atomic coefficients on the olefinic carbon atoms in 2,3-dihydrofuran were –0.26 at C-2 and –0.38 at C-3. The atomic coefficient on the oxygen atom in the LSOMO of singlet excited acetaldehyde was 0.48, whereas the atomic coefficient at the C-1 of acetaldehyde in the HSOMO was 0.49.



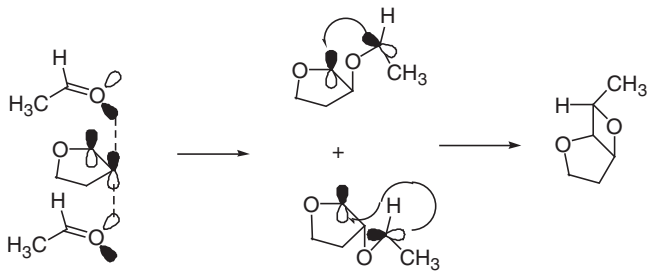


Figure 1 Frontier orbitals interaction in the reaction of 2,3-dihydrofuran with acetaldehyde in its excited singlet state.

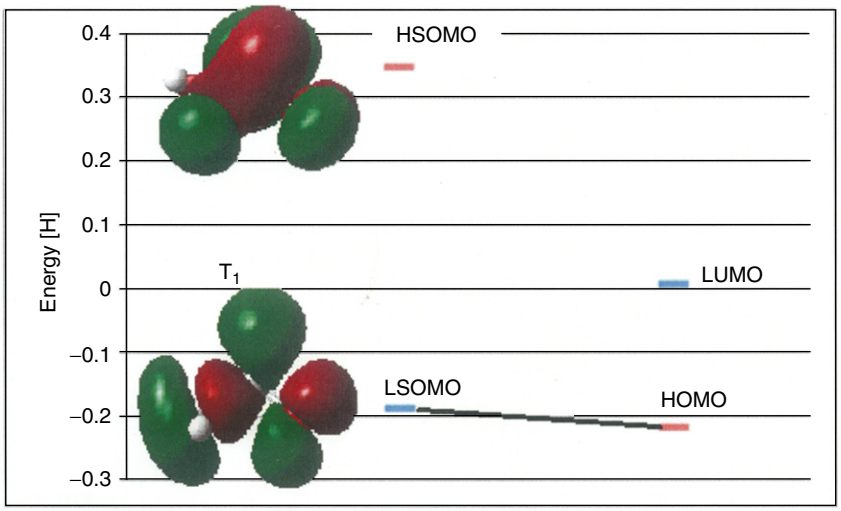
The nature of the LUMO of 2,3-dihydrofuran excludes the possibility of a concerted mechanism. The reaction has to provide for the formation of an extremely labile singlet biradical. In this case, the oxygen atom of acetaldehyde has to attack the C-3 carbon atom in 2,3-dihydrofuran in order to give the more stable biradical intermediate. This interaction can occur as described in Scheme 10.

The reaction, in this case, allowed the formation of only the *exo* isomer. This can explain the observed reactivity admitting that, when the reaction is performed in a concentrated solution, the excited singlet state gave the *exo* isomer, whereas the excited triplet state is responsible for the formation of the *endo* isomer. In the triplet state, the interaction between the frontier orbitals is depicted in Figure 2.

Scheme 10



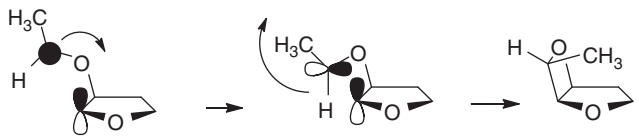


Figure 2 Frontier orbitals interaction in the reaction of 2,3-dihydrofuran with acetaldehyde in its excited triplet state.

The main interaction is that between the LSOMO of the triplet state acetaldehyde and the HOMO of the dihydrofuran. This interaction leads to the formation of the corresponding C–C biradical intermediate (Scheme 11).

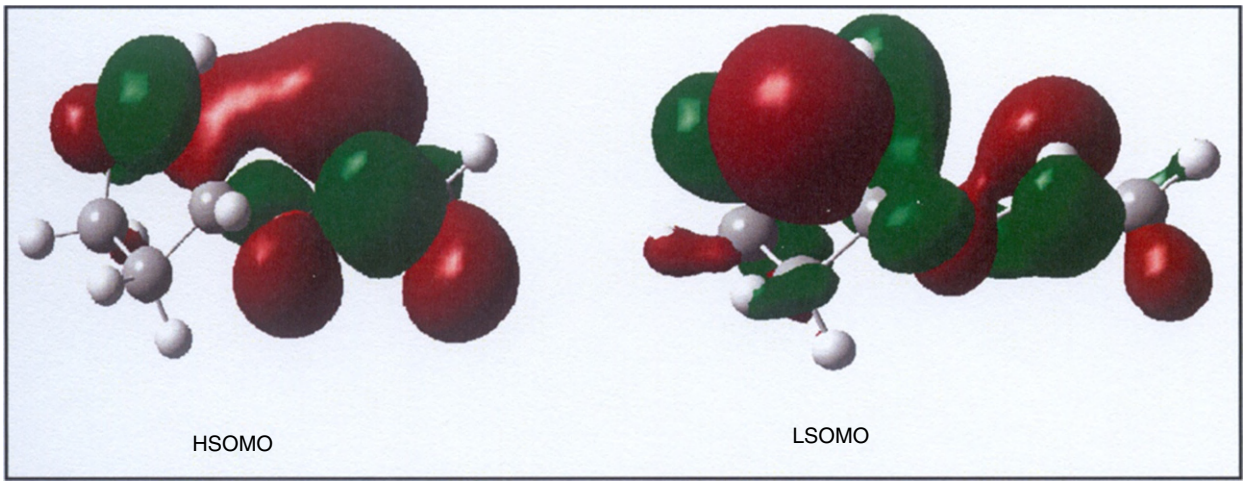
Scheme 11

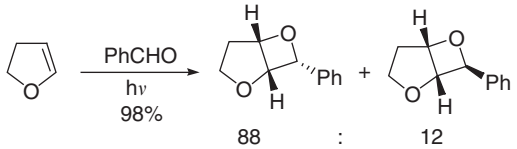
The HSOMO on the biradical intermediate was mainly localized on the aromatic ring and it is extended to the radical carbon. The LSOMO was mainly localized on the dihydrofuran ring (Figure 3). The coupling between the radical carbons in these two orbitals was possible (the atomic orbitals involved can superimpose themselves) only if the *endo* isomer was formed (Scheme 11).

When benzaldehyde was used as carbonyl compound, the reaction showed good regio- and stereoselectivity (Scheme 12).[61,64–66] The adducts were obtained with an overall yield of 98% as a >98:2 regioisomeric mixture; the major isomer is 88:12 *endo–exo* mixture. The stereoselectivity was partially lost when benzaldehyde reacted with a 2,3-dihydrofuran derivative substituted in two positions.[64,67]

A change of regioselectivity was observed when the reaction between 2,3-dihydrofuran and benzaldehyde was performed in a high polar solvent: This result has been interpreted as a proof of an electron-transfer mechanism (Scheme 13).[58,59]

The reaction of dihydrofuran with benzaldehyde is the first example where a spin controlled selectivity is observed.[60,68] In singlet photoreactions, stereoselectivity is often controlled by the optimal geometries for radical–radical combinations. On the contrary, in triplet photoreactions the optimal geometries are those able to favor the intersystem crossing from the triplet excited state to the singlet one. The singlet biradicals should be too short-lived to enable rotation about the endocyclic C–O or C–C bonds, and therefore conformation memory effects on the stereochemistry are expected. The geometries in the triplet state can be quite different from the former ones due to differences of the SOC values. The lifetimes of many triplet biradical intermediates are definitely high enough to enable bond rotations. Therefore, the formation of the thermodynamically favored product can be





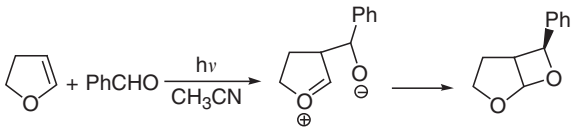


Figure 3 HSOMO and LSOMO of the biradical intermediate in the reaction between acetaldehyde and 2,3-dihydrofuran.

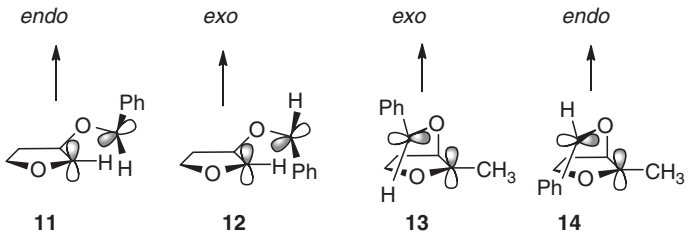
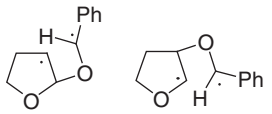


Scheme 12

Scheme 13



expected because the radical–radical combination step should not be influenced by the approach geometry: 'memory effects' should be erased due to the relatively long lifetimes. After transition from the triplet to the singlet potential energy surface, immediate product formation is expected. Thus, the ISC proceeds in a concerted fashion with the formation of a new bond or the cleavage of the primarily formed single bond. As a consequence, the stereoselectivity of the Paternò–Büchi reaction is the result of a combination of several rate constants for cyclization versus cleavage reactions.

Benzaldehyde reacts in its triplet state. This way, a triplet biradical intermediate is formed. To obtain the products, intersystem crossing into the singlet manifold is necessary. The most important factor influencing an intersystem crossing for flexible triplet biradicals is SOC. The angle between p orbitals at the radical centers is approximately 90° for maximum SOC. For the pronounced *endo* selectivity in the reaction between aromatic aldehydes and 2,3-dihydrofuran, the two biradical conformers **11** and **12** can be considered to be responsible, with the alkyloxy substituent localized in a pseudoequatorial position and **11** being more populated because of fewer steric interactions (Scheme 14).

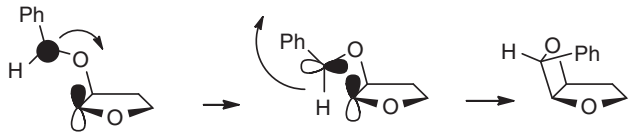
Scheme 14

When a methyl group is present, the increasing *gauche* interactions with the β-alkyloxy substituent led to a certain concentration of **13** and **14**, again with **13** being preferred because of fewer steric interactions. Another explanation for the regio- and stereochemistry appeared.[69] In fact, theoretical calculations showed that the biradical **15** is more stable than **16** by 1.49 kcal mol^{-1} (Figure 4).

15 **16**

Figure 4 Possible biradical intermediates in the reaction of 2,3-dihydrofuran with benzaldehyde.

Furthermore, the HSOMO was mainly localized on the aromatic ring and it is extended to the radical carbon. The LSOMO was mainly localized on the dihydrofuran ring (Figure 6(a)). The coupling between the radical carbons in these two orbitals was possible (the atomic orbitals involved can superimpose themselves) only if the *endo* isomer was formed (Figure 5).[69]



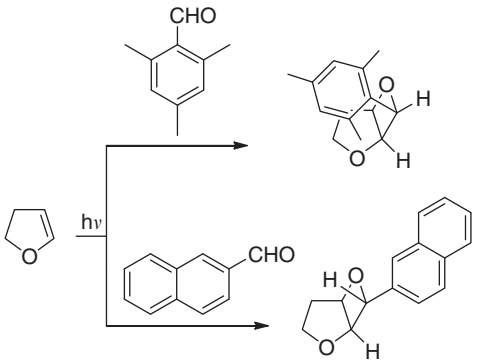


Figure 5 Ring closure reaction in the formation of the *endo* isomer of the adduct between 2,3-dihydrofuran and benzaldehyde.

α- and β-Naphthaldehydes, on the contrary, gave high *exo* selectivity (Scheme 15). The reaction also occurred in the presence of triplet quenchers, whereas fluorescence quenching in the presence of dihydrofuran was observed.

Scheme 15

In this case, the singlet excited state was responsible for the high *exo* selectivity.[61,70] In this case, the coefficients on the HSOMO and LSOMO allowed the coupling of the radical carbons only if the *exo* isomer is obtained (Figures 6 and 7).[71]

When 2,3-dihydrofuran derivatives react with α,β-unsaturated carbonyl compounds, [2 + 2] cycloaddition between the olefins occurs.[72] Benzaldehyde reacts with L-ascorbic acid giving a mixture of regioisomeric compounds with *exo* stereoselectivity.[73]

Irradiation of the oxetane **17** in the presence of 1-methoxynaphthalene and 2,7-dimethoxynaphthalene as sensitizers gave an efficient carbonyl-alkene metathesis of bicyclic oxetanes through an electron transfer process (Scheme 16).[74]

A cycloreversion reaction was supposed also in the photochemical reaction of α,α-diphenyl substituted diazotetrahydrofuranones.[75]

5.05.2.1.2 Reactions with enol esters, enol silyl ethers, and enamines

High regio- and stereoselectivity (*syn* addition) was observed in the reaction of pentafluorobenzaldehyde with enol acetates.[76] The reaction between a 2,3-thiophenone derivative and vinyl acetate gave the corresponding adduct on a ketonic function in low yields.[77]

The reaction between benzaldehyde and a silyl derivative of cinnamyl alcohol gave the corresponding oxetane with high stereoselectivity (Scheme 17).[78]

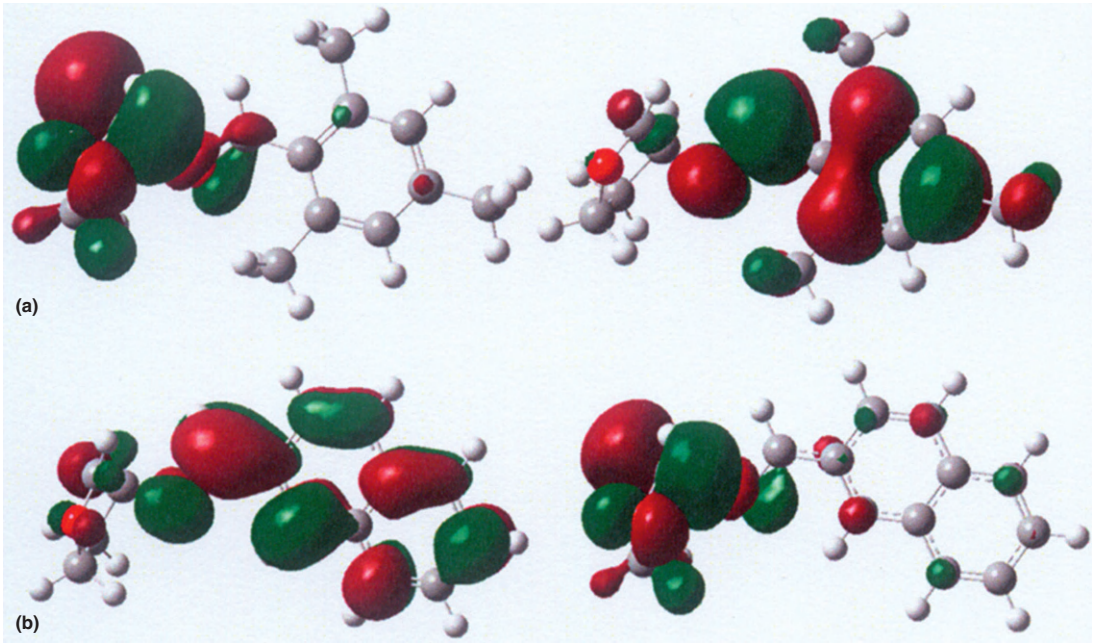

Figure 6 (a) HSOMO (left) and LSOMO (right) of the biradical intermediate in the reaction of trimethylbenzaldehyde with dihydrofuran. (b) HSOMO (left) and LSOMO (right) of the biradical intermediate in the reaction of 2-naphthaldehyde with dihydrofuran. Reproduced from D'Auria, M.; Racioppi, R. *Eur. J. Org. Chem.* **2010**, 3831–3836, with permission of Wiley-VCH.

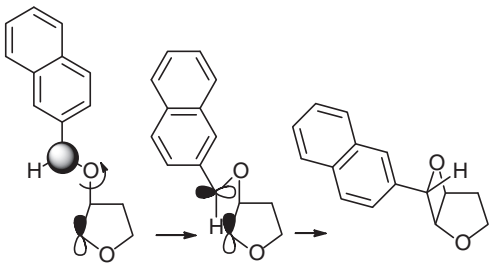

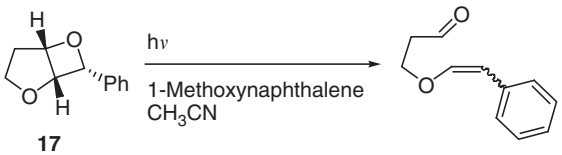

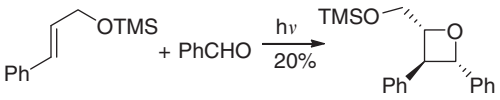

Figure 7 Coupling of the radical centers in the biradical intermediate in the reaction of 2-naphthaldehyde with dihydrofuran.

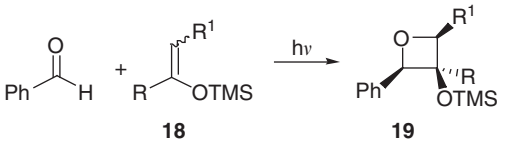
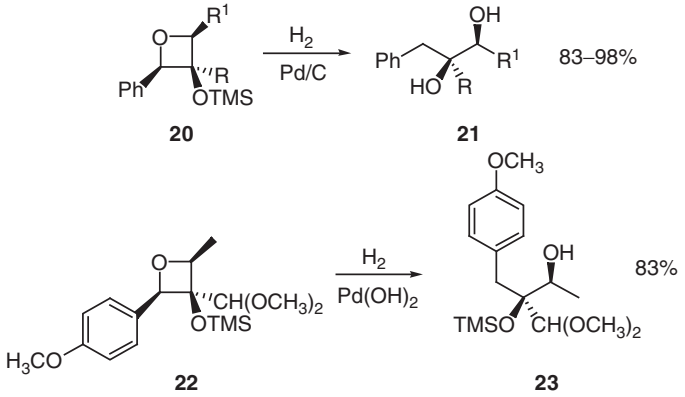


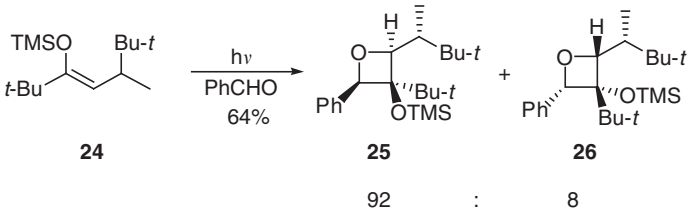
Scheme 16

Scheme 17



3-(Silyloxy)oxetanes **19** were successfully prepared from silyl enol ethers **18** containing carbon–chlorine, carbon–silicon, or carbon–sulfur bonds (Scheme 18).[79–81] Ether and ester groups were compatible with the reaction. The presence of an alkene moiety was also compatible. When a β-alkyl substituted silyl enol ether was used, a *trans* relationship between α and β susbstituents in the oxetanes was observed. This result did not depend on the (*E*)- or (*Z*)- nature of the alkene. The products were obtained with high simple diastereoselectivity (*ds* 74–95%).[82]

Scheme 18



In the triplet biradical, free rotation leads to the highly preferred, sterically least congested conformation. The further reaction pathway of this species includes ISC and an assumed selection step (cleavage versus ring closure) at the singlet 1,4-diradical level which accounts for the high simple diastereoselectivity at C-2/C-3.

The oxetanes **20** can be converted into the corresponding diols **21** using hydrogenolysis under Pd catalysis (Scheme 19). Acid-sensitive substrates can be hydrogenated using $Pd(OH)_2$ as catalyst as reported in the reaction of the acetal **22** (Scheme 19).[83] Also $LiAlH_4$ can be used in order to induce the cleavage of the oxetane ring.[84]

Scheme 19

The presence of a stereogenic center in the *β*-alkyl group (as in **24**) induced a facial diastereoselectivity. In some cases, high diastereoisomeric ratios were observed (Scheme 20).[85]

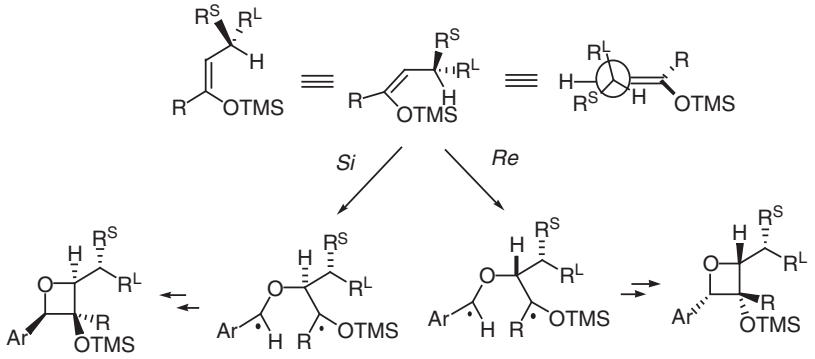
Scheme 20

The diastereoselectivity was probably due to the presence of a conformational preference represented in Figure 8. This conformation allows the *Si* attack.[84]

In this case, a fluoride-promoted cleavage can be used to open the oxetane ring.[85] When the chiral center is in *α* position, low facial diastereoselectivity was observed.[86] The best results were obtained using both the silyl enol ether **27**, which gave the adducts **28** and **29** with a 67/33 *dr*, and the compound **30**, giving the adducts **31** and **32** in 15/85 *dr* (Scheme 21).[87]

In the reaction of **27** with benzaldehyde, two conformers of the biradical intermediate have been observed. These conformers showed almost the same energy (the conformer **A** is more stable than **B** for 3.11 kcal mol^{-1}): the conformers of the biradical are shown in Figure 9.[70] Considering the biradical conformer **A**, the LSOMO of this biradica was at −0.077 Hartries (H), whereas the HSOMO was at −0.073 H (Figure 10). Considering the reactive sites and the atomic coefficients at these sites, the coupling of the radical carbon atoms can occur only as depicted in Scheme 22.

The conformer **A** can give the major stereoisomer **28** observed in the reaction. The results are in agreement with the experimental results showing that the course of this reaction is strictly frontier orbitals controlled. The other biradical conformer gave the other diastereoisomer. The observed diastereoisomer ratio (67:33) can be explained by the low difference between the energies of the conformers of the biradical intermediate (3.11 kcal mol^{-1}).



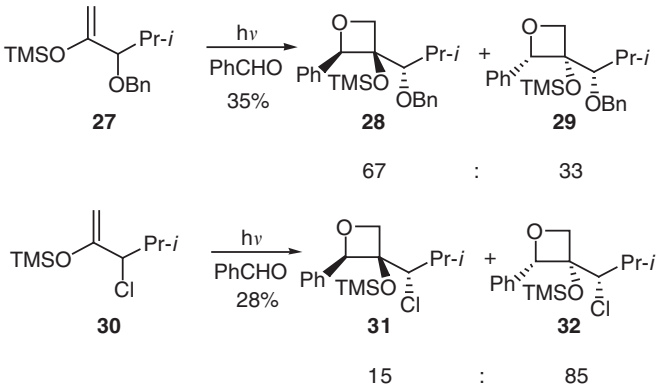


Figure 8 Diastereoselectivity in chiral enol silyl ethers reaction with benzaldehyde.

Scheme 21

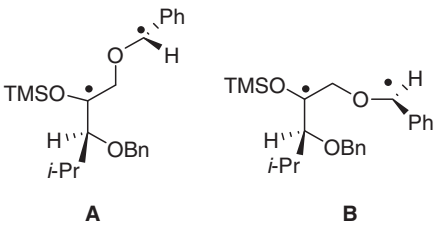

Figure 9 The conformers (**A** and **B**) of the biradical intermediate in the photoreaction between **27** and benzaldehyde.

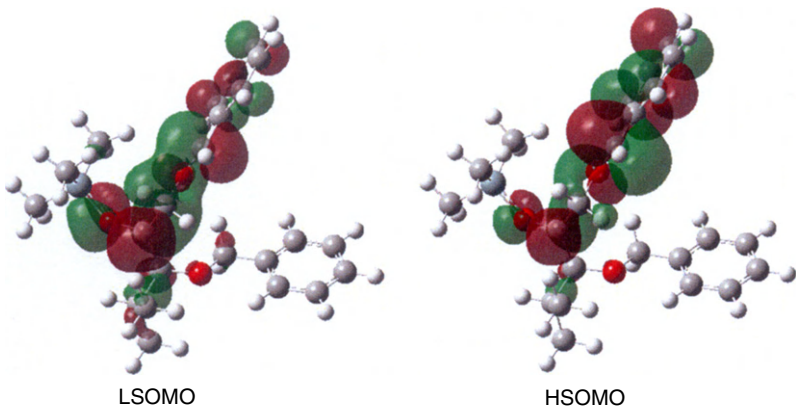

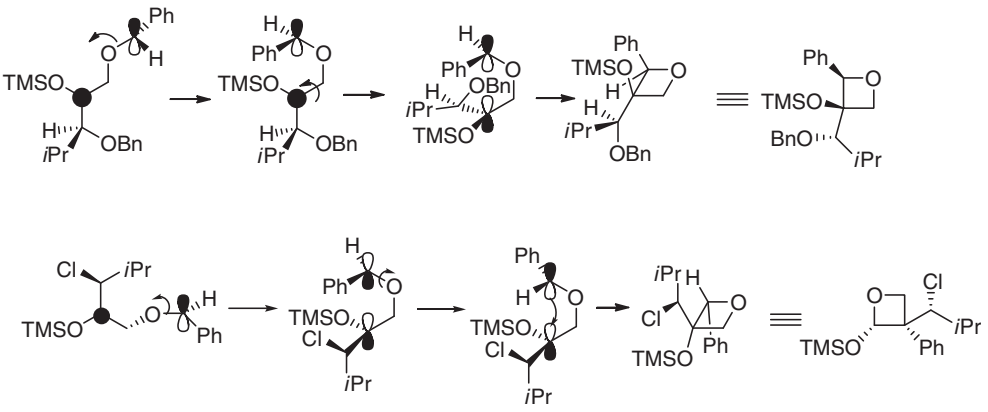

Figure 10 HSOMO and LSOMO of the biradical **A** obtained in the reaction of **27** with benzaldehyde. Reproduced from D'Auria, M.; Emanuele, L.; Racioppi, R. *Lett. Org. Chem.* **2006**, *3*, 244–246, with permission of Wiley-VCH.

Scheme 22

To confirm this result the behavior of **30** has been examined. In this case, the authors observed an inverse diastereoselectivity.[86] Also, in this case, two conformers of the biradical intermediate were possible. The energy difference between these two conformers was 4.6 kcal mol^{-1}. The coupling between the carbon atom considering the atomic coefficients allowed the formation of the observed diastereoisomers (**31** and **32**): the most stable conformer gave compound **32**. The larger diastereoisomeric ratio (85:15) here observed in comparison with that found between **28** and **29** is in agreement with the larger energy difference between the conformers of the biradical intermediate.

The synthetic utility of the oxetanes has been studied considering the presence of a removable protecting group in the side chain of the same oxetane. The possible intramolecular nucleophilic attack on the oxetane ring gave some interesting products (Scheme 23).[87]

1,2-Diketones reacted with trimethylsilyl ketene acetals giving the corresponding oxetanes in low yields.[88] In the reaction of ketene silyl acetals with aromatic carbonyl compounds byproducts have been identified as oxetanes: in some cases they represent the main product.[89] Cyclic ketene silyl acetals **33** reacted with 2-naphthaldehyde to give the corresponding adduct **34**. The treatment of the reaction mixture with water gave the aldol-type product **35** with high stereoselectivity (Scheme 24). The oxetane was obtained with *anti* stereochemistry.[90,91] The effect of both the solvent and the nature of the silyl group has been examined.[92] When silyl O,S-ketene acetals were used as alkene, some interesting results were obtained.[93] In particular when the *E* isomer **36** was used, only the *trans*,*trans*-isomer **37** was obtained (Scheme 24).

The stereochemical behavior was explained by considering the capability of the sulfur atom to coordinate the oxygen atom of the carbonyl compound.[93] The presence of such an atom induced the attack of the carbonyl compound on the side where the sulfur atom is present (Figure 11). The same regio- and stereoselectivity was observed when silyl O,Se-ketene acetals were used.[94]

Oxetanes were obtained in the reaction of *N*-acyl enamines **38** and **41**: these compounds gave the corresponding adducts with high regio- and stereoselectivity (Scheme 25).[95–98] The main product was the thermodynamically more stable isomer.[99]

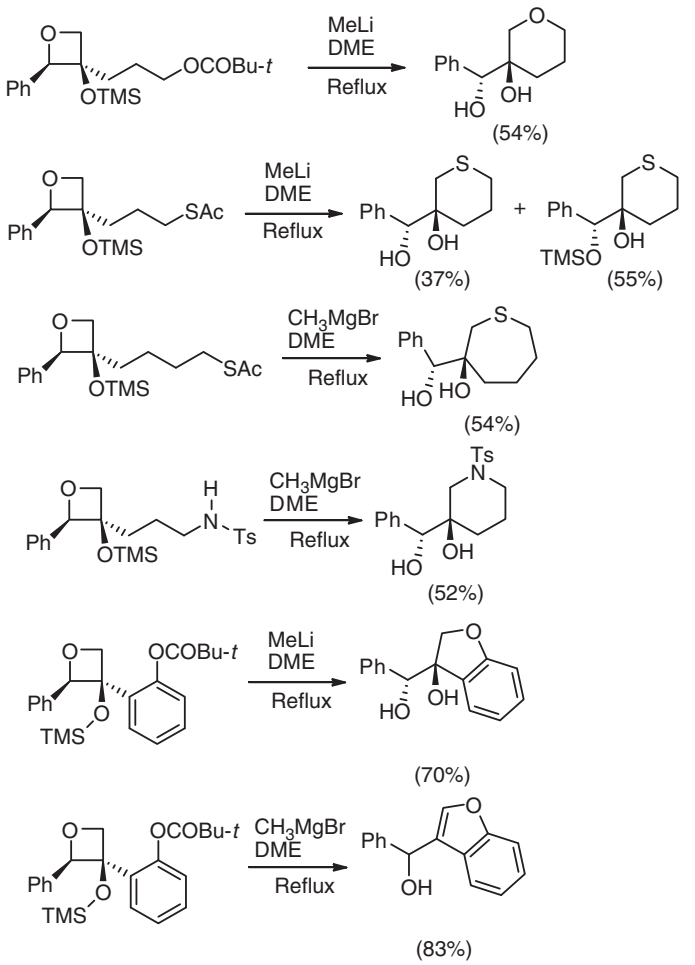
The optimized structure of the biradical intermediate is shown in Figure 12 with the HSOMO at -0.215 H and the LSOMO at -0.241 H.[70]

The coupling of the radical carbon atoms considering the atomic coefficients on the SOMOs allowed the formation of the *exo* isomer, in agreement with the experimental results (Scheme 26).

Chiral enamines did not give the corresponding adduct with high diastereoselectivity. The only exception was found using the enamine **43**. It gave the corresponding adduct with 62% *de* (Scheme 27).[100,101]

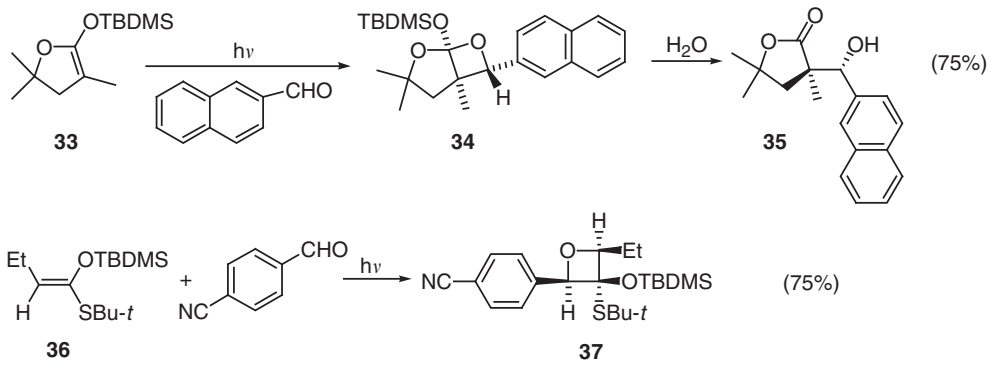
N-Formyl protected oxetanes could be converted into the corresponding *syn*-1,2-amino alcohols through treatment with $LiAlH_4$.[97] Alternatively, the treatment of **44** with TFA gave the oxazolidinone **45**. Furthermore, **45** can be converted into the corresponding *anti*-1,2-amino alcohol **46** (Scheme 28).[97,102]

This approach has been used in the synthesis of both (±)-oxetin (**47**)[103] and (+)-preussin (**48**) (Figure 13).[104,105]



The Paternò–Büchi reaction could be obtained also using alkenes bearing both electron donating groups (nitrogen atoms) and electron withdrawing groups. 2-Morpholinopropenenitrile gave in very low yields a product deriving from a Paternò–Büchi reaction when it reacted with naphthalene-1,4-dicarboxylic acid.[106] The same result was obtained when benzil was used as substrate. On the contrary, when methyl phenylglyoxylate was used as carbonyl compound, the corresponding adduct was isolated in good yields.[107]

When benzil was irradiated in the presence of a 2-aminopropenenitrile derivative, it gave the corresponding adduct in variable yields (Scheme 29).[108] The reaction showed good stereoselectivity. When unsymmetrical benzil derivatives are used, both the isomers were obtained.



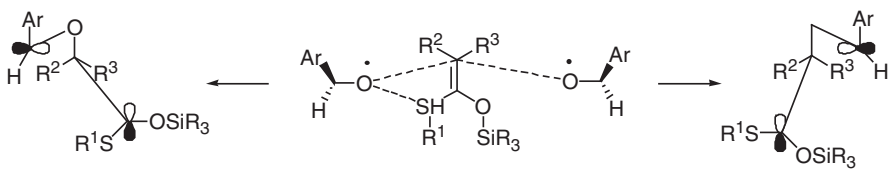
5.05.2.2 Reactions with Heterocyclic Compounds

5.05.2.2.1 Reactions with five-membered heterocycles

The reactivity of pentatomic aromatic heterocycles different from furan toward carbonyl compounds to give the corresponding oxetanes has been the object of other review articles.[109] These compounds showed lower reactivity than furan (see below).

Scheme 23

Scheme 24



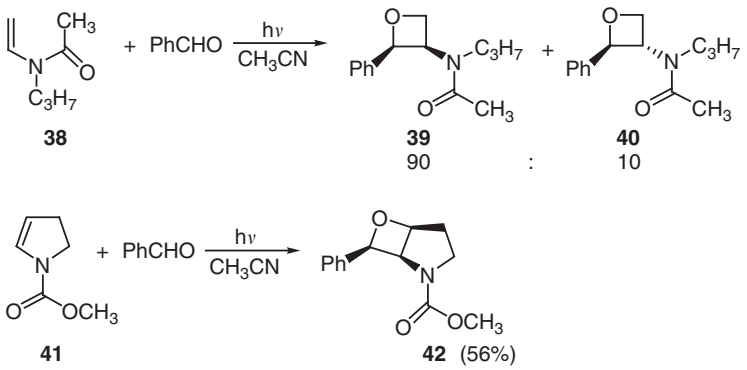


Figure 11 The reaction O,S-ketene acetals with carbonyl compound. A possible explanation of the stereochemical behavior.

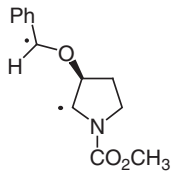
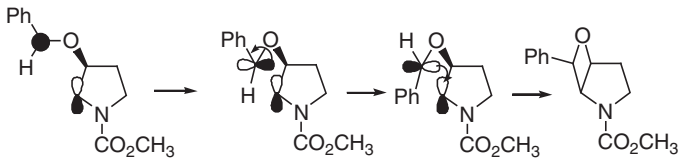
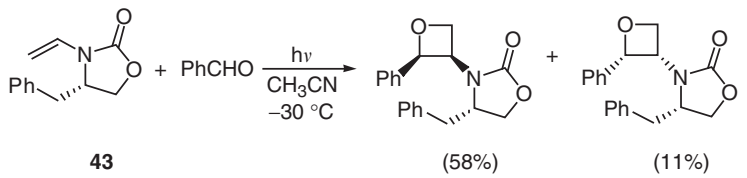
Scheme 25







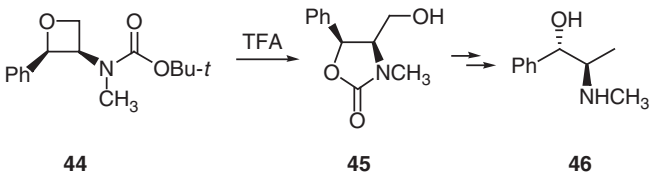


Figure 12 Optimized structure of the biradical intermediate in the reaction **41**→**42**.

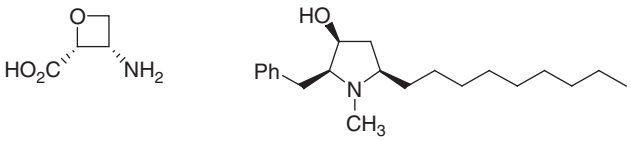
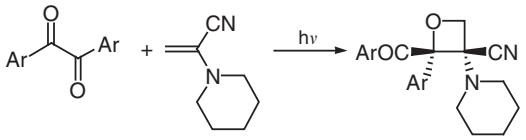
Scheme 26

Scheme 27



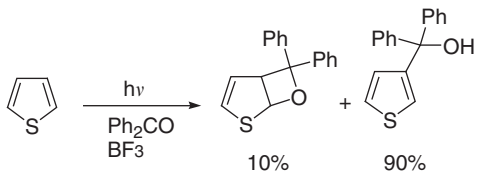
Scheme 28

The reason for this behavior is not clear. It could be related to the different aromaticity of these compounds in comparison with that of furan, or could be due, as reported below, to the quenching properties of the heterocycles.



Thiophene did not react with benzophenone. The reaction occurred only if the irradiation is performed in the presence of BF_3 (Scheme 30).[110] Probably, in this reaction BF_3 was able to catalyze the ring opening of the oxetane.

The benzophenone BF_3 complex, excited by light, leads to an exciplex whose excitation energy was lower than the lowest triplet energy level of thiophene, which under the circumstances cannot act as a quencher. On the contrary, 2,5-dimethylthiophene reacted with benzophenone at -10 °C yielding the corresponding cycloadduct in 62% yield (Scheme 31).[111,112]



47 **48**

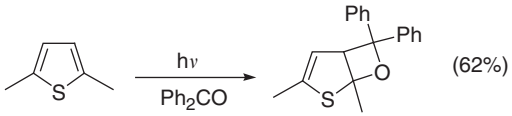


Figure 13 Oxetin (**47**) and preussin (**48**).

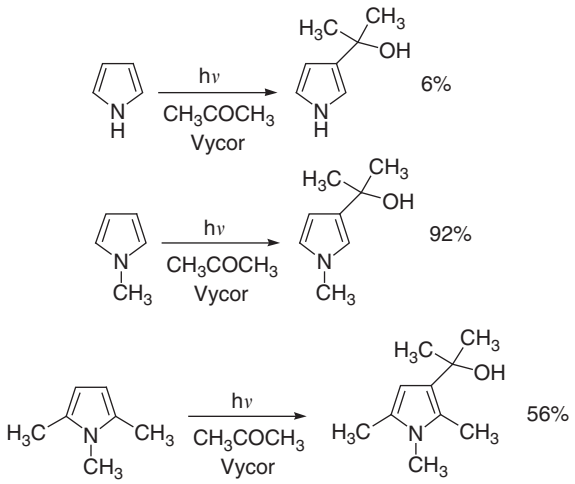
Scheme 29

Scheme 30

Scheme 31

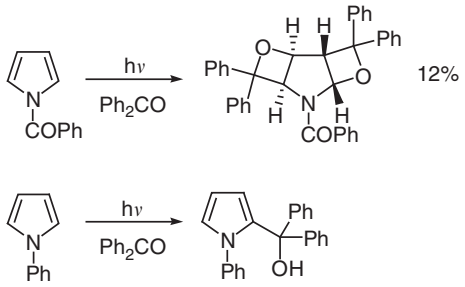
The reaction product could be obtained also using 1-naphthaldehyde (50%), 2-, 3-, and 4-benzoylpyridine (62, 58, and 60%, respectively), and 2-benzoylthiophene (50%), whereas 2-naphthaldehyde, benzaldehyde, and acetophenone did not react.[113] 2,3-Dimethylthiophene also gave the corresponding oxetane when irradiated in the presence of benzophenone (60%).[114] On the contrary, 2,3-dimethyl- and 2,3,5-trimethylthiophene did not react.

Pyrrole, such as thiophene, did not react with benzophenone and did not furnish the corresponding oxetane. However, pyrrole reacted with aliphatic aldehydes and ketones giving the corresponding 3-pyrryl carbinols. The alcohols derived from the cleavage of the corresponding oxetanes (Scheme 32).[115] The yields increased when *N*-methylpyrrole was used as substrate, whereas the reactivity was depressed in the presence of substituents on the pyrrole ring.



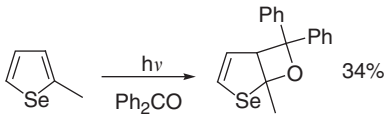
Only when pyrrole, with an electron-withdrawing group such as benzoyl on to the nitrogen atom, was irradiated in the presence of benzophenone, it was able to give the corresponding oxetane (Scheme 33).[116,117] When *N*-phenylpyrrole was used as a substrate, the corresponding 2-pyrryl carbinol was isolated.[116]

Selenophene did not react with benzophenone.[111] On the contrary, the irradiation of 2-methylselenophene gave the corresponding adduct. The reaction occurred on the most hindered side of the molecule (Scheme 34).[118]



Imidazole, *N*-methylimidazole, and 1,2-dimethylimidazole reacted with aliphatic aldehydes and ketones. In all the cases, the product was the corresponding 4-imidazolyl carbinols (Scheme 35).[114,119] The carbinols were obtained through the cleavage of the corresponding oxetanes. On the contrary, the reaction of imidazole with benzophenone gave only 7.7% yield of the corresponding alcohol,[119] whereas, the same reaction, performed in the presence of acetophenone as carbonyl compound, gave only 1.2% yield of the product.[119]

On the photochemical behavior of *N*-methylimidazole, there was no agreement between the work of Jones[115] and that of Matsuura.[119] Whereas Jones reported that *N*-methylimidazole gave the corresponding imidazolyl carbinol in excellent yields, Matsuura reported that the same substrate gave the corresponding carbinol in 9% yield. They also reported that 2-methylimidazole gave a mixture of two products with an overall yield of 22.5% (Scheme 36).[119]



1,2-Dimethylimidazole reacted with benzophenone. However, this compound gave a reaction on the methyl in 2 position in low yield.[120,121] *N*-Benzylimidazole, when irradiated in the presence of benzophenone in *t*-BuOH, gave a reaction on the

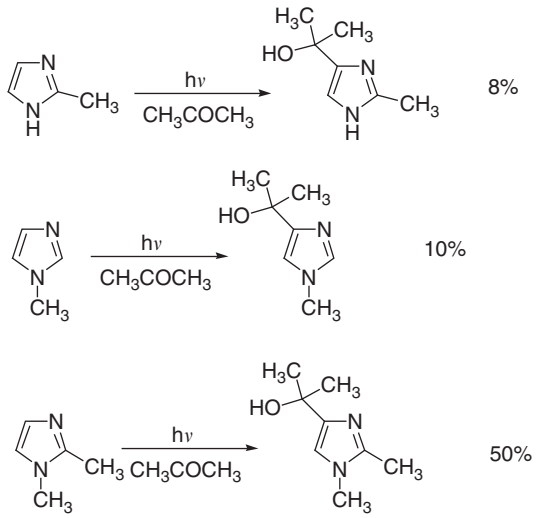
Scheme 32

Scheme 33

Scheme 34

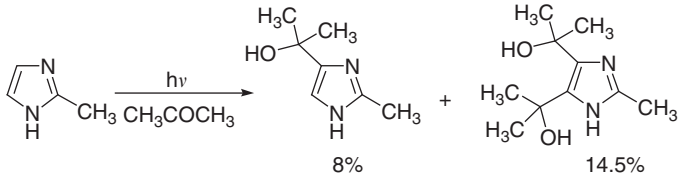
methylene group.[120,121] Only the irradiation of *N*-acetylimidazole allowed one to obtain the corresponding oxetane when the reaction was performed in the presence of benzophenone (Scheme 37). The same result was obtained using *N*-benzoylimidazole and *N*,*N*′-carbonyldiimidazole.[120,121]

The oxetane can also be obtained in the reaction of *N*-methyl-2,4,5-triphenylimidazole with aromatic ketones. It is noteworthy that, in this case, the reaction did not work in the presence of acetophenone and benzaldehyde.[122]



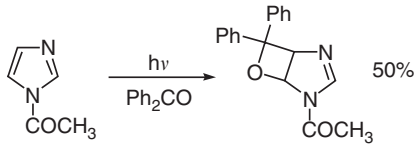
The irradiation in the presence of benzophenone of 2,4-dimethylthiazole gave the corresponding oxetane, whereas the same reaction failed when acetophenone was used as carbonyl compound (Scheme 38).[123] The irradiation in the presence of benzophenone of 3,5- and 4,5-dimethylisoxazole gave the corresponding oxetane in good yields, whereas 4-methylisothiazole gave a reaction on the methyl substituent (Scheme 38).[123]

Recently, the reactivity of isoxazole derivatives has been revisited, showing that some derivatives, such as 3,4,5-trimethylisoxazole, gave the corresponding oxetanes in very good yield (in the case reported in the Scheme 39, almost quantitative yields were obtained) and excellent diastereoselectivity (>99:1).[124]

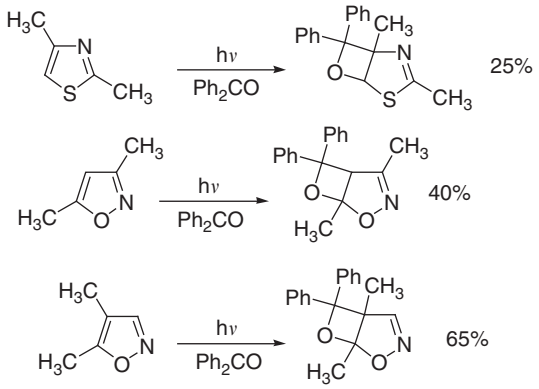


On the contrary, 3-phenyl substituted derivatives did not give the Paternò–Büchi reaction, allowing to obtain only the ring contraction products.[122] In this case, the isoxazole was able to absorb the light giving the corresponding excited state able to give the isomerization reaction.[122–128]

Aliphatic and aromatic carbonyl compounds reacted with oxazole derivatives with good to high *exo* diastereoselectivity, but low facial stereoselectivity. This reaction can be used in the synthesis of *erythro*-α-amino β-hydroxy carboxylic acid derivatives.[129–133]

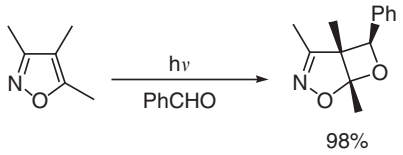


The irradiation of indole with benzophenone did not give the corresponding adduct. On the contrary, a benzoyl derivative of indole reacted with benzophenone, giving the corresponding oxetane (Scheme 40).[134] It did not react with acetophenone,

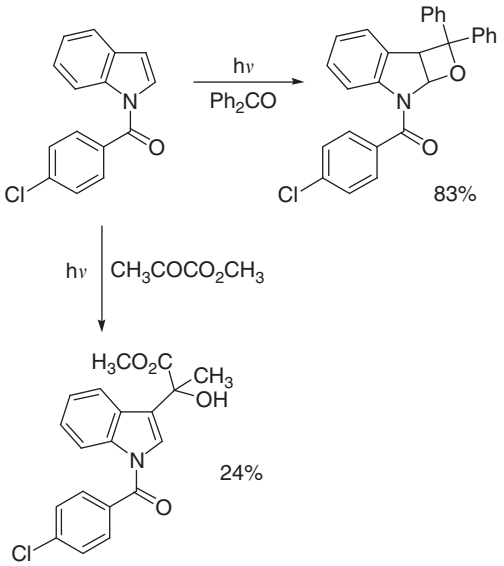


Scheme 35

Scheme 36



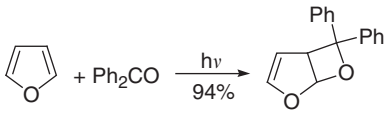
Scheme 37



Scheme 38

benzaldehyde, acetone, and propionaldehyde. When methyl pyruvate was used as the carbonyl compound, the corresponding 3-indolyl carbinol was obtained (Scheme 40).[134]

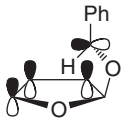
The same reaction has been described on the *N*-acetyl derivative of 7-azaindole. Although the reaction represents a method able to obtain a new class of compounds, the low yields of the product (4%) prevent a synthetic use of this reaction.[134]



Scheme 39

Scheme 40

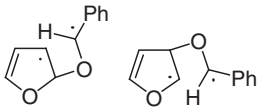
Schenck reported that the irradiation of benzophenone in furan gave the corresponding adduct in 94% yield (Scheme 41).[135] The structure was confirmed by Gagnaire et al.[136]



Scheme 41

Furan and 2-methylfuran were found to react with propanal and benzaldehyde.[111,137–142] In this case, the *exo* stereochemistry at C-6 on the dioxabicyclo[3.2.0]heptene skeleton has been assigned.[143] Good regioselectivity was observed using silyl and stannyl furan derivatives: in this case, the reaction occurred on the less hindered side of the molecule.[144] When 2-silyloxyfuran was irradiated in the presence of aliphatic carbonyl compounds or with benzaldehyde, it gave a 1:1 mixture of regioisomeric products. On the contrary, when benzophenone was used, only the product deriving from the attack on the most hindered side of the molecule was recovered. The same result was obtained using acetone in a reaction when a low concentration of furan was used. In all the cases, an *exo* selectivity was observed.[145] On the contrary, 2-furylmethanol and the corresponding silyl ether gave a low regioselectivity.[145,146]

The high *exo* stereoselectivity of the reaction has been extensively studied: the formation of the product occurred on a triplet 1,4-biradical. The triplet biradical was converted into the singlet one to give the product. In order to explain the pronounced *exo* stereoselectivity, a secondary orbital effect can be postulated: an interaction between the rather flexible α-oxy radical center and the allyloxy ring localized radical in **49**, likely plays a major role (Figure 14).[147,148]



The regioisomeric biradical intermediates **A** and **B** resulting from the head-to-head and head-to-tail addition, respectively, have been examined (Figure 15).[69] The biradical **A** is more stable than **B** by 16.5 kcal mol^{-1}. The biradical **A** exists as two conformers and only that conformer able to give the ring closure was considered.

The HSOMO is mainly localized on the benzaldehyde fragment of the biradical whereas the LSOMO is mainly localized on the furanoid part of the molecule. The HSOMO and LSOMO of the biradical **A** are reported in Figure 16. The coupling between the radical carbons in these two orbitals, considering that the atomic orbitals involved can superimpose themselves, can give only the *exo* isomer, in agreement with the experimental results (Figure 17).

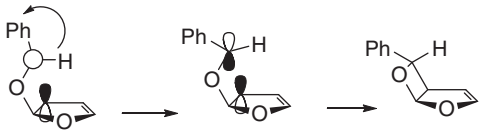

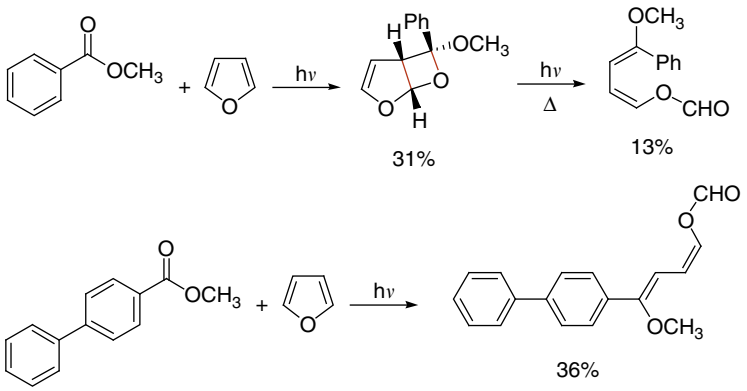

Figure 17 Ring closure reaction in the formation of the *exo* isomer of the adduct between furan and benzaldehyde.

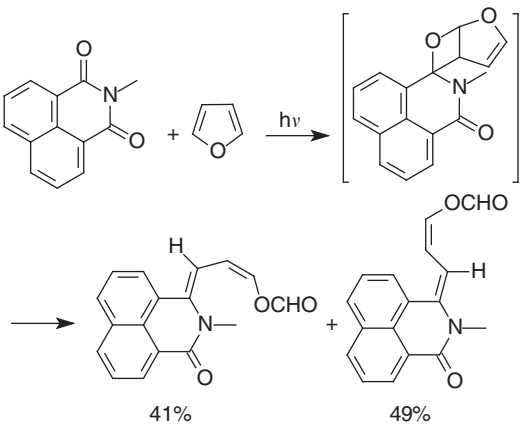
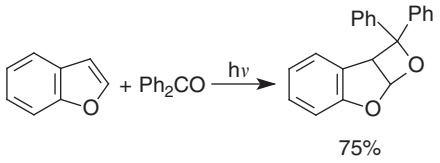
When the reaction was carried out in benzene, dimers can be obtained.[55,149–151] Furan reacted with chloral to give unexpectedly the corresponding 2-furyl carbinols.[152] Furthermore, 2-cyanofuran did not react, whereas 2-furfural diacetate and furfural ethylene acetal showed low reactivity.[152]



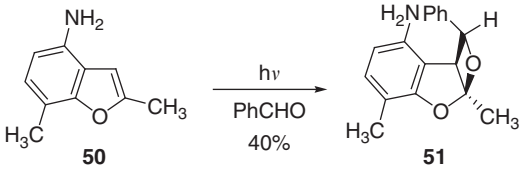
The cycloaddition reaction can be performed on esters. In this case, the adducts can be obtained in a few cases. In most of the examples, they underwent a cycloreversion reaction to give the ring opening products (Scheme 42: the bonds are broken in the cycloreversion reaction are in red).[153] More recently, this result has been questioned and a 95:5 mixture of stereoisomeric adducts was identified as the product.[148] Cycloreversion products were obtained also in the reaction of furan in the presence of furan-2-carboxyaldehyde.[154]

Coupling products can be obtained carrying out the reaction between an amide and furan: also in this case the cycloadduct cannot be isolated, but the subsequent decomposition products can be isolated (Scheme 43).[155] Furan quenches the fluorescence of the substrate, whereas a small new emission at 500 nm appears: this evidence is in agreement with a mechanism involving a reaction in the excited singlet state via the formation of an exciplex.

The reaction of some aromatic carbonyl compounds (benzophenone, benzaldehyde) with benzofuran has also been reported (Scheme 44); when compounds showing high triplet energy were used, dimers of benzofuran were obtained. On the contrary,

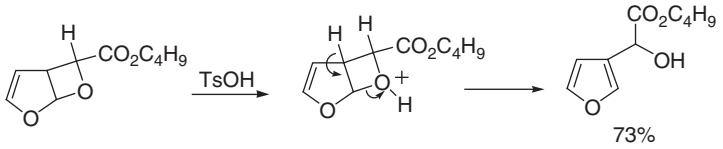


Scheme 42



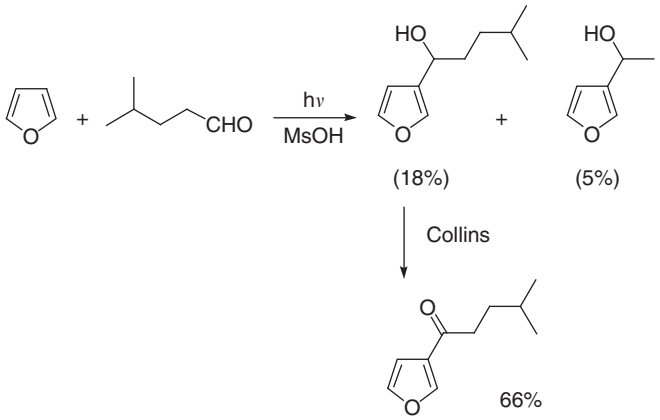
Scheme 43

when carbonyl carbonyl with a low triplet energy were used, oxetanes were the products of the reaction.[156] As in the case of furan, Schenck obtained only one regioisomer. A reinvestigation of the reaction of benzofuran when it was irradiated in the presence of acetophenone or propiophenone, showed that, also in this case, the corresponding oxetanes were the products of the reaction.[157]



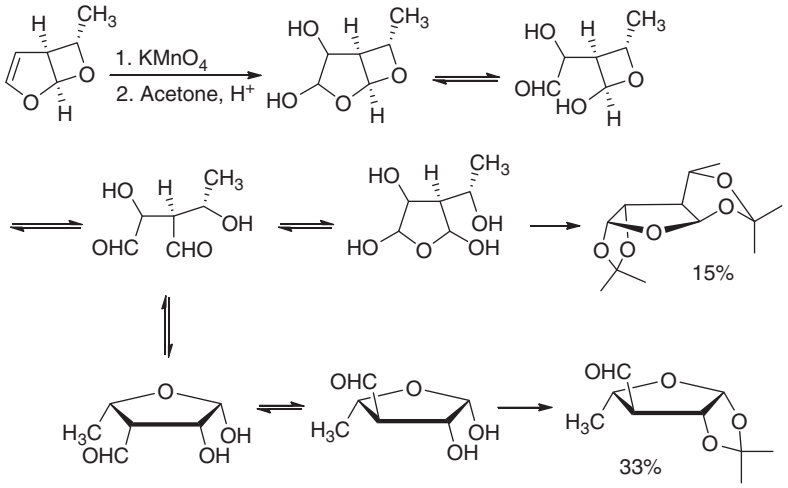
Scheme 44

The irradiation of **50** in the presence of benzaldehyde in benzene gave the corresponding adduct **51** in good yields (Scheme 45).[158] It is interesting to note that the reaction allowed the formation of the *endo* isomer. The reaction between benzo[*b*]furan and benzaldehyde gave an adduct whose stereochemistry has not been described.[156]



Scheme 45

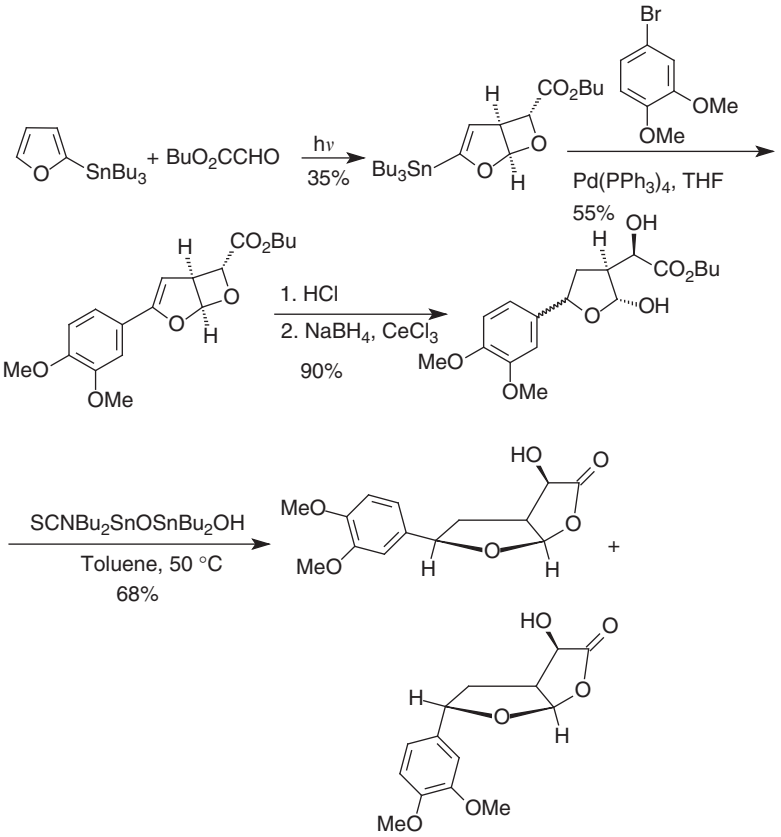
3-Furylcarbinol derivatives could be obtained through the treatment of the oxetanes with TsOH.[142] The formation of a protonated oxetane is in agreement with the high negative entropy of activation (Scheme 46).[159]



Scheme 46

If the irradiation was performed in the presence of an acid, 3-furylcarbinol can be obtained in a one-step procedure in better yields.[160] This procedure has been used in the synthesis of perillaketone, a naturally occurring 3-substituted furan (Scheme 47).[160] On the contrary, Lewis acids catalyzed a different behavior: the treatment with $BF_3 \cdot Et_2O$ gave only 3-substituted furan in THF and 89% of 2-substituted furan in acetonitrile.[159]

Scheme 47



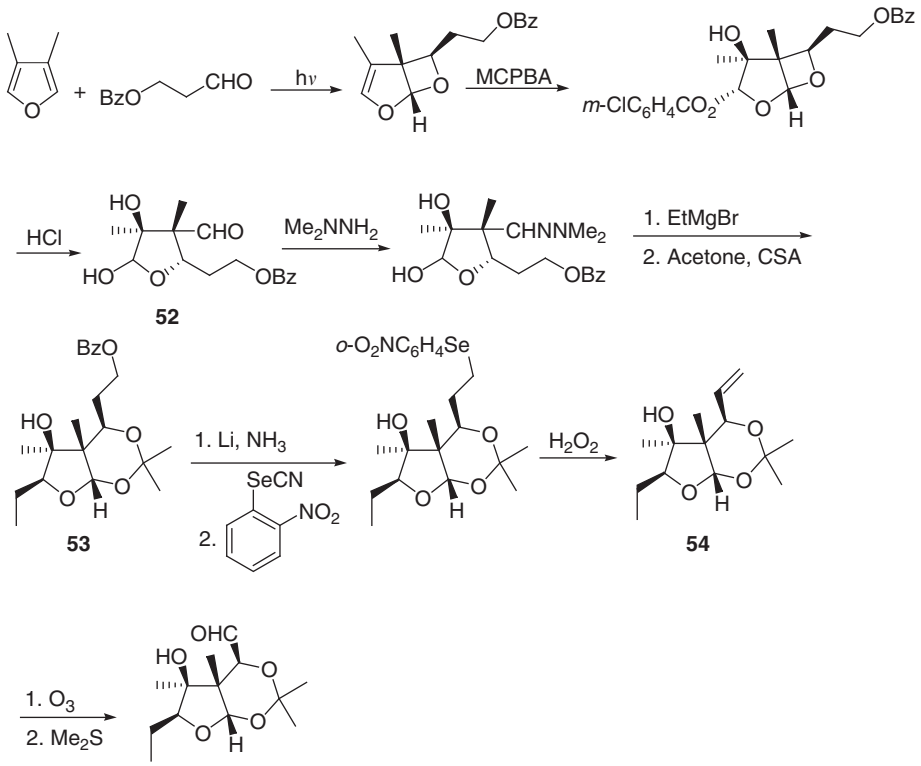
The oxetane derivatives were treated also with $KMnO_4$ and the resulting *cis* diol reacted with acetone in the presence of an acid. This procedure allowed the synthesis of a carbohydrate derivative (Scheme 48).[161]

Scheme 48

An epimerization reaction occurred on the *trans* diol obtained when the oxetane was treated with MCPBA.[161] Schreiber studied the possible chemical modifications on the cycloadduct deriving from the reaction between an aldehyde and a furan.[162]

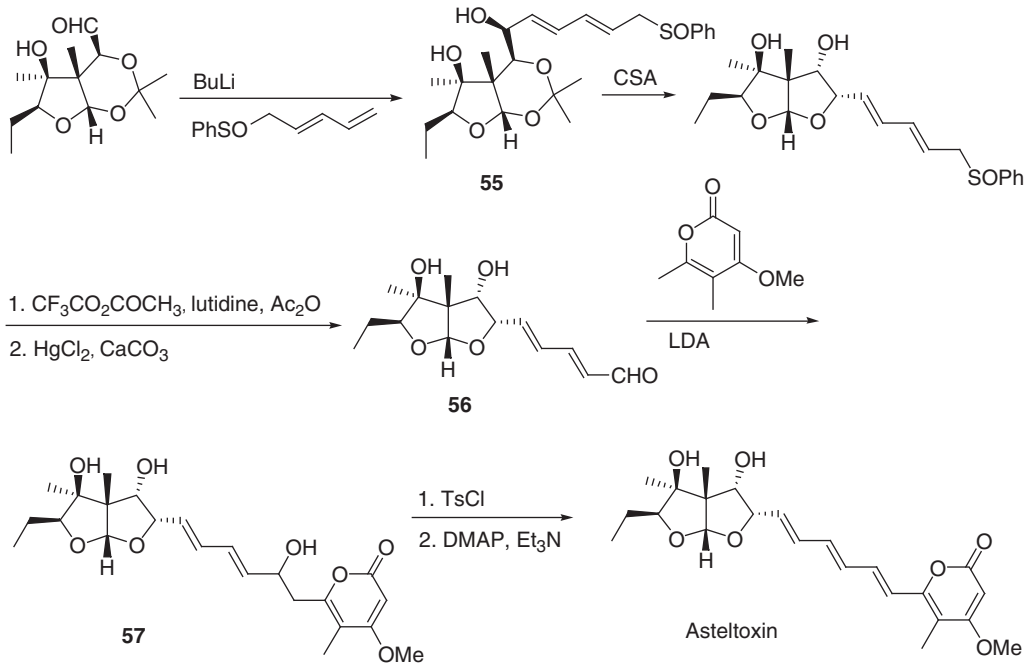
Hydrolytic ring opening, reductions, hetero Diels–Alder, the reaction with MCPBA, and hydroboration–oxidation were the reactions he studied. The reaction with MCPBA was used by Schreiber and coworkers in the synthesis of Asteltoxin,[163,164] and in that of Avenaciolide, an antifungal metabolite.[165] The reaction of tributylstannylfuran with butyl glyoxylate was used in the synthesis of a ginkgolide B-kadsurenone hybrid of two inhibitors of a platelet activating factor (Scheme 49).[144]

Scheme 49



In the synthesis of Asteltoxin, the synthetic sequence implies the photochemical coupling of 3,4-dimethylfuran with a functionalized aldehyde to give the corresponding adduct in 63% yield. The subsequent reaction with MCPBA gave the protected *trans* diol that was converted into **52** through acid hydrolysis. Then, the aldehyde was converted into the corresponding hydrazone and this substrate was treated with EtMgBr to give **53** with complete stereochemical control obtained through chelation. The subsequent conversion of the benzyl ether into a seleno derivative and the elimination of the selenoxide gave **54**. Compound **54** could be treated with ozone to give the corresponding aldehyde that was then converted into Asteltoxin (Scheme 50).

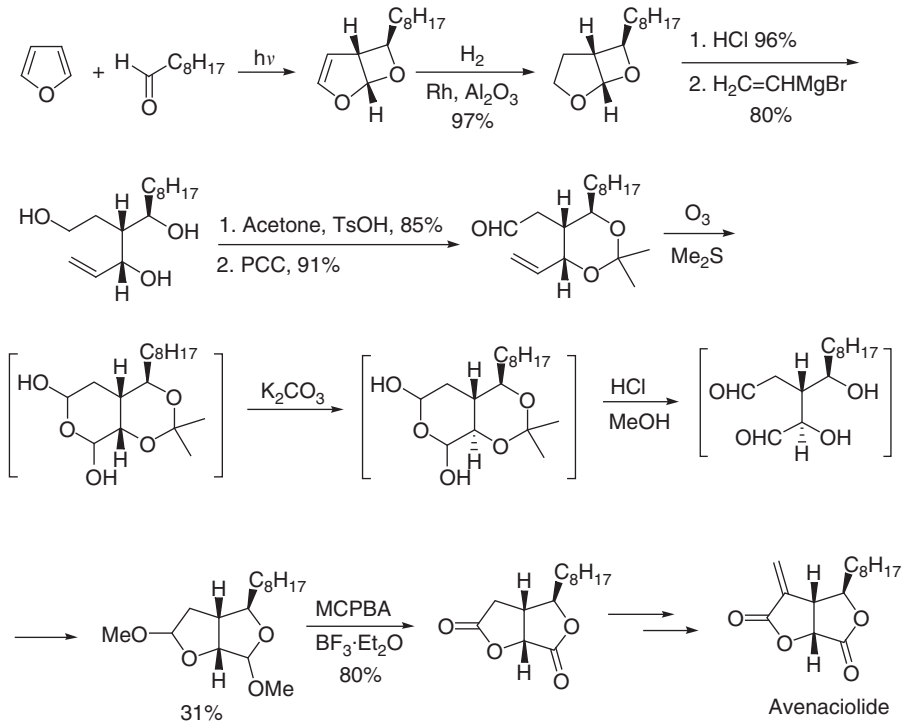
In fact, the aldehydic product could be alkylated with a vinyl anion and the subsequent double [2,3] sigmatropic rearrangement at room temperature furnished **55** as a 3:1 mixture of epimers. Camphorsulfonic acid induced the transposition of the substrate into a bis(tetrahydrofuran) derivative. Pummerer rearrangement and hydrolysis gave aldehyde **56**. Aldol condensation gave **57** and elimination gave Asteltoxin (Scheme 51).



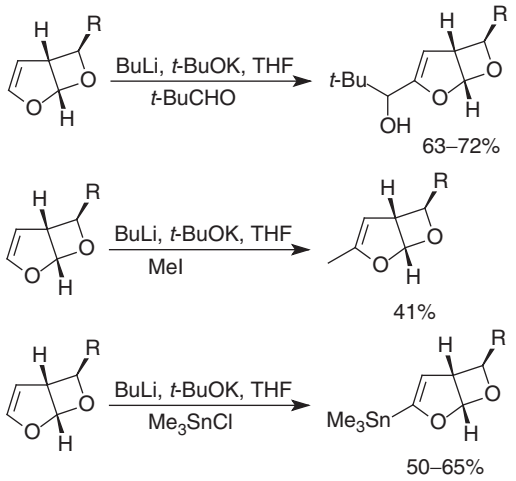
The same research group reported a formal synthesis of Avenaciolide, an antifungal metabolite (Scheme 52). In this case the oxetane (obtained in multigram quantities in high yields and with complete stereochemical control) was treated with hydrogen to give the saturated compound. The key step in this synthetic procedure is a reaction with ozone followed by a base catalysed epimerization with potassium carbonate and cyclization in acidic medium.

Furthermore, the cycloadduct obtained from the reaction between furan and an aldehyde can be treated with an excess of Schlosser's base (BuLi, *t*-BuOK). The reaction gave the corresponding anion which can react with carbonyl compounds or alkyl halides (Scheme 53).[166]

The most important target in this field was oxetanocin (**3**), a nucleoside isolated from *Bacillus megaterium* NK 84-0218 showing anti-HIV activity. An approach to the synthesis of this compound has been reported.[167] The treatment of oxetane **58** with *N*-iodosuccinimmide in the presence of methallyl alcohol gave the corresponding iodoacetals **59** (Scheme 54). The subsequent treatment of **59** with iodonium di-*sym*-collidine perchlorate (IDCP) gave **60** in low yields as a relatively unstable mixture of



Scheme 50

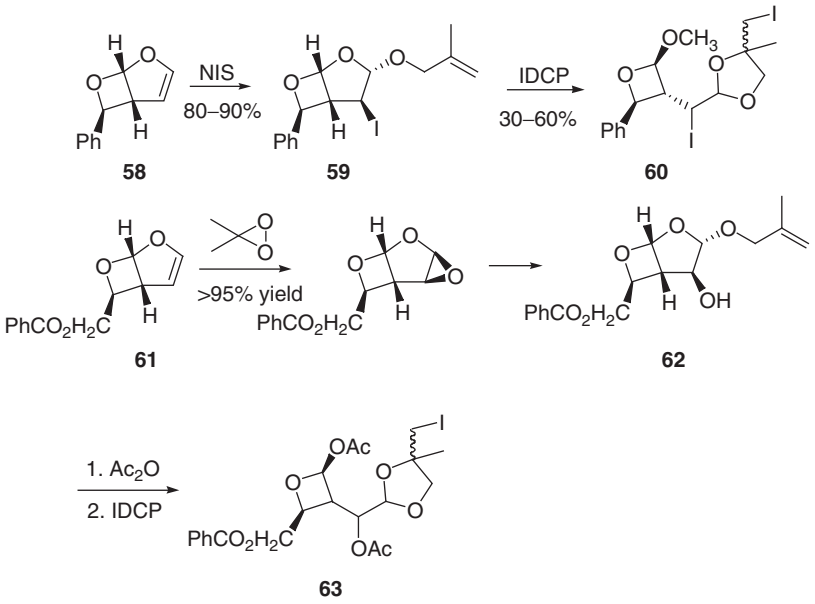


Scheme 51

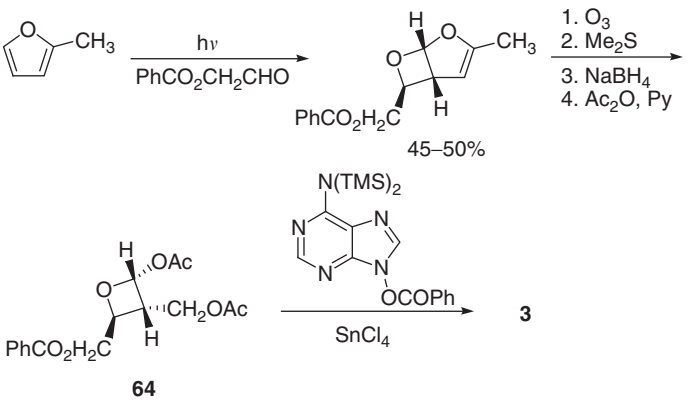
diastereoisomers. Alternatively, treatment of **61** with dimethyl dioxirane gave the corresponding epoxide and the treatment with methallyl alcohol gave the hydroxy acetal **62**. The treatment of **62** with IDCP gave **63** in moderate yields.

Oxetanocin was also obtained carrying out the reaction between 2-methylfuran and benzoyloxyacetaldehyde.[168] The corresponding adduct was treated with ozone and the product was reduced with $NaBH_4$. The obtained alcohols were protected. Product **64** was treated with *N*-benzoyl-disilyladenine and $SnCl_4$ to give **3** (Scheme 55).

Scheme 52

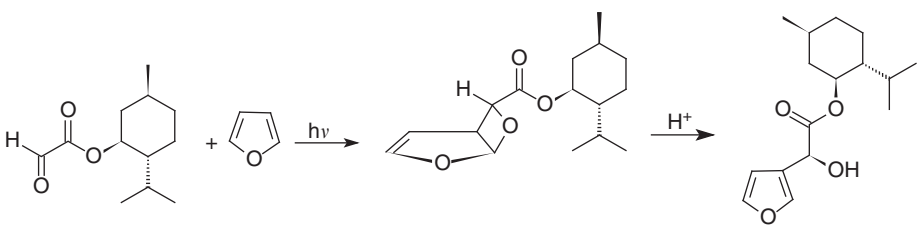


Scheme 53



The reaction of glyoxylates with furan can be performed also using chiral glyoxylate. In particular, the use of *R*-(–)-menthol, 2-octanol, and 2,2-dimethyl-3-butanol as chiral auxiliaries gave the corresponding oxetanes in high yields. These compounds can be converted into the corresponding 3-substituted furans. The furans showed low enantiomeric excess (Scheme 56).[169] On the basis of the experimental data the configuration of the oxetane was 1*R*,5*S*,6*S*.

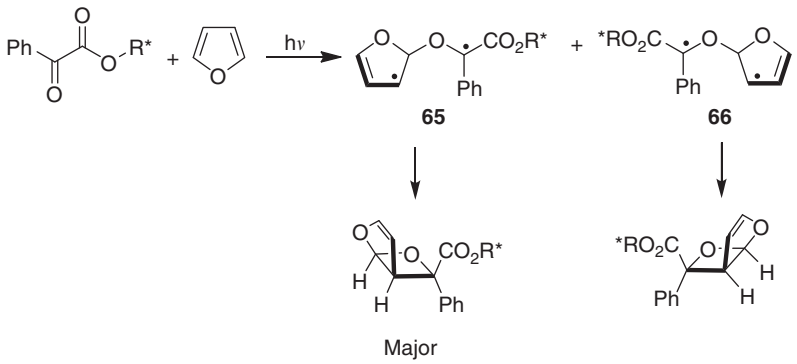
The use of chiral phenylglyoxylate gave better results. The use of chiral alcohols gave diastereoisomeric excess in the range of 4–80% (Scheme 57).[170–172]



An important variability of the diastereoisomeric excess in function of the temperature has been observed with the presence of an inversion temperature.[173] These results were explained assuming that the diastereoselection was produced on two levels: (1) the preferred formation of the diastereoisomeric 1,4-biradical intermediate **65** and (2) the preferred retrocleavage of the energetically unfavored diastereoisomeric intermediate **66** to the starting materials.[174] The diastereoisomeric excess in the high-temperature region ($T > T_{inv}$) is dominantly controlled by steric effects of the chiral auxiliaries, whereas in the low-temperature

Scheme 54

Scheme 55



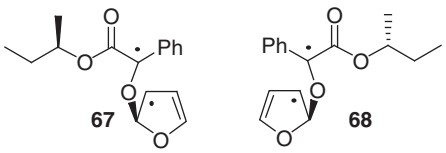
Scheme 56

region ($T<T_{inv}$), the nature of the olefin has a dominating influence. When the reaction is carried out on 2-methylfuran, a 2:1 regioisomeric mixture was obtained with a very high diastereoisomeric excess.[175]

In order to justify the observed stereoselectivity the triplet biradical intermediates in the reaction of some phenylglyoxylate derivatives with furan could be considered.[173] Calculations on these biradical intermediates showed that **67** (the precursor of the observed product) was more stable than **68** by 0.73 kcal mol^{-1} (Figure 18).

Neckers studied the reaction of ethyl phenylglyoxylates with several alkenes showing that it gave the cycloaddition reaction only when electron-rich alkenes were used. Furthermore, the main reaction observed when monosubstituted alkenes were used

Scheme 57



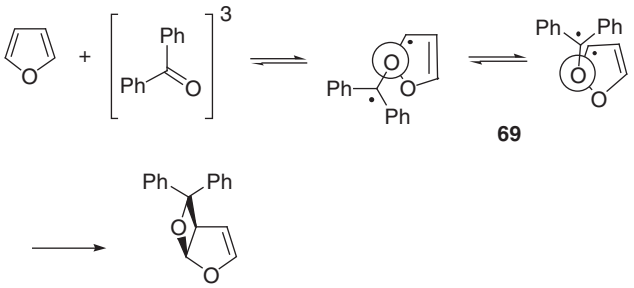


Figure 18 Radical intermediates in the reaction of chiral phenylglyoxylates with furan.

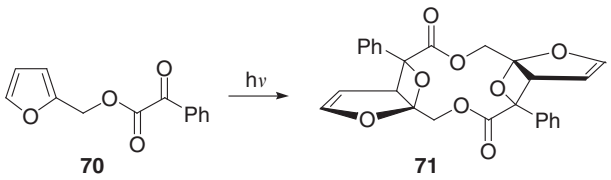
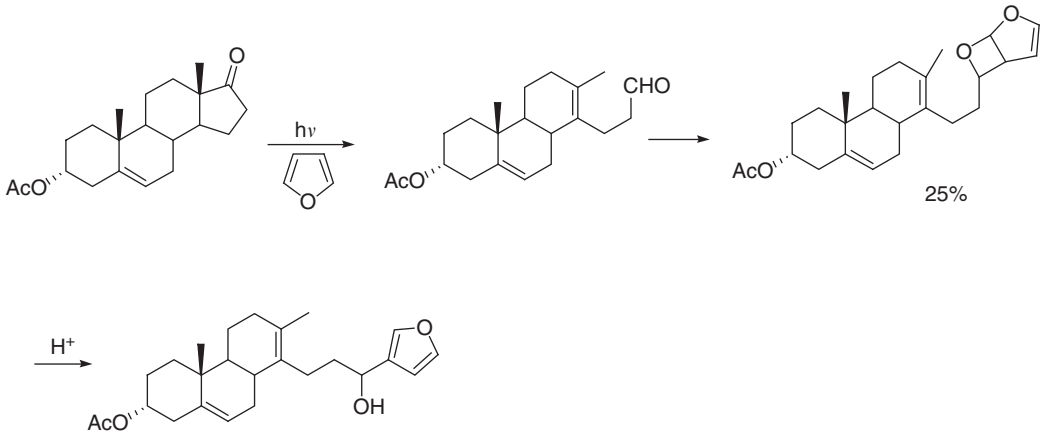
was the Norrish type II reaction and the same behavior was observed reducing the electron richness of the alkenes.[176] Methyl 2-thienylglyoxylate showed a transient absorption at 390 nm and a broad band at approximately 600 nm. This transient band has been assigned to the triplet state. This compound reacted with 2,3-dimethyl-2-butene to give the corresponding adduct.[177]

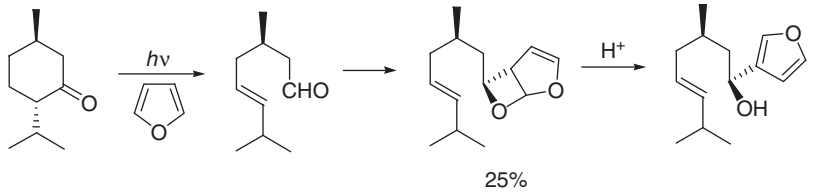
To improve diastereoselectivity, the reaction was carried out in an organized medium, for example, in the presence of different zeolites.[178] NaY was the best solid zeolite support for this reaction. The origin of this behavior can be explained considering the possible effect of the confinement on the reaction. In the Paternò–Büchi reaction the biradical intermediate **69** can assume two possible conformations.[30,68] One has the radical carbons in almost *anti* conformation, whereas the other one shows a *syn* conformation (Scheme 58).



Scheme 58



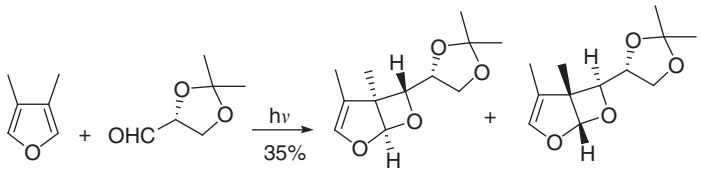
The *syn* conformation can undergo the following cyclization, after the intersystem crossing from the triplet to the singlet state. For the *anti* conformation the most favored process is the retrocleavage to the starting material. The *syn* conformations take up a smaller volume than the *anti* one. The preferential formation of a stereoisomer in the reaction within a zeolite could be explained: the *SS-syn* conformer was obtained preferentially, whereas the *RS* conformer was obtained preferentially in *anti* conformation. The latter conformer has to rotate along the C–O bond to give the *syn* conformation the ability to cyclize. Zeolites could act as agents able to reduce the conformational mobility of the intermediates. They inhibited the rotation of this conformer and, then, favored the formation of the product deriving from the (*S*,*S*)-biradical intermediate.



Recently, Abe reported an attempt to obtain an intramolecular version of the Paternò–Büchi reaction between furan and a carbonyl compound. Nevertheless, the irradiation of the phenylglyoxylate derivative **70** allowed only the formation of the product **71**, deriving from an intermolecular reaction. Low yields were obtained (Scheme 59).[179]

The irradiation of furan in the presence of acyl cyanides yielded the corresponding oxetanes but both diastereoisomeric *endo*- and *exo*-oxetanes are formed. Low asymmetric induction was observed when chiral acyl cyanides were used.[180] Furan reacted also with chiral ketones. In this case, before the 2 + 2 cycloaddition, an α-cleavage reaction modified the expected products (Scheme 60). A chiral product was obtained as a 2:1 diastereoisomeric mixture where the most abundant product has 1*R*,3*R*

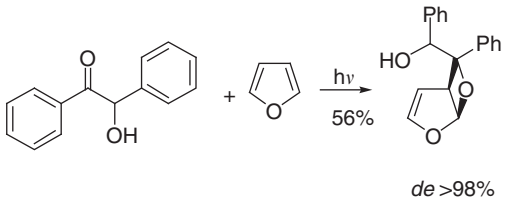
Scheme 59



Scheme 60

configuration when (–)-menthone was used as a substrate.[181] If the irradiation was performed on the ketonic functional group in a protected carbohydrate, a complex reaction mixture was obtained.[182,183]

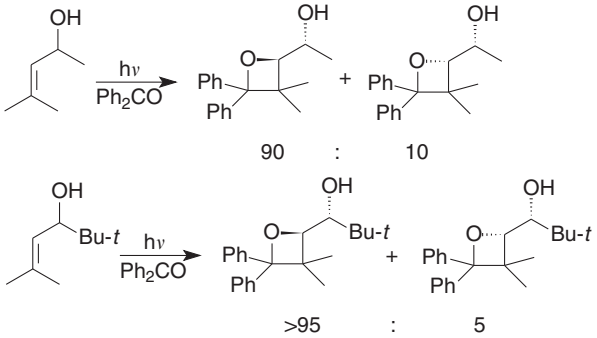
The reaction between 3,4-dimethylfuran and *R*-isopropylidene glyceraldehyde was performed in order to obtain a stereoselective Paternò–Büchi reaction. The coupling products were obtained with an overall yield of 35% as a 1.2:1 mixture of diastereoisomers. Furthermore, the compound **72** was obtained with 54% *ee* (Scheme 61).[184]



72 12 : 1

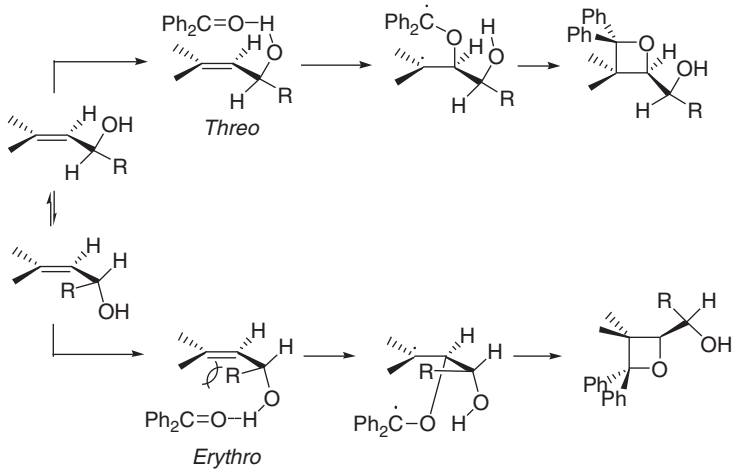
Scheme 61

This behavior suggested a mechanism that was insensitive to the substitution pattern of chiral aldehydes. Reaction between an excited aldehyde (singlet or triplet state) and furan proceeds with initial carbon–oxygen bond formation to produce either of the two biradical species. The stereocenter adjacent to the carbonyl is now in a 1,4-relationship to the newly formed stereocenter at the acetal carbon and is expected to exert little influence as a stereocontrol device.[184] This hypothesis is not in agreement with the stereochemical behavior of using phenyl glyoxylate esters where the chiral carbon atom was farther than in *R*-isopropylidene



glyceraldehyde. The extensive racemization observed probably reflects the photolability of the aldehydes toward racemization under the conditions of the reaction.[184] Nevertheless, compound **72** can be used in a chiral synthesis of the bicyclic part of asteltoxin confirming the assigned absolute configuration.[184] On the contrary, benzoin reacted with furan to give the corresponding adduct in acceptable yield (56%) and *de* > 98% (Scheme 62).[185]

Scheme 62



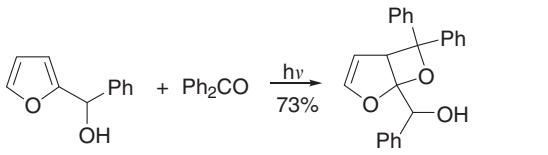
The observed stereoselectivity was explained considering the relative stability of the biradical intermediates. Nevertheless, chiral ketones gave the Norrish Type II reaction as the only observed reaction. In order to avoid Norrish Type II reaction a substrate without γ-hydrogen was used.[186]

In 1990 Griesbeck found that the reaction of benzaldehyde with homoallylic alcohols did not show diastereoselectivity.[61] Nevertheless, Adam showed that allylic alcohols reacted with benzophenone to give the corresponding adducts with high regio- and diastereoselectivity (Scheme 63).[187–190]

Scheme 63

In the presence of protic methanol, the diastereoselectivity dropped drastically, whereas it totally disappeared using the corresponding silyl ethers. These data are in agreement with the presence of a hydroxyl directing effect in the Paternò–Büchi reaction. The formation of a hydrogen bond between triplet excited benzophenone and the substrate in the exciplex favored the formation of the *threo* isomer. On the contrary, the formation of the *erythro* stereoisomer would be less favored due to allylic strain (Scheme 64).

Scheme 64

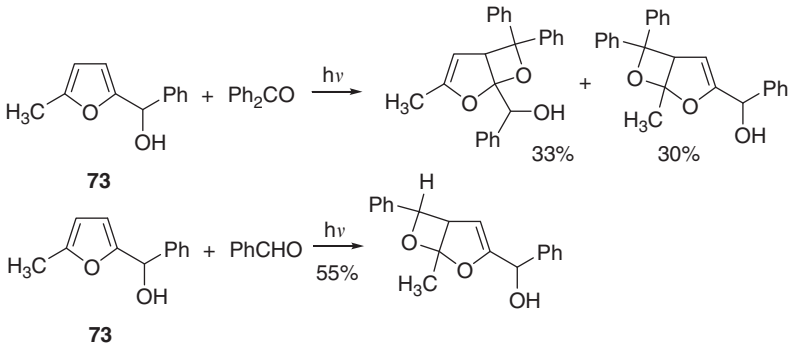


The formation of a hydrogen bond to direct the Paternò–Büchi reaction has been considered by other researchers. Diastereoselective cycloaddition has been obtained using chiral enamide,[191,192] or in the reaction of allylic alcohols with naphthalene rings.[193] When unsymmetrical carbonyl partners such as acetophenone or benzaldehyde were used, the corresponding *cis* isomer was observed with high diastereoselectivity. The regioselectivity was high with acetophenone but lower with benzaldehyde.[188]

Cis diastereoselectivity can be explained using the Griesbeck rule on the possible triplet biradicals formed in the reaction. Steric interactions are minimized when the biradical assumes the optimal conformation and this conformation accounts for the formation of the observed stereoisomer.[190]

When chiral allylic alcohols were used as substrates in the reaction *cis* diastereoisomers were formed. Furthermore, also in this case, a pronounced *threo* diastereoselectivity was observed, in agreement with a less pronounced hydroxyl directing effect when acetophenone and benzaldehyde were used.[188,190] Chiral allyl ether gave the corresponding adduct with high diastereoselectivity.[98] It is to be noted that this result is not in agreement with previous reported data on the reactivity of silyl ethers of allylic alcohols.[187]

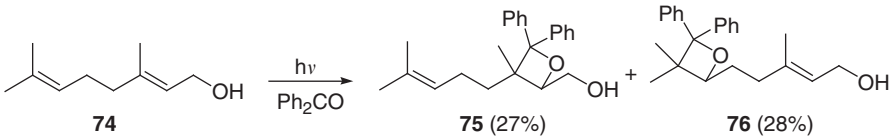
The reaction of 2,3-dihydrofuran-3-ol derivatives (a particular type of allylic alcohol) with benzophenone gave the corresponding adducts. In methanol, a *trans* relationship between the oxetane ring and the hydroxyl group was observed, whereas, in benzene, the *cis* isomer prevailed. The Eyring plot showed that the *trans* isomer increased with a nonlinear behavior on decreasing the temperature.[194]



The reaction of allylic alcohols with carbonyl compounds was tested also on 2-furylmethanol derivatives. The presence of large substituents on the carbon bearing the alcoholic function allows a high regioselectivity (Scheme 65).[195]

One diastereoisomer

Scheme 65

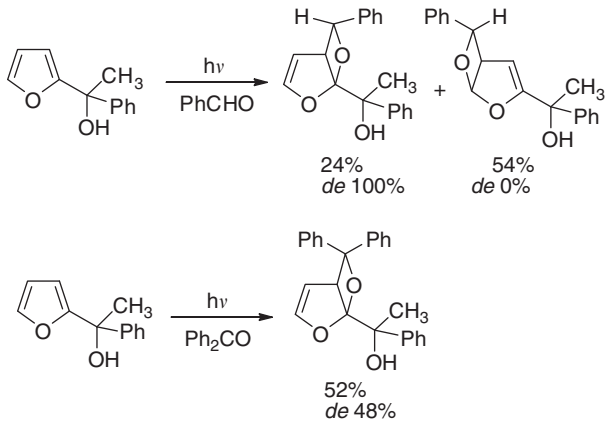


5-Methyl-2-furyl derivatives were used as substrates showing a different regioselectivity. Compound **73** gave a 1:1 mixture of regioisomers, when irradiated in the presence of benzophenone, and a single regioisomer in the presence of benzaldehyde (Scheme 66).[196] In agreement with the results obtained with 2-furyl derivatives, the products deriving from the attack on the side bearing the alcoholic function were obtained as a single diastereoisomer, whereas those deriving from the attack on the side bearing the methyl group were obtained as a mixture of diastereoisomers.

Scheme 66

The above described reactions showed that on furan two possible regioisomers could be obtained. The experimental results showed that, in some cases, the reactions occurred mainly on the side when the hydroxyl group was present, whereas other reactions showed a completely different regioselectivity. The reason of this behavior can be found in kinetic factors depending on the different stability of the biradical intermediates. These considerations are in agreement with the results obtained irradiating geraniol (**74**) in the presence of benzophenone (Scheme 67).[197]

In this case, two different double bonds were present: a double bond able to give a tertiary radical intermediate, and an allylic alcoholic moiety. The authors found that at $-75\ ^{\circ}C$ **76** was obtained in 44% yields whereas **75** was obtained only in 13% yields. Furthermore, at $20\ ^{\circ}C$ the yields were 29% and 15%, respectively. In this case, then, the attack on the terminal double bond was favored.



74 **75** (27%) **76** (28%)

Scheme 67

The reaction of 2-furylmethanol derivatives with aliphatic aldehydes and ketones gave the corresponding adducts with high regioselectivity: the reaction occurred on the most hindered side of the substrate. However, no diastereoselectivity was observed.[198] The relative stability of the biradical intermediates was able to explain the regioselectivity of the reaction. A computational study (density functional theory (DFT)) showed that the biradical obtained on the most hindered side of the molecule was more stable than the other one.[196]

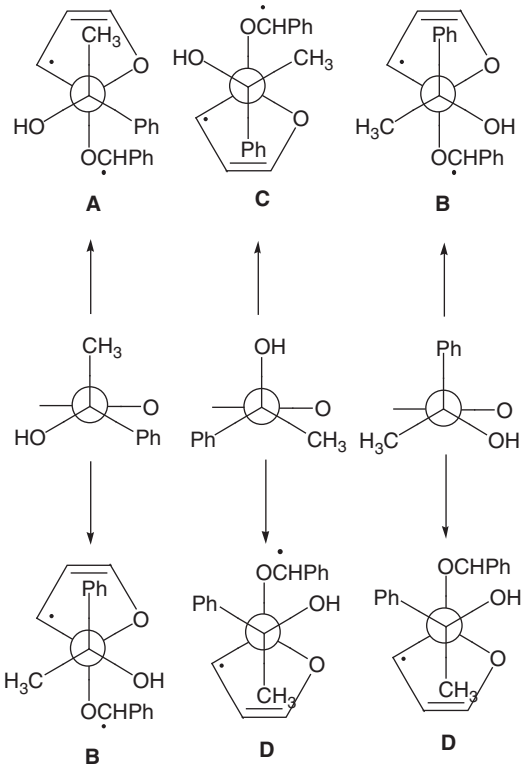
The diastereoselectivity of the reaction between 2-furylmethanol derivatives and aromatic carbonyl compounds clearly showed that it increased in relation to the nature of the substituents on the carbon bearing the alcoholic function as described by Adam. However, whereas Adam considered the allylic strain with a methyl group in β-position as the driving force for the diastereoselectivity, in this case, a methyl group on the C-3 of the furan ring was not present.

In order to have more data to explain the observed stereoselectivity the photochemical behavior of tertiary 2-furylcarbinols was studied.[199] The irradiation of 1-methyl-1-phenyl-1-(2-furyl)methanol with benzaldehyde gave a mixture of two regioisomeric products. The regioisomer on the most hindered side of the molecule was obtained in low yield, but it showed a complete diastereoisomeric control. On the contrary, the main product was a mixture of four diastereoisomeric products (Scheme 68). The reaction of the same compound with benzophenone gave only the product deriving from the attack on the most hindered side of molecule. This compound was obtained with 48% diastereoisomeric excess.

Scheme 68

The regioselectivity was explained, as described above, considering the relative stability of the biradical intermediates. In this case, in the reaction of the 1-methyl-1-phenyl-1-(2-furyl)methanol with benzaldehyde the biradical obtained on the less hindered side of the substrate was more stable than the other one by 18.03 kJ mol^{-1}. Recently, some authors reported that no stereoselectivity was observed using cyclic 2-furyl methanol derivatives.[200] However, in another work, the stereoselective behavior of the same substrates was assumed.[201]

On the basis of these results an explanation of the stereochemical behavior was attempted.[199] 1-Methyl-1-phenyl-1-(2-furyl)methanol showed three conformations. All three conformers were in the range of 1.97 kJ mol^{-1} and they did not show a preference. The directing effect exerted by the hydroxyl group is due to the formation of a hydrogen bond between the hydroxyl group and the oxygen of the excited carbonyl compound, or it is due to the formation of a complex. This type of interaction could favor the formation of a preferential conformation in the biradical intermediate where the hydroxyl group and the oxygen of the carbonyl compound are near. These conformations could have different energies for different diastereoisomeric biradicals, giving an explanation of the observed behavior. In the case of 1-methyl-1-phenyl-1-(2-furyl)methanol, if the hydroxyl group drove the attack of the oxygen of the carbonyl group, the conformations of the biradical intermediate represented in Figure 19 were obtained. **B** and **D** were the preferential conformations: calculations on these conformations showed that there was a difference of 13.26 kJ mol^{-1} between the energies of these two conformations. This difference can account for the observed complete diastereoselectivity of the reaction. In the reaction of the same substrate with benzophenone, the corresponding conformers **B** and **D** showed a difference energy of 7.79 kJ mol^{-1}: this difference is in agreement with the observed diastereoselectivity.



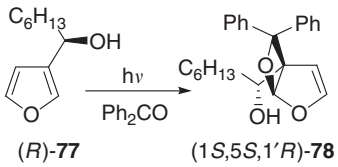


Figure 19 Possible conformations of the biradical intermediate from the reaction of 1-methyl-1-phenyl-1-(2-furyl)methanol with benzaldehyde.

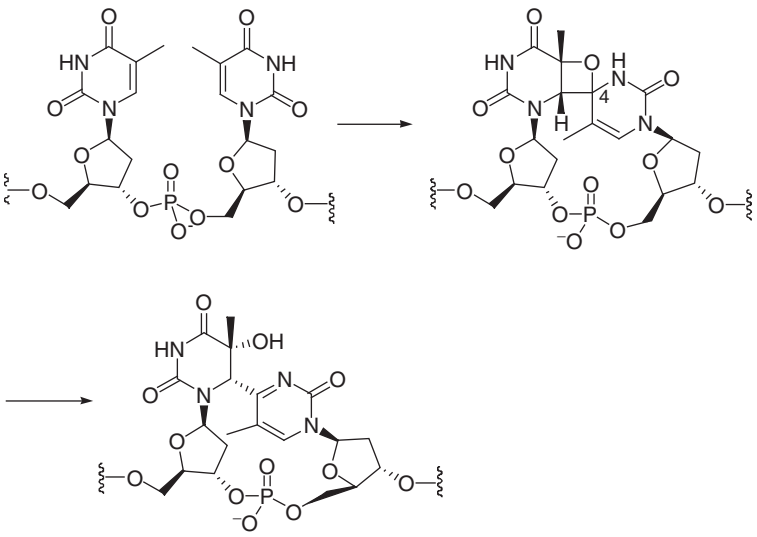
The same approach can be used to justify the stereochemical behavior of the reaction of allylic alcohols with benzophenone.[202] The irradiation of (*R*)-**77** in the presence of benzophenone gave the (1*S*,5*S*,1′*R*)-**78** (Scheme 69).[203]

Scheme 69

The above reported results in this section represent all the available data on the Paternò–Büchi reaction on pentaatomic heterocycles. One can see that, with the exception of furan, there are very few data: in particular, (1) most of the unsubstituted tested compounds different from furan did not react, (2) only a few substituted derivatives showed a significative reactivity toward excited carbonyl compounds.

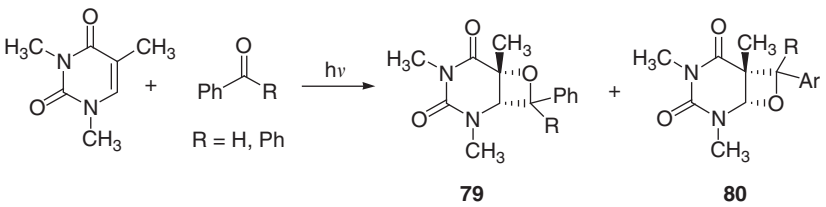
This behavior may be due to different reasons. First, the different aromaticity of the compounds could play an important role in order to define the reactivity of the compounds. Furan is the lowest aromatic pentaatomic heterocyclic compound known, whereas the other compounds show higher aromaticity. However, this type of explanation cannot justify why thiophene does not react whereas simple dimethylthienyl derivatives react and why some dimethylthienyl derivatives react whereas some others do not show any reactivity.



A different explanation was identified in the quenching properties of these heterocycles. Thiophene and monomethyl derivatives are efficient quenchers of triplet benzophenone. The Stern–Volmer plot showed a linear relationship.[204,205] On the contrary, 2,5-dimethylthiophene (a compound able to give the cycloaddition reaction) is not a good quencher of the triplet benzophenone.[206] In this case, the Stern–Volmer plot is not linear. This situation is commonly encountered when the quencher employed quenches two excited states. It seems reasonable that pyrrole acts as quencher of both triplet benzophenone and the exciplex between triplet benzophenone and pyrrole.[206]

On the basis of these investigations, the common five-membered heterocycles may be classified into two categories in regard to their quenching properties: those with electron-donating groups, which give Stern–Volmer plots in the shape of straight lines, and those substituted with halogens and electron-attracting groups, such as *N*-benzoylpyrrole, which give parabola-shaped curves.

Those in the first category give oxetanes when they are bad quenchers. Since these compounds do not presumably form exciplexes, they should go from starting materials to products through a biradical intermediate. However, those in the second category most likely give oxetanes when they are good quenchers, as may be shown for 2,5-dibromothiophene, and furthermore they go from starting materials to products through an exciplex.[207]

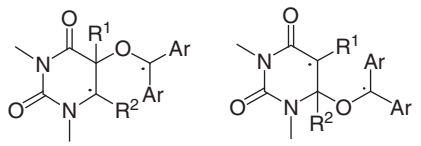


5.05.2.2.2 Reactions of six-membered heterocycles

The (6–4) photoproduct is an adduct of two pyrimidines that occupy adjacent sites on the same DNA strand. It is the second major lesion induced in DNA by UV radiation. Although statistically four times less frequent than CPD lesion, (6–4) photoproducts are believed to be severely mutagenic. Its formation is believed to occur via an initial Paternò–Büchi type cycloaddition to form an oxetane intermediate. Subsequent C4–O bond cleavage gave the observed (6–4) photoproducts (Scheme 70).

Scheme 70

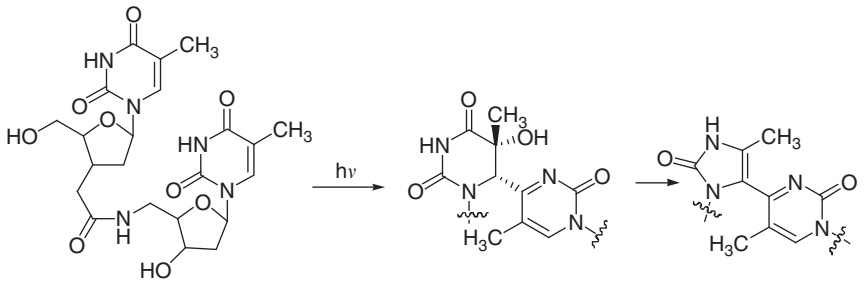
The (6–4) photoproduct is one of the major mutagenic classes of DNA photoproducts and is involved in the etiology of skin cancer. The oxetane **79** was prepared in a triplet reaction and both electron donor and acceptor substituents were found to be able to photosensitize the splitting reaction (Scheme 71).[208–211] Only one regioisomer (**79**) was observed. The other regioisomer **80** was rarely observed.[212]



Scheme 71

The temperature can determine the regiochemistry of the reaction. At −38 °C the regioisomer **79** dominates (61:39). However, at 70 °C the regioisomeric behavior of the reaction is inverted.[212,213] A change of the selectivity-determining step has been determined considering a nonlinear Eyring plot. Two different cases can be assumed: the situation where the conformational changes of the triplet intermediates were slower than ISC at low temperature and the case where the conformational changes exceed the ISC process.[213] When the conformational interchange is faster than the ISC process, the population of high potential energy conformations decreases, whereas the population of a lower potential energy conformer increases.

A weak solvent effect was observed on the regioselectivity of the reaction.[214] Substituents on benzophenone modified the regiochemistry of the reaction: when *p*-methoxybenzophenone is used on 1,3-dimethyluracil the isomer **79** is obtained (**79**/**80** > 95:5), whereas, using *p*-cyanobenzophenone, a 32:68 **79**/**80** ratio was observed.[215,216] The benzophenones with electron-withdrawing groups gave more efficient Paternò–Büchi reactions and lower **79**/**80** ratios, whereas benzophenones with

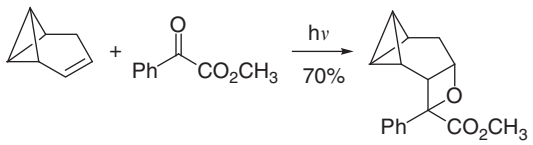


electron donating groups underwent less efficient Paternò–Büchi reactions and had higher **79**/**80** ratios.[217] The quantum yields correlated with the energy gap between SOMO of benzophenone derivatives and the HOMO of the uracil. Recently, a computational approach to this reaction appeared.[218] The authors studied the biradical intermediates **81** and **82** (Figure 20). They found that **82** is more stable than **81**, and that the formation of **81** is faster than **82**. Then, **80** can be considered as a thermodynamic product, whereas **79** a kinetic one.

81 **82**

Figure 20 Biradical intermediate in the reaction of dimethyluracil.

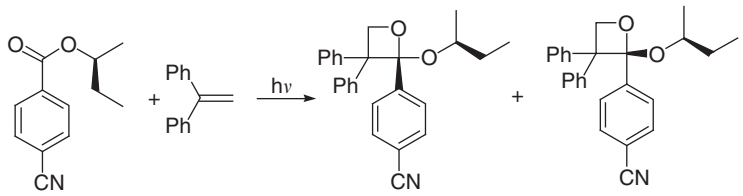
Recently, it has been observed that, due to the energy barriers between the two stable conformers, the equilibrium was more favorable for the formation of the oxetane **80**, rather than oxetane **79** at a higher temperature. Triplet benzophenones with a short lifetime would give rise to a less efficient Paternò–Büchi reaction.[217] The oxetane was obtained also in the reaction between benzophenone and benzophenone-derived drugs and thymidine.[211,219] An enantioselectivity factor for triplet deactivation was found using enantiopure ketoprofen. The use of enantiopure ketoprofen showed that thimidine was able to give an enantioselective quenching of the chiral ketoprofen triplet state. This quenching was related to the formation of the C–O bond, the first step of oxetane formation.[67] An intramolecular reaction between thymidine esterified by ketoprofen has been reported.[220] The irradiation of **83** gave **85** deriving from the (6–4) photoadduct **84** (Scheme 72).[221]



83 **84** **85**

Scheme 72

A reaction between 5-fluoro-1,3-dimethyluracil with 1,5-dimethoxynaphthalene has been reported.[222] The reaction gave product where an aromatic ring of naphthalene is broken. The presence of the intermediate adduct has been proposed.



5.05.2.3 Other Intermolecular Reactions

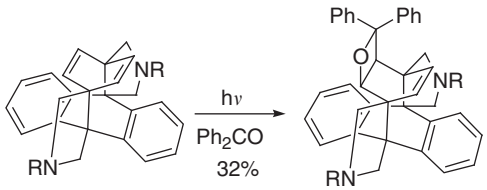
5-Substituted adamantan-2-ones gave the corresponding cycloadducts via the n,π^* excited singlet state. This substrate gave a regiospecific reaction with a low stereoselectivity (the best result was 59:41 ratio in favor of the *anti* isomer).[223–226] Methyleneadamantane reacted with acetone. However, the Paternò–Büchi adduct was obtained in only 5% yield.[223] The reaction of biacetyl with benzvalene gave the corresponding adduct, whereas benzophenone gave, as the only product, benzene.[44] When homobenzvalene was used as the alkene in the reaction with ethyl phenylglyoxylate, the irradiation gave the corresponding adduct in 70% yield with high stereoselectivity (Scheme 73).[227]

Scheme 73

Esters could be used as carbonyl compounds in the reaction with chiral alkyl cyanobenzoate derivatives (Scheme 74).[228,229]

86 **87** (1′*S*,2*R*)-**88** (1′*S*,2*S*)-**89**

Scheme 74



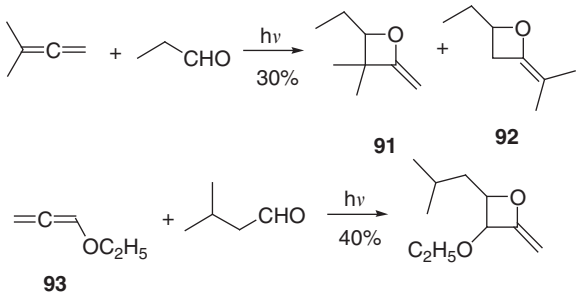
The reaction occurred through the first excited singlet state. The authors showed the presence of a charge transfer band at 300–330 nm. Irradiating at 254–290 nm, a good diastereoselectivity was observed (*de* 77%). The irradiation at 330 nm afforded the formation of an epimeric mixture. The photocyclization was likely to proceed via a short lived 1,4-biradical mechanism. Then, the diastereo-face-differentiating complexation of chiral alkyl cyanobenzoate with the olefin donor is responsible for the observed *de* values. Calculations showed that the conformational population in the charge-transfer complex is almost the same in agreement with the observed lack in diastereoselectivity.

A stereoselective behavior has been described in the reaction between benzophenone and cyclooctene. At $-95\,^{\circ}C$ the *cis* adduct was formed with a very high diastereoselectivity from *cis*-cyclooctene. On the contrary, at $-20\,^{\circ}C$ both diastereoisomers were generated. At higher temperatures, the *trans* adduct dominated. Over a broad temperature range (-80 to $+60\,^{\circ}C$), the more strained *trans*-cyclooctene gave nearly exclusively the *trans* adduct.[93,94] Triplet ketone could attack the double bond to give two biradical intermediates and the authors suggested that temperature-dependent conformational changes of the biradical competed with the cyclization to the oxetane and the retro cleavage to the *cis*-cyclooctene. The activation barrier between two conformers of the biradical intermediate could explain the increase of *trans*-oxetane with the temperature.[94]

1-Acetylisatin reacted with styrene and furan derivatives to give the *endo* adduct with high stereoselectivity.[230,231]

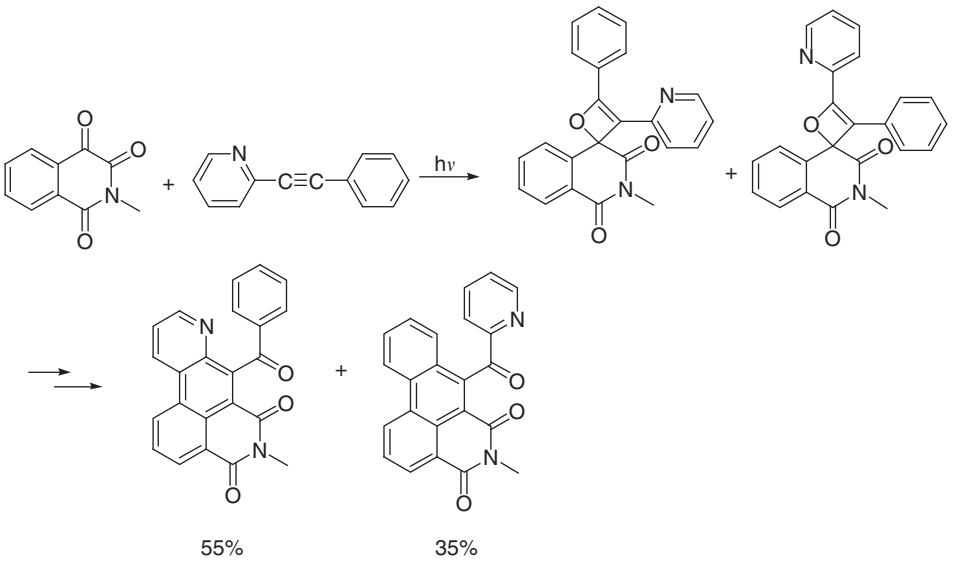
Quinones reaction with stilbene derivatives has been described.[73,232] In this case, a charge-transfer absorption band was observed at 480 nm. Time-resolved (ps) absorption spectrum showed an absorption at 480 nm (chloranil anion radical) and a broad band at approximately 760 nm. After 50 ps, a transient absorption typical for triplet chloranil at 510 nm was observed. The reaction occurred through selective excitation at 480 nm. Quinones reacted with diarylacetylene giving a product deriving from the ring opening of a transient oxetene. Time-resolved (ps) absorption spectrum was in agreement with an electron-transfer mechanism.[233] When 2-chloro-5-methoxybenzoquinone reacted with arylacetylenes, CIDNP experiments suggested a mechanism where the attack of the triplet quinone on the acetylene gives a biradical intermediate.[92] The same behavior has been observed in the reaction between quinone and quadricyclane and norbornadiene.[234,235] The adduct was also found in the reaction between quinones and acenaphthylene.[77]

Benzophenone can react also with a paracyclophane derivative **90** (Scheme 75).[236]



90

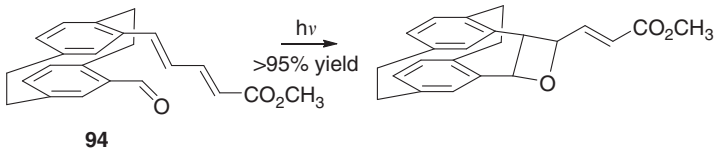
Scheme 75



The Paternò–Büchi reaction can also be applied to other unsaturated systems other than alkenes, such as dienes,[10] allenes,[237] acetylenes,[238] and ketenimines.[237] When tetramethylallene reacted with aromatic ketones the main products resulted from bis-addition of the carbonyl compounds to give dioxaspiroheptanes.[239,240] On the contrary, 1,1-dimethylallene gave only the monoaddition 2:1 mixture of **91** and **92** in a reaction with aliphatic aldehydes (Scheme 76).[241] A higher regioselectivity was obtained using the allene **93** (Scheme 76).

The irradiation of isoquinoline-1,3,4-trione with alkynes gave a product deriving from an initial Paternò–Büchi reaction on the carbonyl at C-4 to give the corresponding oxetene (Scheme 77).[242]

DFT calculations on the relative stability of the biradical intermediate showed that the more stable one was the precursor of the main product of the reaction.

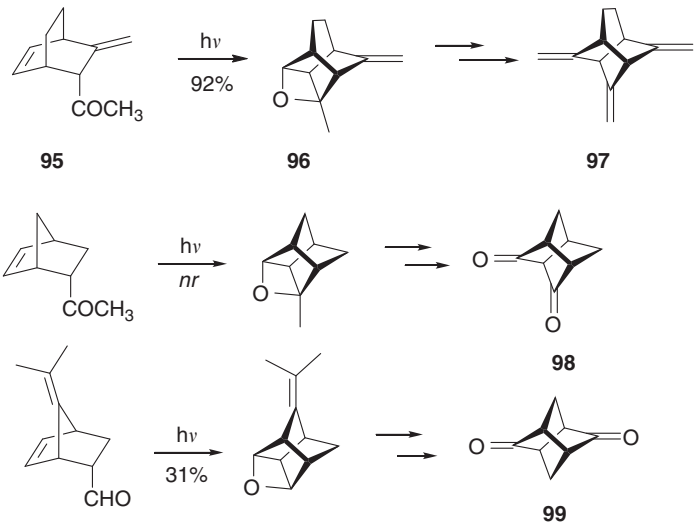


Scheme 76

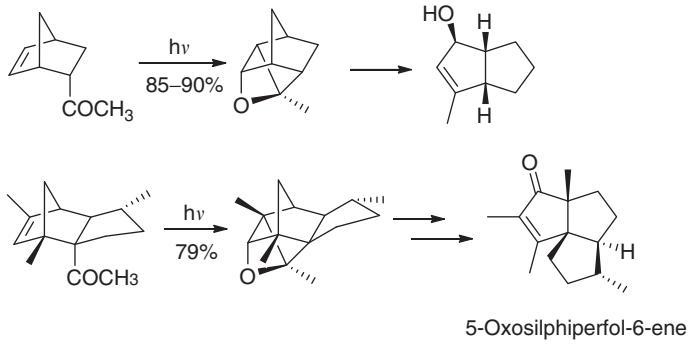
Scheme 77

5.05.3 Intramolecular Reactions

An intramolecular Paternò–Büchi reaction on a paracyclophane derivative **94** has been reported giving the corresponding adduct in quantitative yield (Scheme 78).[90]

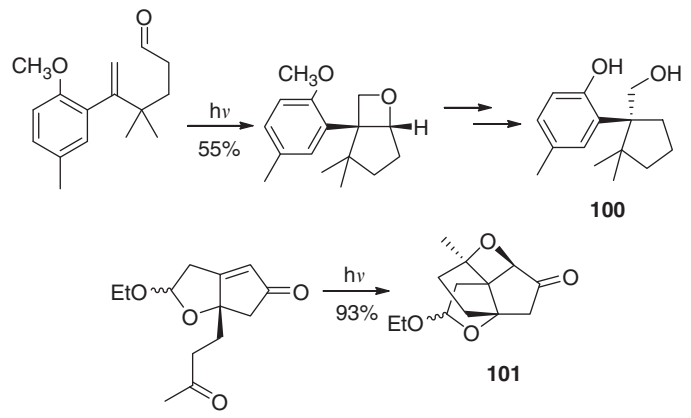


Scheme 78



An intramolecular Paternò–Büchi reaction of **95** to give **96** has been used in the synthesis of 2,7,9-trimethylenetricyclo[4.3.0.0^{3,8}]nonane **97** (Scheme 79).[243]

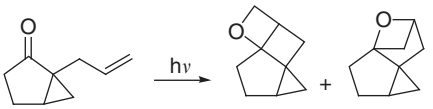
The same synthetic scheme was used in the synthesis of 2,7,9-trimethylenetricyclo[4.3.0.0^{3,8}]non-4-ene.[244] The preparation of some stelladiones such as tricyclo[3.3.0.0^{3,7}]octane-2,4-dione **98** or tricyclo[3.3.0.0^{3,7}]-octane-2,6-dione **99** (Scheme 79).[245] This type of intramolecular reaction was the key step used in the synthesis of diquinanes and triquinanes (Scheme 80).[246–248]



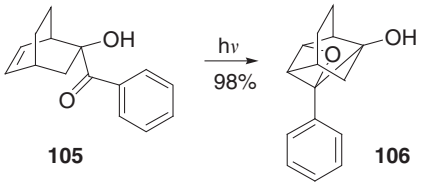
The synthesis of 1,13-herbertenediol **100** was performed using an intramolecular Paternò–Büchi reaction between an aldehydic group and an α-alkyl substituted styrene moiety (Scheme 81).[249] An intramolecular stereoselective Paternò–Büchi reaction was the key step also in the synthesis of some derivatives of *R*-(+)-sclareolide.[250] A synthesis of the scaffold of merrilactone A also involved an intramolecular 2 + 2 cycloaddition to give the adduct **101** (Scheme 81).[251]

Scheme 79

Scheme 80



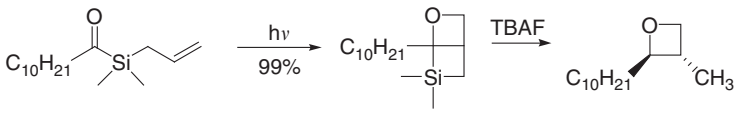
Scheme 81



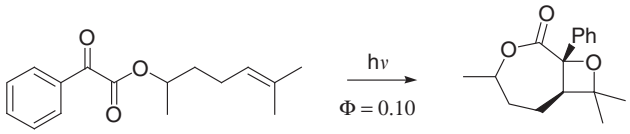
However, a project devoted to obtain tromboxane analogs using an intramolecular reaction of a carbonyl group with an enol ether, failed.[252]

An intramolecular reaction on allyl cyclopentanone derivatives has been reported.[230,253,254] In this case both *straight* **103** and *crossed* **104** oxetanes can be obtained (Scheme 82). Using 2-allylcyclopentanone nearly equal amounts of these isomers were obtained. However, the use of the more rigid starting material **102** allowed the preferential formation the *straight* isomer.

An intramolecular cycloaddition reaction was found in the reaction of **105** to give **106** (Scheme 83).[255]

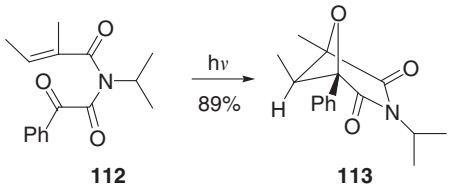


Scheme 82



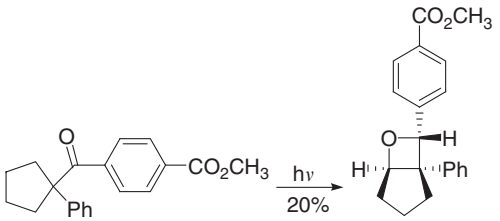
Scheme 83

Compound **107** gave in quantitative yield the oxetane **108** through an intramolecular reaction. The oxetane thus obtained could be converted into **109** via fluoride desilylation (Scheme 84).[256]



Scheme 84

When alkenyl phenylglyoxylates were used as substrates, Norrish type II is the main reaction in most of the cases, with the exception, for example, of compound **110** able to give the adduct **111** (Scheme 85).[257,258]



Scheme 85

N-Isopropyl-*N*-tigloylbenzoylformamides gave an intramolecular cycloaddition reaction in high yields (50–99%) to give the *syn* adduct (*syn*/*anti* = 2.1).[259,260] The compound **112**, irradiated in solid state, showed a different behavior: the crystals of **112** are in a chiral group, so **112** gave **113** with a *syn*/*anti* = 6.7 and *syn*-**113** was obtained with a high *ee* value (> 99%) (Scheme 86).[260]

Scheme 86

When the ketone **114** was irradiated in the solid state, the only possible reaction was a Norrish Type I reaction. The reaction gave an alkene and a carbonyl compounds, able to react in an intermolecular reaction giving the corresponding adduct **115** (Scheme 87). The reaction occurred with high stereoselectivity, and, when performed on a chiral salt gave the product with *ee* in the range 42–52%.[237]

Glossary

Enantiomorphous crystals When they crystallize, molecules can be repetitively arranged in 230 different ways (230 space groups) in a three-dimensional network. Of these, 165 space groups possess inverse elements of symmetry (linked to symmetry operations of the second kind or improper operations), such as planes or centers. These elements of symmetry enable the transformation of an object into its mirror image. Consequently, enantiopure compounds cannot crystallize in these space groups. A total of 65 space groups do not possess inverse elements of symmetry. Only symmetry operations of the first kind or proper operations linked, for instance, to rotation are possible. Enantiopure compounds, therefore, only crystallize in one of these 65 space groups (or more of them in the case of polymorphism) and form enantiomorphous crystals. After the formation of molecules from atoms, crystallization of these molecules constitutes a second step of structure building of material. Chiral objects such as molecules can be formed from achiral objects such as atoms. Consequently, achiral molecules may also form enantiomorphous crystals with chiral morphologies. Generally, the same number of single crystals of each enantiomorphology (handedness) is formed although techniques have been developed to direct the crystallization toward only one enantiomorphology. Chemical transformation in such crystals is applied to absolute asymmetric synthesis. Most frequently, however, achiral molecules and racemic mixtures of chiral molecules prefer crystallizing in achiral space groups.

Mesoporous silica Mesoporous silica possesses tunable pore diameters of 2–30 nm and surface areas $>600\ m^2\ g^{-1}$. Generally, such materials are produced by combination of supramolecular templating and sol-gel chemistry. Surface-modified mesoporous silica is applied to adsorption, catalysis, separation, drug delivery, and sensing.

Photochemical electron transfer Molecules change their chemical properties when they are electronically excited. Thus, the redox-potentials of organic molecules are different at the ground state and at the excited state. In many cases, an electron transfer between two molecules only occurs if one of them is photochemically excited. Using the photochemical electron transfer, the redox chemistry of many organic compounds is considerably enriched.

Photochemical excitation When a molecule absorbs light (UV, visible), an electron is transferred from one orbital to another (electronic excitation). For example, in a carbonyl function, an electron may be transferred from the nonbonding orbital n to the π^* orbital ($n\pi^*$ excitation). The corresponding molecule reaches the lowest excited singlet state S_1. In the same molecule, by absorbing light with a lower wavelength (higher energy), the second excited state S_2 may be reached by transfer of one electron from the π orbital to the π^* orbital ($\pi\pi^*$ excitation). Most organic molecules possess a singlet ground state S_0 in which all electron spins are paired. When such molecules are electronically excited, they may also change their spin multiplicity and the corresponding triplet states T_1 or T_2 are reached by intersystem crossing. Generally, these triplet states possess lower energy and the intersystem crossing is exothermic.

Photochemical sensitization A photochemical reaction may also be induced by sensitization. In this case, not the substrate but another compound (sensitizer) absorbs light and transfers its excitation energy to the substrate. The latter becomes electronically excited and undergoes a

 doi:10.1016/B978-0-08-097742-3.00506-1

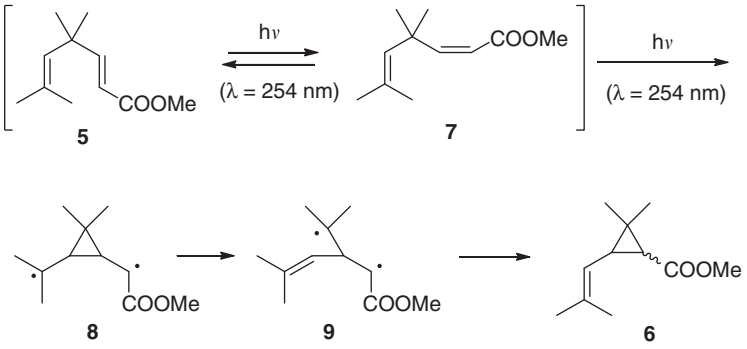
photochemical reaction. The sensitizer may transfer its singlet energy and the substrate reaches a singlet excited state. The sensitizer may also transfer its triplet energy (triplet sensitizer) to the substrate, which reaches directly a triplet excited state. These two sensitizing processes are frequently applied to organic photochemical reactions.

Zeolite Zeolites are crystalline aluminosilicates containing regularly arranged pores and cavities (ca. 3–15 Å). They are widely used as sorbents, catalysts, or ion exchange materials. Zeolite Y ($M_{56}(AlO_2)_{56}(SiO_2)_{136}$) is a synthetically obtained zeolite possessing faujasite structure.

5.06.1 Introduction

The di-π-methane photoisomerizations belong to those photochemical reactions that impress by their mechanistic complexity and beauty. In many cases, these reactions are well foreseeable and therefore frequently applied to organic synthesis. As in many of such cases, starting from simple substrates, in only one defined and selective step, a complex structure is generated.[1–3] Most commonly, the reaction takes place in molecules possessing two olefinic double bonds or one olefinic and one C=X double bond connected by a sp^3 hybridized carbon atom.[4,5] Generally, the mechanism is presented as a two-step process (Scheme 1). After excitation of the 1,4-diene **1**, the 1,4-biradical **2** is formed. A rearrangement takes place leading to **3**. In the last step, radical combination yields the cyclopropane derivative **4** as the final product. However, mainly in the past but also more recently, a concerted mechanism is discussed.[6–8] Furthermore, a direct transformation of the electronically excited 1,4-diene **1** into the 1,3-biradical **3** via a 1,2-aryl shift was discussed for benzonorbornadiene derivatives.[9] The reaction occurs at the singlet or the triplet state and is induced either by direct light absorption of the substrate or by photochemical sensitization. As can easily be deduced from the general scheme, the reaction may occur in two senses when the double bonds are carrying different substituents. A lot of investigations on this topic have been carried out and this aspect has been frequently reviewed.[5,6,10–13] This chapter focuses on applications of the di-π-methane rearrangement to organic synthesis. In specific cases, aspects of regio- and stereoselectivity will be discussed. Several previous reviews and book chapters also deal with this aspect.[14] Therefore, examples are preferentially chosen from the recent literature.

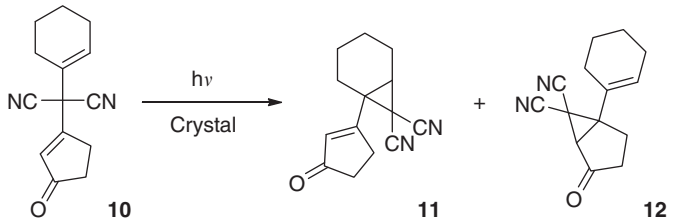
Scheme 1



5.06.2 Di-π-methane Photoisomerization

As already briefly mentioned, the di-π-methane photoisomerization may occur at the singlet or at the triplet state. In the case of the all-carbon variant, these are $\pi\pi^*$ states. It was shown that in the case of open chain structures, the isomerization mainly occurs at the singlet state. In this case, the di-π-methane rearrangement is considered as a concerted process and would be described as a formal $[_\sigma 2_a + _\pi 2_a]$ cycloaddition.[15] At the triplet state, however, *cis*/*trans* isomerization is frequently observed as a competing reaction.[14] In contrast to these acyclic substrates, more constrained cyclic and polycyclic compounds readily undergo di-π-methane photoisomerization at the triplet state. Thus, many sensitized processes have been reported.

5.06.2.1 Acyclic Substrates

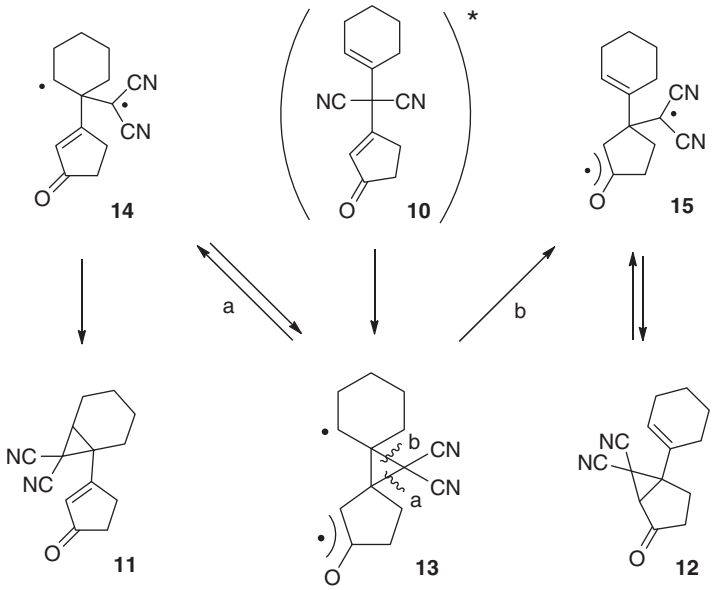


An interesting application of the di-π-methane photoisomerization to synthesis is the transformation of compound **5** by direct irradiation in hexane into methyl chryanthemate **6**, which possesses insecticidal activities. When compound **5** was irradiated at $\lambda = 254$ nm, a mixture of four products was isolated. The starting material was recovered as a *cis*/*trans* mixture (**5**/**7**, 1:1) (80%) and the chrysanthemate **6** formed as a *cis*/*trans* mixture of 1:2 (20%) (Scheme 2).[16] Prolonged irradiation under these conditions let to degradation of the product. When irradiated in the presence of acetophenone as triplet sensitizer, only a mixture of the *cis*/*trans* isomers **5** and **7** was formed. These observations suggest that the di-π-methane rearrangement occurs at the singlet state, whereas the *cis*/*trans* isomerization may occur at the singlet and the triplet state.[17] An extensive mechanistic study was performed with similar compounds carrying a diphenylvinyl moiety.[18] A detailed investigation performed with a large variety of triplet sensitizers revealed that the di-π-methane photoisomerization in acyclic systems may also occur at the triplet state.[19] The outcome of such reactions then highly depends on the structure of the sensitizer. A photostationary equilibrium is established between compounds **5** and **7**. In order to optimize the reaction and to limit degradation at prolonged irradiation, a further investigation may be performed by studying the photostationary equilibrium, as has been previously done for industrial photochemical

transformations such as vitamin D production.[20] More adapted photochemical reactors such as microstructured continuous flow systems[21] may be helpful.

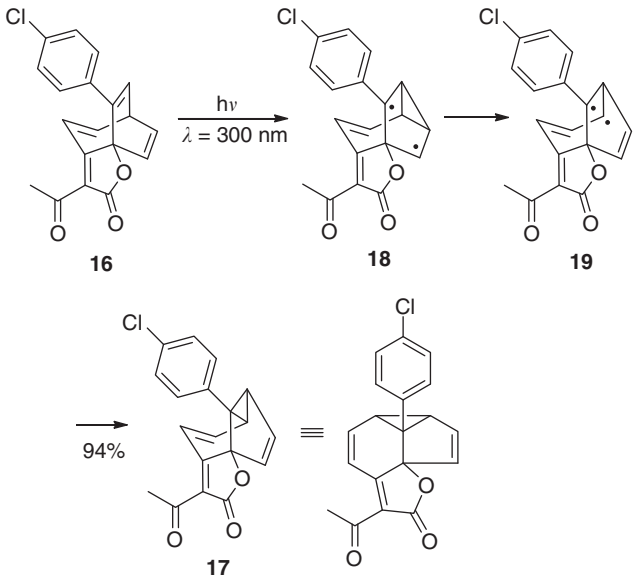
Scheme 2

Asymmetric synthesis was carried out with the di-π-methane rearrangment using absolute chiral induction. Several achiral compounds form crystals with chiral space groups. In such enantiomorphous crystals,[100,101] the substrates are placed in a chiral environment.[22–24] When transformed by solid-state irradiation, the products are generally obtained in high optical purity. Photochemical transformations are particularly suitable because photons easily enter into the crystal. In contrast, transformations at the ground state with chemical reagents only occur at the crystal surface. Crystals of the achiral malodinitrile derivative **10** are enantiomorphous and have the space group $P2_12_12_1$. When such crystals are irradiated, two asymmetric di-π-methane isomerizations take place (Scheme 3, Table 1).[25] The enantioselectivity is induced by the chiral environment in the crystal and depends on the irradiation time, the conversation, and the reaction temperature. The same reaction, but without any chiral induction, was observed in solution. The product ratio **11**:**12** also depends on these reaction parameters. Based on these observations, the mechanism depicted in Scheme 4 was suggested. The $\pi\pi^*$ excited substrate **10** rearranges to the biradical **13** (also compare Scheme 1). The next steps determine the regioselectivity of the isomerization. Either bond a or bond b is broken, leading to the corresponding 1,3-biradical intermediates **14** and **15**. Radical combination yields the final products **11** and **12**. Equilibria between the two radical intermediates **13** and **14** on one hand and between product **12** and intermediate **15** on the other have been discussed. They are determined by the relative stability of the delocalized oxoallyl radicals **13** and **15**. As the conversion in the solid state progresses, the formation of regioisomer **12** is favored over that one of **11**. Attempts to apply this method of chiral induction to slightly varied structures were so far unsuccessful because in such cases crystals with achiral space groups were obtained.[26]



Scheme 3

Table 1 Enantio- and regioselectivity of the reaction of **10** in solution and in the solid state (Scheme 3)

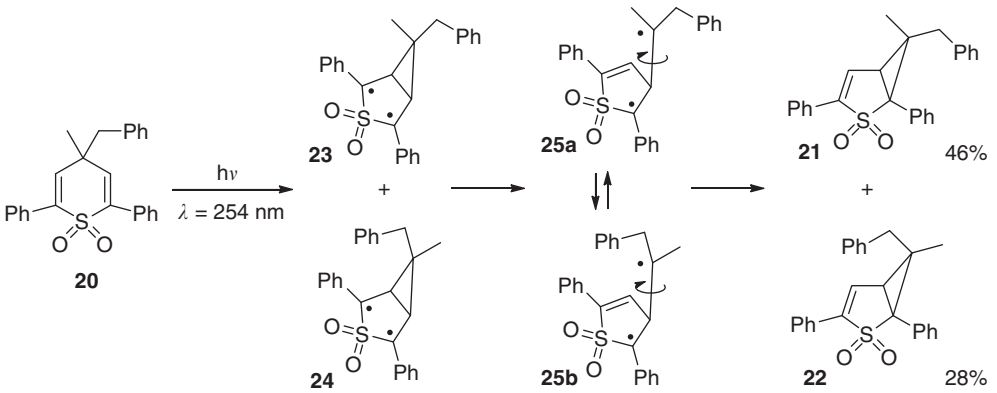


Medium	*Time (h)*	*Conversion (%)*	*Ratio **11**:**12***	*Enantiomeric excess (%)*	
				11	***12***
Solution (MeCN)	22	100	3.2:1	0	0
Neat (crystals)	2–8	9–51	1.2:1–1:1.9	22–44	55–96

5.06.2.2 Cyclic Substrates

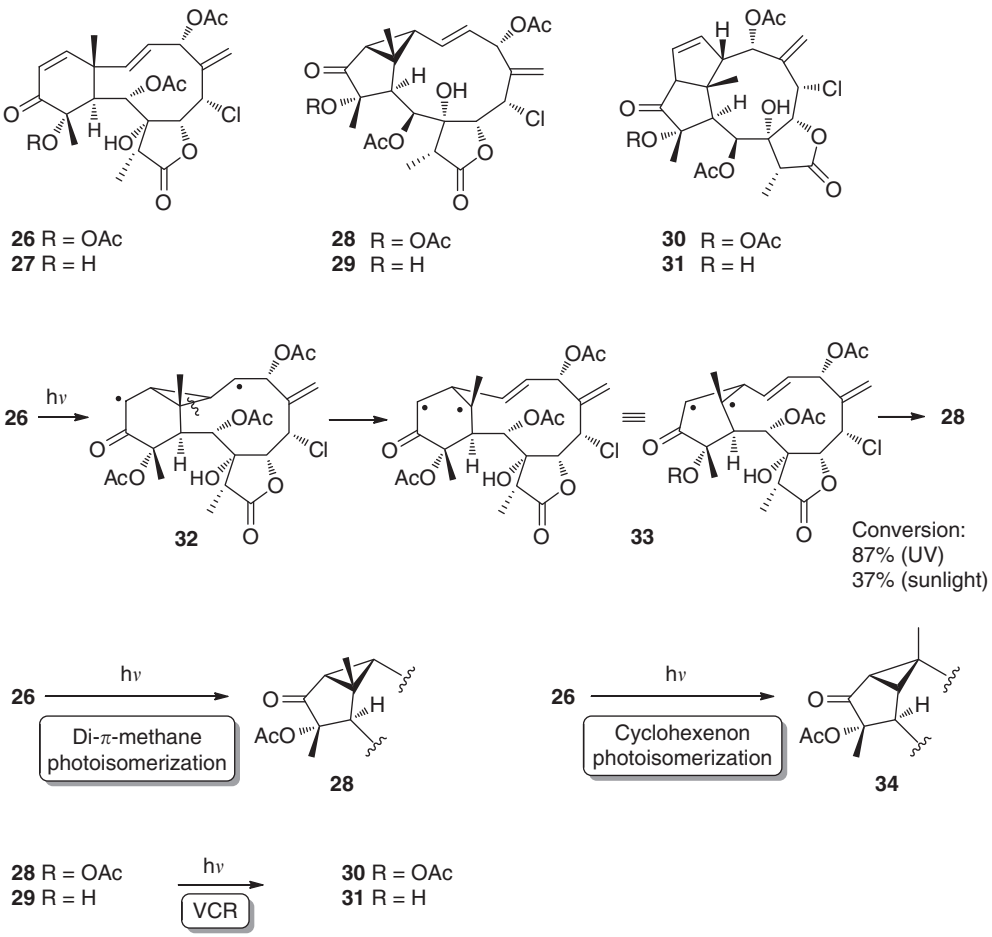
The di-π-methane photoisomerization is facilitated when the 1,4-diene moiety is included in a cyclic or polycyclic system. Thus, the polycyclic compound **16** was efficiently transformed into the cyclopropane derivative **17** by direct excitation (Scheme 5).[27]

Scheme 4



Scheme 5

It must be pointed out that this reaction is stereo- and regio-specific. The selectivity is certainly induced by the favored formation of intermediates **18** and **19** possessing both a benzyl radical center.

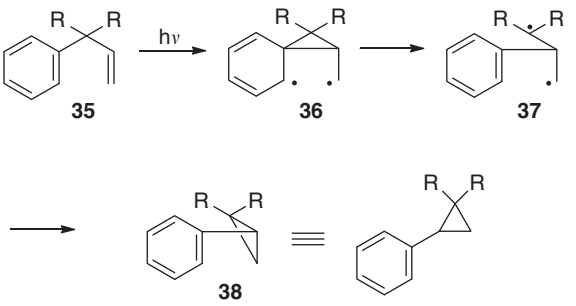


Heterocyclic compounds such as 4-*H*-thiopyran-1,1-dioxides undergo easily di-π-methane photoisomerization.[28] Thus, compound **20** has been transformed into stereoisomers **21** and **22** (Scheme 6).[29] After excitation, the biradical intermediates **23** and **24** are generated. At this stage, a certain diastereoselectivity is induced. Bond breaking at the cyclopropane moiety leads to the 1,3-biradical intermediate **25a,b**. A conformational equilibrium between *syn* (**25b**) and *anti* (**25a**) arrangements also contributes to the stereoselectivity.

The di-π-methane photoisomerization was also observed or discussed in the context of the biosynthesis of natural products. Among other diterpenoids, compounds **26**, **27**, **28**, **29**, **30**, and **31** have been recently isolated from the Caribbean gorgonian coral *Erythropodium caribaeorum* (Scheme 7).[30] It was previously suggested that compounds **28** and **29** result from a di-π-methane rearrangement of **26** and **27**, respectively. In order to prove this hypothesis, compound **26** was separated and irradiated with light under different conditions.[31] In the case of UV irradiation (medium pressure Hg lamp) in benzene, after 3 h, a high conversion of compound **26** was observed. When a 5% solution in methanol was exposed to sunlight, a conversion of 37% was reached after

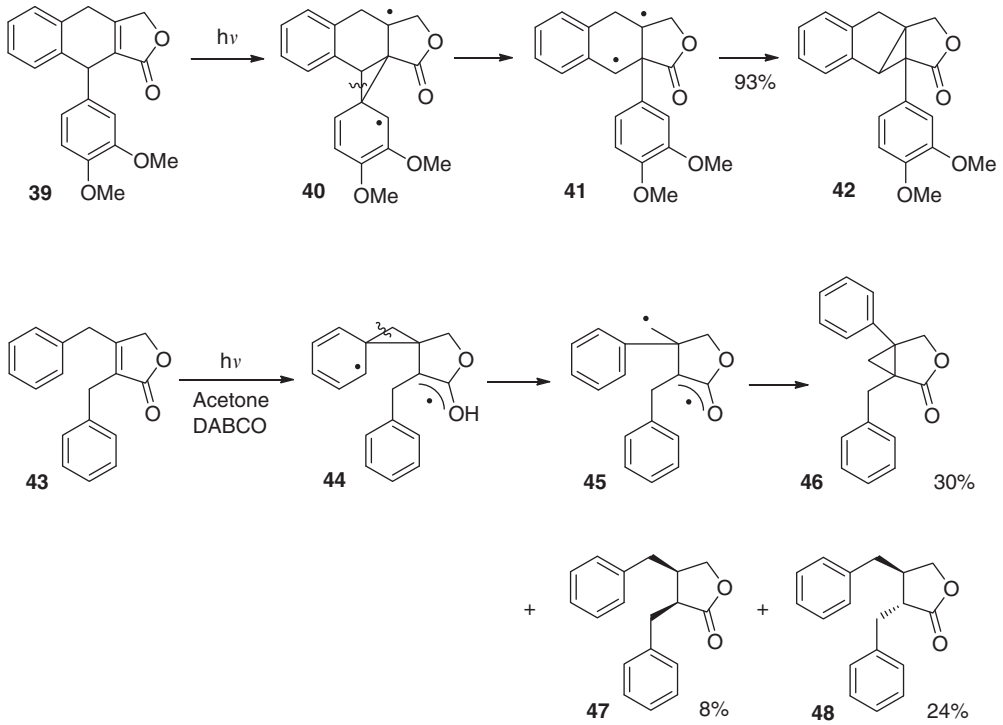
Scheme 6

8 days. The latter conditions resemble more with those of the biosynthesis. The transformation occurs via the corresoponding 1,4- and 1,3-biradical intermediats **32** and **33**. Compounds **26** and **27** also contain a cyclohexenone substructure. A photochemical cyclohexenone rearrangement also generates a bicyclo[3.1.0] moiety. In this case, however, the methyl group would be placed in a different position on the cyclopropane ring (compare **28** and **34**). As **34** was not contained in the isolated natural product nor generated by photochemical transformation of **26**, it was concluded that the bicyclo[3.1.0] substructure was generated by a di-π-methane photoisomerization. Furthermore, it was suggested that compounds **30** and **31** are generated by a photochemical vinylcyclopropane rearrangement (VCR) of **28** and **29**, respectively.[30]



Scheme 7

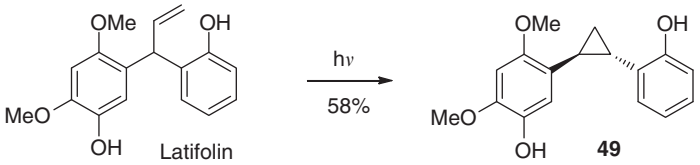
5.06.2.3 Transformations Involving Aromatics as Unsaturated Moiety



5.06.2.3.1 Reaction centers arranged in an acyclic system

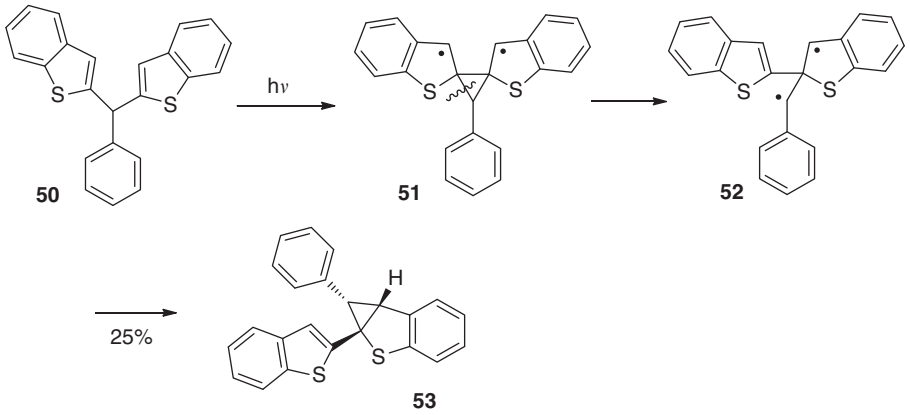
Di-π-methane photoisomerizations have been carried out with substrates in which an aromatic moiety gets involved. In such cases, the aromaticity is temporally suppressed when the 1,4-biradical intermediate **36** is formed from **35** (see general Scheme 8).[32] The rearrangement to the corresponding 1,3-biradical **37** occurs in the way that the aromatic character is regenerated and the final product **38** is formed from **37** by radical combination.

Scheme 8



Details of the regioselective di-π-methane rearrangment involving aromatics have been studied with furanone derivatives. These investigations have been carried out in the context of synthetic studies of lignanes.[33] Two examples are depicted in Scheme 9. On direct irradiation, the furanone derivative **39** forms the 1,4-biradical intermediate **40** in which the aromatic character of the 3,4-dimethoxyphenyl moiety is suppressed.[34] The formation of the 1,3-biradical **41** regenerates the aromaticity in this substituent. Radical combination then leads to the final product **42** in high yield. It must be pointed out that the transformation is regiospecific and only the 3,4-dimethoxyphenyl substituent is involved in the rearrangement, whereas the benzene aromatic system of the 1,4-dihydro naphthalene moiety does not react. A corresponding derivative possessing no substituents on the phenyl group is transformed in acetone solution with almost the same efficiency as compound **39**.[35] Under such conditions, acetone also acts as triplet sensitizer. In the case of the transformation of the furanone derivative **43** possessing two benzyl groups, a different regioisomer is formed (Scheme 9).[35,36] The phenyl group of the substituent in the β-position yields first the corresponding 1,4-biradical **44**. This intermediate is additionally stabilized by delocalization of one radical position by the carboxyl function. As in the previous case, C–C bond breaking in the cyclopropane moiety leads to the regeneration of the aromaticity and

Scheme 9

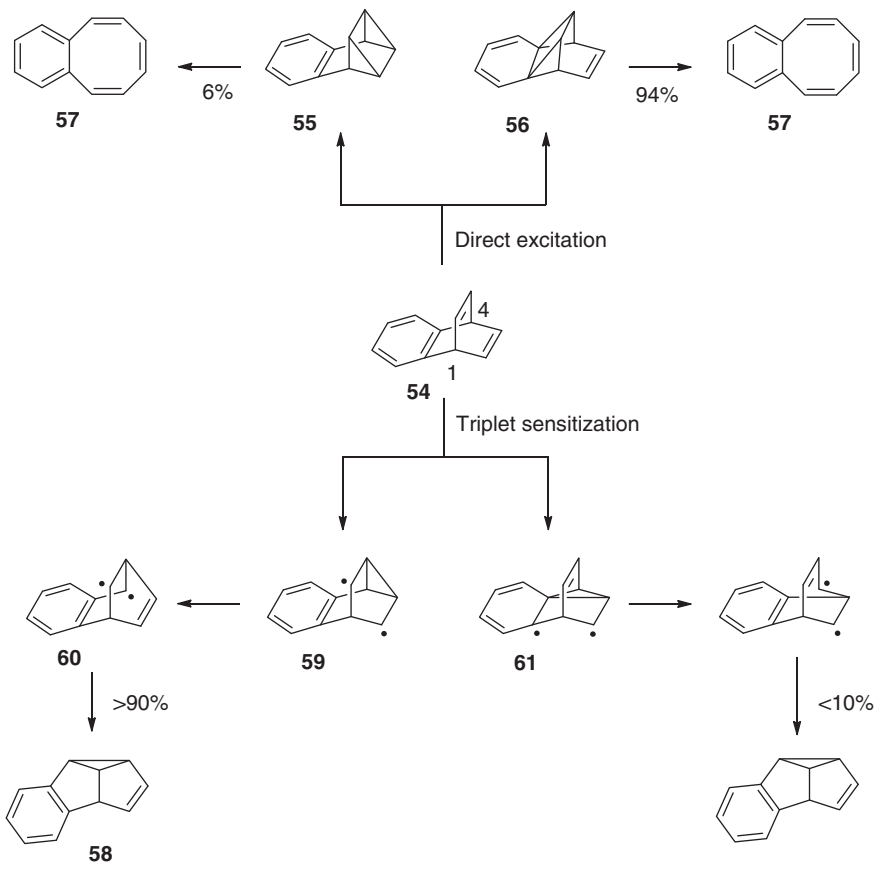


to formation of the 1,3-biradical intermediate **45**. Radical combination finally yields compound **46**. A similar reaction carried out with a furanone derivative carrying only one benzyl substituent in the *β*-position was less efficient.[37] This observation may be explained in part by the conformational flexibility of this system, which enables side reactions. Furthermore, products **47** and **48** resulting from a photoreduction process were obtained. This side reaction occurred because the transformation was carried out in the presence of 1,4-diazabicyclo[2.2.2]octane. Further studies on the chemo-, regio-, and stereoselectivity as well as on the influence of spin multiplicity on the transformation of similar compounds have been carried out.[38]

In a similar reaction, latifolin was transformed (Scheme 10). This important neoflavonoid is isolated from the heartwood of *Dalbergia latifolia*. In this compound, two benzene substituents and one vinyl group are linked to the sp^3 hybridized carbon atom. On irradiation in benzene solution and in the absence of a sensitizer, latifolin readily yields the cyclopropane derivative **49**. In this case, only the *trans* isomer was isolated,[39] whereas the irradiation of similar compounds under the same reaction conditions yielded mixtures of *cis*/*trans* isomers of the corresponding cyclopropane derivatives.

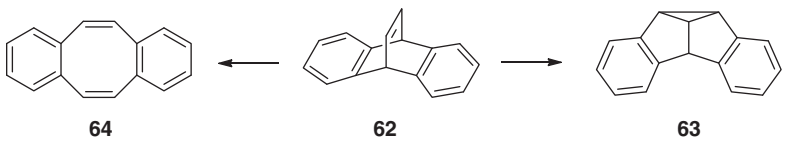
Scheme 10

Di-π-methane photoisomerizations have also been carried out with heterocycles. In Scheme 11 such an example is depicted.[40] On direct excitation, the dibenzothiophene derivative **50** forms the typical biradical intermediates **51** and **52**. The final product **53** is obtained in moderate yield by radical combination of intermediate **52**. In such transformations, the products of the di-π-methane rearrangement often undergo further photochemical rearrangements.[40,41] Compounds such as **50** possessing three π-bonds capable of being involved in photochemical rearrangements may also undergo a tri-π-methane photoisomerization.[41,42]



Scheme 11

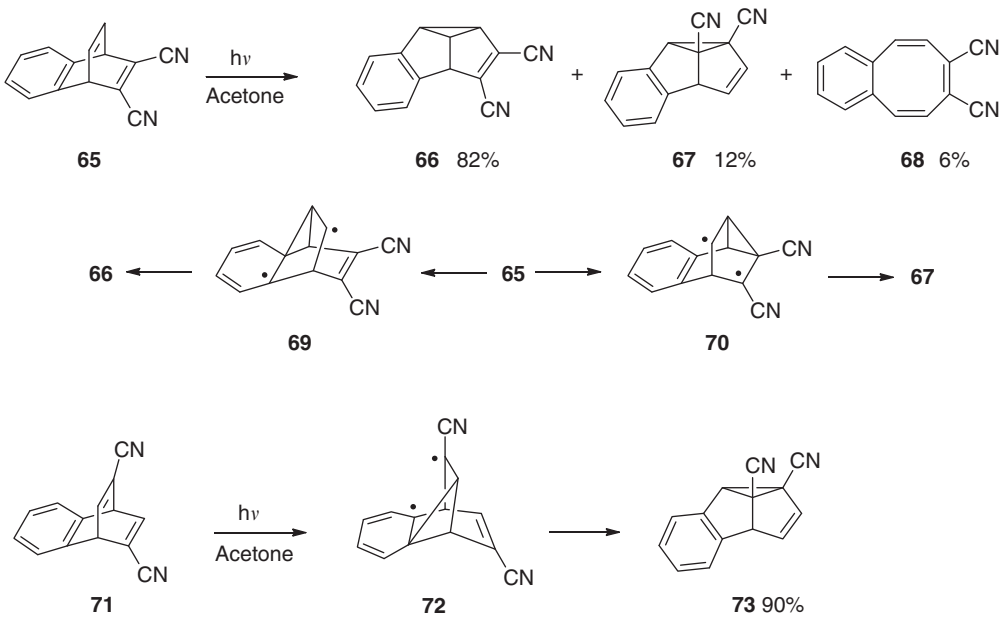
5.06.2.3.2 Reaction centers arranged in cyclic systems



5.06.2.3.2.1 Benzo and dibenzobarrelene derivatives

Many investigations have been carried out with benzo- or dibenzobarrelene derivatives and related compounds.[11,13,14,43,44] In these compounds, two reaction pathways are generally observed depending on whether electronic excitation occurs by direct light absorption (singlet reaction) or by triplet sensitization (Scheme 12). The reaction pathways have been identified and discussed on the basis of the results obtained from the transformation of compound **54**, which was isotopically labeled in positions 1 and 4. In the first case, compounds such as **54** undergo intramolecular [2 + 2] photocycloaddition leading to intermediates **55** and **56**.[45] The formation of **56** is favored although the aromaticity of the benzo-moiety is suppressed. A subsequent rearrangement leads to the final product benzocyclooctatetraene **57**. In the case of triplet sensitization – the reaction is carried out in acetone as solvent – a di-π-methane rearrangement occurs. Once again, two reaction pathways can be distinguished. Only product **58** was obtained indicating that the reactions take place via the intermediates **59** (vinyl-vinyl bridging) and **60**. In contrast to the singlet reaction leading to **57**, in the triplet reaction the suppression of the aromatic character in intermediate **61** via a benzo-vinyl bridging is avoided.

Scheme 12



In the case of dibenzobarrelene derivatives such as **62** (Scheme 13), a competition between the formation of di-π-methane isomerization products **63** and dibenzocyclooctatetraene **64** was also observed. The course of the reaction depends on the substitution pattern.[46]

Scheme 13

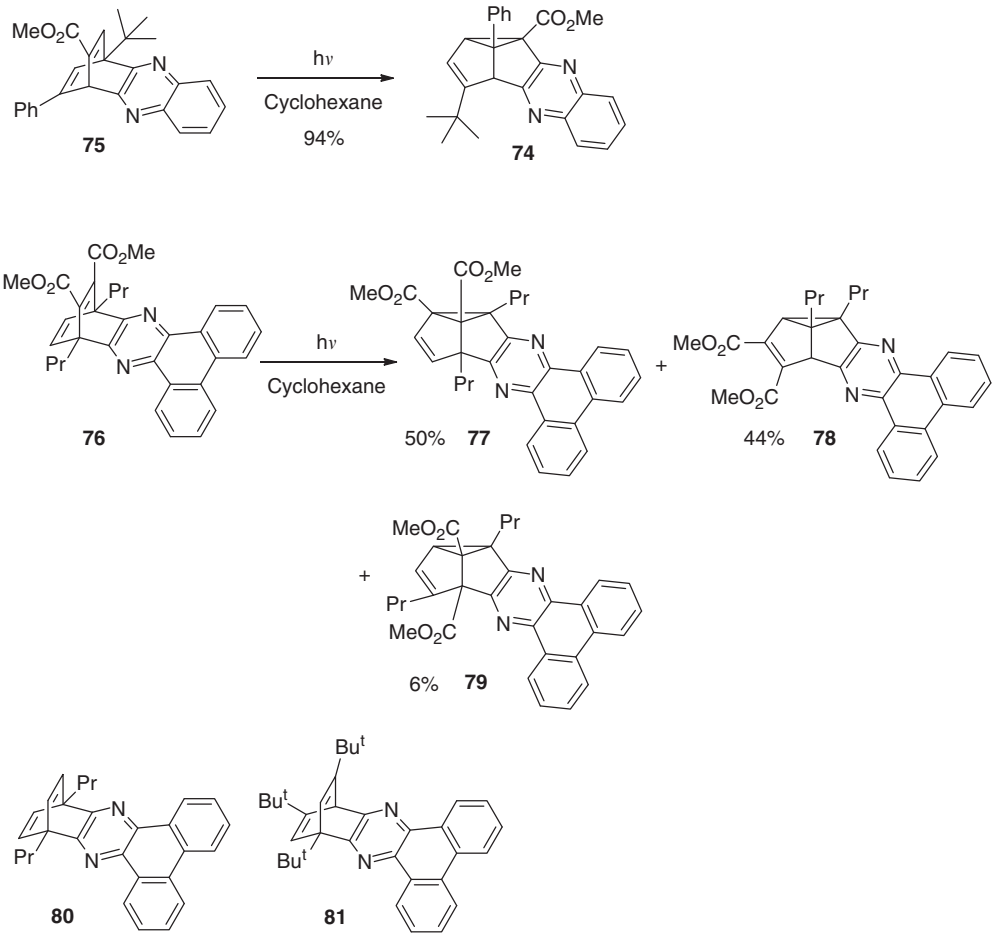
In the following Schemes, some recent examples of benzobarrylene reactions are depicted. Electron withdrawing substituents such as a cyano group on the benzobarrylene core determine the reaction pathway.[47] A dicyano derivative (**65**) was transformed into the di-π-methane isomerization products **66** and **67** (Scheme 14).[48] The reaction was performed in acetone as solvent and triplet sensitizer. Only minor amounts of the corresponding benzocyclooctatetraene derivative **68** were obtained. The major positional isomer **66** was formed via the intermediate **69** (vinyl-benzo bridging) in which the aromatic character is suppressed. The minor isomer **67** resulted from a rearrangement via intermediate **70** (vinyl-vinyl bridging). As previously discussed, the benzocyclooctatetraene derivative **68** might result from a singlet reaction. The corresponding transformation of the positional isomer **71** was more efficient. Only one product (**73**) was obtained in high yield. In this case intermediate **72** (vinyl-benzo bridging) was generated. Additional information on the reaction mechanism was obtained from the transformation of similar benzobarrylene derivatives under the same conditions.[49]

Aromatic heterocyclic compounds have also efficiently been transformed. Thus, the polycyclic benzopyrazino derivative **74** was obtained from the reaction of the corresponding benzobarrylene substrate **75** (Scheme 15).[50] The product was formed via intermediates from vinyl-vinyl bridging. Although no mechanistic studies have been performed in this case, it was assumed that the reaction took place at the triplet state. The corresponding dibenzoquinoxalino derivative **76** was transformed under the same conditions,[51] but the reaction was less selective. The percentage values shown in Scheme 15 represent the product ratio. The main products **77** and **78** were formed involving intermediates of a vinyl-vinyl bridging. In the case of the minor product **79**,

Scheme 14

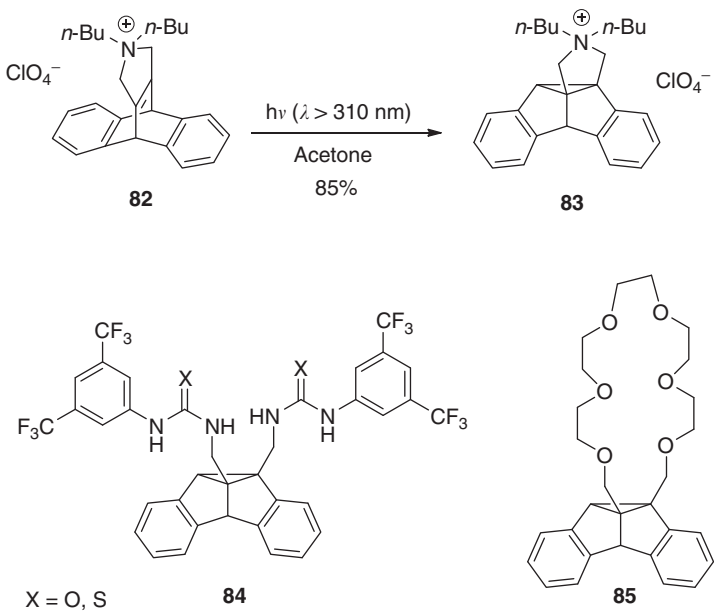
intermediates with a vinyl-heteroaryl bridging were generated. Because the C═N bond of the quinoxaline moiety is involved, this reaction was also designed as an aza-di-π-methane isomerization (see Section 5.06.4). The aza-analog reaction was mainly observed in the transformations of compounds **80** and **81**.

The di-π-methane rearrangement of dibenzobarrelene derivatives (compare Scheme 13) was intensively studied and applied to the synthesis of functional products. Thus, the irradiation of the quaternary ammonium derivative **82** in acetone efficiently yielded the isomerization product **83** (Scheme 16).[52] Compound **83** was used as phase transfer catalyst in alkylation reactions. In particular in the alkylation of β-ketoesters, this compound was more efficient than the classical catalyst TBAC (tetrabutylammonium chloride). The high tolerance of functional groups in these reactions was also observed in the transformations of corresponding urea and thiourea derivatives **84**.[53] Crown ether derivatives (**85**) have also been obtained.[54]



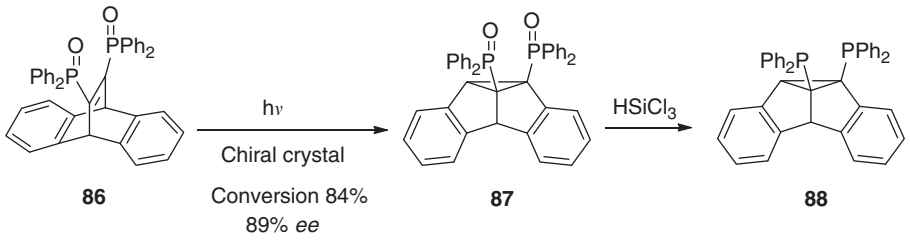
A lot of dibenzobarrelene derivatives have been transformed in the solid phase. As already pointed out above (compare Scheme 3, Table 1), this technique was used for chiral induction.[22–24] Photochemical transformations of solids are particularly easy and thus this method may play a central role in chiral induction in photochemical reactions.[55] Various techniques have been applied in this context. Among them, the crystallization of achiral compounds in chiral space groups leading to enantiomorphous crystals[100,101] is certainly the most attractive one because it allows absolute asymmetric synthesis. The bisphosphinoxid derivative **86** crystallized in the chiral space group $P2_12_12_1$ (Scheme 17).[56] The crystallization is carried out from ethanol solution and crystals contain one ethanol molecule per molecule of **86**. Enantiomorphous crystals are thus obtained in which one enantiomeric conformation of **86** is frozen. This conformation directs the reaction on one enantiomeric pathway and **87** is obtained in high enantiomeric excess. Reduction of the rearranged product leads to the phosphine derivative **88** that is a chiral ligand for transition metal catalyzed asymmetric hydrogenation.

The corresponding carboxylate derivatives have also been transformed. In this case, chiral ammonium ions were used to induce chiral crystallization.[57] Irradiation of chiral salts is an alternative and more general approach to obtain enantiopure compounds via solid-state photochemistry.[58] Cocrystallization with a chiral molecule is another method to induce chirality in the di-π-methane photoisomerization.[59] Recently, the reaction was also carried out in other chiral media such as chiral mesoporous silica[60,102] or ionic liquids.[61] All of these approaches apply the concept of photochemical transformations in confined environments.[62]

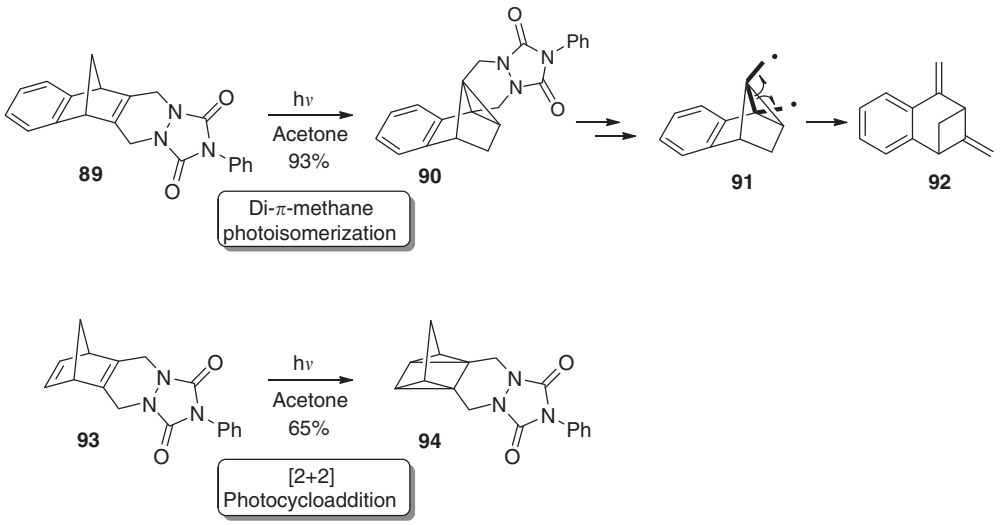


5.06.2.3.2.2 Barrelene related derivatives

Benzonorbornadiene derivatives also undergo di-π-methane photoisomerization (for some early examples see[63]). Thus, compound **89** was efficiently transformed into the polycyclic triazolidine derivative **90** under triplet sensitization conditions (Scheme 18).[64] The di-π-methane rearrangment product **90** was transformed via the intermediate **91** into the benzopinene analog **92**. It must be pointed out that, under the same conditions, the corresponding derivative **93** devoid of the annulated benzene ring undergoes [2 + 2] photocycloaddition leading to **94**.

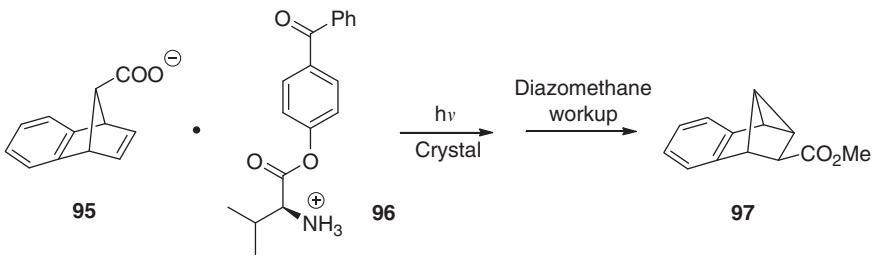


As briefly mentioned in Section 5.06.2.3.2.1, irradiation of salts with at least one optically pure ion may be applied to asymmetric synthesis. Such an efficient transformation was carried out with the salt **95•96** (Scheme 19, Table 2).[65] When performed at low temperature, a high enantioselectivity was detected for product **97**. At room temperature, the stereoselectivity is



Scheme 15

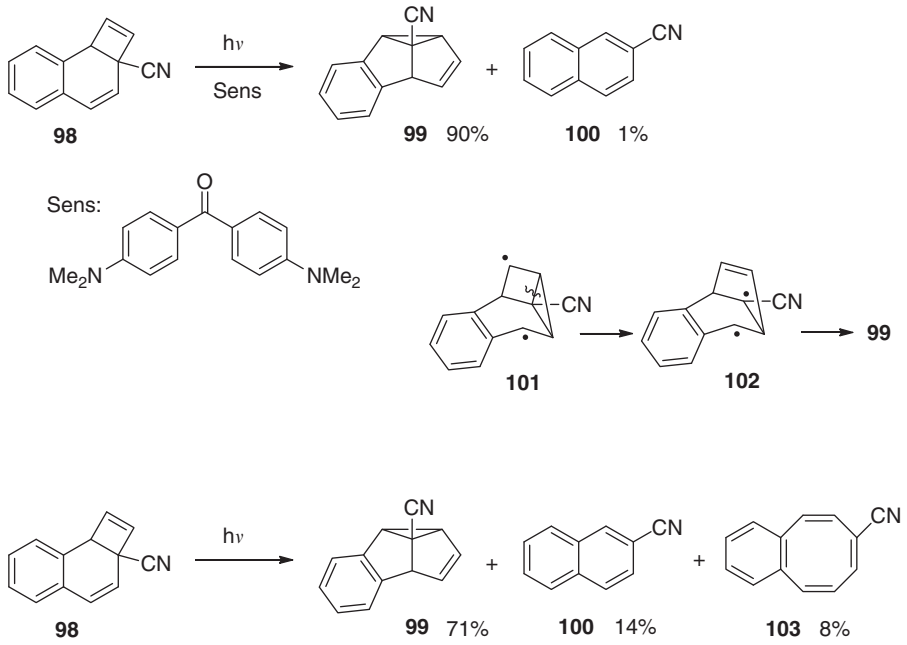
Scheme 16



Scheme 17

Scheme 18

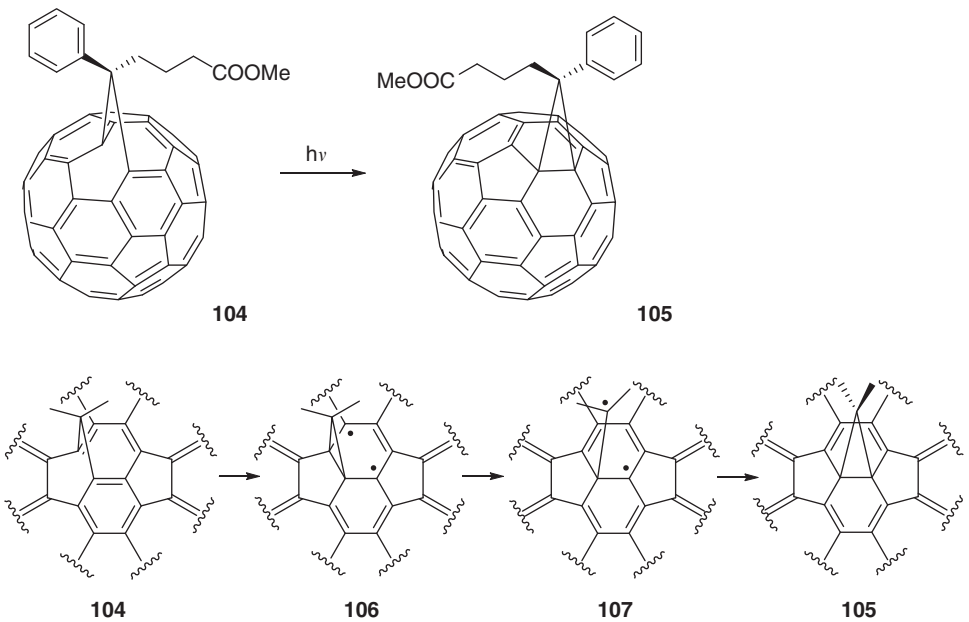
somewhat lower but the transformation is significantly faster. The L-valine derivative **96** not only acts as auxiliary to establish a chiral environment in the crystal but it also carries a benzophenone moiety as the triplet sensitizer.



Scheme 19

Table 2 Enantioselectivity of the solid state reaction of the chiral salt **95•96** (Scheme 19)

Time	*Temperature*	*Conversion (%)*	*Enantiomeric excess (%)*
4 h	− 20 °C	100	91
1 min	Room temperature	58	84
5 min	Room temperature	100	82

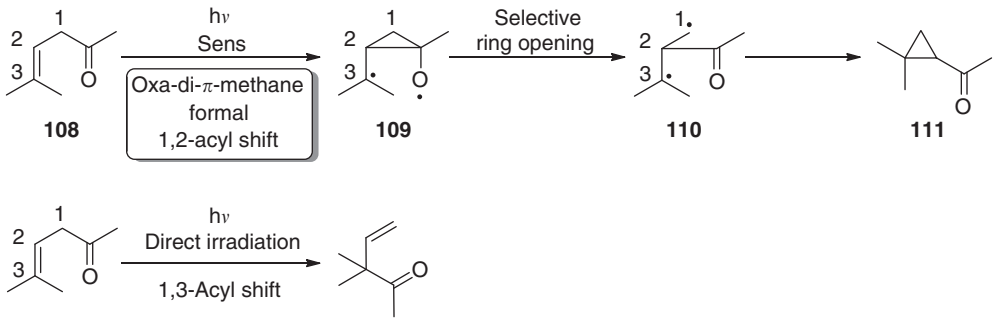


6-Cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene **98** (Scheme 20) may be considered as a regioisomeric structure of the benzobarrelene core. When irradiated in the presence of Michler's ketone as sensitizer, the di-π-methane photoisomerization product **99** was obtained in high yields.[66] Small amounts of 2-cyanonaphthalene **100** were also isolated. Intermediates **101** and **102** are involved in the formation of the major product **99**.[66,67] When the reaction is induced by direct excitation, the yield of

compound **99** diminishes, whereas the amount of **100** increases. Furthermore, the benzocyclooctatetraene derivative **103** is formed, resulting from competitive processes. Its formation dominates in some reactions of cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes. The complex reaction mechanisms of the photochemical transformations of such cyano substituted tricyclic compounds have been systematically investigated.[67,68] Similar studies have also been performed with the unsubstituted core structure and a methyl derivative.[69]

Scheme 20

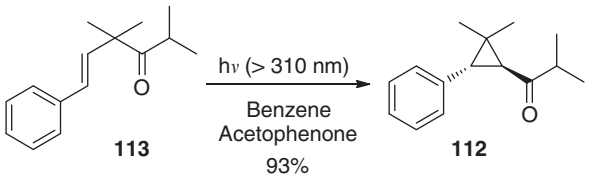
A photochemical rearrangement observed with C_{60} fullerene derivatives has been explained by a di-π-methane photoisomerization. On direct excitation, compound **104** was transformed into the cyclopropane derivative **105** (Scheme 21).[70] Starting compounds such as **104** are easily obtained from the reaction of the corresponding diazo compounds with C_{60}.[71] Only one regioismer is formed in which the phenyl ring is orientated *syn* with respect to a former five-membered ring of the fullerene



Scheme 21

moiety. Compounds such as **105** are only isolated in minor amounts from this latter transformation. In the first step of the di-π-methane rearrangement, a C–C sigma bond is formed in the fullerene moiety. The resulting species **106** may be compared with the 1,4-biradical intermediate of a typical di-π-methane isomerization (compare Scheme 1). The cleavage of a C–C bond in the cyclopropane moiety leads to the 1,3-biradical intermediate **107** in which one radical is largely delocalized. The final product **105** is formed by radical combination. In the overall transformation, a bridge between a five-membered and a six-membered ring (5,6 ring junction) move to a bridge between two six-membered rings (6,6 ring junction). More precisely, a bicyclo[4.3.1] system is transformed into a tricyclo[4.4.1.$0^{1,6}$] system. The reaction was quantitative after 1 h of irradiation. The transformation was also carried out under thermal conditions; however, up to 6 h of heating to 180 °C was needed. Several derivatives such as the corresponding *t*-butyl ester could not be transformed under such drastic thermal conditions.[72] Under mild photochemical reaction conditions, the isomerization product was obtained with 96% yield after 0.5 h of irradiation.

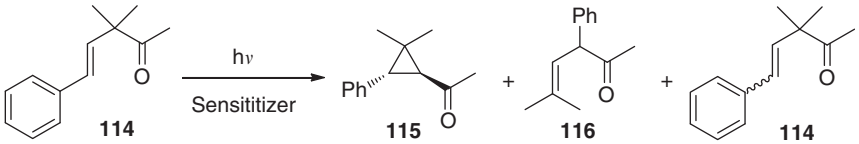
5.06.3 Oxa-Di-π-methane Photoisomerization



5.06.3.1 Basic Mechanistic Considerations and ODPM Photoisomerization of Acyclic β,γ-Unsaturated Carbonyl

The oxa-di-π-methane photoisomerization (ODPM) occurs by irradiation of a β,γ-unsaturated carbonyl framework **108**.[14] A formal mechanistic overview closely related to the two-step process previously mentioned for di-π-methane photoisomerization is highlighted in Scheme 22. In most cases, ODPM rearrangements are induced by triplet sensitization, whereas direct irradiation leads to a 1,3-acyl shift reaction, which is the major competitive photochemical process. Notably, the biradical intermediate **109** (or in the case of a concerted mechanism, a structurally related minimum along the reaction coordinate) produced in the primary photochemical process always undergoes a selective ring opening to produce the 1,3 biradical **110** leading the cyclopropyl ketone **111**. The overall process corresponds to a 1,2-acyl shift.

Scheme 22

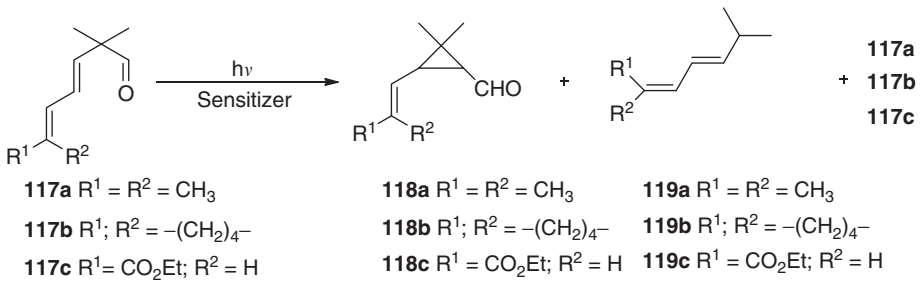


Although an acyclic β,γ-unsaturated carbonyl was chosen in Scheme 22 to illustrate the connectivity of the ODPM reaction, it is actually rarely observed with such substrates. Indeed, as previously mentioned, direct irradiation mainly induces a 1,3-acyl shift occurring at the singlet state S_1 (n,π^*). Moreover, when acyclic β,γ-unsaturated carbonyl are excited to a triplet state (either by direct irradiation followed by intersystem crossing or by triplet sensitization), deactivation by a free rotor effect predominantly leads to *E*/*Z* double bond isomerization. Extensive literature search in the field allows to identify the structural requirement that favors efficient ODPM rearrangement of acyclic β,γ-unsaturated ketones.[14] The ODPM photoisomerization was observed when the central carbon of the β,γ-unsaturated carbonyl was dialkylated, or mono alkylated with a sterically hindered group, and when the carbon–carbon double bond is a part of a conjugated system. For example, the ODPM rearrangement product **112** was obtained in 93% yield on irradiation of compound **113** in the presence of acetophenone as sensitizer (Scheme 23).[73] The presence of the phenyl ring is expected to favor ODPM by stabilization of radical intermediates. Conformational constraints induced by substituentes at the central carbon additionally favor the transformation of these biradicals into cyclopropane rings.

Scheme 23

However, this simple substitution pattern is not sufficient to induce ODPM rearrangements, as illustrated by the absence of the formation of the ODPM photoisomerization product on irradiation of compounds **114** in triplet sensitization conditions with

benzophenone (Scheme 24). Nevertheless, recently a new aspect of the ODPM photoisomerization of acyclic β,γ-unsaturated ketone was reported.[74] The reactivity of compounds **114** and related structural analogs was reinvestigated under triplet sensitization conditions using a broader range of triplet sensitizers. It was found that the ratio between different photoproducts nicely correlates with the triplet energy of the sensitizers (Table 3). As depicted in Scheme 24, on irradiation in the presence of different triplet sensitizers, variable yields of compounds **115**, **116**, and an *E*/*Z* mixture of the starting material **114** were obtained.



Scheme 24

Table 3 Product distribution depending on the triplet energy of the sensitizer (Scheme 24)

Triplet sensitizer	*Estimated $\Delta E_{D\text{-}A}$ (kcal mol^{-1})*	*Yield (%)*		
		115	***116***	***114***
Acetophenone	12	–	–	91
Thioxanlthone	1	50	–	20
4-Phenylbenzophenone	−1	10	28	35
Chrysene	−5	–	6	56

Based on the results obtained with several acyclic β,γ-unsaturated ketones and different sensitizers, it was concluded that when the triplet energy of the sensitizers is 12 kcal mol^{-1} higher than that of the alkene moiety, the *E*/*Z* isomerization of the olefin is the only observed photochemical process (Table 3). In contrast, when the triplet energy of the sensitizer is slightly higher (1–5 kcal mol^{-1}) than that of the alkenes moieties, the ODPM photoisomerization becomes the major photochemical process, and the corresponding products are obtained in yields higher than 50%. Finally, if the triplet energy of the sensitizer is lower than that one of the alkene groups (1–5 kcal mol^{-1}), the formation of ODPM products is usually observed in lower yields and 1,3-acyl migration to form the corresponding enone becomes a competitive photochemical process.

In another report concerning the fundamental understanding of ODPM photoisomerization, it was demonstrated that, in contrast to previous observations, the excited state S_2 (π,π^*) of the alkene may be involved in some ODPM reactions.[75] The ODPM photoisomerization of β,γ-unsaturated aldehydes was also studied. In this case, decarbonylation becomes an additional competitive photochemical reaction. Nevertheless, some β,γ-unsaturated aldehydes, which possess the favorable structural features described for ketone derivatives, undergo OPDM photoisomerization by triplet sensitization (Scheme 25, Table 4).[76] Moreover, as previously demonstrated for ketone derivatives,[74] high yields of ODPM products are obtained by judicious choice of the triplet sensitizer.[77] For example, when compound **117a** was irradiated in the presence of 3-methoxyacetophenone, the ODPM product **118a** is obtained in 52% yield; when 4-phenylbenzophenone was used as sensitizer under the same reaction conditions, an even higher yield of the ODPM product **118a** is observed.

Scheme 25

As reported in Table 4, this phenomenon seems to be general for this compound family. The high yields obtained using this methodology could provide a useful synthetic route to cyclopropanecarboxylic acids present in pyrethrins and pyrethroids natural products.

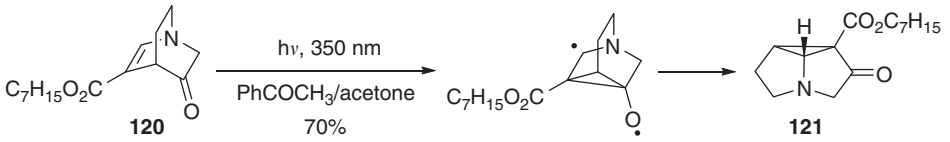


Table 4 Product distribution depending on the sensitizer (Scheme 25)

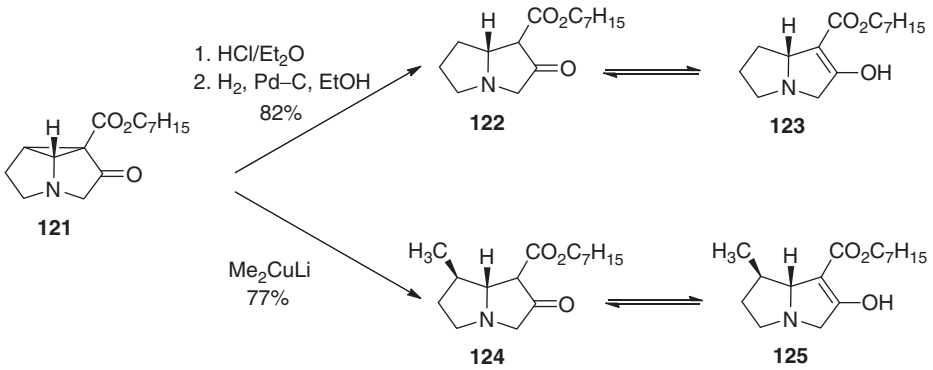
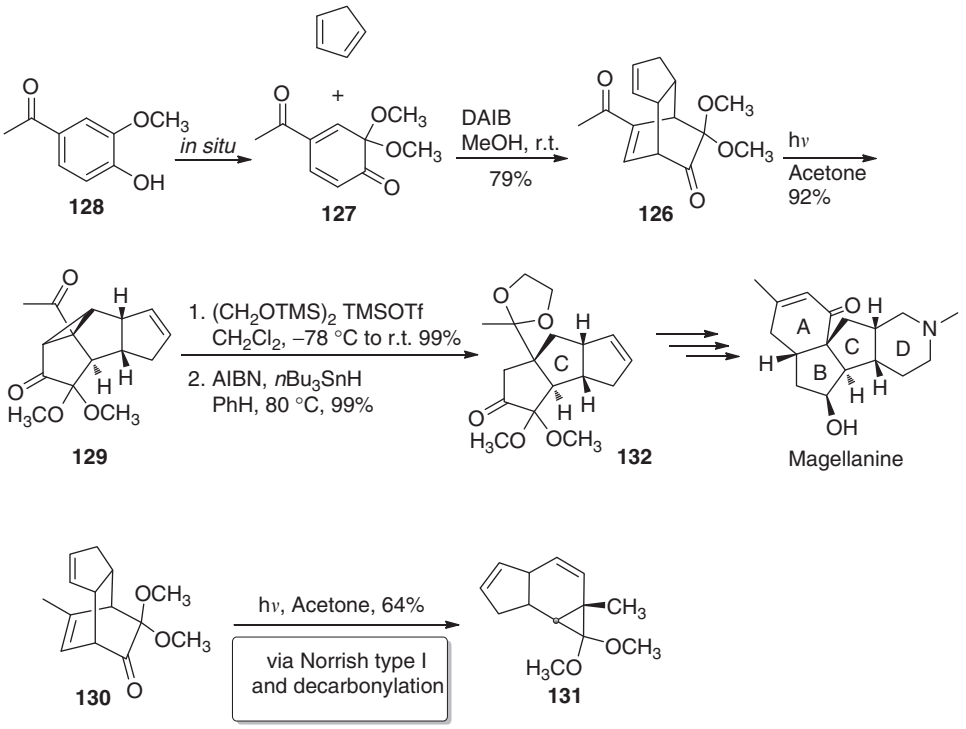
Substrates	*Sensitizer*	*Yield of **118** (%)*	*Yield of **119** (%)*	*Recovered **117** (%)*
117a	3-Methoxyacetophenone	52	6	30
117a	4-Phenylbenzophenone	94	–	–
117b	3-Methoxyacetophenone	47	6	30
117b	4-Phenylbenzophenone	94	–	–
117c	3-Methoxyacetophenone	22	4	52
117c	4-Phenylbenzophenone	96	–	–

Despite the fundamental interest of these recent advances in the understanding of the ODPM photoisomerization of acyclic β,γ-unsaturated carbonyl compounds, they did not find widespread applications to the synthesis of complex organic molecules yet. The situation is completely different for cyclic β,γ-unsaturated ketones. Indeed, in many cases, the conformational constraints induced by the cyclic structure allow the formation of ODPM photoisomerization products in a high yield and in a predictable way. This behavior is well illustrated by the involvement of ODPM photoisomerization as efficient key step in the synthesis of natural products. In addition, several new synthetic strategies allowing efficient access to complex but unnatural molecular scaffolds and new asymmetric transformation were reported. Some relevant examples reported in the recent literature are described in the following section.



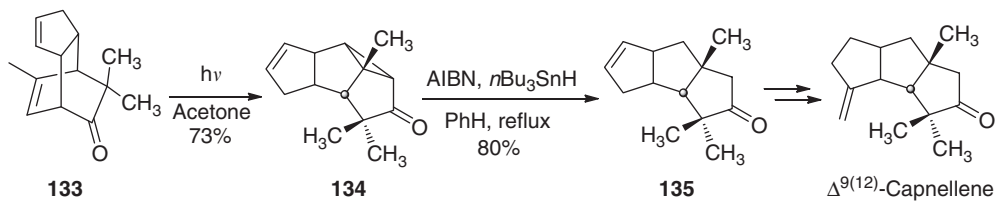
5.06.3.2 Synthetic Application of ODPM Photoisomerization

The pyrrolizidine skeleton is present in numerous biologically active alkaloids.[78] A straightforward access to this skeleton involving ODPM photoisomerization of nitrogen containing bicyclic systems was proposed (Scheme 26).[79] The 1-aza-3-carboalkoxybicyclo[2.2.2]oct-2-en-5-one (quinuclidinone) **120** serving as the photoprecursor was synthesized according to previously described procedures. The photochemical irradiation (using a 450 W medium-pressure lamp) of a solution of compound **120** in acetophenone or 5/95-acetophenone/acetone afforded the ODPM product **121** in 70% yield. Noteworthy, when acetone was used as solvent and sensitizer, a very low conversion (2%) into the ODPM product was observed.



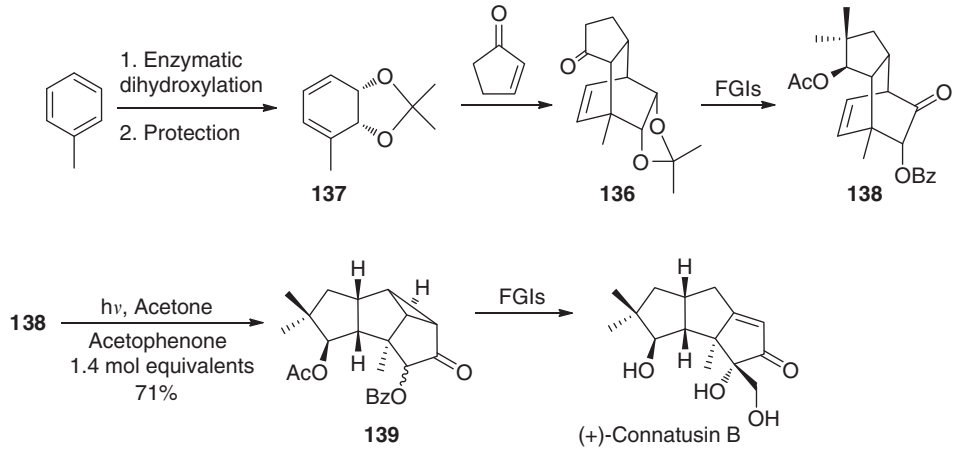
Scheme 26

The pyrrolizidine skeleton was then obtained by reductive cleavage of the cyclopropane ring, affording compound **122** in equilibrium with its keto enol form **123** in 82% yield (Scheme 27). Alternatively, a regioselective cyclopropane ring opening was achieved by the addition of lithium dimethylcuprate affording compound **124** in 77% yield as a single stereoisomer, which is in equilibrium with its keto enol form **125**. The latter transformation is analogous to the 1,4-addition of cuprates to α,β-unsaturated carbonyl compounds.



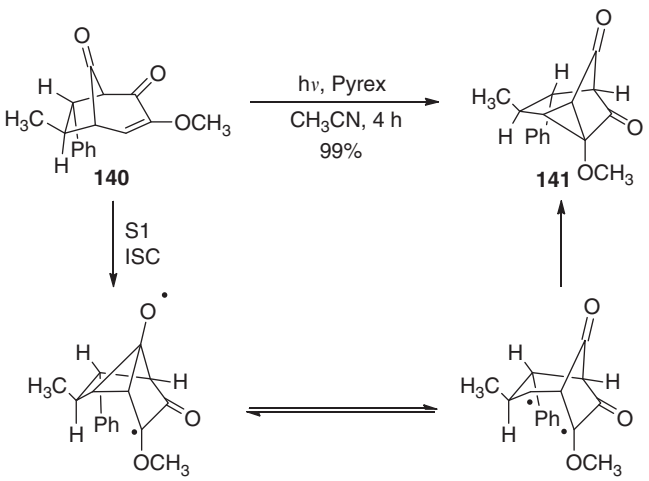
Scheme 27

Two-step sequences involving Diels–Alder reactions and ODPM photoisomerizations were extensively used to build up linear triquinanes scaffolds.[80–83] As an illustrative example, this type of sequence was successfully involved in the total synthesis of the challenging polycyclic alkaloid megellanine (Scheme 28).[84] Compound **126** was easily obtained by a Diels–Alder reaction between cyclopentadiene and the masked *o*-benzoquinone **127**. The latter compound is readily generated *in situ* from acetovanillone **128**. This Diels–Alder reaction is regio- and stereocontrolled and affords compound **126** possessing four contiguous stereocenters in 79% yield. The ODPM rearrangement was achieved by irradiation of compound **126** in acetone, affording the tetracyclic diketone **129** in 92% yield. The presence of the acetyl group is crucial to ensure a high yield in the ODPM photoisomerization, most probably by stabilization of typical radical intermediates involved in this reaction. This fact is nicely illustrated by the photochemical reaction obtained by irradiation of compound **130**, which includes a methyl group instead of the acetyl group, under the same reaction conditions. In this case, a Norrish type I reaction followed by decarbonylation afforded compound **131** in 64% yield.[85] The cyclopropane ring opening of **129** was then achieved in quantitative yield, after protection of the acetyl group, using tributyltin hydride/azobisisobutyronitrile. Starting from the key intermediate **132**, three main tasks were then achieved to complete the total synthesis of megellanine. Several steps were necessary to carry out the functional interconversion of ring B and construction of ring A. Finally, the cyclopentene ring was converted into the piperidine ring D by oxidative cleavage and double reductive amination.



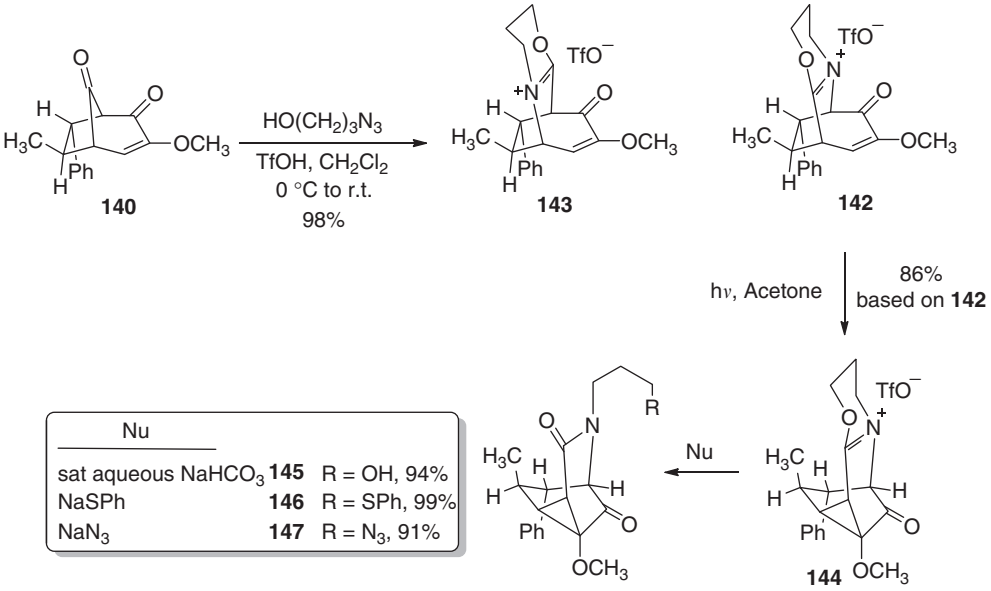
Scheme 28

The same methodology was applied to the total synthesis of Δ-$^{9(12)}$-capnellene, a triquinane sesquiterpene isolated from the soft coral *Capnella imbricate*. The irradiation of compound **133** in acetone afforded the ODPM product **134** in 73% yield (Scheme 29). The advanced intermediate **135** toward the synthesis of Δ-$^{9(12)}$-capnellene was then obtained in 80% yield by reductive ring opening of compound **134**.[85]



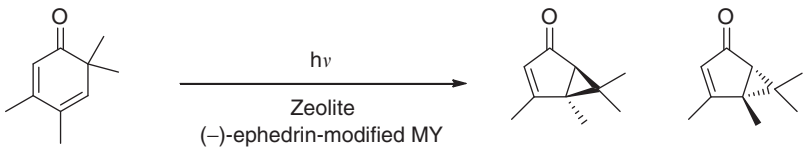
Scheme 29

The enantioselective synthesis of various linear triquinane sesquiterpenoids was also performed using ODPM photoisomerization as a key step. As illustrated by the total synthesis of (+)-cannatusin B,[86] the success of the strategy is based on the synthesis of enantiopure cyclopenta-fused bicyclo[2.2.2]octenone **136** (Scheme 30).[87,88] The scaffold was built up by a Diels–Alder reaction between cyclopentenone and the enantiopure diene **137**, which is obtained by enzymatic dihydroxylation of toluene. Further functional groups interconversions lead to compound **138**, which was subjected to the ODPM rearrangement. Irradiation of compound **138** in the presence of 1.4 mol equivalents of acetophenone afforded the ODPM product **139** in a 71% yield. Suitable functional interconversion including reductive ring opening of the cyclopropane was then achieved to complete the total synthesis of enantiopure (+)-cannatusin B.



Scheme 30

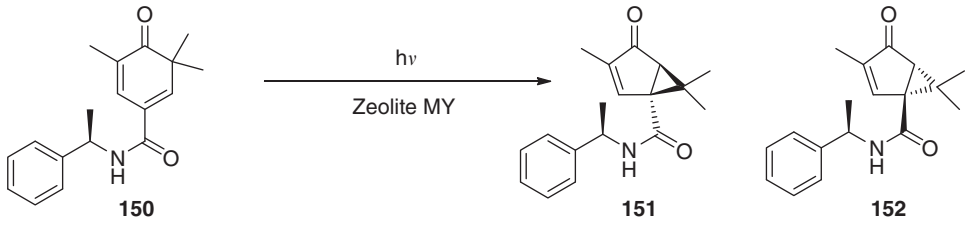
Photochemical reactions are efficient tools to rapidly accomplish the synthesis of complex pattern as found in natural products. They were also frequently used to synthesize challenging nonnatural molecular architectures like caged hydrocarbons or molecules possessing high strain.[2,89] In related approaches, photochemical reactions have been successfully used in a diversity-oriented synthesis toward underrepresented scaffolds. The high value of this last strategy is illustrated by the photochemical study of bicyclo[3.2.1]octanoid **140** (Scheme 31).[90] The presence of a β,γ-unsaturated ketone moiety in the compound **140** allows the ODPM rearrangement. Remarkably, product **141** is obtained in quantitative yield by irradiation of an acetonitrile or acetone solution of compound **140** using a Pyrex vessel (Scheme 31). Under such reaction conditions, it was suggested that the ODPM rearrangement occurs at a triplet excited state resulting from singlet excitation followed by intersystem crossing. The ODPM reaction tolerates modifications of the substituents on the bicyclo[3.2.1]octanoid moiety even if the presence of an α,β-unsaturated ketone moiety is a prerequisite. The presence of the strained cyclopropane ring in the ODPM product **141** was further exploited for the discovery of new transformations. Indeed, compound **141** was successfully engaged in several reactions such as retro-Dieckmann, Grignard addition, azido-Schmidt or dipolar cycloadditions resulting in a substantially increased scaffold diversity.



Scheme 31

Another interesting aspect of this work relates to the successful aza-di-π-methane rearrangement (see Section 5.06.4) of the β,γ-unsaturated iminium substrate **142** (Scheme 32). The iminium ions **143** and **142** were readily obtained in 98% yield from the bicyclo[3.2.1]octanoid precursor **140** by an azido-Schmidt reaction.[91] Irradiation of an acetone solution of this mixture of regioisomers leads to the transformation of compound **142** (the only one which possesses the required β,γ-unsaturated iminium pattern) via the aza-di-π-methane rearrangement, affording product **144** in 86% yield. This compound can undergo nucleophilic ring opening to afford cyclopropyl amides **145**, **146**, and **147** in high yields using previously described methodologies.

Scheme 32

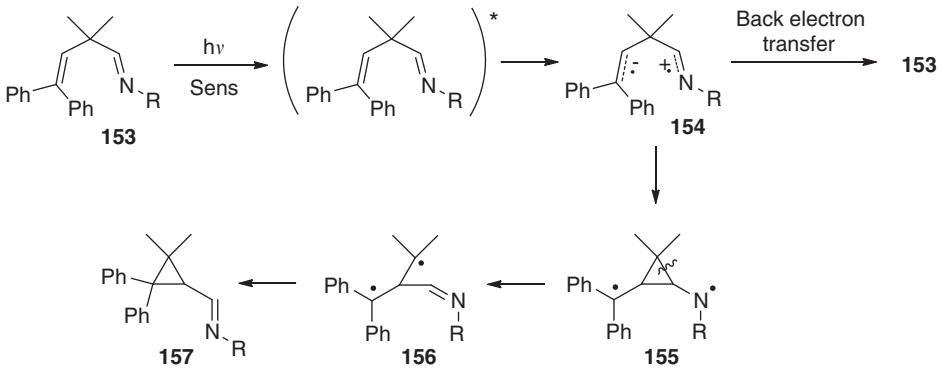


The achievement of asymmetric chemical reactions at the excited state is more challenging than in the ground state and often-required unusual strategies. It was previously demonstrated that in several photochemical reaction the asymmetric induction could be achieved by 'caging' a liquid reactant close to a chiral inductor using a zeolite super cage.[92,103,104] Moreover, the zeolite cavity may also be used to control the nature of the excited state of an enone through cation binding.[93] The photochemistry of 2,4-cyclohexadienones such as compound **148**, was investigated in zeolite medium, based on previous reports describing that the nature of the excited state involved in solution is strongly dependent on the reaction medium (Scheme 33).[94] In a nonpolar solvent such as hexane the formation of a ketene intermediate is observed occurring from the $n\pi^*$ excited state; in contrast, when the transformation is carried out in polar solvents such as trifluoroethanol, the reaction occurs at a $\pi\pi^*$ excited state affording the ODPM rearrangement product in a high yield. As anticipated by the authors, the ODPM rearrangement occurring from the $\pi\pi^*$ excited state is the only photochemical process observed when the reaction is carried out in the cavity of an alkali ion exchanged Y zeolite. Moreover, irradiation of a mixture of compound **148** and (−)-ephedrine as chiral inductor included in zeolite NaY (hexane slurry; 1 molecule of 2,4-cyclohexadienone per 10 supercages and 1 molecule of (−)-ephedrine per 1 cage) afforded compound **149** as the only product with an enantiomeric excess of 32%. Among the wide range of evaluated chiral inductors, the highest *ee* value was obtained using the (−)-ephedrine. The enantiomeric excess was improved using the same chiral inductor, when the reaction was carried out at lower temperature (− 55 °C, *ee* 49%). More interestingly, the nature of the zeolite cation has a strong influence on the enantiomeric excess as revealed by the *ee* obtained using different (−)-ephedrine-modified alkali ion exchanged Y zeolites.

MY	LiY	NaY	KY	RbY	CsY
ee	0%	32%	26%	5%	0%

Scheme 33

A diasteroselective approach was also evaluated by inclusion of chiral 2,4-cyclohexadienone **150** in different alkali ion exchanged Y zeolites (Scheme 34). The irradiation of compound **150** in trifluoroethanol afforded the ODPM products **151** and **152** in a low diastereoisomeric excess (5%). However, when the reaction was carried out in Y zeolites (hexane slurry; 1 molecule of 2,4 cyclohexadienone per 20 supercages) diastereoisomeric excesses up to 59% were obtained.



MY	Trifluoroethanol	LiY	NaY	KY	RbY	CsY

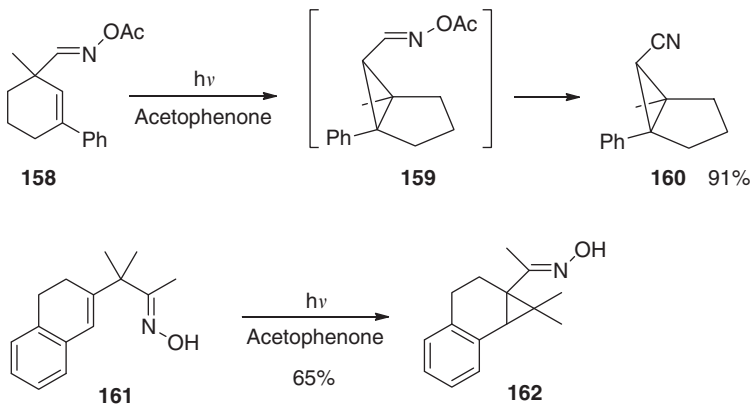
Scheme 34



5.06.4 Aza-Di-π-methane Photoisomerization

Similar to the previously presented oxa-di-π-methane photoisomerization, reactions have been carried out with imines of type **153** (Scheme 35). The reactivity depends on the electronic properties of the substituent R.[14,95,96] After photochemical excitation, intramolecular electron transfer may occur leading to the intermediate **154**. Back electron transfer regenerates the starting product **153**, which limits the efficiency of the reaction. In the case of different benzyl substituents for R, a Hammett relationship was observed between a variety of aromatic groups and the product quantum yield.[96] The excellent correlation is based on σ^+ values. This observation indicates that in **154**, a positive charge is localized on the imine function and that this intermediate plays an important role in the proposed mechanism. More recently, the reaction was also induced by photochemical electron transfer sensitization.[97] The zwitterionic intermediate **154** generates the typical 1,4-biradical intermediate of the di-π-methane photoisomerization **155**. A rearrangement of this intermediate leads to the 1,3-biradical **156**; radical combination generates the final product **157**.

Scheme 35

The aza-di-π-methane photoisomerization was successfully performed with a variety of oxime acetates. Two examples are depicted in Scheme 36. On irradiation in the presence of acetophenone as triplet sensitizer, compound **158** was transformed into **159**.[11] During workup, acetic acid was eliminated from the photo product, giving nitrile **160** in high yields. Only the *endo* isomer was isolated. Various examples of nitrile formation in the context of the aza-di-π-methane photoisomerization of oxime derivatives have been published.[98] The same reaction conditions with acetophenone as triplet sensitizer were applied to the transformation of the ketoxime **161** into the rearranged product **162**.[98] It should further be pointed out that the hydroxyl function of the ketoxime group did not need to be acylated. In this case, the reactivity is increased by the conformational rigidity of the substrate. The triplet sensitized aza-di-π-methane photoisomerization of acylated aldoximes was also applied to the synthesis of pyrethroid derivatives.[99] As already mentioned above, such compounds possess insecticidal properties.

Scheme 36

5.06.5 Conclusion

Starting from simple precursors, the di-π-methane photoisomerization and its oxa-di-π-methane and the aza-di-π-methane analogs provide facile access to complex polycyclic products. As in many cases of photochemical reactions, a lot of mechanistic studies have been carried out. Although the reaction is possible at the singlet state, most of the transformations occur at the triplet state. When carried out in solution, the reactions can thus be easily performed via triplet sensitization. Less frequently, electron transfer sensitization was applied. For the purpose of asymmetric synthesis, the di-π-methane rearrangements were studied in confined environments such as in crystals or zeolithes. These isomerizations were also applied to organic synthesis, in particular to the total synthesis of natural or biologically active products. In this context, it must be pointed out that significant molecular complexity is generated in only one step and under mild reaction conditions. Thus syntheses may be considerably facilitated, for example, by diminishing the number of steps.

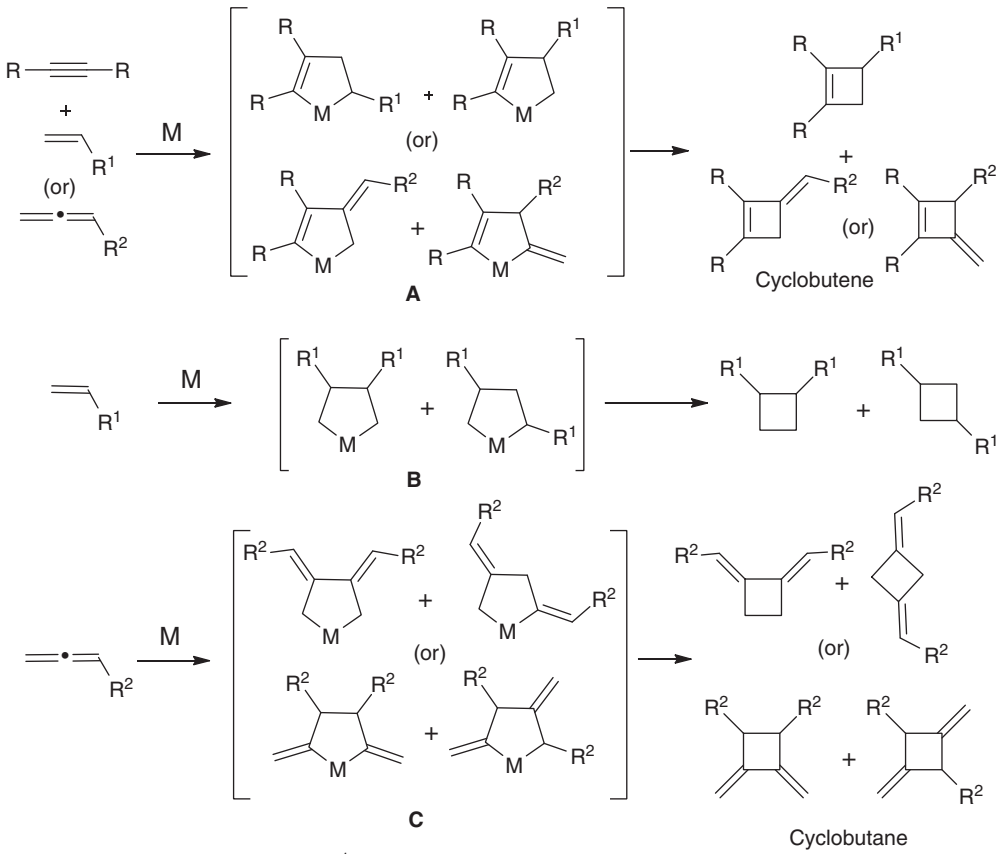
Glossary

Chiral auxiliary A chiral fragment that is temporarily incorporated into a substrate in order to control the stereochemical outcome of a chemical transformation.
Cycloaddition reaction An addition reaction in which a ring is formed.
Enantiomeric excess (*ee*) The excess of one enantiomer over the other in a mixture of enantiomers.
Endo* and *exo Terms used to identify the stereochemistry of a substituent on a bridged ring system; for a bicyclic compound, the prefix *endo* is reserved for the substituent located *syn* to the longer bridge (more atoms) and the prefix *exo* is for the substituent *syn* to the shorter bridge.
Expressed mathematically Enantiomeric excess = % of major enantiomer − % of minor enantiomer.
Metallacycle A cyclic compound comprising at least one metal center within the ring.
Oxidizing agent (oxidant) In a redox reaction, the reactant that causes the oxidation, and is itself reduced.

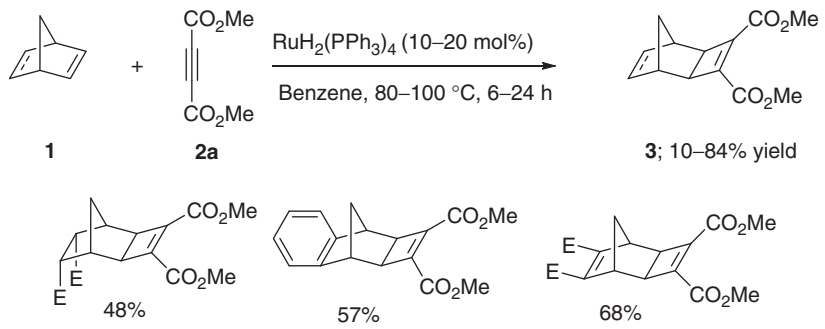
5.07.1 Introduction

Cycloaddition reactions, in general, are one of the most powerful and frequently applied methods for the construction of cyclic frameworks.[1] In general, $[m+n]$ cycloadditions can be induced by heat, light, Lewis acids, high pressure, and sonication.[1] The [2 + 2] cycloaddition is a thermally forbidden process as predicted by the Woodward–Hoffmann rules,[2] but it can be achieved photochemically via biradical intermediates (Scheme 1). Many of these reactions require the presence of a polarized functional group in the substrate to facilitate the transformations. Substrates without polar substituents usually show poor reactivity and require extreme reaction conditions. The transition metal-catalyzed reactions provide new opportunities for the cycloadditions of otherwise unactivated substrates and for cycloadditions which are difficult to achieve or theoretically forbidden. Metal-catalyzed cycloadditions have made a great contribution to the preparation of a variety of cyclic compounds.[3] In particular, metal-catalyzed [2 + 2] cycloaddition reactions provide a synthetically important method for the construction of cyclobutanes or cyclobutenes using simple and easily available materials. These four-membered ring products have been applied in many organic transformations owing to the natural ring strain that leads to selective and facile bond cleavage within the ring. These reactions are generally highly atom- and step-economical. The proposed mechanism for the metal-catalyzed [2 + 2] cycloaddition of two different carbon–carbon multiple bonds (alkynes, alkenes, allenes, etc.) generally involves the coordination of these substrates to a low-valence metal center, followed by oxidative cyclometalation to give a metallacyclopentane or metallacyclopentene intermediate as the key steps (Scheme 2).[4] Reductive elimination of **A**, **B**, or **C** affords the cyclobutene or cyclobutane products and regenerates the active metal species for the next catalytic cycle. Many reviews on different metal-catalyzed cycloaddition reactions, including [2 + 2 + 1], [2 + 2 + 2], [3 + 2], and [4 + 2] cycloadditions, are known, but so far, only a small number of short reviews focusing on metal-catalyzed [2 + 2] cycloaddition in organic synthesis have appeared. Moreover, all of these reviews only covered the [2 + 2] chemistry partially.[3] In this chapter, we will cover the metal-mediated and -catalyzed [2 + 2] cycloaddition reactions and related chemistry comprehensively. For convenience and clarity, the [2 + 2] cycloaddition reactions are first classified according to the various types of unsaturated π substrates involved and then according to the type of metal catalysts used. Finally, attention is focused on the reaction mechanism, substrate scope, the limitations of the reaction, and the synthetic applications.



Scheme 1 Traditional method for the [2 + 2] cycloaddition reaction.

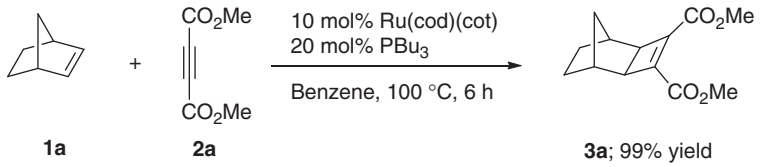
5.07.2 Intermolecular Metal-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes



5.07.2.1 Ru-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

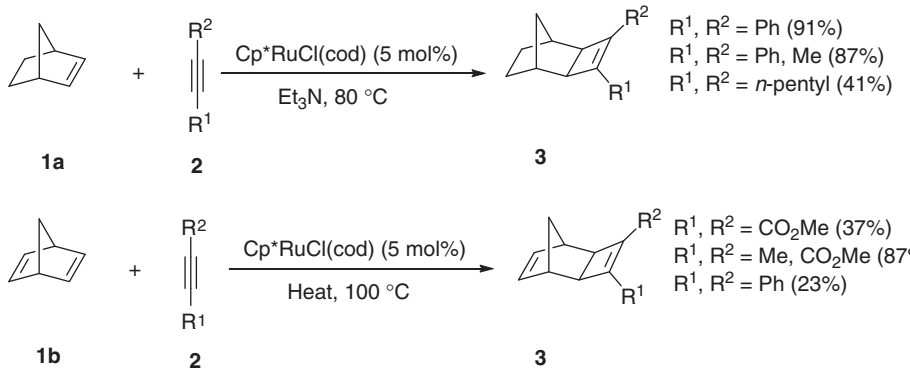
The metal-catalyzed [2 + 2] cycloaddition of alkynes with alkenes is a powerful and efficient tool to synthesize cyclobutene derivatives. In this context, ruthenium complexes represent one of the major metal catalysts.[4] The reaction is quite easy and very flexible, giving the user access to a wide range of [2 + 2] cycloaddition products. Initially, Mitsudo et al. used a low-valent ruthenium complex as the catalyst for the [2 + 2] cycloaddition of norbornenes with acetylenes. Thus, the reaction of equimolar amounts of a bicyclic alkene and an alkyne in the presence of a catalytic amount of $RuH_2(PPh_3)_4$ in benzene at 80–100 °C for

Scheme 2 Possible metallacyclopentene and -pentane intermediates for the synthesis of cyclobutenes and cyclobutanes.



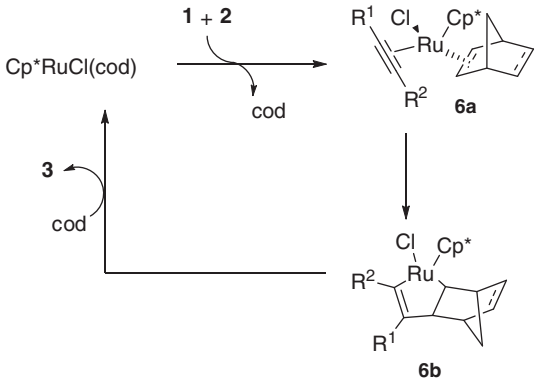
6–24 h gave modest to good yields (10–84%) depending on the type of bicyclic alkene chosen (Scheme 3).[5a] In almost all cases, the cycloadditions were found to be highly stereoselective, forming only the *exo* adducts.[5b]

Scheme 3 Ruthenium-catalyzed [2 + 2] cycloaddition of norbornene with DMAD; E = CO_2Me.



Later, the Mitsudo group also studied other Ru catalysts to increase the yields of cycloadducts. Interestingly, the best result in the [2 + 2] cycloaddition reaction of norbornene **1a** with dimethyl acetylenedicarboxylate (DMAD) (**2a**) was obtained with the combination of [Ru(cyclooctadiene (cod))(cyclooctatetraene (cot))]/PBu_3 as the catalyst, which led to product **3a** in 99% yield (Scheme 4).[6] However, the use of low-valent ruthenium complexes with oxidation states of 0 or II, such as [Ru(cod)(cot)], [$RuH_2(PPh_3)_4$], and [$RuH_2(CO)(PPh_3)_3$], as catalysts had a severe limitation with regard to the alkynes: only alkynes with strongly electron-withdrawing (CO_2R) groups attached could be used for this reaction.

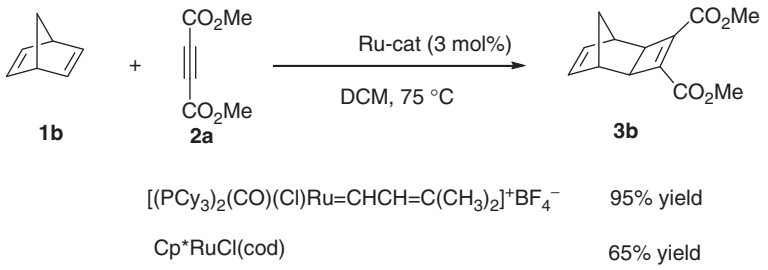
Finally, Mitsudo et al. found that pentamethylcyclopentadienyl(Cp^*)RuCl(cod) was a remarkable catalyst for the [2 + 2] cycloaddition of norbornene derivatives with various alkynes. Both aliphatic and aromatic internal alkynes readily reacted with



Scheme 4 Ru(0)-catalyzed [2 + 2] cycloaddition of norbornene with DMAD.

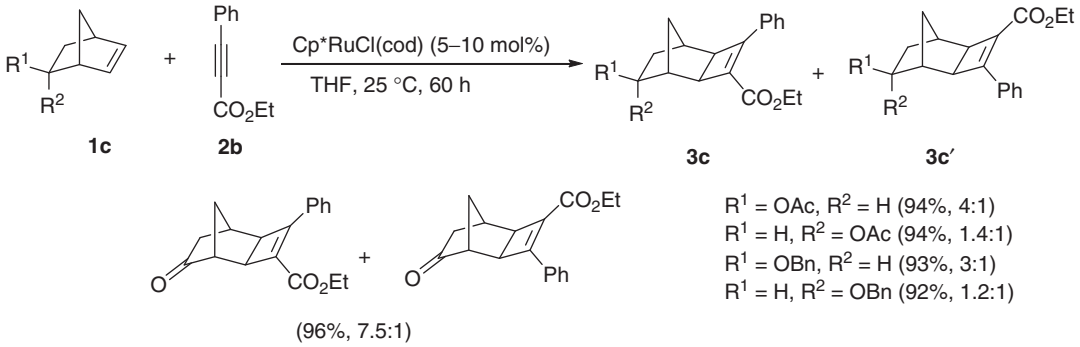
norbornene to give the corresponding [2 + 2] cycloadducts in high yields (Scheme 5).[7] However, the reaction of terminal alkynes with norbornadiene (NBD) or norbornene gives cyclobutenes in low yield along with 1,3-disubstituted benzene derivatives. Based on their experiments, the authors proposed that the active species in the catalytic mechanism is predominantly the neutral [Cp*RuCl] moiety and not the cationic $[Cp^*Ru]^+$ species. This mechanism also explains the exclusive formation of the *exo* cycloadducts (Scheme 5).

Scheme 5 [Cp*RuCl]-catalyzed [2 + 2] cycloaddition.



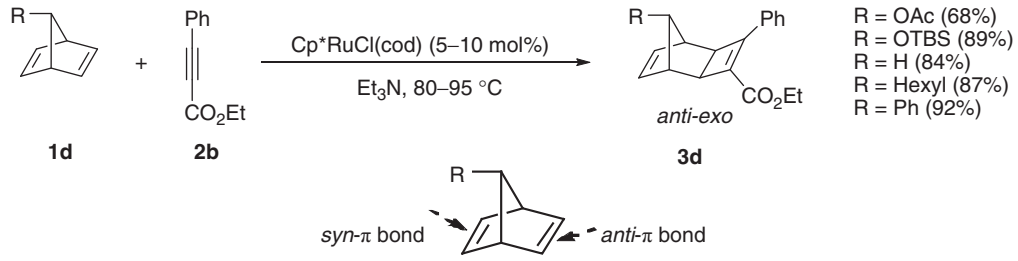
A possible reaction mechanism for the [2 + 2] cycloaddition is shown in Scheme 6. The first step is the dissociation of the labile cod ligand from the Ru-complex to generate the active neutral [Cp*RuCl] species. Highly regioselective *exo* coordination of a bicyclic alkene **1** and alkyne **2** to the Ru center forming π-complex **6a**, followed by oxidative cyclometalation leads to a ruthenacyclopentene **6b**. Density functional theory (DFT) calculations also show that generation of this intermediate is the rate-determining step in the catalytic cycle. Reductive elimination of **6b** results in the formation of the *exo*-[2 + 2] cycloadduct **3** and regenerates the active [Cp*RuCl] species for the next catalytic cycle. The coordination of the bicyclic alkene to the ruthenium occurs on the *exo* face because it is thought to have increased π-electron density over the *endo* face due to hyperconjugative effects.[8]

Scheme 6 [Cp*RuCl]-catalyzed [2 + 2] cycloaddition.



It is noteworthy that there are instances in the literature in which cationic Ru-species predominate. For example, Yi et al. have demonstrated that the [2 + 2] cycloaddition of **2a** with NBD **1b** in the presence of a catalytic amount of $[(PCy_3)_2(CO)(Cl)Ru{=}CHCH{=}C(CH_3)_2]^+BF_4^-$ in dichloromethane (DCM) at 75 °C gives the corresponding [2 + 2] cycloadduct

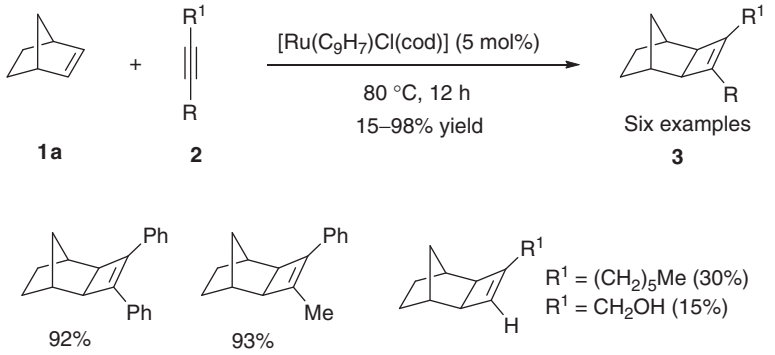
in 95% gas chromatography (GC) yield,[9] whereas under similar reaction conditions Mitsudo's group obtained only a 65% GC yield using Cp*RuCl(cod) (Scheme 7).



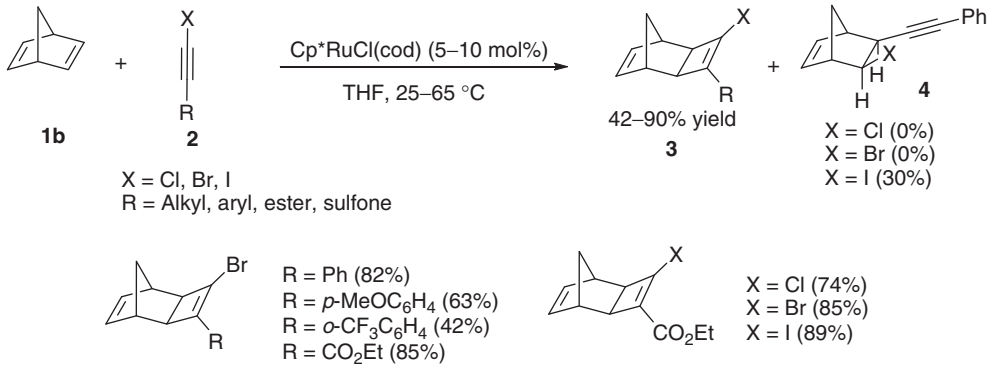
Scheme 7 Cationic Ru-catalyzed [2 + 2] cycloaddition.

Later on, Tam's group revealed a series of Cp*RuCl(cod)-catalyzed [2 + 2] cycloaddition reactions between bicyclic alkenes and alkynes. In 2000, the first example of remote substituent effects on the regioselectivity of ruthenium-catalyzed [2 + 2] cycloaddition of 2-substituted norbornenes with ethyl 3-phenylpropiolate **2b** was reported.[10] This cycloaddition occurred even at room temperature (r.t.), giving the *exo* cycloadducts in excellent yields. Regioselectivities of 1.2:1–7.5:1 were observed with norbornenes **1c** with various substituents on the C2 position (Scheme 8).

Scheme 8 Ruthenium-catalyzed [2 + 2] cycloadditions of 2-substituted norbornene with alkyne **2b**.



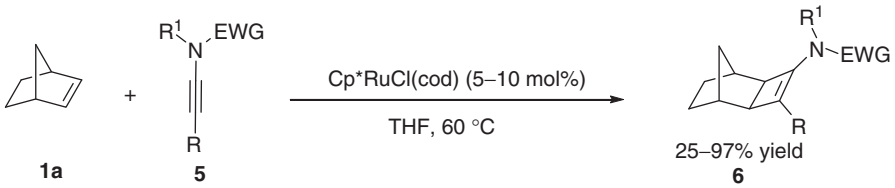
The same research group has developed a ruthenium-catalyzed [2 + 2] cycloaddition of 7-substituted NBDs **1d** with ethyl 3-phenylpropiolate **2b**. The catalytic reaction is completely regio- and stereoselective, giving only the *anti–exo* cycloadducts as single regio- and stereoisomers in good yields (Scheme 9).[11] The results of experimental and theoretical studies on the relative reaction rate of different 7-substituted NBDs showed that electron-deficient alkenes reacted slower than electron-rich alkenes. The authors anticipated that the *exo* face of the *syn*-π bond is sterically shielded by the R substituent, and so the Ru-catalyzed cycloaddition occurred preferentially on the *exo* face of the *anti*-π bond.



Scheme 9 Ruthenium-catalyzed [2 + 2] cycloadditions of 7-substituted NBDs with alkyne **2b**.

Gimeno and coworkers found that [Ru(η^5-C_9H_7)Cl(cod)] is a highly efficient and selective catalyst for the [2 + 2] cycloaddition of norbornene with internal alkynes, giving *exo* cycloadducts in excellent yields (Scheme 10).[12] However, the cycloadditions of 1-heptyne or propargyl alcohol proceed with lower yield and selectivity. In fact, terminal alkynes drive the reaction toward cyclotrimerization that is more facile than the [2 + 2] cycloaddition.

Tam's group reported a Ru-catalyzed [2 + 2] cycloaddition of NBD with alkynyl halides in moderate to good yields (42–89%).[13] The effects of the different halogens on the alkyne were also investigated (X = Cl, Br, I; Scheme 11). Cycloadditions of

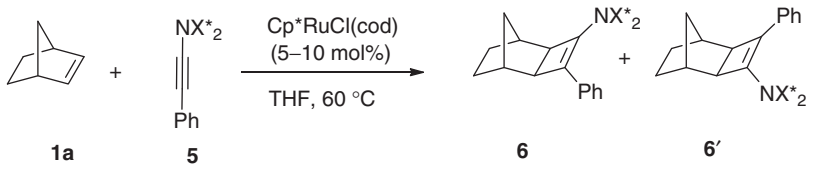


Scheme 10 Ruthenium-catalyzed [2 + 2] cycloadditions of norbornene with alkynes.

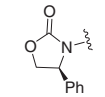
Scheme 11 Ruthenium-catalyzed [2 + 2] cycloadditions between NBD and alkynyl halides.

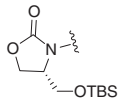
alkynyl chlorides and bromides occurred smoothly at 25 °C, giving the corresponding *exo* cycloadducts in good yields. Interestingly, iodoalkynyl ester reacted well with NBD to give the corresponding cycloadduct **3** in 89% yields, whereas 1-iodo-2-phenylethyne gave the cycloaddition in modest yield along with the corresponding addition product **4**.

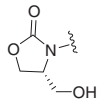
Tam then extended the reaction to ynamides that are less reactive than electron-deficient alkynes. The cycloadditions took place slowly at 25–60 °C, requiring reaction times of 72–168 h. Moderate to good yields of the cycloadducts were obtained using various acyclic and cyclic ynamides (Scheme 12).[14]



Scheme 12 Ruthenium-catalyzed [2 + 2] cycloaddition of NBD with ynamide.

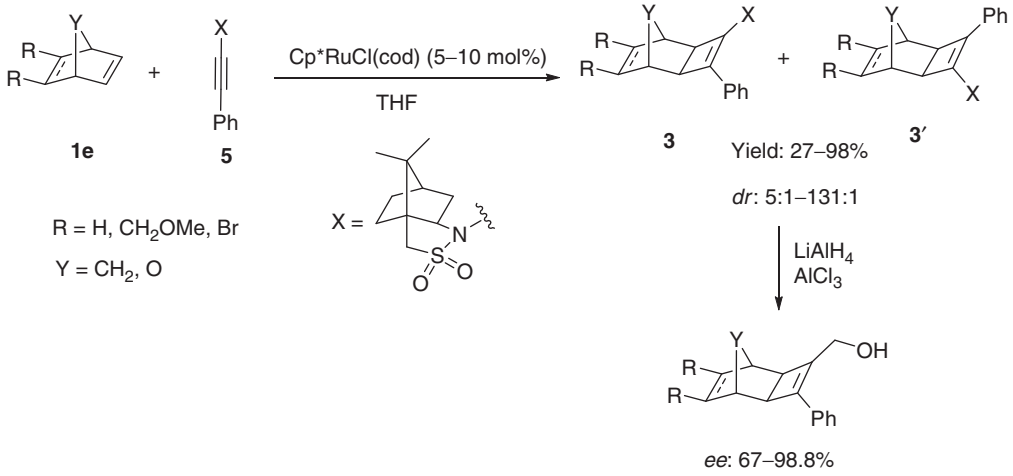






Ru-catalyzed [2 + 2] cycloadditions with chiral cyclic ynamides afforded the cycloadducts in good yields but with low to moderate diastereoselectivity (Scheme 13). The diastereomeric ratios (*dr*) were determined using ^{1}H nuclear magnetic resonance (NMR).

In the examples discussed so far, the cycloaddition of norbornene-type alkenes with alkynes generally afford the corresponding *exo* isomers. Effective asymmetric cycloadditions represent a more daunting task. Tam's group demonstrated an asymmetric induction in ruthenium-catalyzed [2 + 2] cycloadditions between alkenes and alkynes bearing chiral auxiliaries. This method was found to be highly stereo- and regioselective, and excellent levels of asymmetric inductions (up to 98.8% enantiomeric excess (*ee*) after removal of the recoverable chiral auxiliary) were observed (Scheme 14).[15]



In 2006, Tam described the reaction between bicyclic alkenes with alkynyl sulfides and alkynyl sulfones in the presence of 5–10 mol% of Cp*RuCl(cod) in tetrahydrofuran (THF) in the dark at 90 °C for 72–168 h. The cycloaddition was highly chemo- and stereoselective, affording cyclobutene derivatives as single isomers in moderate to good yields (Scheme 15).[16]

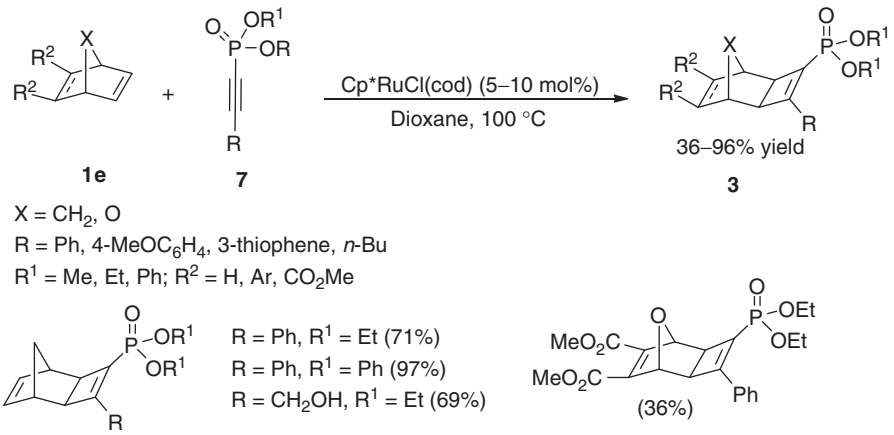
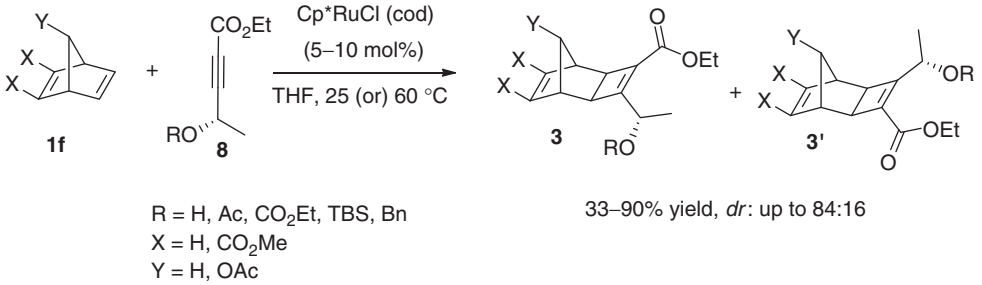


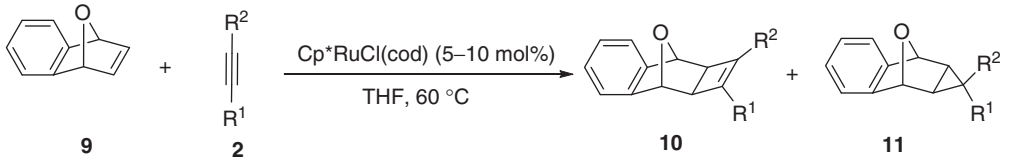
Scheme 15 Ruthenium-catalyzed [2 + 2] cycloaddition of bicyclic alkenes with alkynyl sulfides and sulfones.

In the same year, Tam also studied the reactivity of different types of alkyne substrates in Ru-catalyzed [2 + 2] cycloadditions with a bicyclic alkene.[17] They observed that the electronic effect of the alkyne plays an important role on the rate of the cycloaddition, and the reactivity increases dramatically as the alkyne becomes more electron deficient. They also observed that the steric bulkiness of the substituent on the alkyne decreases the reactivity (Scheme 16).

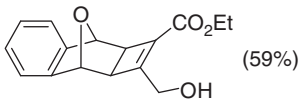


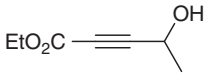
Scheme 16 Relative rate of Ru-catalyzed [2 + 2] cycloadditions of alkynes with NBD.

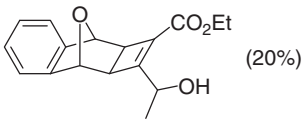
Similarly, the reaction between bicyclic alkenes and alkynyl phosphonates afforded cyclobutene adducts in moderate to good yields.[18] Various alkynyl phosphonates bearing diethyl, dimethyl, and diphenyl substituents reacted efficiently with bicyclic alkenes in a chemo- and stereoselective manner (Scheme 17).

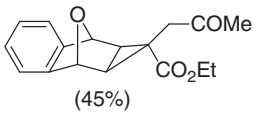


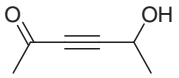
Scheme 17 Ruthenium-catalyzed [2 + 2] cycloadditions of bicyclic alkenes with alkynyl phosphonates.

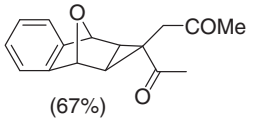


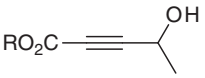


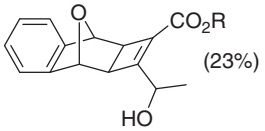


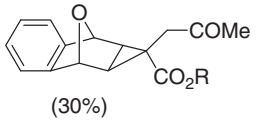






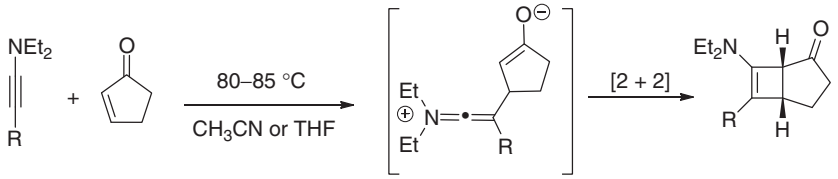






Tam and coworkers investigated a diastereoselective ruthenium-catalyzed [2 + 2] cycloaddition between chiral propargylic alcohols and bicyclic alkenes.[19a] Various bicyclic alkenes underwent the reaction to give cyclobutenes in good yields but with modest to moderate diastereoselectivities (Scheme 18).

Scheme 18 Ruthenium-catalyzed [2 + 2] cycloadditions of bicyclic alkenes with propargylic alcohols.



However, when expanding the scope of this reaction to oxabicyclic alkenes, the unexpected cyclopropane **11** was isolated as the major product and cyclobutene as the minor component in some cases (Scheme 19). The formation of the cyclopropane was shown to be highly selective, giving only one stereoisomer.[19b]

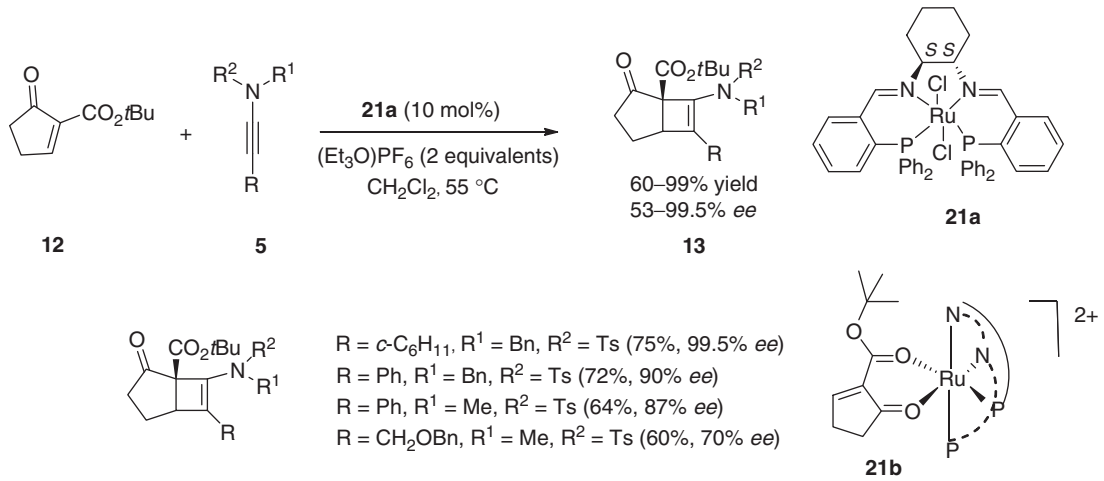
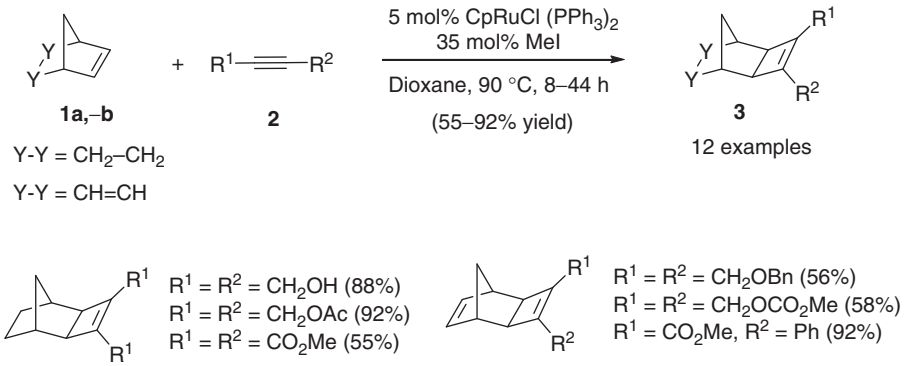
Scheme 19 Ruthenium-catalyzed [2 + 2] cycloadditions of bicyclic alkenes with propargylic alcohols.

Earlier in 1976, Ficini disclosed a useful method for the synthesis of aminocyclobutenes on reaction of ynamines with cyclic enones via a thermally driven stepwise [2 + 2] cycloaddition (Scheme 20).[20]

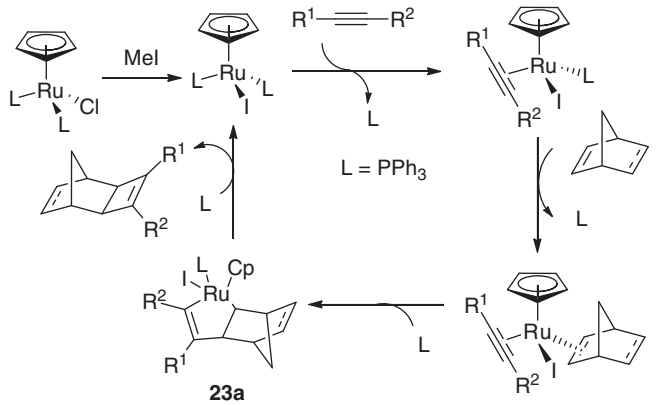


Scheme 20 Ficini's ynamine [2 + 2] cycloaddition.



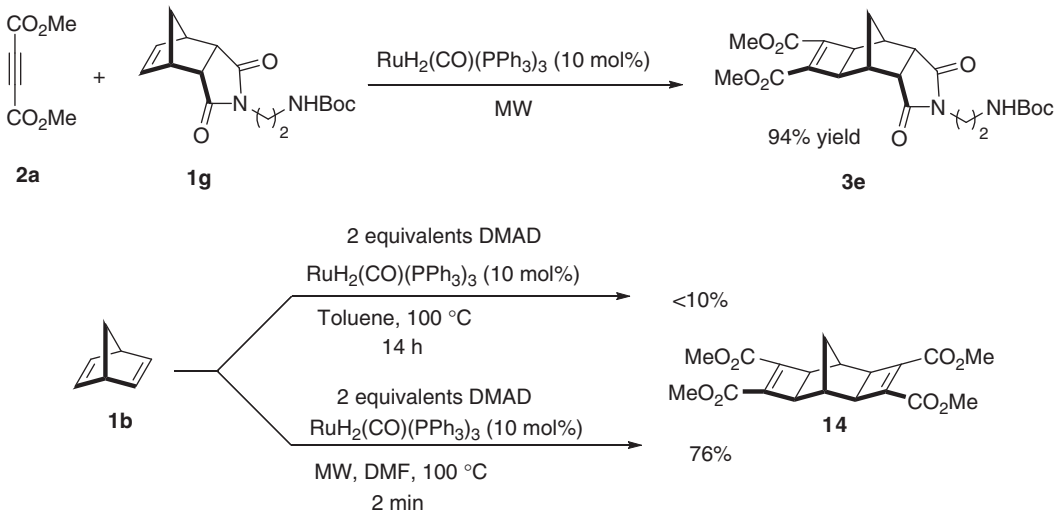
The development of metal-catalyzed processes has become an emerging field over the past decade. The first Ru-catalyzed enantioselective [2 + 2] cycloaddition (Ficini reaction) between ynamides **5** and the cyclic enone **12** was reported by Schotes and Mezzetti in 2011 (Scheme 21).[21] In this process, 10 mol% of a complex formed from ruthenium/(1*S*,2*S*)-*N*,*N*′-bis[*o*-(diphenylphosphino)benzylidene]cyclohexane-1,2-diamine (PNNP) complex and $(Et_3O)PF_6$ (2 equivalents) was found highly efficient in terms of yield and enantioselectivity. Under the reaction conditions, a wide range of ynamide substrates effectively reacted with cyclic enones to give the corresponding amidocyclobutenes **13** with high yield and excellent enantioselectivity. The authors suggested that the dicationic nature of **21b** is the possible key feature to ensure the catalytic activity. The coordination of the unsaturated *β*-keto ester to the chiral, oxophilic ruthenium/PNNP fragment appears to be an efficient strategy for enantioselection.

In 2003, Tenaglia and Giordano noticed that the electron-rich $[RuCl_2(PPh_3)_2$/MeI] system effected an intermolecular [2 + 2] cycloaddition of norbornenes with disubstituted alkynes to afford cyclobutenes in satisfactory to excellent yields (Scheme 22).[22] MeI played an important role for this reaction to proceed; no cycloadduct was observed in its absence. Previously, it was known that haloalkanes are able to coordinate with the metal center of Ru-complexes via *σ*-donation of a halogen lone pair. Another possibility is that methyl iodide might react with PPh_3 to give the corresponding phosphonium salt, thus removing a phosphine ligand to enhance the coordinating ability of the catalysts. These complexes easily undergo ligand substitution with common coordinating solvents.



Based on the above observation, the authors proposed a possible reaction mechanism for the [2 + 2] cycloaddition of norbornenes with alkynes as shown in Scheme 23. First, the active precatalyst $CpRuI(PPh_3)_2$ is generated on reaction with MeI. Then, coordination of the alkyne and the alkene to the Ru center followed by oxidative cyclometalation gives the

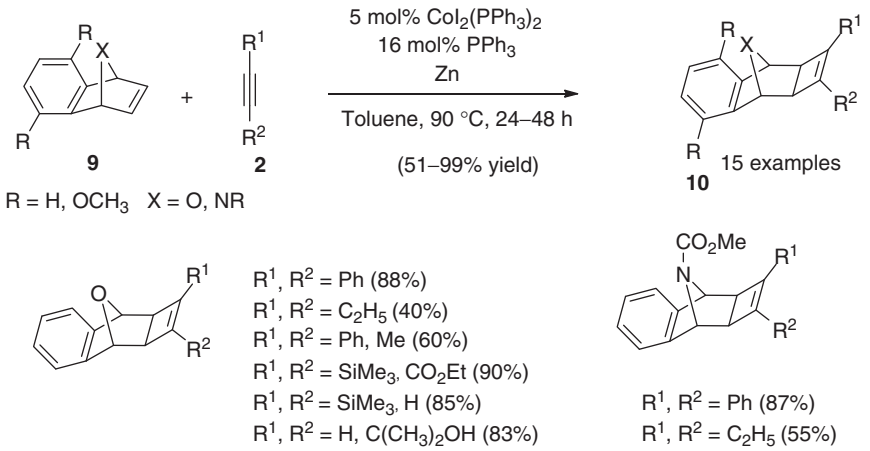
Scheme 21 Ruthenium-catalyzed enantioselective [2 + 2] cycloadditions of unsaturated cyclic enones with ynamides.



Scheme 22 The $RuCl_2(PPh_3)_2$/MeI system employed for [2 + 2] cycloadditions of norbornenes with alkynes.

Scheme 23 Proposed mechanism for the [2 + 2] cycloaddition of norbornenes with alkynes.

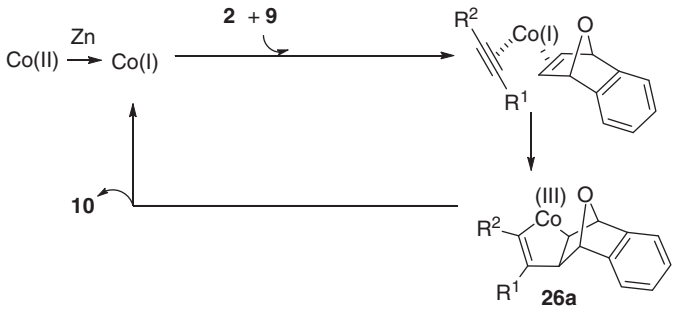
ruthenacyclopentene intermediate **23a**. Subsequent reductive elimination of **23a** affords the cycloaddition product **3** in a highly regio- and stereoselective manner and regenerates the active Ru species.



Various cyclobutene diesters were synthesized using a ruthenium-catalyzed, microwave (MW)-assisted [2 + 2] cycloaddition of norbornenes with DMAD (**2a**). High yields of the desired products were realized in only 2 min reaction time. This methodology was successfully applied to the synthesis of dicyclobutene tetraester **14** via twin cycloaddition of norbornenes with DMAD in a single-step manner. It is noteworthy that the conventional heating gave < 10% yield of this product (Scheme 24).[23]

Scheme 24 MW-assisted [2 + 2] cycloadditions of norbornenes with DMAD catalyzed by a Ru-complex.

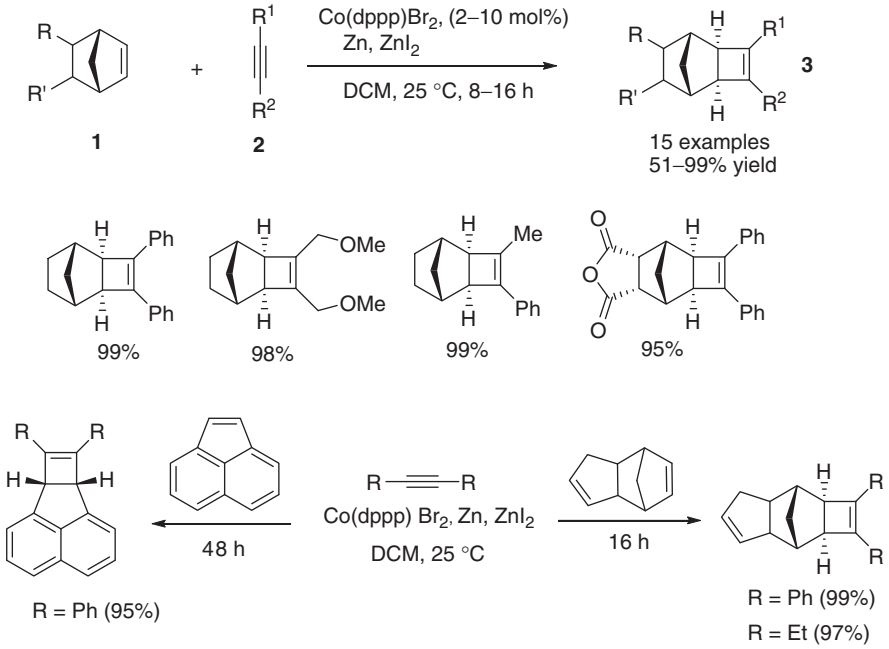
5.07.2.2 Co-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes



Cobalt catalysis is attractive because of the low cost of the catalysts as well as the unique reactivities or selectivities that are often achieved. Cobalt complexes have also been extensively used as catalysts for Pauson–Khand- and [2 + 2 + 2]-cycloaddition reactions.[24] Because of these observations, few reports on Co-catalyzed [2 + 2] cycloaddition are known. 7-Oxa- and azabicyclic alkenes are a class of activated substrates that show substantial coordinating ability to transition-metal centers due to the large bond-angle strain of the alkenes.[25] In this context, Cheng's group observed a cobalt-catalyzed cross [2 + 2] cycloaddition of bicyclic alkenes with alkynes. Thus, the reaction of 7-oxabenzonorbornadiene (**9**, X = O) with diphenylacetylene (**2**) in the presence of $Co(PPh_3)_2I_2$ (5 mol%), PPh_3 (16 mol%), and zinc powder in toluene at 90 °C for 24 h gave cyclobutene product **10** in excellent yield (Scheme 25).[26] Control reactions indicate that, in the absence of either the cobalt complex or zinc powder, no **10** was formed. This catalytic reaction requires excess PPh_3 in order for the reaction to proceed smoothly. In the absence of extra PPh_3, the cobalt complex decomposed readily under the reaction conditions and no catalytic activity was observed. Addition of PPh_3 to the solution improved the stability of the catalyst and increased the yields of product **10**.

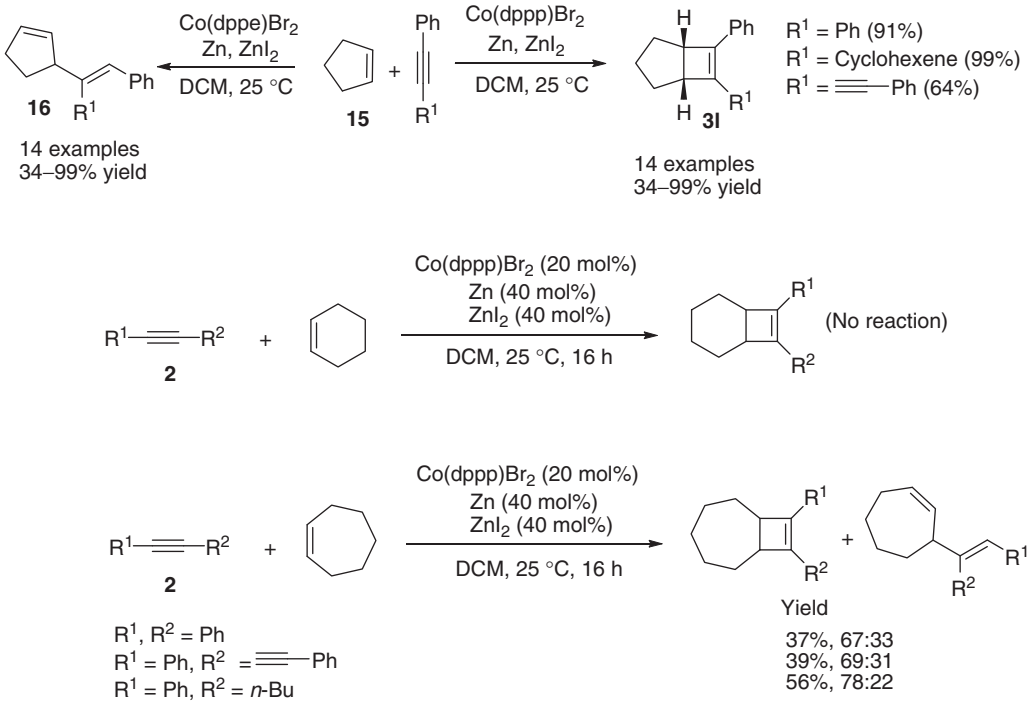
Scheme 25 Cobalt-catalyzed [2 + 2] cycloadditions of bicyclic alkenes and alkynes.

Under similar reaction conditions, various symmetrical, unsymmetrical, and terminal alkynes reacted well with 7-oxabenzonorbornadiene to give the corresponding cyclobutene derivatives in good yields. The structures and yields of the individual products **10** are shown in Scheme 25.



A possible mechanism for the cobalt-catalyzed [2 + 2] cycloaddition of bicyclic alkenes and alkynes is shown in Scheme 26. Reduction of $Co(PPh_3)_2I_2$ to a Co(I) species by zinc metal initiates the catalytic reaction. Coordination of an alkyne and

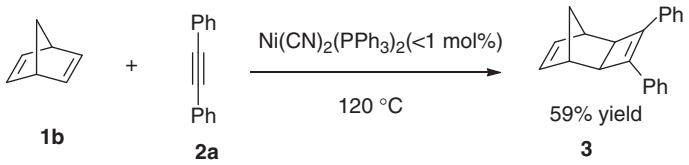
Scheme 26 Proposed mechanism for the cobalt-catalyzed [2 + 2] cycloaddition of bicyclic alkenes and alkynes.



7-oxabenzonorbornadiene (**9**) to the cobalt center followed by oxidative cyclometalation affords the cobaltacyclopentene intermediate **26a**. Subsequent reductive elimination of **26a** gives the cyclobutene product and regenerates the Co(I) species.

On the basis of Cheng's work, Hilt and his group achieved a very similar intermolecular [2 + 2] cycloaddition of alkynes with alkenes. The substrates reacted in the presence of Co(1,3-bis(diphenylphosphino)propane (dppp))Br_2 (2 or 10 mol%), Zn (10 mol%), and ZnI_2 (10 mol%) in DCM at 25 °C to give the expected cycloadducts in good to excellent yield (Scheme 27).[27a] The *exo* relative configuration of the cyclobutene ring was confirmed by two-dimensional NMR spectroscopic analysis. In these reactions, both symmetrical and unsymmetrical alkynes worked equally well. However, when terminal alkynes were used as substrates, only very little of the desired [2 + 2] cycloaddition product was detected using GC-mass spectrometry (MS). With these substrates, [2 + 2 + 2] cyclotrimerization of the terminal alkynes led to the corresponding substituted benzenes. The reaction of cyclopentadiene dimer with internal alkynes led exclusively to products derived from the participation of the strained double bond, in excellent yields of 97–99% (Scheme 27). Interestingly, acenaphthylene reacted with diphenylacetylene to generate the corresponding cyclobutene in 95% isolated yield after a reaction time of 2 days.

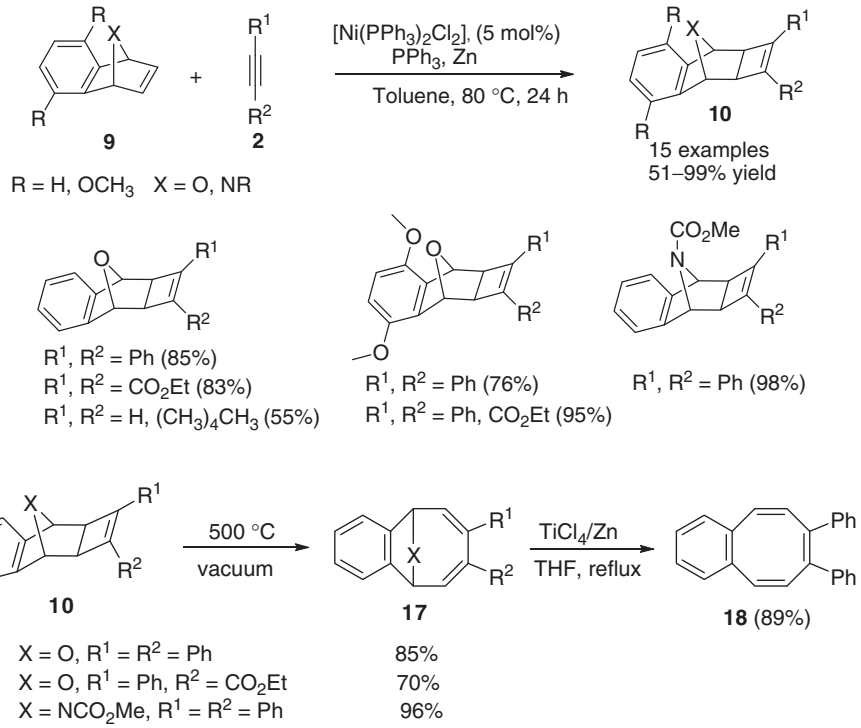
Scheme 27 Cobalt-catalyzed [2 + 2] cycloaddition reactions between norbornenes and alkynes.



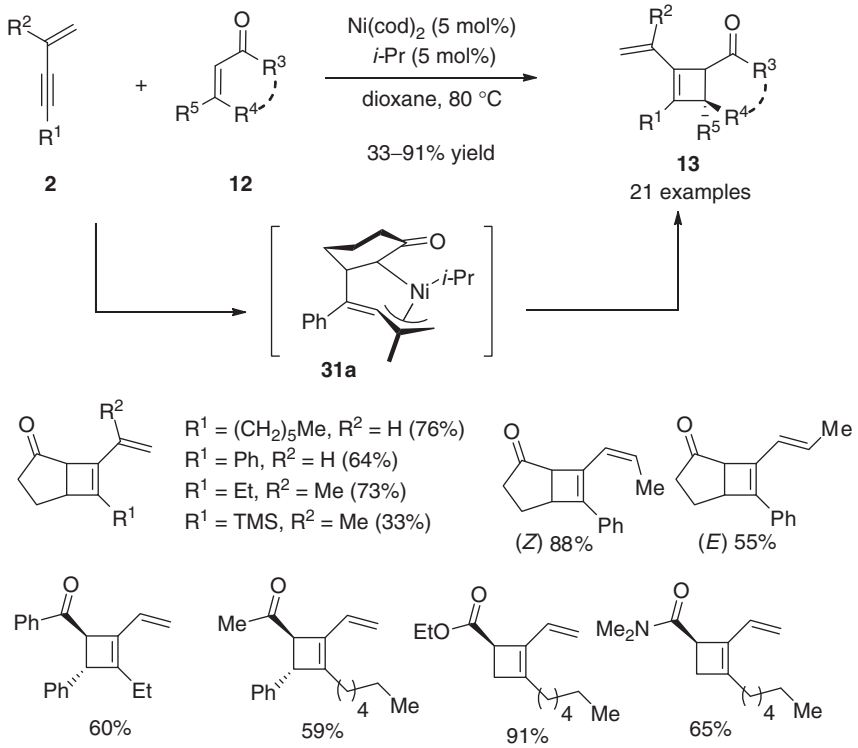
In 2010, the same author published a [2 + 2] cycloaddition of cyclopentene with internal alkynes by using the same cobalt system, which also led to cyclobutene derivatives in good to excellent yield.[27b] Various internal alkynes were compatible with the catalytic reaction. However, alkynes bearing bulky substituents such as 1,2-bis(trimethylsilyl (TMS))acetylene were unreactive under these conditions. It is surprising that cyclohexene did not undergo the [2 + 2] cycloaddition, whereas cycloheptene gave the expected cycloadduct in moderate yield along with the 1,4-diene coupling products. However, the Co(1,3-bis(diphenylphosphino)ethane (dppe))Br_2 complex favored Alder–Ene reactions of alkenes with internal alkynes in the presence of Zn, and ZnI_2 in CH_2Cl_2 to give the 1,4-diene products **16** in good to excellent yields with a high stereoselectivity (Scheme 28).

Scheme 28 Cobalt-catalyzed Alder–Ene reaction or [2 + 2] cycloaddition of cyclopentene with unsymmetrical alkynes.

5.07.2.3 Ni-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes



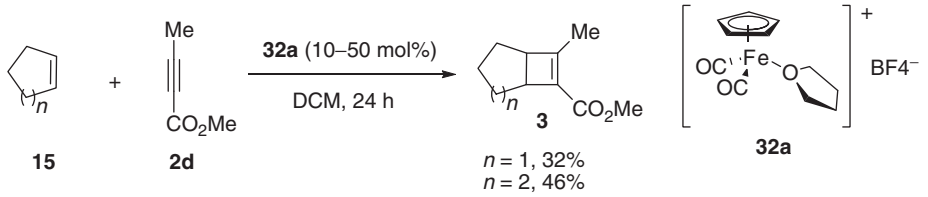
The first nickel-catalyzed [2 + 2] cycloaddition of NBD was reported in 1964 (Scheme 29). However, only very few types of acetylenes, for example, diphenylacetylene, underwent the [2 + 2] cycloaddition with NBD.[28] Instead, most activated acetylenes reacted with NBD to give alternative homo-Diels–Alder reaction products.



Scheme 29 Ni-catalyzed [2 + 2] cycloaddition of NBD with diphenylacetylene.

Cheng et al. also found that oxa- and azabenzonorbornadiene **9** underwent [2 + 2] cycloaddition with alkynes **2** in the presence of $NiCl_2(PPh_3)_2$, PPh_3, and zinc powder in toluene at 90 °C to give the *exo*-cyclobutene derivatives **10** in high yields (Scheme 30).[29] Other nickel-complexes such as $NiBr_2$/Zn and $Ni(cod)_2$ were also active, giving the cyclobutenes in low yields along with homocycloaddition products of oxabenzonorbornadiene. It is noteworthy that dialkylacetylenes did not undergo such [2 + 2] cycloadditions with bicyclic alkenes. On thermolysis, the cyclobutene derivatives **10** underwent a novel ring expansion, converting the fused four- or six-membered rings into an eight-membered cod moiety in high yields. For example, flash vacuum pyrolysis of **10** at 500 °C readily afforded diene **17** in 85% yield with 99% selectivity. Subsequent deoxygenation of **17** (X = O, $R^1 = R^2 = Ph$) with $TiCl_4$ and Zn gave the cot derivative **18** in 89% yield.

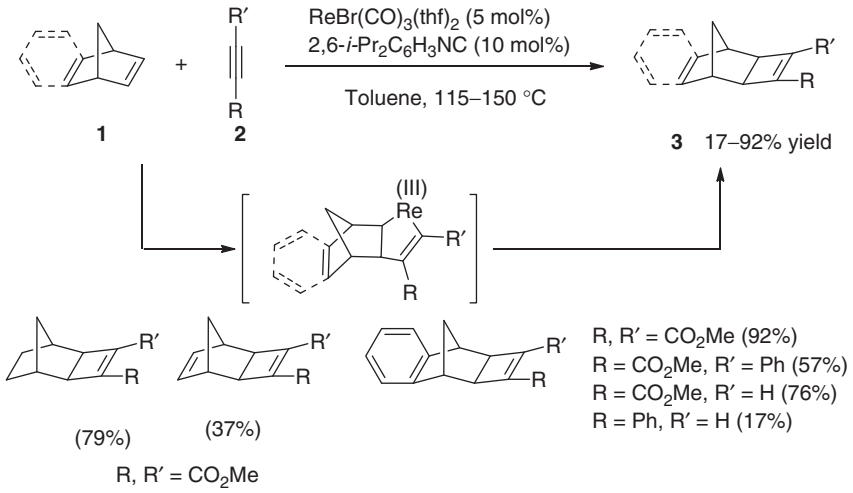
More recently, Ogoshi and coworkers developed a nickel-catalyzed intermolecular [2 + 2] cycloaddition of conjugated enynes with alkenes to provide cyclobutene derivatives in good yields with high chemo- and regioselectivity. Various electron-deficient alkenes as well as the electronically neutral norbornene underwent [2 + 2] cycloaddition with conjugated enynes in the presence of 5 mol% of $Ni(cod)_2$/*N*,*N*′-bis(2,6-diisopropylphenyl)imidazol-2-ylidene (IPr) in dioxane at 80 °C for 5 h to give cyclobutanes in good yields (Scheme 31).[30] Notably, the use of conjugated enynes completely suppressed possible side reactions, such as oligomerizations and cyclotrimerizations or [2 + 2 + 2] cycloadditions. The authors isolated the η^3-butadienyl nickelacycle intermediate (**31a**).



Scheme 30 Ni-catalyzed [2 + 2] cycloadditions of 7-oxa- and 7-azabenzonorbornadienes with alkynes.

Scheme 31 Ni(0)-catalyzed [2 + 2] cycloaddition of conjugated enynes with alkenes.

5.07.2.4 Fe-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

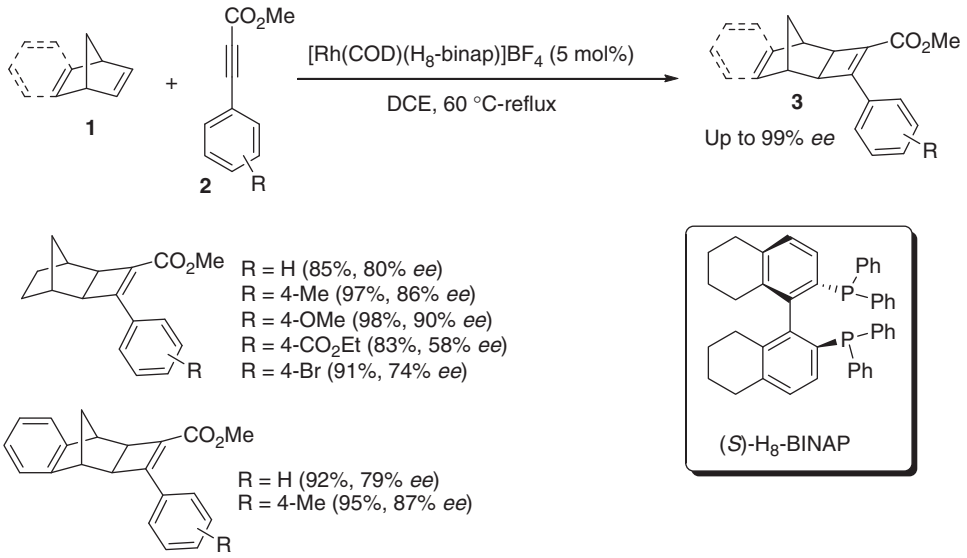


The use of iron catalysts in organic synthesis is attractive because of their abundance, low price, and low toxicity.[31] Previously, cyclopentadienyldicarbonyliron (Fp^+) (= $[CpFe(CO)_2]^+$) was found to function as a unique catalyst for cycloaddition and ene-type reactions involving the co-condensation of acetylenic-esters and olefins. Thus, treatment of methyl propiolate with olefins in the presence of the iron complex **32a** in DCM afforded cyclobutenes in moderate yield (Scheme 32).[32] The course of the reaction is strongly dependent on the structure of the olefin reactant; 1,2-disubstituted cyclic and acyclic alkenes yielded cyclobutenes along with the formation of 1,3-diene products. In addition, some of the olefins also gave lactones, whereas 1,l-disubstituted or trisubstituted alkenes gave only the latter products. Monosubstituted olefins yield principally the corresponding Fp complexes.

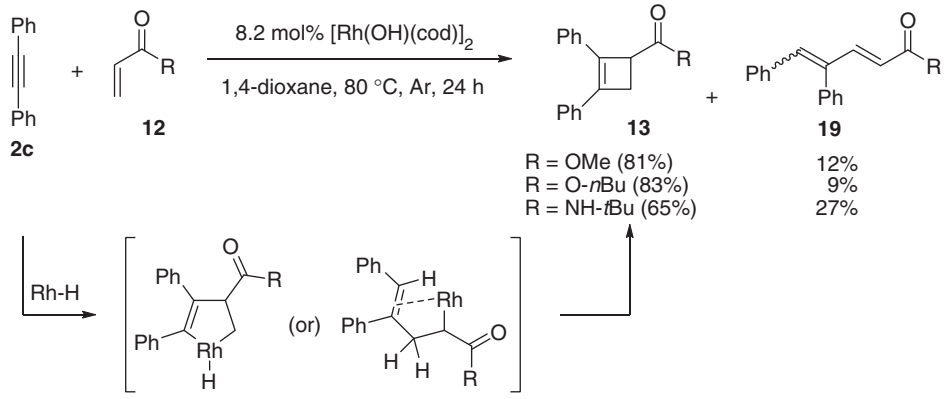
Scheme 32 Fe-catalyzed [2 + 2] cycloadditions of 1,2-disubstituted alkenes with methyl propiolate.

5.07.2.5 Re-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

Takai and coworkers reported that treatment of norbornenes and either internal or terminal acetylenes with a catalytic amount of $[ReBr(CO)_3(THF)]_2$ and 2,6-diisopropylphenyl isocyanide as an additive in toluene at 150 °C cleanly afforded the corresponding cyclobutene derivatives in good to excellent yields (Scheme 33).[33] In this reaction the role of the isocyanides was not clear; they may inhibit the polymerization of the acetylenes and improve the product yield. These reactions supposedly proceed via the formation of a rhenacyclopentene intermediate and a subsequent reductive elimination.



Scheme 33 Re-catalyzed [2 + 2] cycloadditions of norbornenes with alkynes.



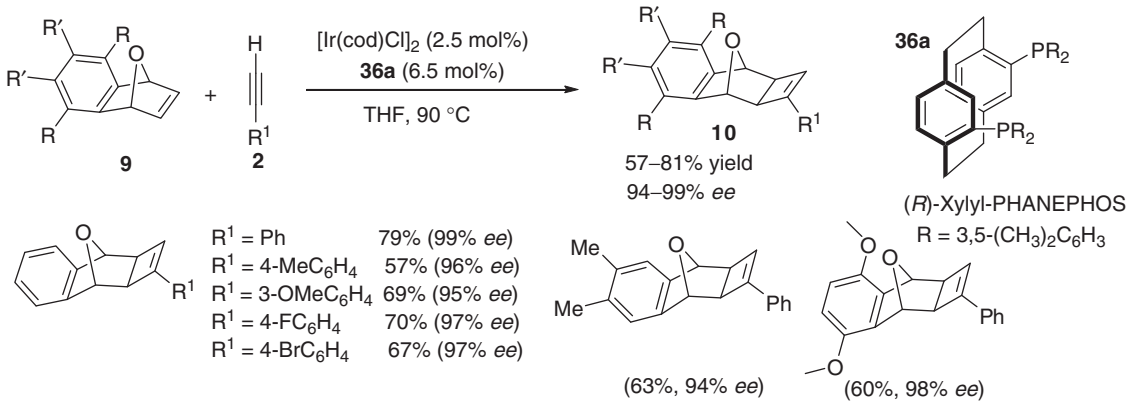
5.07.2.6 Rh-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

The metal-catalyzed asymmetric [2 + 2] cycloaddition is one of the most convergent strategies for the synthesis of chiral cyclobutene products. In this respect, Shibata et al. introduced a Rh-catalyzed enantioselective [2 + 2] cycloaddition of alkynyl esters with norbornene derivatives. The chiral tri- and tetracyclic cyclobutenes were obtained in moderate to high *ee*'s. The electron-withdrawing moiety on an alkyne terminus was important to promote the [2 + 2] cycloaddition and the ester oxygen atom played a key role in the asymmetric induction (Scheme 34).[34]

In 2011, Baba and coworkers discovered a new method for the synthesis of cyclobutenes from alkynes and electron-deficient alkenes. Thus, the reaction of diphenylacetylene **2c** and methyl acrylate (**12**, R = OMe) in the presence of $[Rh(OH)(cod)]_2$ in 1,4-dioxane at 80 °C for 24 h gave cyclobutene **13** in 81% yield along with the corresponding Mizoroki–Heck-type ene–yne coupling product **19** (Scheme 35).[35] Under similar reaction conditions, other olefins such as acrylamide derivatives also worked well for

Scheme 34 Rh-catalyzed enantioselective [2 + 2] cycloadditions of norbornene with alkynyl esters.

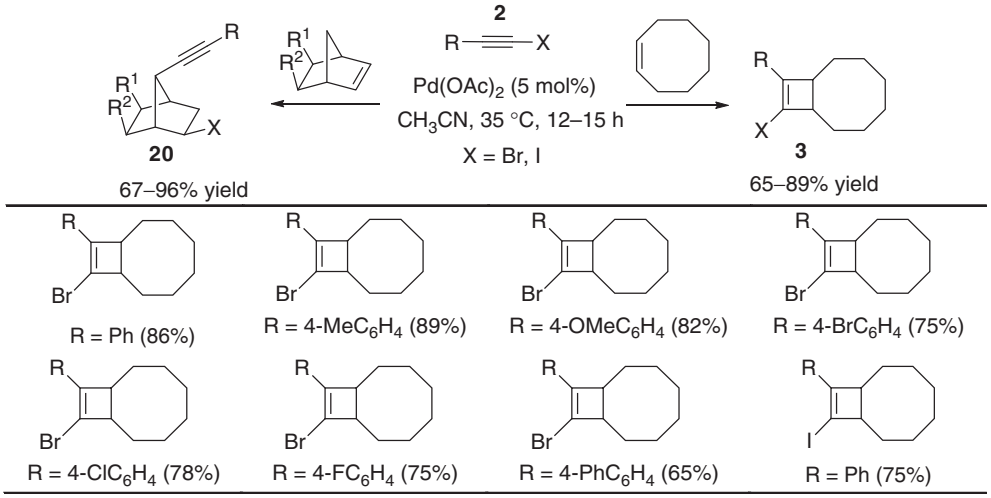
Scheme 35 Synthesis of cyclobutenes from diphenylacetylene and electron-deficient olefins catalyzed by a Rh(I) complex.



this reaction. The authors speculated about two plausible pathways, including either a metallacyclopentene intermediate or the hydrometalation of the alkyne. The coordinatively unsaturated environment of the Rh-H species seems to be necessary for the reaction pathways. Finally, the authors confirmed that a Rh-H species was generated from $[Rh(OH)(cod)]_2$ by several experimental studies.

5.07.2.7 Ir-Catalyzed [2 + 2] Cycloaddition of Terminal Alkynes and Oxabicyclic Alkenes

Shao and coworkers found a first catalytic asymmetric [2 + 2] cycloaddition of oxabicyclic alkenes and terminal alkynes using $[Ir(cod)Cl]_2$/(*R*)-xylyl-4,12-bis(diphenylphosphino)-[2.2]-paracyclophane (PHANEPHOS) as the catalyst (Scheme 36).[36] This iridium-catalyzed enantioselective [2 + 2] cycloaddition constructs four stereocenters in a single step with excellent enantioselectivity (94–99% *ee*).

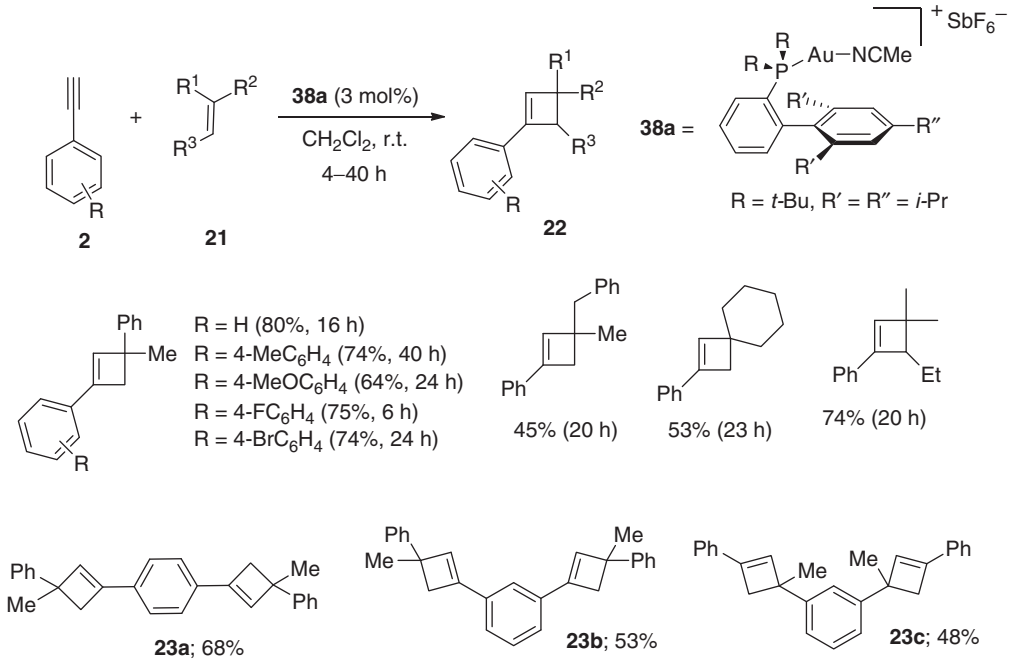


5.07.2.8 Pd-Catalyzed [2 + 2] Cycloaddition of Bromoalkynes and Cyclooctene

Very recently an unprecedented $Pd(OAc)_2$-catalyzed [2 + 2] reaction of bromoalkyne and cyclooctene was reported by Jiang and coworkers. Various aromatic alkynyl bromides carrying electron-withdrawing or donating groups underwent the [2 + 2] cycloaddition with cyclooctene to generate the corresponding cycloaddition products in moderate to good yields.[37] Interestingly, even the highly sensitive phenylethynyl iodide worked well. However, the ring size of the alkenes played a key role in the formation of the product. Other alkenes such as cyclohexene, cyclopentene, and cyclododecene were completely ineffective for the

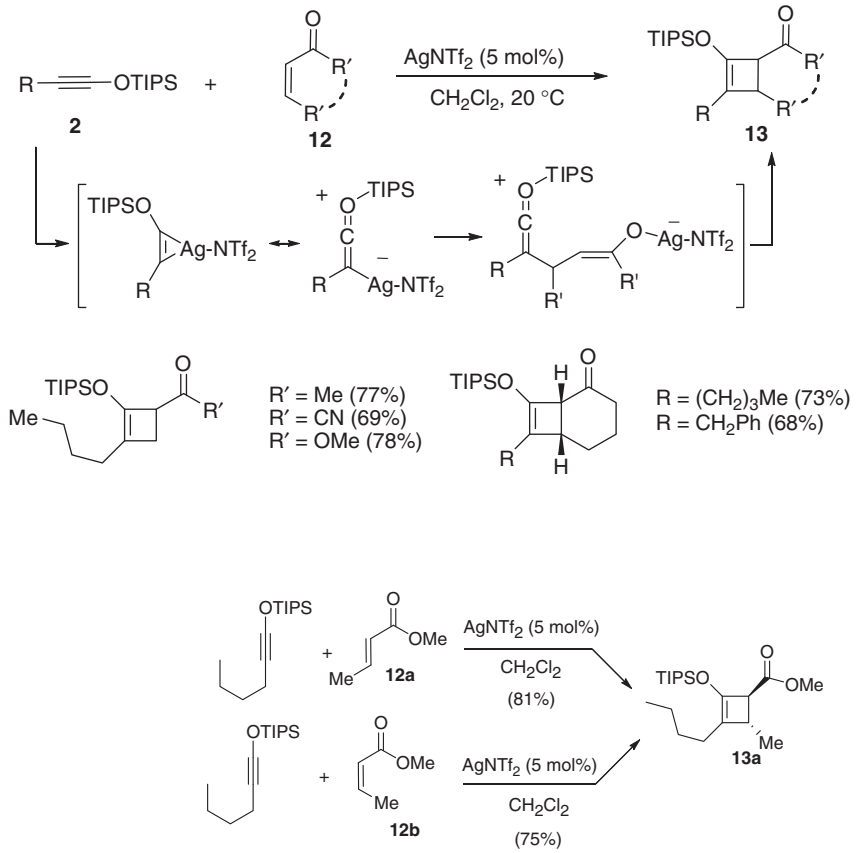
Scheme 36 Ir-catalyzed asymmetric [2 + 2] cycloadditions of oxabicyclic alkenes with terminal alkynes.

catalytic reaction whereas cycloheptene is less effective. However, the strained alkenes (norbornene derivatives) unexpectedly gave the 7-alkynyl halonorbornane **20** in good yield (Scheme 37).



Scheme 37 Pd(II)-catalyzed [2 + 2] cycloadditions of haloalkynes with cyclooctene.

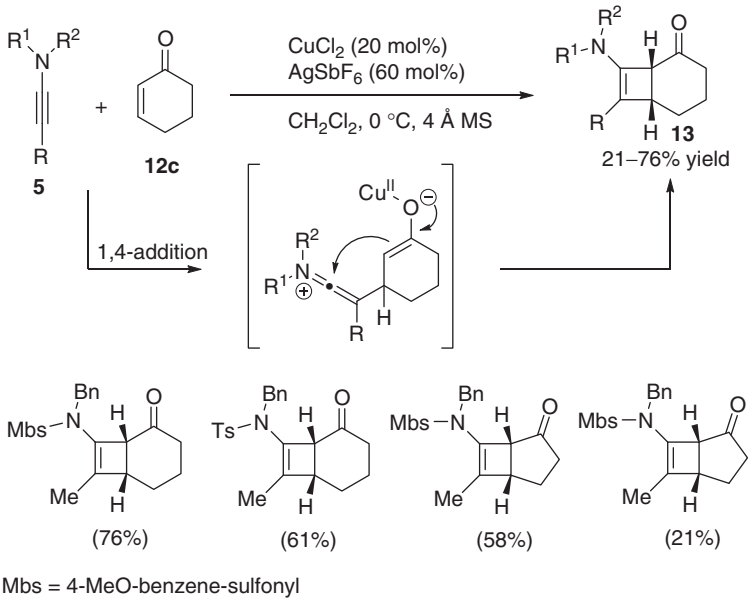
5.07.2.9 Au-Catalyzed [2 + 2] Cycloaddition of Terminal Alkynes and Alkenes



Echavarren and coworkers reported that Au(I)-catalyzed intermolecular [2 + 2] cycloadditions of terminal alkynes with alkenes lead to substituted cyclobutenes in a regioselective manner (Scheme 38).[38] The use of a sterically hindered cationic Au(I) complex (**38a**) as catalyst is key for the success of this reaction. The reaction proceeds satisfactorily with terminal alkynes having either electron-rich or electron-poor substituents. The biscyclobutenes **23a–c** were also obtained from *p*- and *m*-diethynylbenzene, respectively (Scheme 38). The cyclobutene derivatives from terminal alkynes and alkenes are usually difficult to obtain by using transition metal catalysts, due to facile [2 + 2 + 2] alkyne cyclotrimerization reactions. It should be noted that no [2 + 2 + 2] cyclotrimerization products were detected during these gold-catalyzed reactions, showing another advantage of this system.

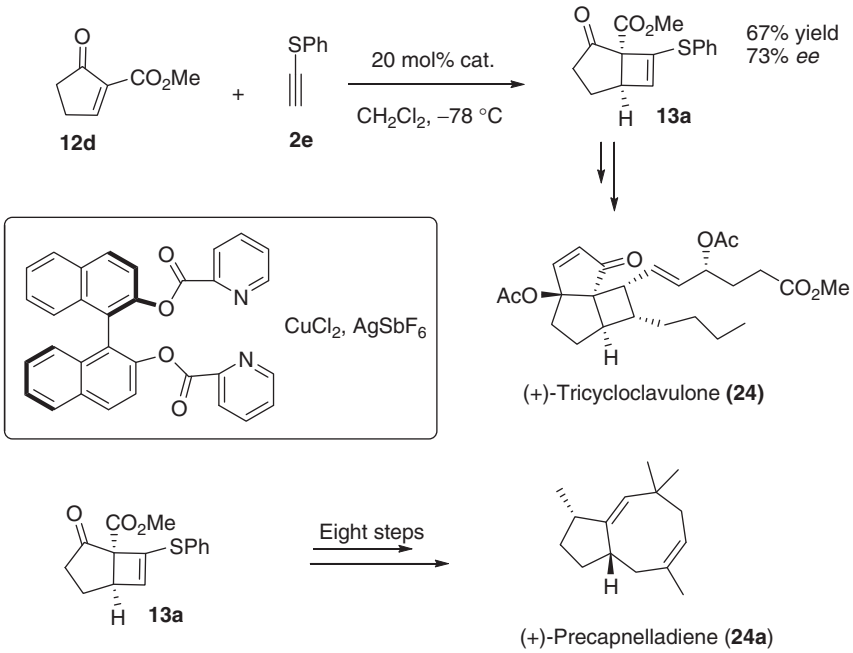
5.07.2.10 Ag-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

Kozmin et al. reported the first intermolecular silver-catalyzed [2 + 2] cycloadditions of siloxyalkynes with various unsaturated carbonyls to form complex siloxy cyclobutenes (Scheme 39).[39] A wide range of alkenes with electron-withdrawing substituents, including acrylonitrile, methyl acrylate, and cyclohexenone, successfully participated in the reaction. The authors proposed a sequential mechanism that involves the activation of the alkyne by Ag(I), 1,4-addition, subsequent trapping of the ketenium ion intermediate and cyclization to give the final product. An interesting feature of this reaction is that treatment of the *E*- and *Z*-crotonates **12a** and **12b** with siloxy alkyne **2** invariably resulted in the formation of the *trans*-substituted siloxy cyclobutene **13a**.



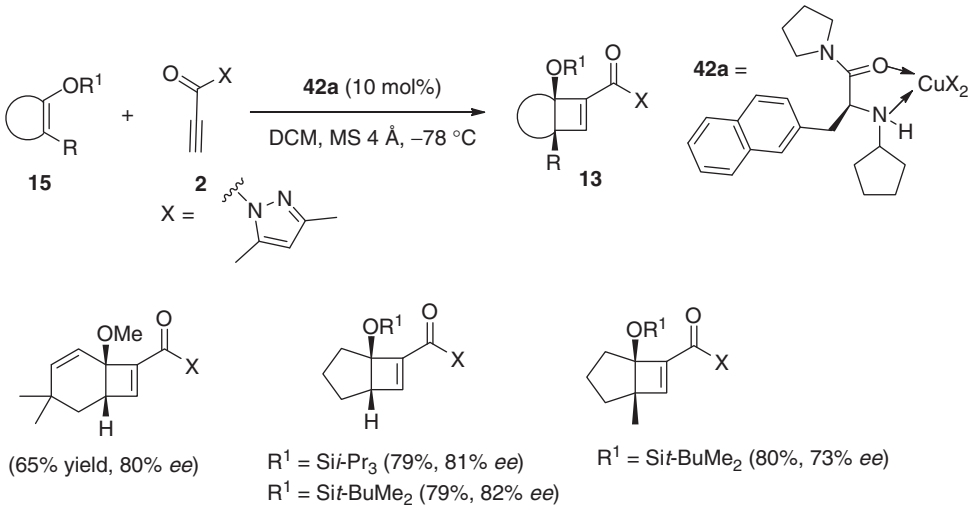
Scheme 38 Au(I)-catalyzed intermolecular [2 + 2] cycloaddition of terminal alkynes with alkenes.

Scheme 39 Silver-catalyzed [2 + 2] cycloadditions of siloxyalkynes with unsaturated carbonyls.



5.07.2.11 Cu-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

Hsung's group reported the first copper-catalyzed Ficini-[2 + 2] cycloaddition of *N*-sulfonyl-substituted ynamides **5** with enones such as **12c**, which provide direct access to cyclobutenamines (Scheme 40).[40] This catalytic reaction proved compatible with a wide variety of *N*-sulfonyl ynamides and cyclic and acyclic enones. The authors proposed a stepwise mechanism with a nucleophilic 1,4-addition by the ynamide onto the enone activated via the cationic Cu(II) catalyst to give a keteniminium intermediate, which subsequently undergoes intramolecular addition to afford the observed cyclobutenamine derivatives.

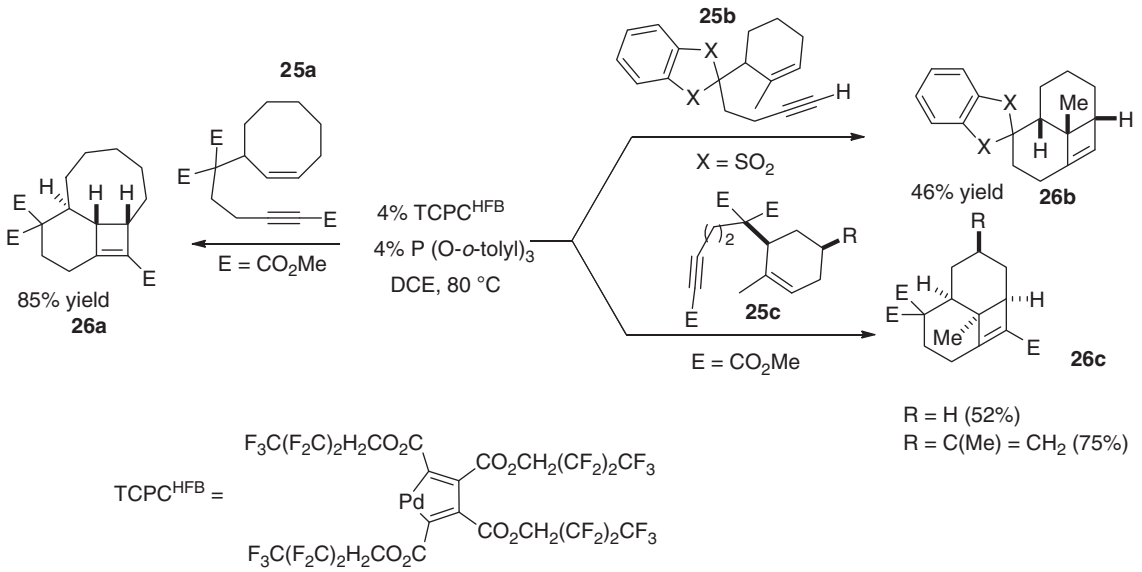


Scheme 40 Copper-catalyzed Ficini-[2 + 2] cycloadditions of *N*-sulfonyl-substituted ynamides with enones.

Ito, Iguchi, and coworkers developed enantioselective [2 + 2] cycloaddition of 2-methoxycarbonyl-2-cyclopenten-1-one **12d** with phenylthioacetylene catalyzed by chiral Lewis acids, which give cyclobutene **13a** in good yield. This protocol has been successfully applied to the enantioselective total synthesis of tricycloclavulone (**24**),[41a,b] as well as to the formal synthesis of (+)-precapnelladiene (**24a**)[41c] by using the [2 + 2] cycloadduct as the key intermediate (Scheme 41).

Scheme 41 Enantioselective [2 + 2]-cycloadditions of a cyclic enone with phenylthioacetylene.

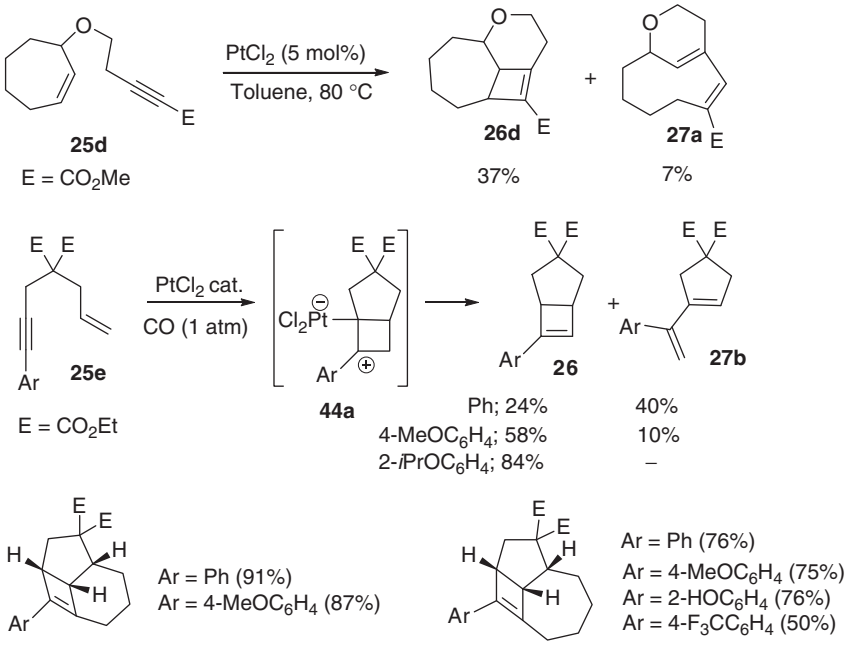
A highly effective copper-catalyzed enantioselective [2 + 2] cycloaddition of enol ether derivatives with propiolamides was developed by Ishihara and Fushimi in 2008. Various substituted alkenes **15** underwent facile cycloaddition with propiolamide **2** to furnish the densely substituted cyclobutenecarboxamides **13** with high *ee*'s (Scheme 42).[42]



Scheme 42 Copper-catalyzed enantioselective [2 + 2] cycloadditions of enol ether derivatives with propiolamides.

5.07.3 Intramolecular Metal-Catalyzed [2 + 2] Cycloaddition of Alkynes and Alkenes

5.07.3.1 Pd-Catalyzed Intramolecular [2 + 2] Cycloaddition



Metal-catalyzed intramolecular [2 + 2] cycloaddition reactions offer a highly efficient and atom-economical synthetic strategy for increasing molecular complexity and diversity in a single step. In this context, Trost et al. have observed that in the presence of a low-valent palladium catalyst ($TCPC^{HFB}$), the 1,7-enyne **25a** undergoes an intramolecular [2 + 2] cycloaddition to give a highly strained cyclobutene ring, which contained an unexpected *trans*-fused 8/6-ring system (Scheme 43).[43] However, 1,7-enynes **25b** and **25c**, which contain cyclohexene rings, gave a *cis–cis* ring fusion.

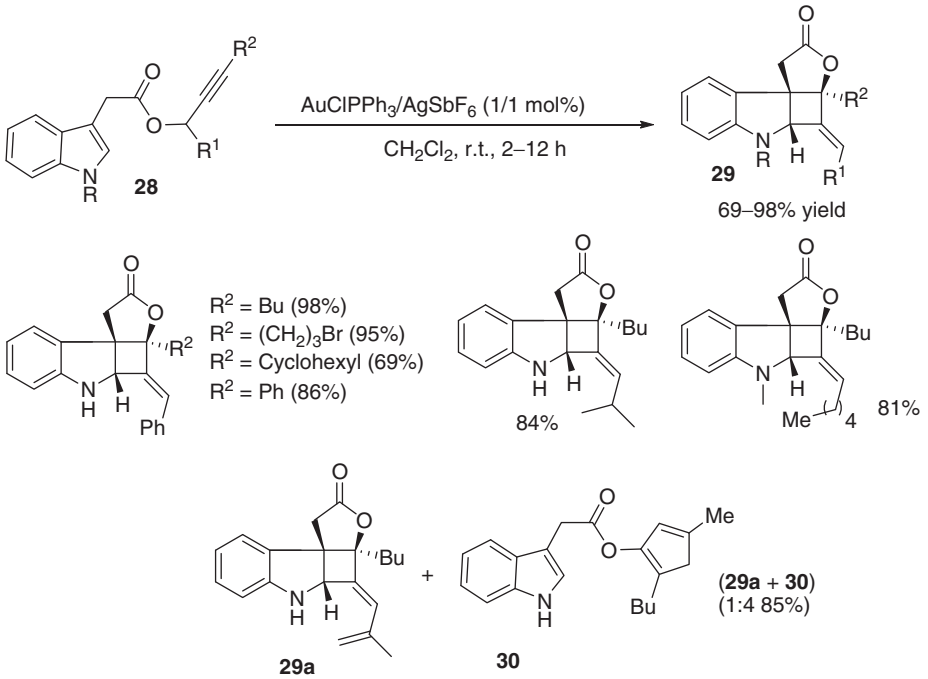
Scheme 43 Palladium-catalyzed intramolecular [2 + 2] cycloadditions of 1,7-enynes.

5.07.3.2 Pt-Catalyzed Intramolecular [2 + 2] Cycloaddition

In 2001, Fürstner et al. reported a $PtCl_2$-catalyzed formal enyne metathesis reaction leading to 1,3-dienes. For example, treatment of enyne **25d** in the presence of 5 mol% $PtCl_2$ in toluene at 80 °C for 24 h gave the cyclobutene **26d** in 37% yield along with the enyne metathesis product **27a** in 7% yield (Scheme 44).[44a]

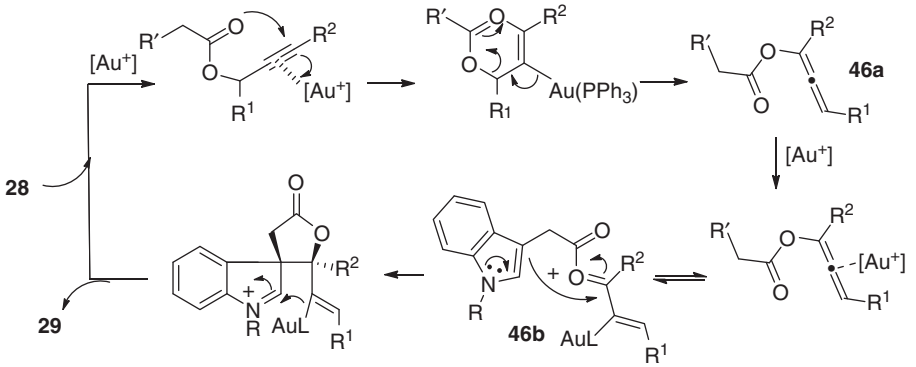
Scheme 44 Platinum-catalyzed cyclobutene synthesis.

The authors tried various reaction conditions to improve the yield of the cyclobutenes. Thus, treatment of enyne **25e** in the presence of 5 mol% $PtCl_2$ in toluene under 1 atm of carbon monoxide at 80 °C provided cyclobutene **26d** in 24% yield with the regular metathesis product **27b** in 40% yield. Gratifyingly, enyne **25e**, bearing a *p*-methoxyphenyl ring is able to stabilize a putative benzylic cation of type **44a** more effectively, and therefore clearly favors **26** over **27b**. However, the reaction was fairly slow and required >16 h for completion. Various related enynes with electron-donating and -withdrawing groups cyclized remarkably well to the corresponding cyclobutenes in good yields.[44b]



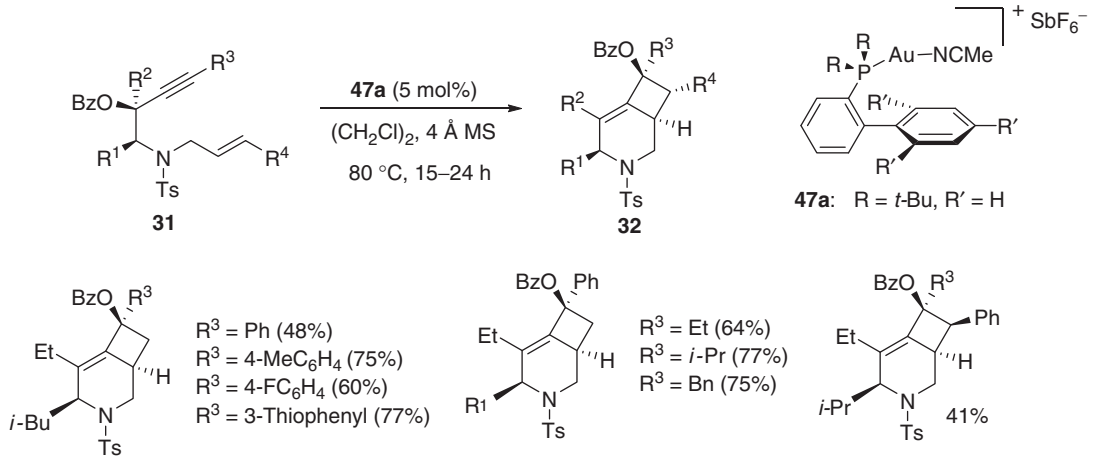
5.07.3.3 Au-Catalyzed Intramolecular [2 + 2] Cycloaddition

The indole ring system is a common heterocycle found in many natural and pharmaceutical compounds.[45] Zhang reported a Au(I)-catalyzed synthesis of highly functionalized 2,3-indoline-fused cyclobutanes via sequential 3,3-rearrangement and [2 + 2] cycloaddition. Various propargylic indole-3-acetates **28** underwent [2 + 2] cycloaddition in the presence of 1 mol% of $AuCl(PPh_3)/AgSbF_6$ in CH_2Cl_2 for 2 h to give cyclobutanes in good yields (Scheme 45).[46] In the tetracyclic product **29**, the cyclobutane is fused to a 2,3-indoline and a γ-lactone; only one geometrical isomer was observed, in which the exocyclic double bond was *E*-configured. It should be noted that the treatment of ester **28a** with a 2-propenyl group at the propargylic position under the same reaction conditions resulted in a 1:4 mixture of the desired cyclobutane **29a** and the cyclopentenone derivative **30**.



The proposed mechanism involves activation of the C–C triple bond of the propargylic ester **28** by $[Au(PPh_3)]^+$, promoting a 3,3-rearrangement of the indole-3-acetoxy group that leads to the formation of allenylic ester **46a** (Scheme 46). The allene moiety of **46a** is further activated by the cationic Au(I) complex, resulting in the formation of **46b** with the opposite double bond geometry. Cyclobutane **29** with an exocyclic *E*-double bond is formed via cyclization of the oxonium group in **46b** to the 3-position of the indole ring, followed by intramolecular trapping of the resulting iminium species by the alkenyl gold(I) group.

Very recently, Chan et al. developed a very unique method for the preparation of azabicyclo[4.2.0]oct-5-enes that relies on gold(I)-catalyzed tandem 1,3-migration/[2 + 2] cycloaddition of 1,7-enyne benzoates (Scheme 47).[47] Other Au(I) and Au(III) complexes as well as $PtCl_2$ as the catalyst gave similar outcomes. The scope of the reaction was broad. The reaction was shown to tolerate a diverse set of substrates and furnished stereochemically well-defined cyclobutane-fused piperidines in good yields.



The authors proposed a mechanism that involves initial activation of the alkyne moiety of the 1,7-enyne benzoates by the gold(I) catalyst, resulting in a *syn*-1,3-migration of the carboxylic ester group and formation of allenene **48a** via **I** and **II**. Next, the gold catalyst likely coordinates with the alkene moiety; a subsequent intramolecular cyclization step would then deliver **32** with release of the gold(I) catalyst (Scheme 48).

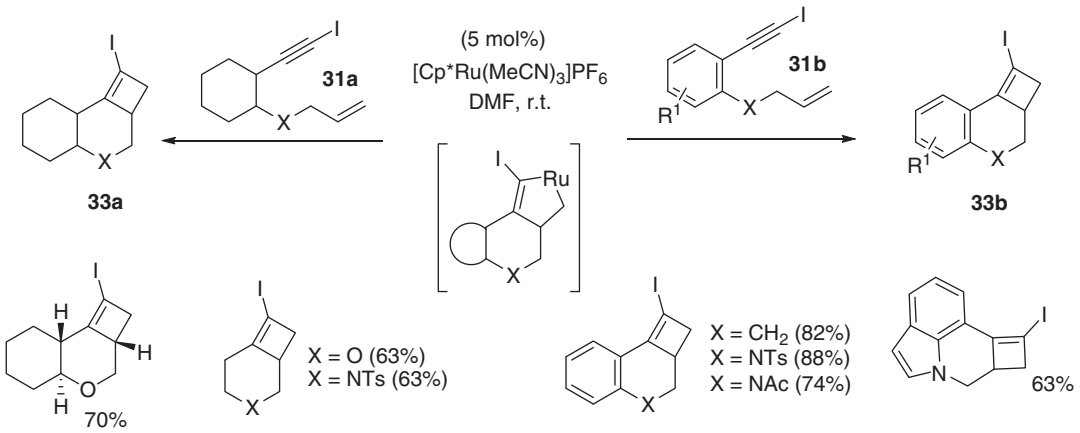
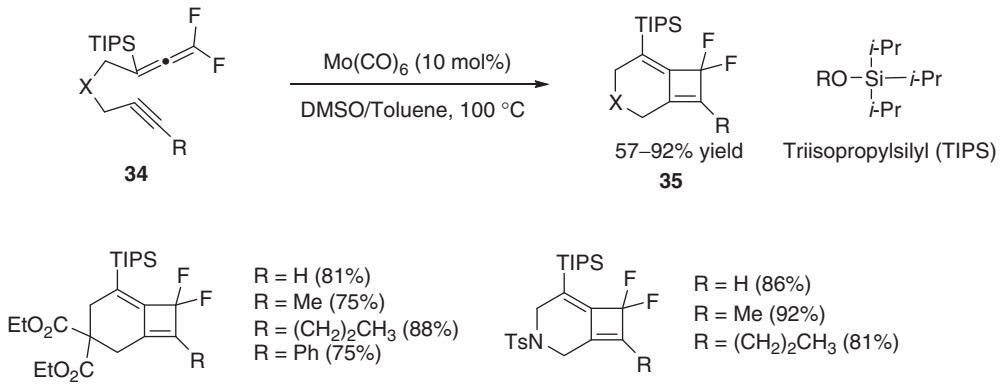


Scheme 47 Gold(I)-catalyzed tandem 1,3-migration/[2 + 2] cycloaddition of 1,7-enyne benzoates.

Scheme 48 Proposed mechanism of the intramolecular [2 + 2]-cycloaddition of 1,7-enyne benzoates.

5.07.3.4 Ru-Catalyzed Intramolecular [2 + 2] Cycloaddition

In 2007, Fürstner's group reported that enynes bearing an iodide at their alkyne terminus reacted in the presence of catalytic amounts of $[Cp^*Ru(MeCN)_3]PF_6$ in dimethylformamide (DMF) to give strained iodocyclobutene derivatives in good to excellent yields (Scheme 49). Various aromatic or aliphatic enynes incorporating ether or amido groups in the tether between the olefin and the iodoalkyne compounds were converted into the corresponding cyclobutenes. It is also important to mention that the substituent on the alkyne plays a major role in the cyclization process. Thus, alkynyl bromides were less reactive than the corresponding iodides and required a higher catalyst loading to reach full conversion. More notably, alkynyl chlorides, terminal and internal alkynes were totally inactive under the same reaction conditions. The authors believed that these reactions proceeded via the formation of a ruthenacyclopentene intermediate and subsequent reductive elimination.[48]

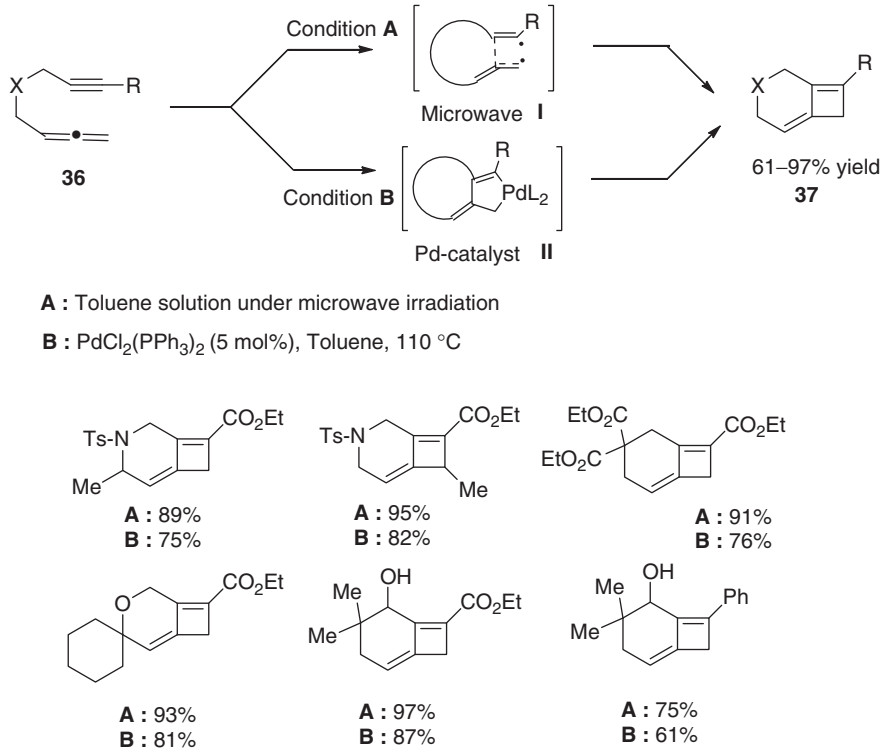


Scheme 49 Formation of iodocyclobutene derivatives and proposed reaction mechanism for this transformation.

5.07.4 Metal-Catalyzed [2 + 2] Cycloaddition of Alkynes and Allenes

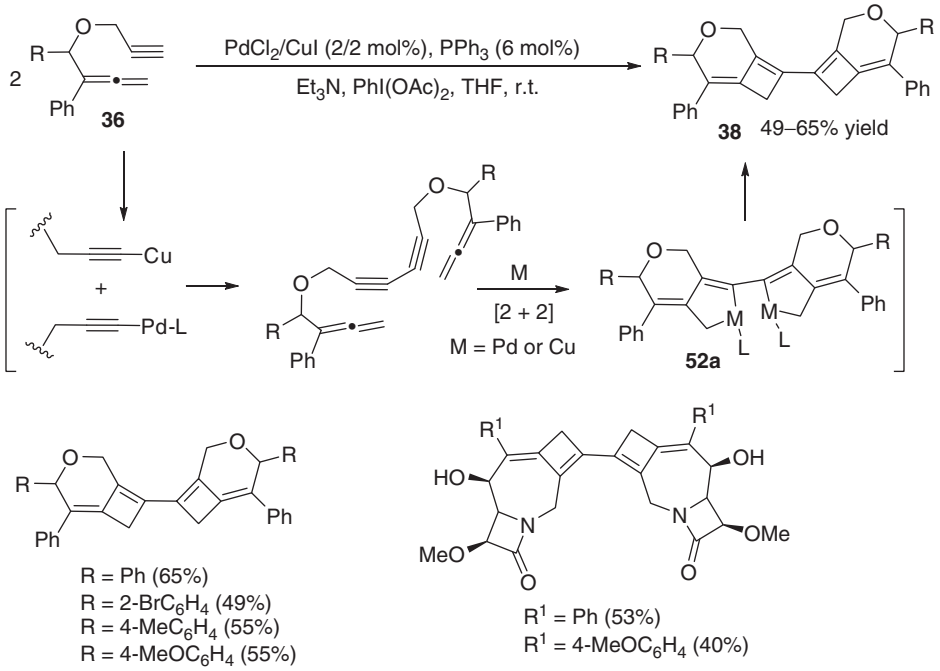
5.07.4.1 Molybdenum-Catalyzed Intramolecular *gem*-Difluoroallene-Alkyne [2 + 2]-Cycloaddition

The intramolecular [2 + 2] cycloaddition of an allene and alkyne group via a metallacyclopentene intermediate is also a powerful and promising methodology for the synthesis of cyclobutene products. Mo-, Pd-, and Ru-catalyzed cycloadditions of this type will be described here. Molybdenum is not a very common metal in [2 + 2] cycloadditions and so its applications are rather limited. However, Hammond and Shen reported an unexpected synthesis of bicyclo[4.2.0]octadienes by a novel molybdenum-catalyzed intramolecular *gem*-difluoroallene-alkyne [2 + 2]-cycloaddition (Scheme 50).[49] In all cases, CF_2-fused cyclobutenes were obtained in good to excellent yield. More notably, the intramolecular allene–alkyne cycloaddition showed that the rate of the reductive



Scheme 50 Molybdenum-catalyzed intramolecular [2 + 2]-cycloadditions of *gem*-difluoroallenes and alkynes.

elimination step was faster than carbonylation, since no Pauson–Khand product was detected even in the presence of 1.5 equivalents of $Mo(CO)_6$.



5.07.4.2 Palladium-Catalyzed Intramolecular [2 + 2] Cycloaddition of 1,6- and 1,7-Allenyne

In 2005, Oh et al. developed a palladium-catalyzed or MW-mediated [2 + 2] cycloaddition of 1,6- and 1,7-allenyne carboxylates which led to the formation of fused bicyclo[m,2,0]alkadienes in good yields.[50] Under these reaction conditions, various substituted allenynes were successfully employed to provide [2 + 2] cycloaddition products (Scheme 51). The authors proposed a mechanism involving a MW irradiation of the allenyne to give a biradical intermediate (**I**), which then undergoes rapid cyclization to afford the cyclobutene product. However, for the palladium-catalyzed [2 + 2] cycloaddition, the reaction proceeds likely via a metallacyclopentene (**II**), but the details are not yet known.

Scheme 51 Intramolecular [2 + 2]-cycloaddition of allenynes under conditions **A** and **B**.

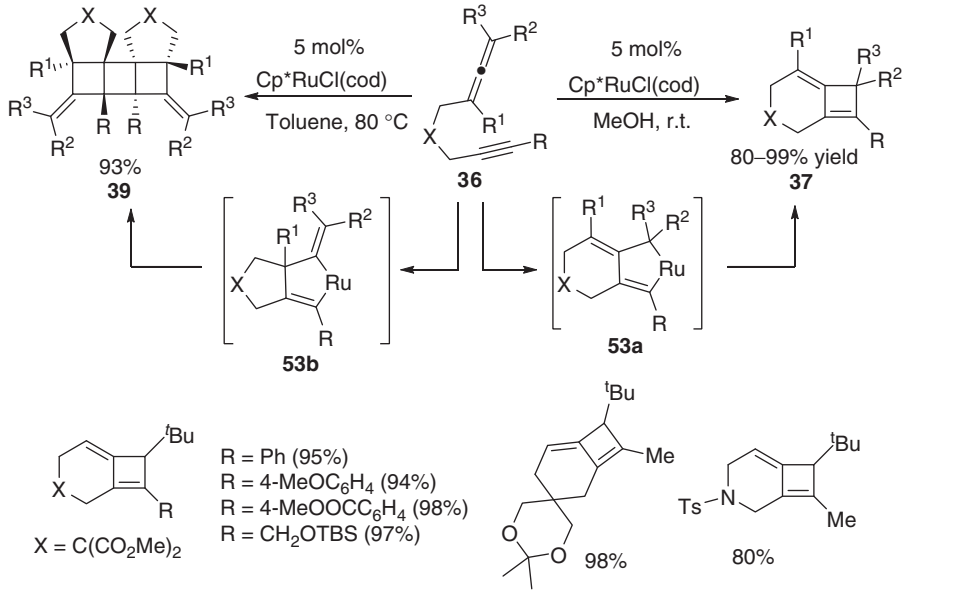
In 2009, Alcaide and Almendros reported a bimetallic Pd/Cu-catalyzed domino alkyne homocoupling/double [2 + 2] cycloaddition reaction of allenynes which delivers bis(heterocyclic)-fused cyclobutene rings (Scheme 52).[51] Under the reaction

Scheme 52 Pd-catalyzed or Cu-promoted double [2 + 2] cyclization of bis(allenynes).

conditions, enantiopure bis(tricyclic) *β*-lactams were conveniently prepared in good yields. For the double [2 + 2] allenyne cyclization, it is believed that the metal salt regioselectively forms a *π*-complex with both the triple bond and a double bond of substrates **36**. Such *π*-complexes may undergo migratory C–C coupling to give pallada- or cupra-cycles **52a**. The observed regioselectivity of the reaction could be explained in terms of the regioselective formation of metallacycles **52a**, which are controlled by the stereoelectronic effects of the aryl substituent in the allenynes. Cyclization toward the internal allenic double bonds is probably restricted by the ligands on the metal and the aryl substituent at the putative quaternary stereocenter.

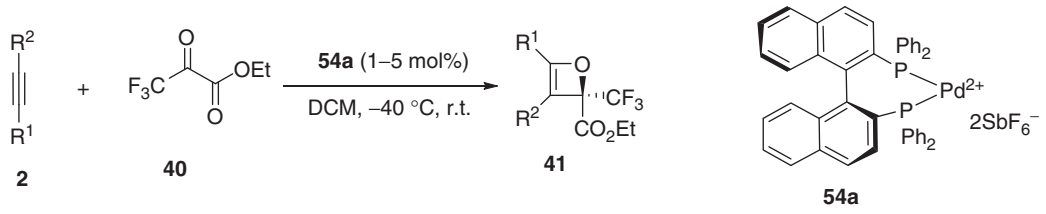
5.07.4.3 Ruthenium-Catalyzed Intramolecular [2 + 2] Cycloaddition of α,ω-Allenynes

Saito et al. disclosed the synthesis of two quite different types of products **37** and **39** from *α,ω*-allenynes in the presence of Cp*RuCl(cod) as the catalyst (Scheme 53).[52] The formation of these two different products greatly depends on the chosen solvent. Treatment of allenyne **36** with Cp*RuCl(cod) as catalyst in the presence of methanol produced only the [2 + 2] cycloaddition product **37** in quantitative yield, whereas the use of toluene as the solvent led to the exclusive formation of the cyclodimerization product **39** in excellent yield. Two types of ruthenacycles (**53a** and **53b**) could be formed from an allenyne and the ruthenium complex as shown in Scheme 53 to account for these outcomes. The authors believed that the [2 + 2] cycloaddition was initiated by a cationic ruthenium complex generated *in situ* from Cp*RuCl(cod) and methanol.

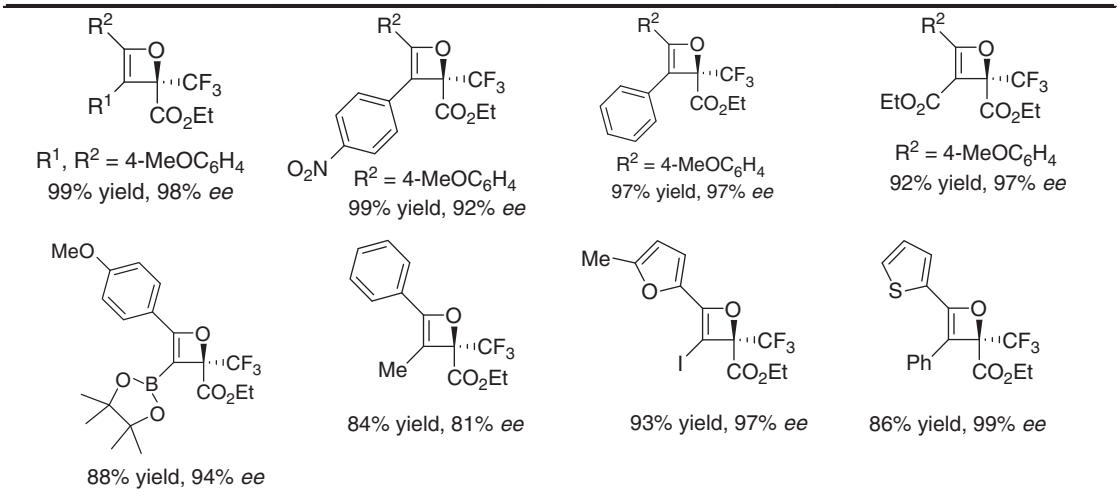


5.07.5 Palladium-Catalyzed [2 + 2] Cycloaddition of Alkynes and Ketones

Very recently, Mikami and coworkers reported an enantioselective synthesis of stable oxetenes via [2 + 2] cycloaddition of alkynes **2** with trifluoropyruvate **40** by using the dicationic (*S*)-BINAP–Pd complex **54a** as the catalyst (Scheme 54).[53] The cycloaddition occurred at low temperature (− 40 °C) with excellent enantioselectivity of up to 99%. Alkynes bearing both electron-donating and -withdrawing substituents on the aromatic ring worked well to give the desired oxetenes in good yields with excellent asymmetric inductions. Notably, the [2 + 2] cycloaddition of alkynes bearing very reactive iodide and pinacolborane groups also proceeded smoothly at − 20 °C to give highly enantioenriched oxetenes.

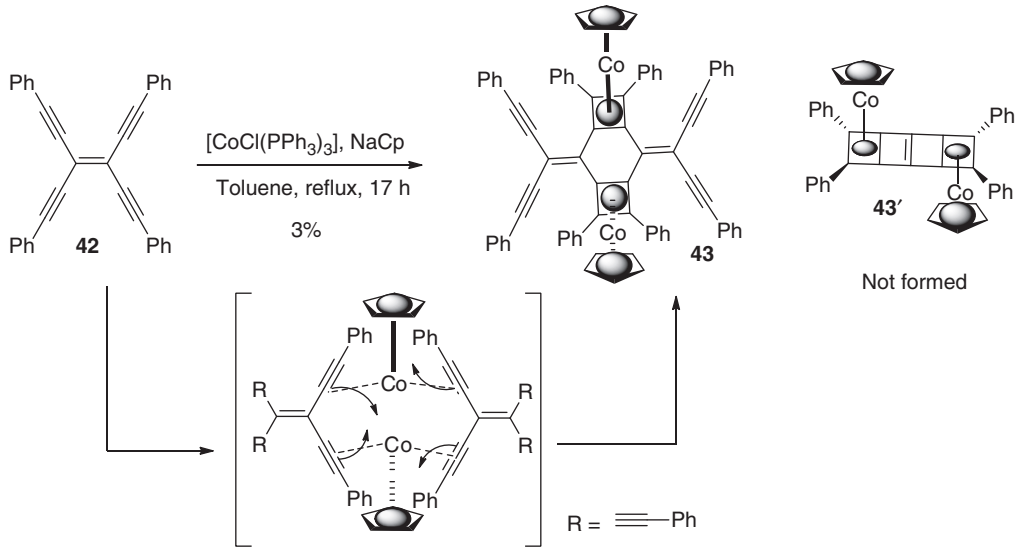


5.07.6 Metal-Catalyzed [2 + 2] Cycloaddition of Alkynes



5.07.6.1 Cobalt-Mediated Intramolecular [2 + 2] Cycloaddition of a Vinyl Tetraalkyne

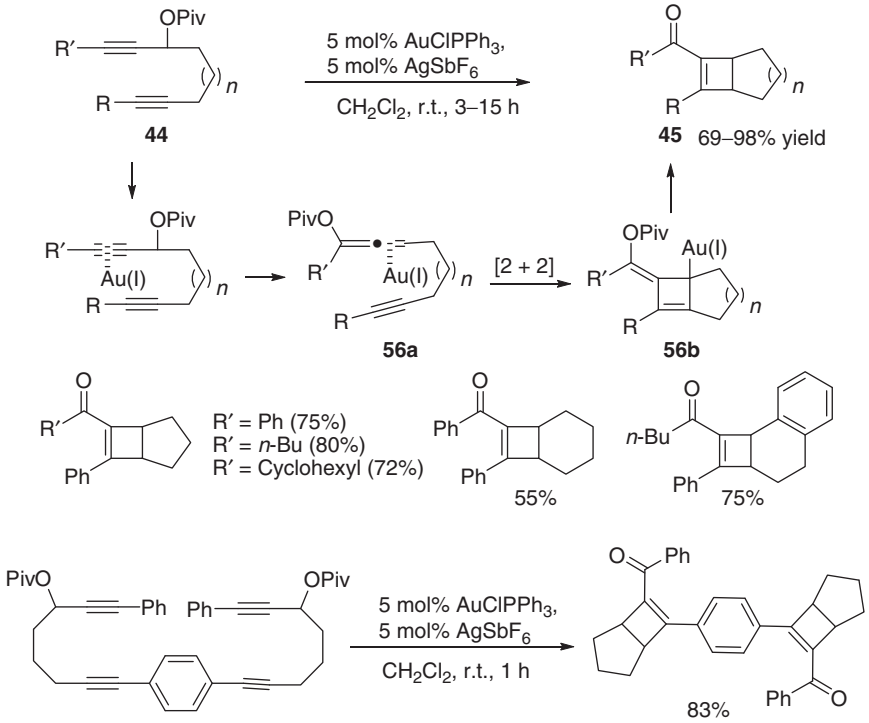
Fossey et al. observed an interesting Co(I)-mediated double [2 + 2] cyclodimerization of the tetraalkyne derivative **42** to afford the stable binuclear cobalt complex **43** in good yield (Scheme 55).[54] Unfortunately, the highly strained fused tetracyclic complex **43′**



Scheme 53 Ruthenium-catalyzed [2 + 2] cycloadditions and cyclodimerizations of allenynes.

Scheme 54 Catalytic asymmetric [2 + 2] cycloadditions of alkynes with trifluoropyruvate.

did not form. The authors emphasized that the double cycloaddition reaction was carried out under a dry nitrogen atmosphere, but no precautions were taken to protect the crude reaction products from external moisture or oxygen. The double [2 + 2] cyclodimerization product was confirmed using single crystal X-ray analysis. The crystal structure shows that two newly formed cyclobutadiene rings are separated by only 2.378 Å forcing the cobalt η^5-cyclopentadienyl (Cp) units to sit on opposite faces of the planes of the newly formed cyclobutadiene rings.

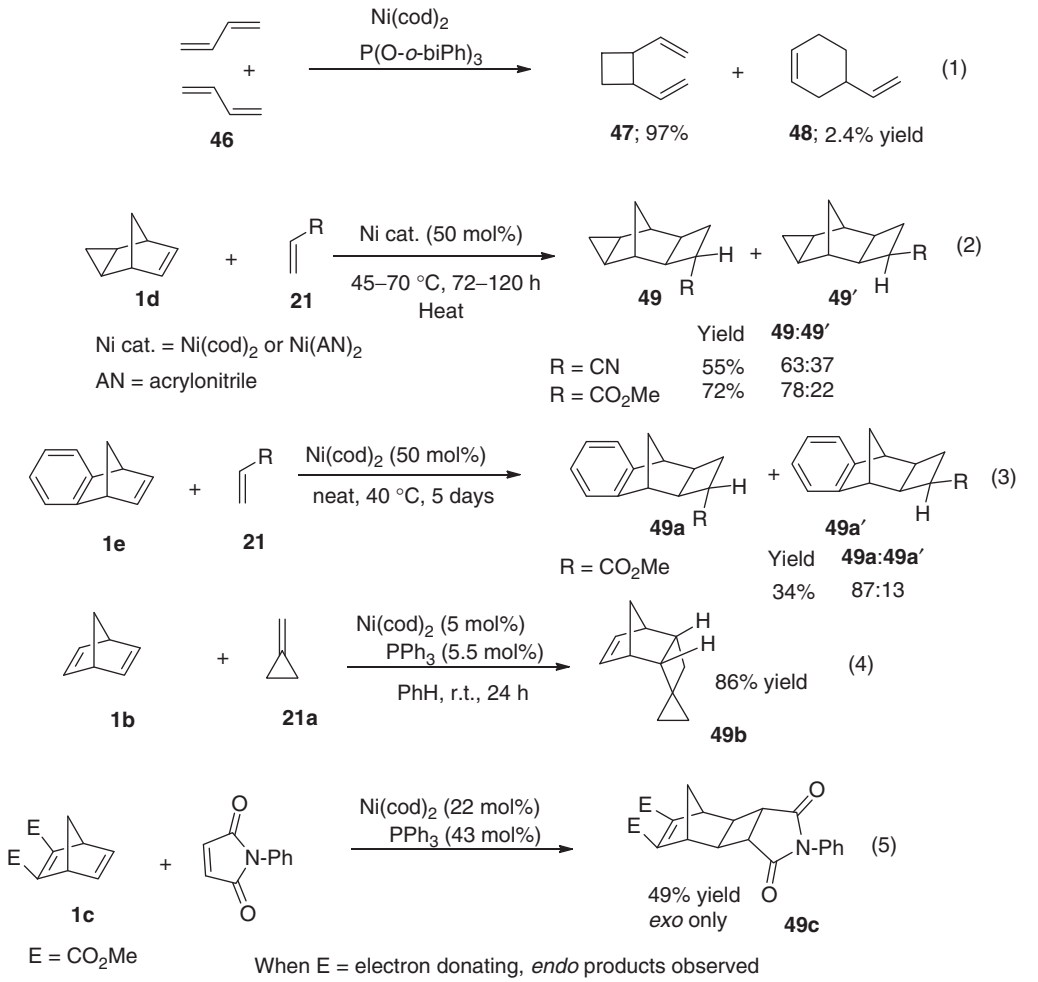


Scheme 55 Synthesis of a binuclear cobalt(I) complex.

5.07.6.2 Au-Catalyzed Intramolecular [2 + 2] Cycloaddition of 1,8-Alkadiynylic Pivaloates

In 2008, Oh and Kim reported the synthesis of fused cyclobutenes **45** via a gold-catalyzed [2 + 2] cycloaddition of 1,8-alkadiynylic pivaloates **44** (Scheme 56).[55] The corresponding cycloadducts were obtained in good yields in all cases. Interestingly, two alkyne-pivaloate molecules linked by a phenyl (Ph) group underwent the [2 + 2] cycloaddition to give the corresponding dimeric bicycles, which are useful building blocks.

A plausible mechanism for the gold-catalyzed cyclization of substrates **44** is shown in Scheme 56. Initial coordination of gold(I) to the propargylic ester induces migration of the pivaloate to give the allene intermediate **56A**, which then undergoes [2 + 2] cycloaddition to give intermediate **56B**, from which the final product **45** is released on protonolysis.

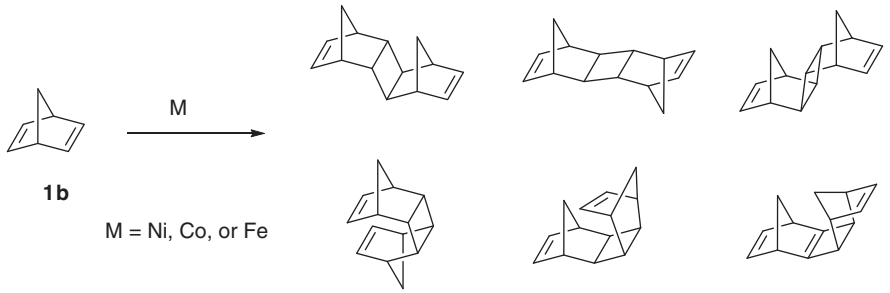


Scheme 56 Gold(I)-catalyzed [2 + 2] cycloaddition of 1,8-alkadiynylic pivaloates.

5.07.7 Metal-Catalyzed [2 + 2] Cycloaddition Between Two Alkenes

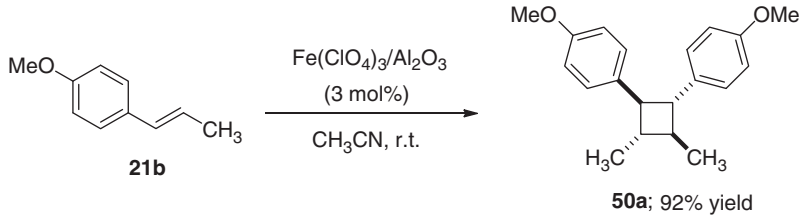
5.07.7.1 Nickel-Catalyzed Intermolecular [2 + 2] Cycloaddition of Alkenes

The [2 + 2] cycloaddition between two alkenes is an attractive transformation for the direct construction of strained cyclobutanes. Early examples include Ni(0)-catalyzed [2 + 2] cycloadditions of 1,3-butadiene, or of strained alkenes (cyclopropanated norbornene, benzonorbornadiene, and NBD) with alkenes to give the corresponding cycloadducts in good yields (Scheme 57; equations 1–5).[56]



Scheme 57 Early examples of Ni(0)-catalyzed [2 + 2] cycloaddition reactions of alkenes.

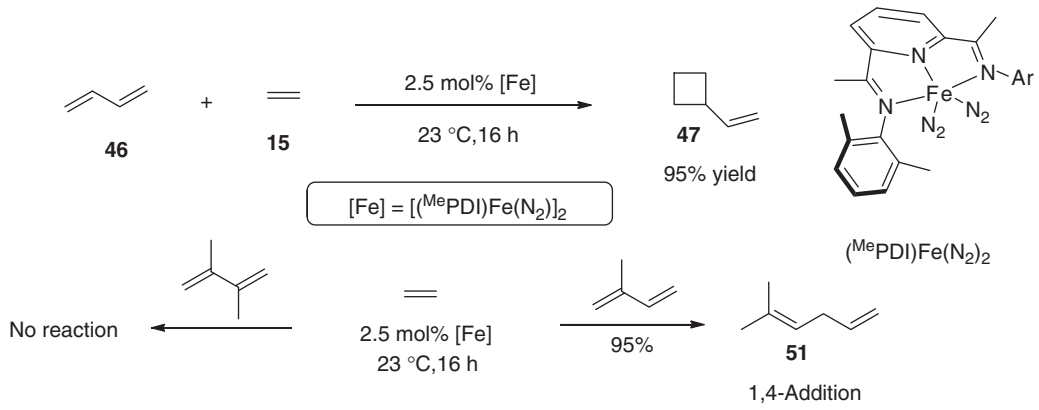
The transition metal-catalyzed dimerization of NBD **1b** was reported in 1957.[57] Since then, various dimerization reactions of NBD have been observed with Ni, Co, and Fe complexes as the catalysts, providing a range of dimerization products (Scheme 58).



5.07.7.2 Iron-Catalyzed Intermolecular [2 + 2] Cycloaddition

A Fe(III)-catalyzed [2 + 2] cyclodimerization of *trans*-olefin **21b** was described by Nakamura in 2001.[58] Excellent results were obtained with a catalyst supported on aluminum oxide (3 mol%), which afforded exclusively the C_2-symmetric cyclobutane **50a** in 92% yield (Scheme 59). It should be noted that the reaction with chiral catalysts bearing bisoxazoline (BOX) ligands remained unsuccessful ($ee \leq 7\%$).

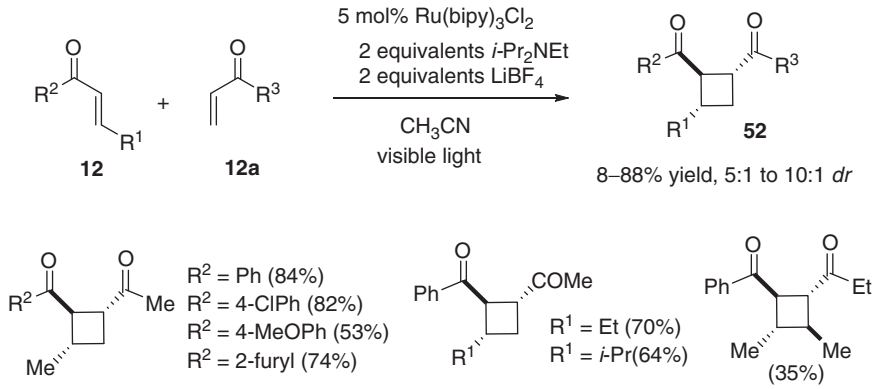
Chirik's group developed an intermolecular [2 + 2] cycloaddition between butadiene and ethylene to form vinylcyclobutane by using a bis(imino)pyridine iron dinitrogen complex as the catalyst. The reaction of an equimolar mixture of ethylene and butadiene in the presence of 5 mol% of the iron catalyst in benzene-d_6 at 23 °C provided the [2 + 2] cycloaddition product **47** in



Scheme 58 Overview of Ni, Co, and Fe-catalyzed dimerizations of NBD.

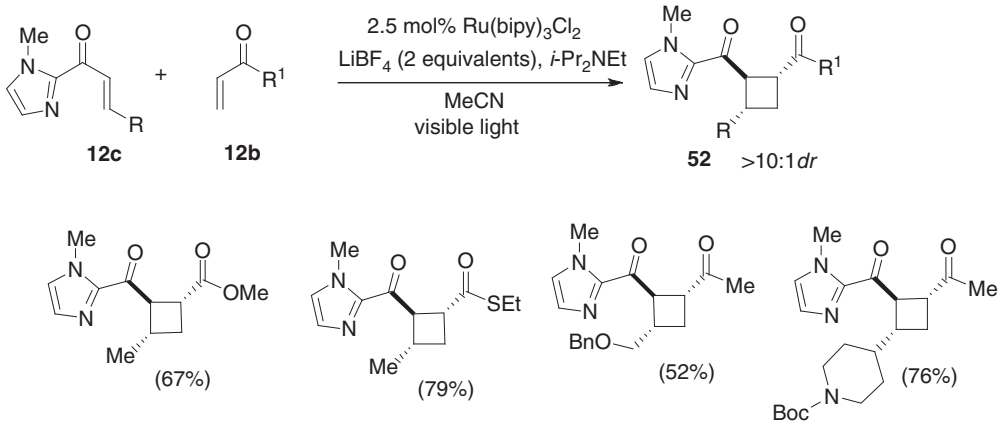
Scheme 59 Fe(III)-catalyzed [2 + 2] cyclodimerization of a *trans*-olefin.

95% yield. Under similar reaction conditions, isoprene reacted with ethylene to give an unexpected 1,4-addition product in high yield rather than the [2 + 2] cycloadduct. It is important to mention that more highly substituted dienes did not react with ethylene under these reaction conditions (Scheme 60).[59]



Scheme 60 Iron-catalyzed intermolecular [2 + 2] cycloaddition of ethylene and butadiene.

5.07.7.3 Ruthenium-Catalyzed Intermolecular [2 + 2] Cycloaddition

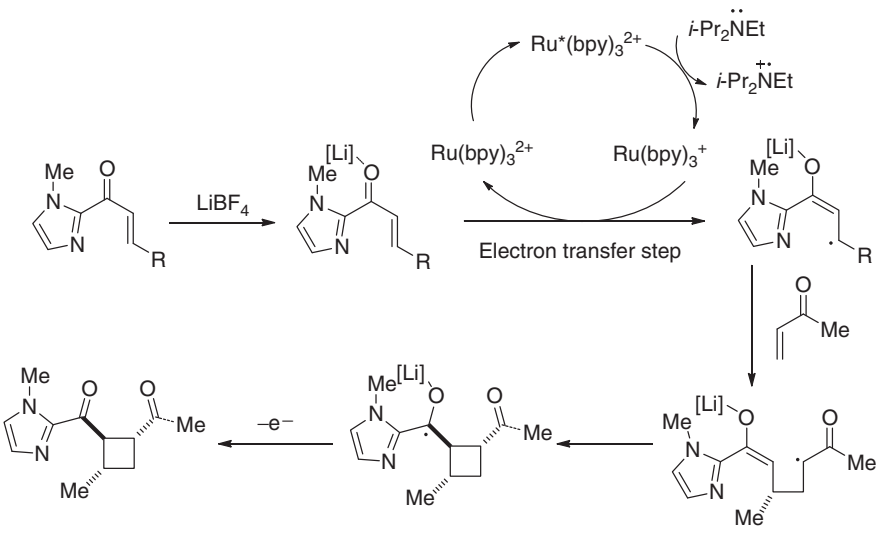


Yoon and coworkers developed an efficient method for the Ru-catalyzed crossed [2 + 2] cycloaddition of acyclic enones promoted by visible light (Scheme 61).[60] The excellent chemo- and stereoselectivity observed in this reaction represents a considerable advance in the construction of strained four-membered rings. Acyclic enones having α- and β-substitutions participate in this highly stereoselective cycloaddition reaction. However, β-substituted enones gave lower yields. The authors speculated that β-substituents sterically reduce the Michael acceptor ability of the enone, causing homodimerization of **12** to be the predominant pathway.

In a similar fashion, Yoon and coworkers have revealed an inter- and intramolecular [2 + 2] cycloaddition of α,β-unsaturated 2-imidazolyl ketones with a variety of Michael acceptors on irradiation with visible light in the presence of Ru(2,2′-bipyridyl(bipy))$_3^{2+}$.[61] In most of the intermolecular reactions, the best yield and highest *dr* were obtained when the aryl enone was added slowly via a syringe pump to the reaction mixture, presumably to minimize the homodimerization. Under these conditions, the concentration of aryl enone is minimized with respect to methyl acrylate, although keeping the ratio of Lewis acid

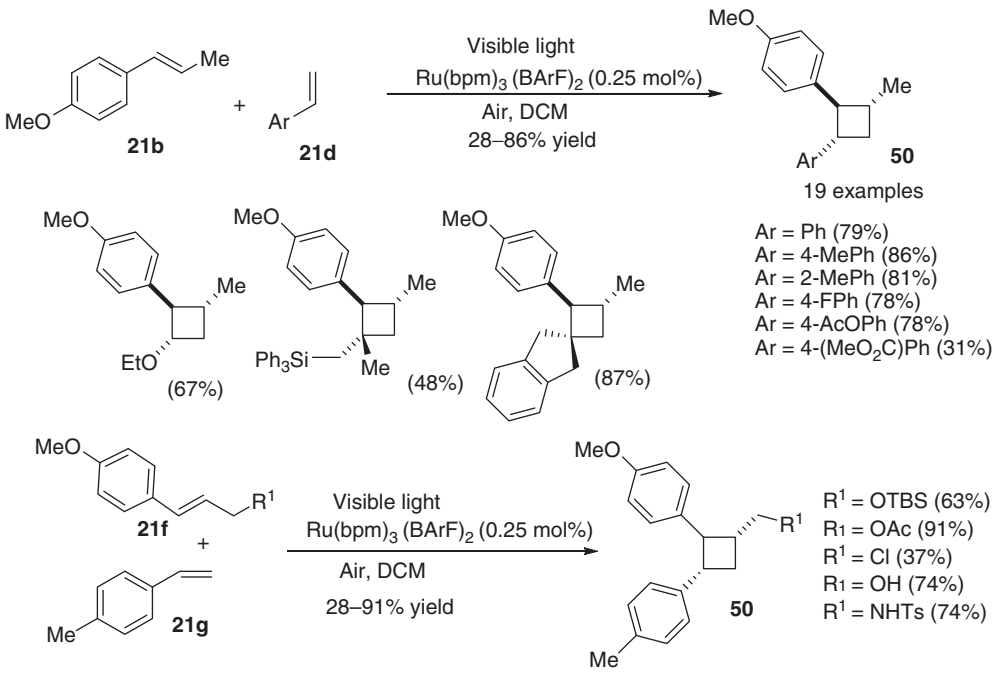
Scheme 61 Ru-catalyzed crossed [2 + 2] cycloadditions of acyclic enones promoted by visible light.

to substrate high. By using this slow addition protocol, the desired cycloadduct could be isolated in good yield with excellent diastereoselectivity (Scheme 62).



Scheme 62 Crossed intermolecular [2 + 2] cycloadditions of α,β-unsaturated 2-imidazolyl ketones.

The proposed mechanism for these transformations involves photoexcitation of Ru(2,2′-bipyridyl(bpy))$_3^{2+}$ with visible light resulting in a photoexcited state (Ru(bpy)$_3^{2+}$) that can undergo reductive quenching by *i*-Pr$_2$NEt. The resulting Ru(bpy)$_3^{+}$ complex is a powerful reducing agent that can transfer an electron to the enone activated by coordination to a lithium cation, which triggers the [2 + 2] cycloaddition and regenerates the Ru^{2+} photocatalyst (Scheme 63).

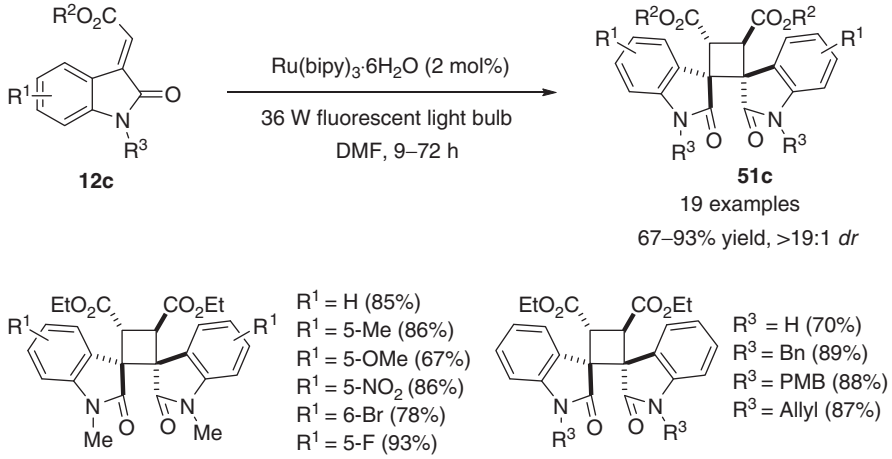


Very recently, the same authors developed a highly efficient method for the chemoselective radical cation-mediated crossed [2 + 2] cycloaddition of styrenes under photocatalytic conditions. Thus, irradiation of a mixture of 1,2-disubstituted alkenes and monosubstituted alkenes in the presence of 0.25 mol% Ru(bpm)$_3^{2+}$ (bpm = 2,2′-bipyrimidine) in DCM at −15 °C gave cross-cycloaddition products **50** in excellent yield (Scheme 64).[62] Control studies confirmed that no reaction occurred in the absence of light or the photocatalyst. Under similar conditions, a wide variety of styrene derivatives were suitable coupling partners in this reaction. Interestingly, α-substituted styrenes reacted in a highly diastereoselective manner, whereas β-substituted styrenes gave homodimerization. The extension of the photocatalytic [2 + 2] cycloaddition reactions to substituted allylic benzene derivatives was also successful, giving the corresponding cyclobutanes in good yields.

Later, Xiao and coworkers have explored the intermolecular [2 + 2] cycloaddition reaction of 3-ylideneoxindoles by visible-light photocatalysis. The irradiation of a DMF solution of a 3-ylideneoxindole in the presence of 2 mol% Ru(bipy)$_3$Cl$_2$.6H$_2$O with a 36 W fluorescent light bulb provided spirocyclobutane **51c** in 93% yield with a *dr* of > 19:1 (Scheme 65).[63] The photocatalysis reaction is highly diastereoselective and regioselective. Various 3-ylideneoxindoles with electron-donating and -withdrawing groups are compatible with the catalytic reaction.

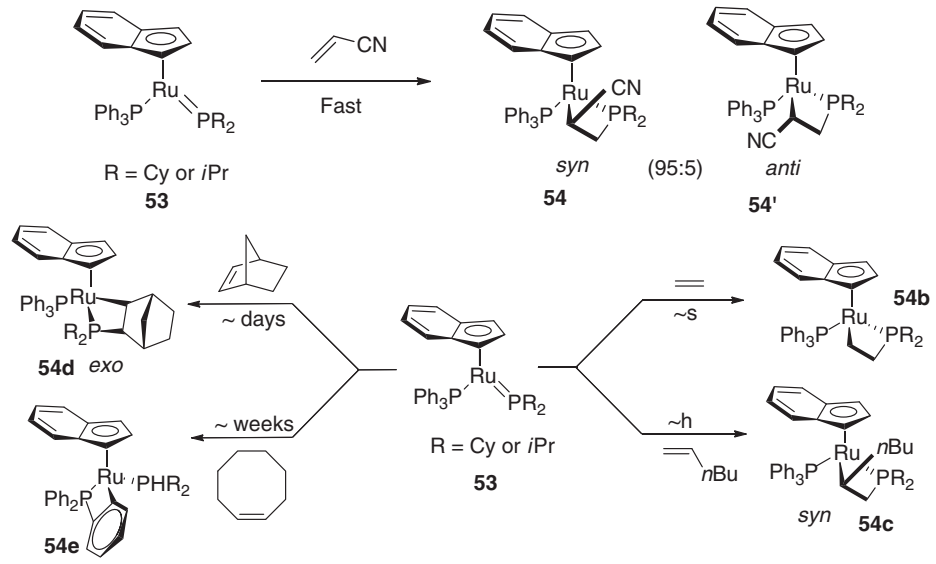
A terminal phosphido complex of ruthenium containing a Ru=PR$_2$ π bond showed high activity in 1,2-addition reactions of polar and nonpolar substrates.[64] In this context, Rosenberg et al. reported a [2 + 2] cycloaddition of a planar phosphido complex with both activated and simple alkenes to yield metallaphosphacyclobutanes.[65] The five-coordinate half-sandwich complex [Ru(η^5-indenyl)(PR$_2$)(PPh$_3$)] (**53**) reacts rapidly with acrylonitrile to give two isomers of the metallacyclic product, **54** and **54′**, in which the nitrile group on the ruthenium-bound α-carbon atom is oriented either *syn* or *anti* with respect to the Ru–indenyl bond (Scheme 66). X-ray crystallography confirmed that *syn* isomer is the major product in the solid state. In solution, these complexes

Scheme 63 Mechanism of the radical anion [2 + 2] cycloaddition.



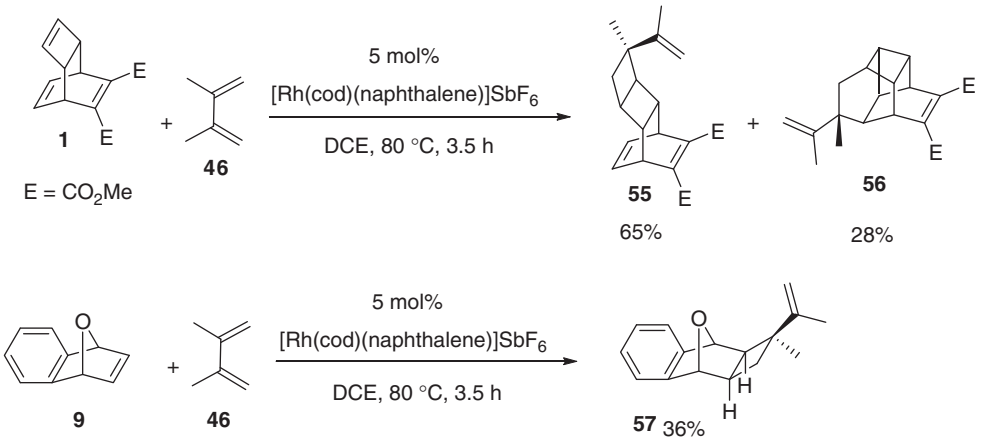
Scheme 64 Chemoselective crossed [2 + 2] cycloadditions of styrenes under photocatalytic conditions.

showed diagnostic upfield $^{31}P\{^{1}H\}$ NMR signals due to the phosphorus atom in the metallacycle (e.g., *syn*-**54**: $\delta = 13.3$ ppm), and upfield $^{13}C\{1H\}$ NMR signals for the α-carbon atom attached to Ru (e.g., *syn*-**54**: $\delta = 28.3$ ppm).



Simple alkenes also undergo [2 + 2] cycloaddition reactions with the Ru=PR_2 bond of **53** (Scheme 66). Solutions of **53** placed under 1 atm of ethylene rapidly and quantitatively transformed into [Ru(η^5-indenyl)(κ^2-$CH_2CH_2PR_2$)(PPh_3)] (**54**) at r.t., as determined by $^{31}P\{1H\}$ NMR analysis. Similar products were obtained from the addition of 1-hexene and the strained internal alkene norbornene; the latter gave exclusive addition to the *exo* face. However, for more sterically demanding substrates long reaction times were required, which resulted in competing decomposition to the orthometalated complex **54e**.

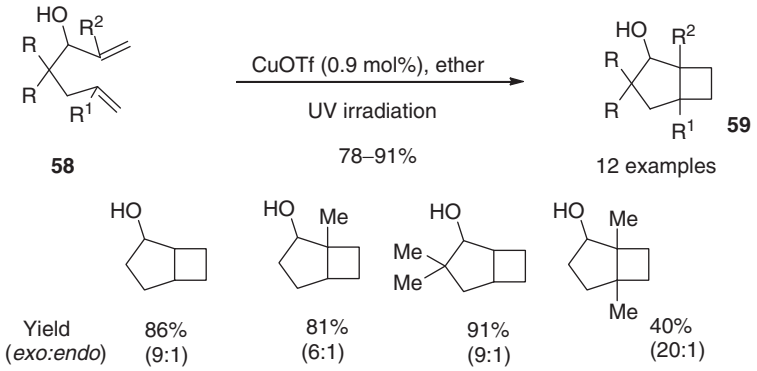
5.07.7.4 Rhodium-Catalyzed Intermolecular [2 + 2] Cycloaddition



In 2009, Wender et al. reported intermolecular [2 + 2] cycloaddition reactions of a tricyclic substrate with dienes catalyzed by cationic Rh(I)-complexes, which gave the corresponding cyclobutanes in 65% yield (Scheme 67).[66] In all cases, a minor amount

Scheme 65 Intermolecular [2 + 2]-cycloadditions of 3-ylideneoxindoles by visible light photocatalysis.

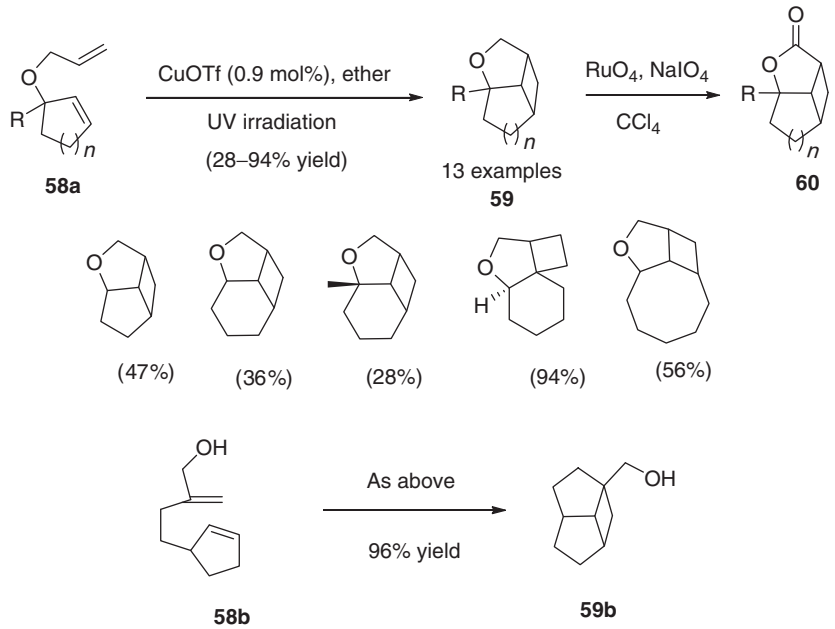
Scheme 66 [2 + 2] Cycloadditions of a planar phosphido complex with both activated and simple alkenes.



Scheme 67 Cationic Rh(I)-catalyzed intermolecular [2 + 2] cycloaddition reactions with dienes.

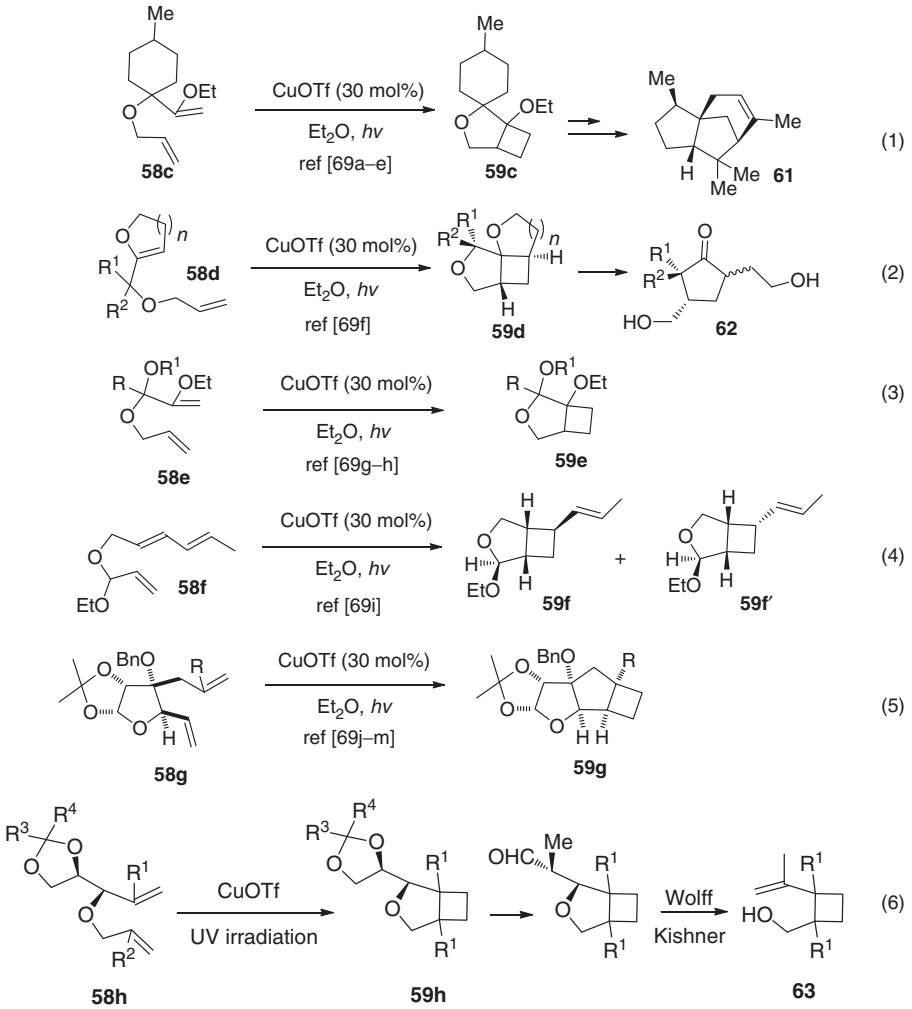
of [2 + 2 + 2] cycloaddition products were obtained. Under similar reaction conditions, 1,4-epoxy-1,4-dihydronaphthalene (**9**) reacted with 2,3-dimethyl-1,3-butadiene **46** to give only vinylcyclobutane **57** in 36% yield. The authors proposed a mechanism for the [2 + 2] reaction via rhodium coordination to the *exo* face of the cyclobutene carbon–carbon double bond, although the [2 + 2 + 2] reaction is derived from *endo* face coordination.

5.07.8 Intramolecular [2 + 2] Cycloaddition Between Two Alkene Groups



5.07.8.1 Copper-Catalyzed Intramolecular [2 + 2] Cycloaddition of Two Alkenyl Groups

The intramolecular [2 + 2] photocycloaddition of alkenes is an extremely useful synthetic tool for the preparation of strained cyclobutanes. An intramolecular Cu(I)-catalyzed photocycloaddition of functionalized alkenes was reported by Salomon et al.[67] Thus, UV irradiation of 1,6-heptadien-3-ol **58** in the presence of CuOTf in Et_2O cleanly afforded 3-hydroxybicyclo[3.2.0]heptanes **59** in good yields as *endo* and *exo* epimers (Scheme 68).[68a]



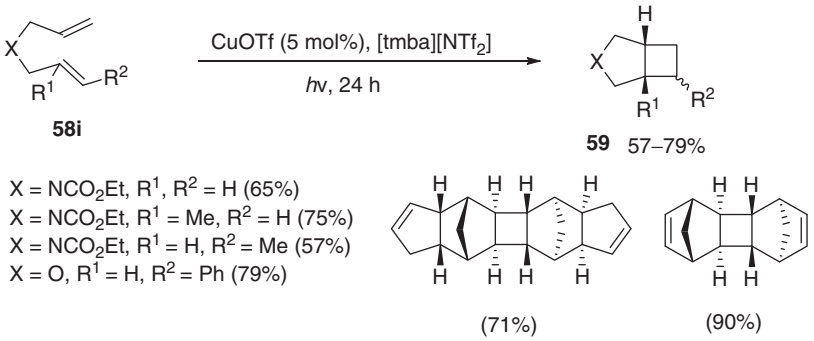
Scheme 68 CuOTf-catalyzed synthesis of 3-hydroxybicyclo[3.2.0]heptanes.

Under similar reaction conditions, various homoallylvinyl or diallyl ethers underwent photocycloaddition to give a variety of polycyclic THFs in reasonable yields. The utility of the reaction was further demonstrated by selective oxidation of the methylene group of the THF photoproducts **59** to butyrolactones (Scheme 69).[68b,c] These photoreactions tolerated hydroxyl, acetoxy, allyl, and vinyl substituents. Subsequently, similar protocols also applied to the formation of polycyclic cyclobutanes.[68d]

Scheme 69 CuOTf-catalyzed photocycloaddition of alkenes.

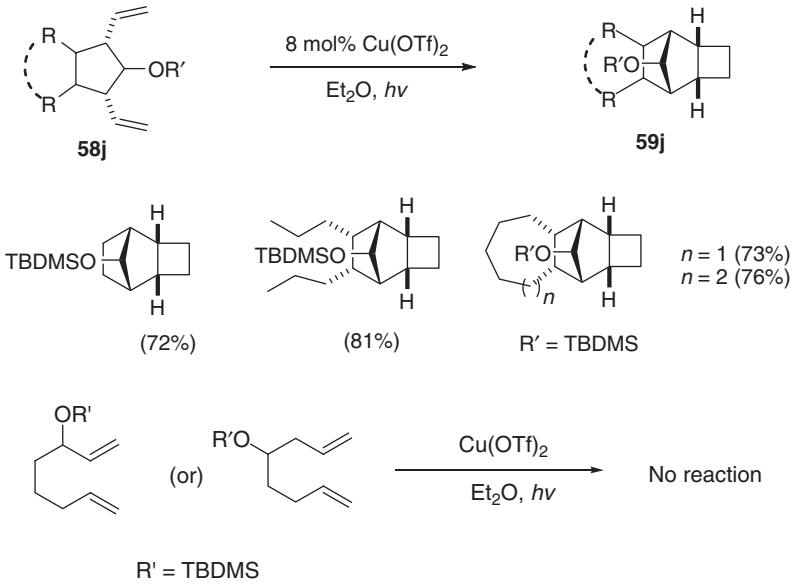
In addition to Salomon's work, Ghosh's group independently developed an intramolecular photocycloaddition of alkenes (Scheme 70). In 1993, the authors found that treatment of dienes with CuOTf in Et_2O provided a range of cyclobutane derivatives in good yields. The resulting cyclobutane derivatives are key compounds for the synthesis of (+)-α-cedrene and cyclopentanones (equations 1 and 2).[69a–e] The same methodology was successfully applied to the reductive coupling of internal alkynes with conjugated alkenes. Under similar reaction conditions, various functionalized dienes underwent intramolecular [2 + 2] cycloaddition to give fused cyclobutanes in good yield (Scheme 70; equations 3–6).[69f–m]

Scheme 70 CuOTf-catalyzed photocycloadditions of alkenes.



Asymmetric induction in intramolecular Cu(I)-catalyzed [2 + 2] photocycloadditions of alkenes has been investigated by Ghosh et al. in 2004. Their approach involved a cleavage of THF rings present in oxa-bicyclo[3.2.0]heptanes, which resulted in the formation of useful *cis*-1,2-disubstituted cyclobutanes in enantiomerically pure form.[69n]

In a similar manner, Ghosh et al. reported an intra- and intermolecular copper-catalyzed [2 + 2] photocycloaddition of alkenes **58i** in the presence of the ionic liquid [tmba][NTf_2] (tmba = *N*-trimethyl-*N*-butylammonium, NTf_2 = bis(trifluoromethylsulfonyl)-imide) at r.t. The process gave access to azabicyclo[3.2.0]heptanes and oxa-bicyclo[3.2.0] heptanes in good yields (Scheme 71). An intermolecular reaction of dicyclopentadiene and norbornene had also been realized to afford cyclobutene products in high yields.[69]

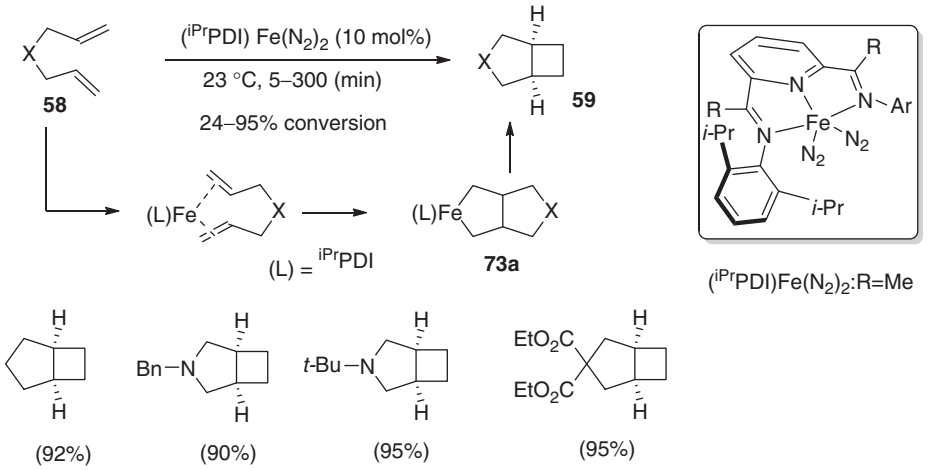


Bach's group developed a Cu-catalyzed photocycloaddition of 1,6-dienes of type **58j**, which gave to enantiomerically pure bicyclo[4.2.0]octanes. The *t*-butyldimethylsilyl (TBDMS)-protected cyclic 1,6-dienes **58j** turned out to be a key factor in the process as no reaction takes place with open-chain 1,7-dienes (Scheme 72).[70]

5.07.8.2 Iron-Catalyzed Intramolecular [2 + 2] Cycloaddition of α,ω-Dienes

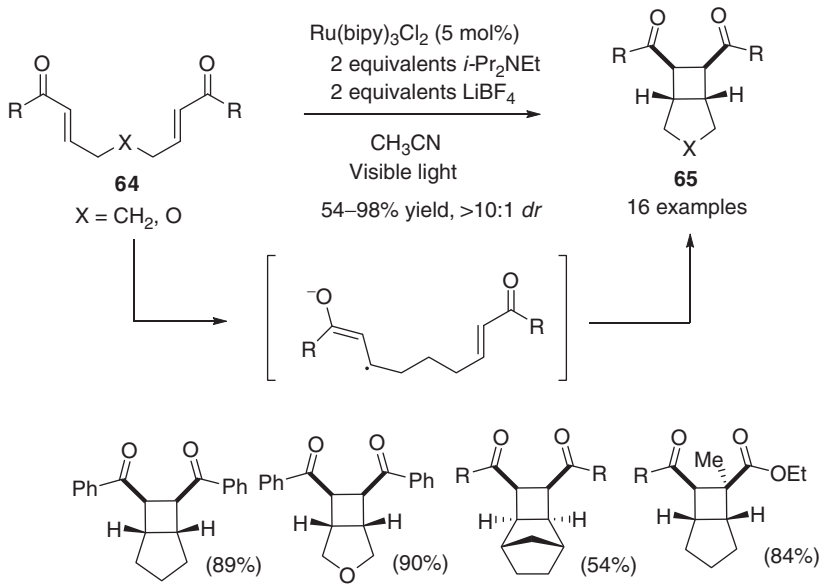
In 2006, Chirik and coworkers discovered an efficient method for the synthesis of cyclobutanes via iron-catalyzed intramolecular [2π + 2π] cycloaddition of the corresponding α,ω-dienes (Scheme 73).[71] The key feature of the catalytic cycle is the redox activity of

Scheme 71 Inter- and intramolecular copper-catalyzed [2 + 2] photocycloadditions of alkenes in an ionic liquid.



Scheme 72 Copper-catalyzed photocycloaddition of 1,6-dienes.

the supporting bis(imino)-pyridine ligand. The iron catalyst is tolerant of various functional groups and all of the cycloadditions gave *cis* products in good yields. However, some substrates such as **58** ($X=SiMe_2$) and those with internal olefins (allyl-*tert*-butylcrotylamine or *tert*-butyldicrotylamine) were not successfully cyclized even though the reaction is thermodynamically favorable. The authors proposed a mechanism for the formation of the bicyclic cyclobutane. The cycloaddition involves initial substitution of the N_2 ligands by the diene molecule, followed by C–C coupling to form the metallacycle intermediate **73a**. This intermediate undergoes formal reductive elimination to give cyclobutane **59** as the final product and regenerates the iron diene complex.



5.07.8.3 Ruthenium-Catalyzed Intramolecular [2 + 2] Cycloaddition of Enones

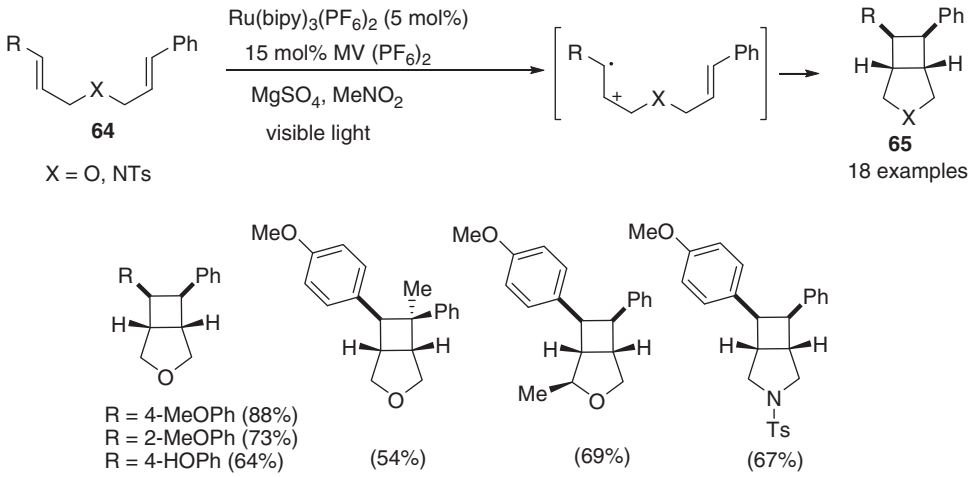
Yoon and coworkers found that bis(enone) **64** undergoes efficient [2 + 2] cycloaddition on visible light irradiation in the presence of 5 mol% of $Ru(bipy)_3Cl_2$ and $LiBF_4$ and *i*-Pr_2NEt as additives (Scheme 74).[72] The *meso* diastereomer of the cyclobutane-containing bicyclic dione **65** was produced with excellent selectivity. The use of $LiBF_4$ and *i*-Pr_2NEt was crucial for the success of the reaction; no [2 + 2] cycloaddition occurred without these additives. Various bis-enones underwent intramolecular [2 + 2] cycloaddition to give the corresponding cyclobutanes **65** in good yields with excellent diastereomeric selectivity. The authors speculated that a photoreductant generated by irradiation of $Ru(bipy)_3^{2+}$ served as an excellent photocatalyst for the intramolecular anion radical-mediated [2 + 2] enone cycloadditions.

Subsequently, Yoon et al. demonstrated that $Ru(bipy)_3^{2+}$ is a powerful photocatalyst for the [2 + 2] cycloaddition of both electron-rich and electron-deficient olefins, which furnish cyclobutanes in good yield and diastereoselectivity (Scheme 75).[73] The mechanism involves $Ru(bpy)_3^{3+}$ generated on visible light irradiation of $Ru(bpy)_3^{2+}$ in the presence of MV^{2+} (MV^{2+} = methyl viologen hexafluorophosphate ($MV(PF_6)_2$)) as the oxidant to oxidize electron-rich styrenes, affording a key radical cation

Scheme 73 Iron-catalyzed [2 + 2] cycloadditions of α,ω-dienes.

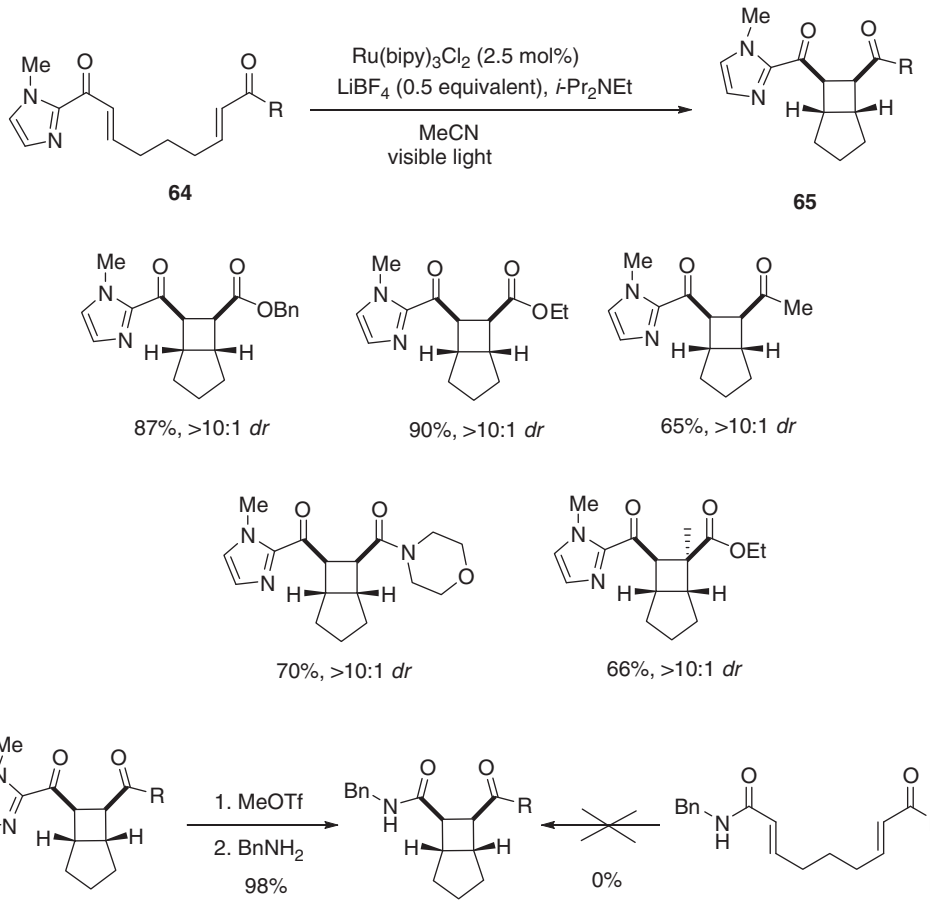
Scheme 74 [2 + 2] Cycloadditions of enones under visible light photocatalysis.

intermediate which then undergoes the [2 + 2] cycloaddition. Interestingly, the cycloaddition reaction could be conveniently carried out on a gram scale by using sunlight to give cyclobutane **65** in excellent yield.



The intramolecular photoreductive [2 + 2] cycloaddition always gives somewhat higher yields in the presence of 0.5 equivalent of $LiBF_4$. Under similar reaction conditions, intramolecular cycloadditions worked well with a variety of acceptor moieties including esters, ketones, and amides[61] (Scheme 76).

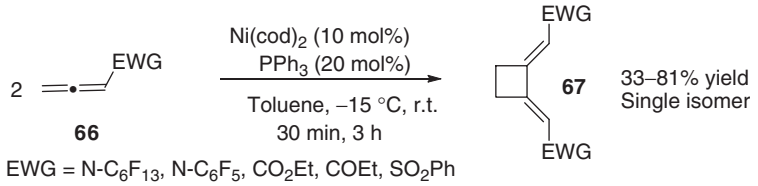
Cleavage of the imidazolyl auxiliary from the cycloadducts affords cyclobutane carboxamides, esters, thioesters, and acids in good yield. It is noteworthy that direct cycloaddition of the corresponding unsaturated acid derivatives does not proceed under similar reaction conditions.



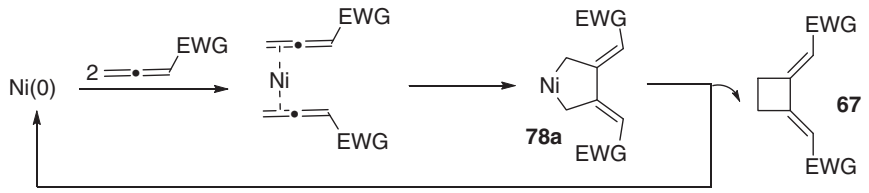
5.07.9 Metal-Catalyzed [2 + 2] Cycloaddition of Two Allenes

5.07.9.1 Nickel-Catalyzed Intermolecular [2 + 2] Cycloaddition of Allenes

Allenes are unique substrates with characteristic reactivity and steric properties, which originate from the cumulated propadienyl structures. Although allenes have gained much attention as synthetic intermediates, their applications in [2 + 2] cycloaddition are still relatively unexplored compared to those of alkenes and alkynes.



Scheme 75 Photo-oxidative [2 + 2] cycloadditions.



Scheme 76 Intramolecular photoreductive [2 + 2] cycloadditions and cleavage of the imidazolyl group.

In 2000, Saito and Yamamoto described a Ni(0)-catalyzed [2 + 2] annulation of electron-deficient allenes **66** to give bismethylenecyclobutane products under mild conditions.[74] The catalytic reaction is completely regioselective and only head-to-head cyclodimerization was observed. The corresponding cycloadducts **67** were isolated as single isomers in good to fair yields (Scheme 77). However, it is noteworthy that the presence of an electron-withdrawing group (EWG) is crucial for the [2 + 2] cycloaddition to proceed efficiently in a highly regioselective manner. Other allenes resulted in the formation of a complex mixture composed of oligomeric compounds.

Scheme 77 Ni(0)-catalyzed head-to-head cyclodimerization of electron-deficient allenes.

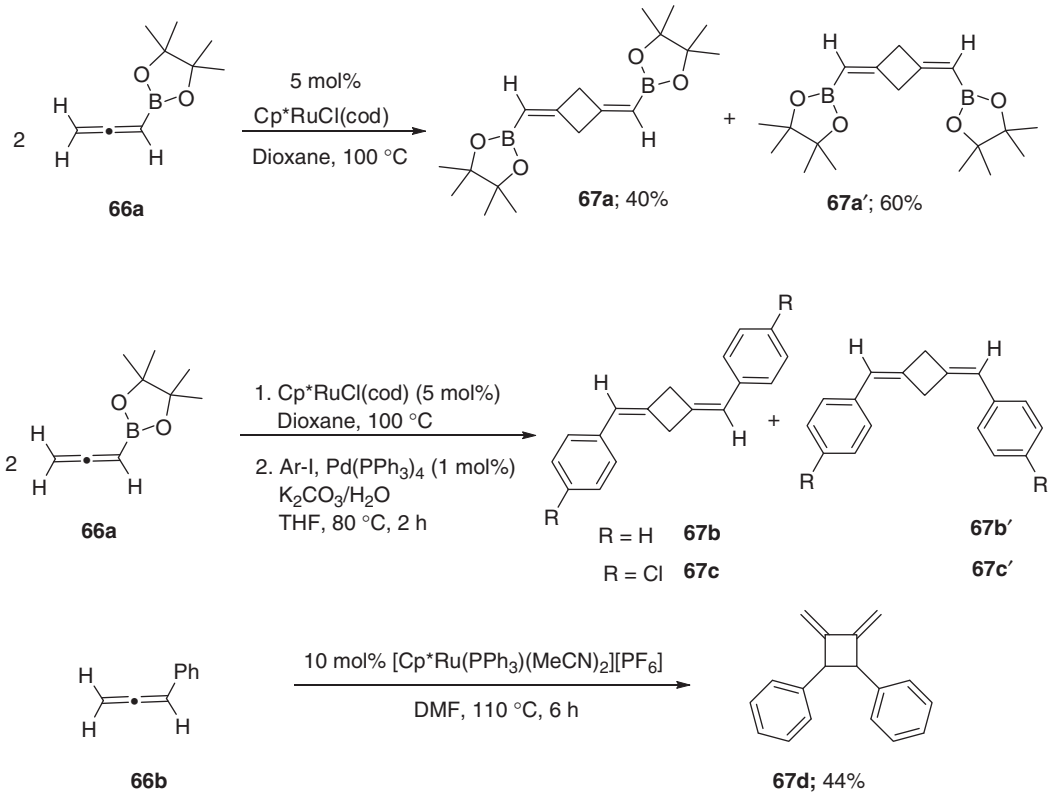
A possible catalytic reaction mechanism for the cyclodimerization of allenes is proposed in Scheme 78. Regioselective coordination of two molecules of the allenes to the Ni(0) center followed by oxidative coupling leads to a nickelacyclopentane intermediate **78a**. Reductive elimination of this intermediate gives the final product **67** and regenerates the Ni(0) species.

Scheme 78 Proposed mechanism for the cyclodimerization of electron-deficient allenes.

5.07.9.2 Ruthenium-Catalyzed Intermolecular [2 + 2] Cycloaddition of Allenes

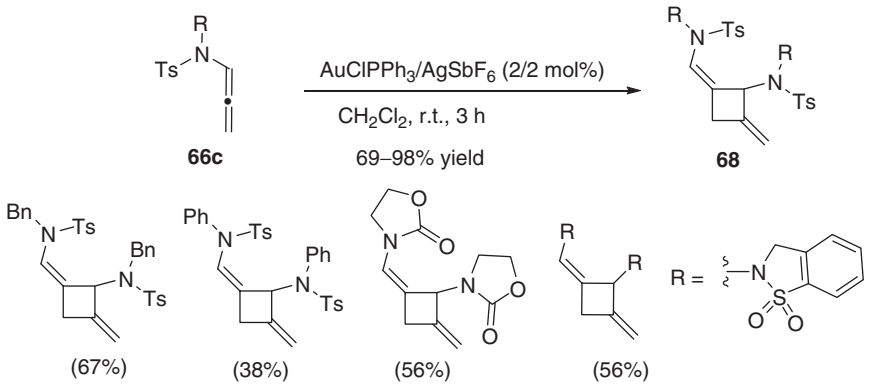
1,3-Dialkylidenecyclobutanes are key precursors for the formation of non-Kekule hydrocarbon diradicals with a triplet ground state: the 1,3-dialkylidenecyclobutane-2,4-diyls.[75] The previous method for the preparation of 1,3-dimethylenecyclobutanes involves a six-step synthesis from allene and acrylonitrile. Dixneuf and coworkers developed an interesting ruthenium-catalyzed synthesis of 1,3-dimethylenecyclobutanes via head-to-tail [2 + 2] cyclodimerization of allenyl-boronates to give the isomeric products **67a** + **67a′** in moderate yield with a 2:3 ratio (Scheme 79). Importantly, the decomposition of **67a** + **67a′** with concomitant release of pinacol was always observed, which hindered the separation of the two isomers.[76]

Furthermore, the authors found a sequential Ru-catalyzed [2 + 2] cyclodimerization of allenyl boronate **66a** and a palladium-catalyzed Suzuki coupling (Scheme 79). The reaction of allenyl boronate **66a** in the presence of 5 mol% of [Cp*RuCl(cod)] in refluxing dioxane at 100 °C was followed by the addition of an aryl iodide in the presence of a catalytic amount of $Pd(PPh_3)_4$ and base (K_2CO_3); under these conditions, the [2 + 2] cyclodimerization products **67b,c** were formed. Although a mixture of the two Ph-substituted isomers (*E*,*E*) and (*Z*,*Z*) was obtained, recrystallization allowed the major (*E*,*E*)-isomer to be isolated in moderate yields. Total regioselectivity has been achieved during the dimerization of phenylallene **66b** by using the sterically hindered ruthenium catalyst $[Cp^*Ru(PPh_3)(MeCN)_2][PF_6]$. Only the tail-to-tail coupling compound **67d** was isolated in 44% yield (Scheme 79).



5.07.9.3 Gold-Catalyzed [2 + 2] Cycloaddition of Allenes

Interestingly, a series of alleneamides underwent dimerization in the presence of $AuCl(PPh_3)/AgSbF_6$ in DCM at r.t. Under these reaction conditions, benzyl (Bn)-, Ph-, oxazolidinone, and 2,3-dihydrobenzo[*d*]isothiazole-substituted alleneamides underwent dimerization to give 1,3-dimethylenecyclobutanes in moderate to good yields (Scheme 80).[77]

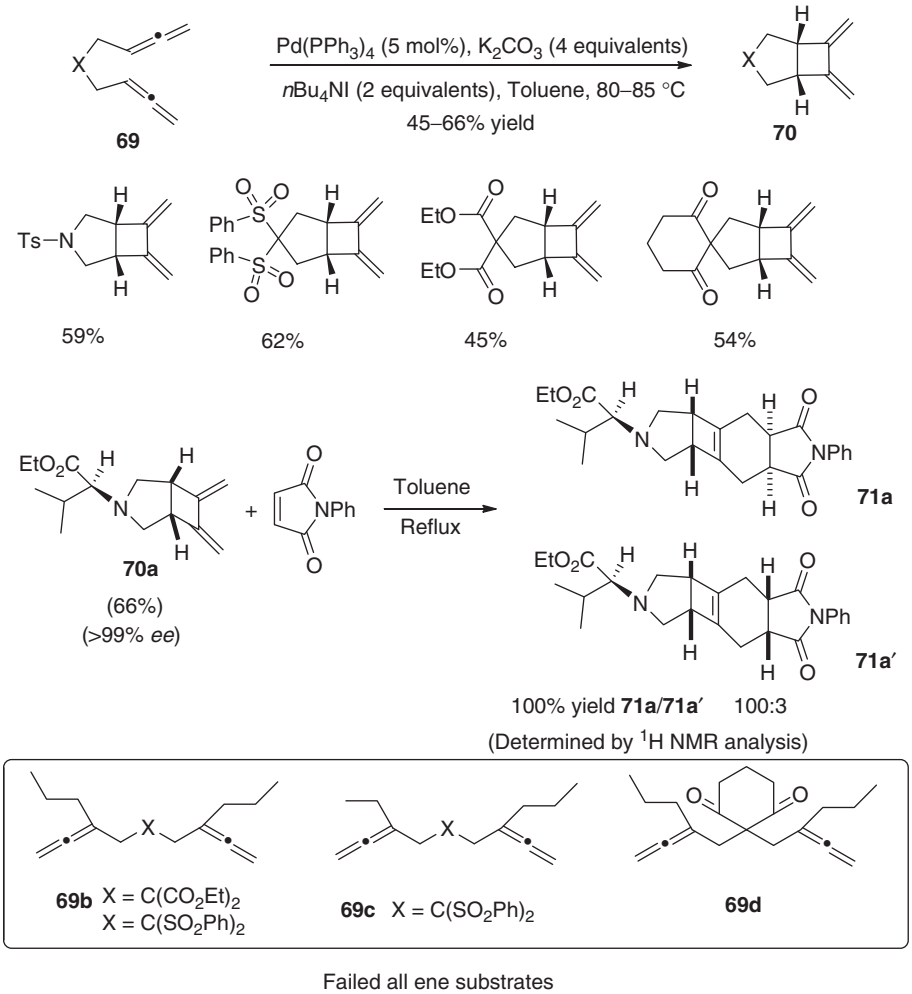


5.07.10 Intramolecular [2 + 2] Cycloaddition of Bisallenes

5.07.10.1 Palladium-Catalyzed Intramolecular [2 + 2] Cycloaddition of 1,5-Bisallenes

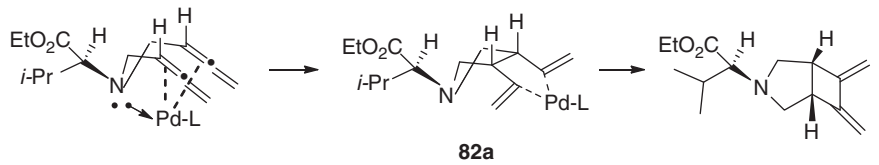
Ma's group observed a regiocontrolled synthesis of cyclobutenes via Pd(0)-catalyzed [2 + 2] cycloaddition of 1,5-bisallenes.[78] After several optimization studies, $[Pd(PPh_3)_4]$, K_2CO_3, and nBu_4NI was found to be most effective, furnishing bicyclo[3.2.0] derivatives **70** in moderate to good yields. The catalytic reaction did not proceed in the absence of K_2CO_3 and nBu_4NI. More notably, when X is the chiral L-valine ester, compound **70a** was formed in greater than 99% *ee* (Scheme 81), which indicates that the reaction proceeds without racemization of the α-amino acid ester. To demonstrate the utility of compound **70a** in organic synthesis, the authors carried out the [4 + 2] Diels–Alder cycloaddition of **70a** with *N*-phenyl maleimide to afford the 2-azabicyclo[2.2.2]octane (isoquinuclidine) derivative **71a** in 80% isolated yield (Scheme 81). The palladium system does not effectively catalyze cycloadditions of compounds **69b–d** having substituents on the proximal side, probably for steric reasons.

Scheme 79 Ru-catalyzed [2 + 2] cycloadditions of allenyl-boronates or phenylallene.



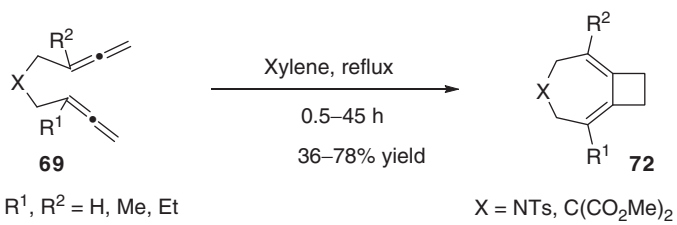
Scheme 80 $AuClPPh_3/AgSbF_6$-catalyzed dimerization of allenamides.

The proposed mechanism is shown in Scheme 82. The first step involves coordination of the 1,5-allene's internal C═C bond to the Pd-center assisted by the electron lone pair on the N atom, leading to the exclusive formation of intermediate **82a**. Subsequent reductive elimination affords the cycloaddition product. In the present catalytic reaction, the role of nBu$_4$NI is not entirely clear, which could act as a ligand facilitating the reductive elimination process.

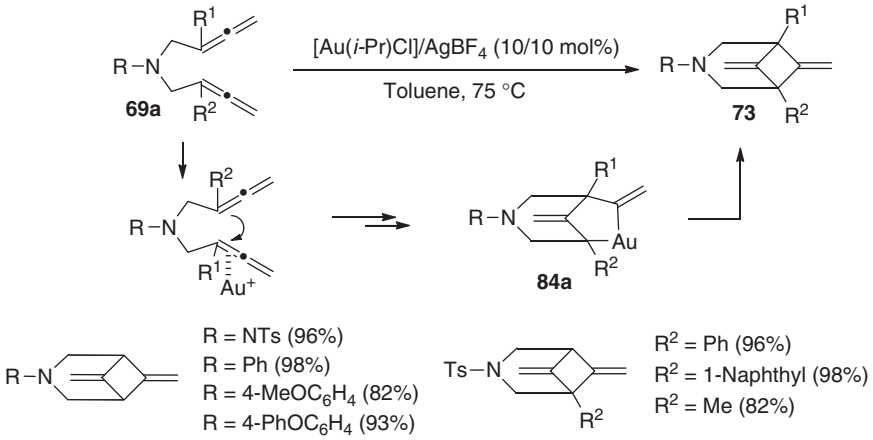


However, the thermal [2 + 2] cyclization of 1,5-bisallenes **69** in refluxing xylene afforded bicyclo[5.2.0] products of type **72** via tail-to-tail [2 + 2] cyclization. Thermal tail-to-tail [2 + 2] cycloadditions represent a facile and versatile access to cyclobutane derivatives in good yield (Scheme 83).[78]

5.07.10.2 Gold-Catalyzed Intramolecular [2 + 2] Cycloaddition of 1,5-Bisallenes



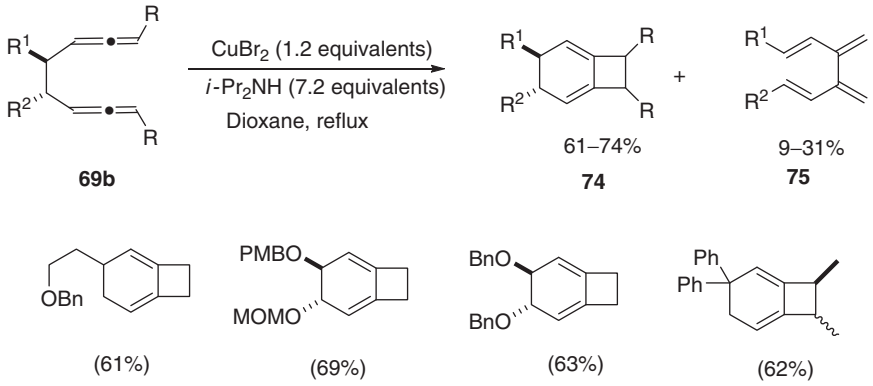
In 2009, Kang and Chung reported an efficient cationic N-heterocyclic carbene (NHC)-gold-catalyzed [2 + 2] cycloaddition of amino-tethered 1,5-bisallenes to produce 6,7-dimethyleneazabicyclo[3.1.1]heptanes (Scheme 84).[79] The formal head-to-head



Scheme 81 $Pd(PPh_3)_4$-catalyzed [2 + 2] cycloadditions of 1,5-bisallenes.

Scheme 82 Proposed mechanism for the palladium-catalyzed formation of cyclobutanes from bisallenes.

Scheme 83 Thermal [2 + 2] cycloadditions of bisallenes.

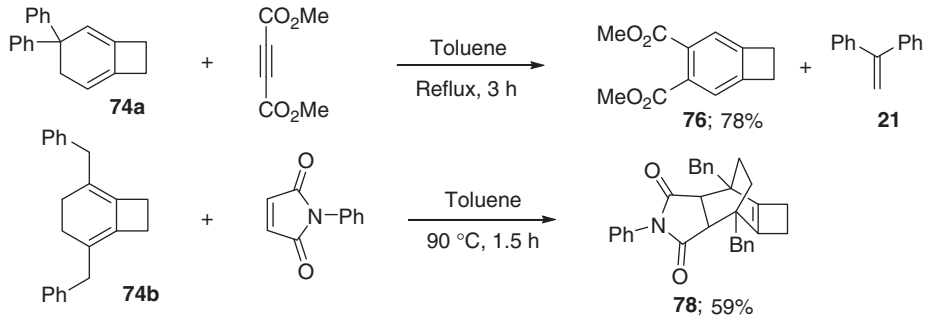


Scheme 84 Cationic NHC-gold catalyzed [2 + 2] cycloadditions of amino-tethered 1,5-bisallenes.

cycloaddition products are observed in good to excellent yields. One allene acts as a nucleophilic reagent attacking another Au^+-coordinated allene group in the 1,5-bisallene molecule to form a C–C single bond. The mechanism of this transformation was studied using DFT calculations. Among the several mechanistic scenarios, the authors envisioned that **84a** is the key intermediate, which forms the final product **73** via reductive elimination.

5.07.10.3 Copper-Mediated Intramolecular [2 + 2] Cycloaddition of 1,4-Bisallenes

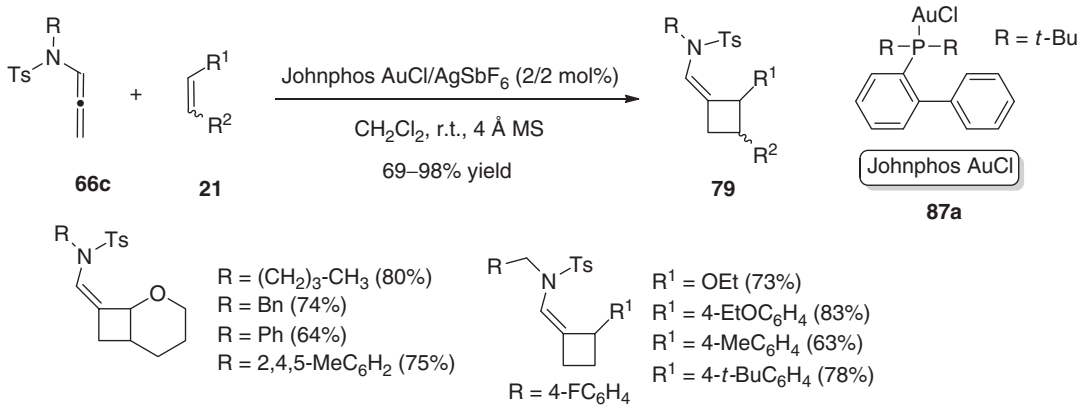
It is well known that 1,4-bisallenes easily undergo formal [3,3]-sigmatropic rearrangement to produce tetraenes on heating.[80] Interestingly, in the presence of $CuBr_2$/*i*-Pr_2NH, the 1,4-bisallenes undergo a [2 + 2] cycloaddition to afford highly selective bicyclo[4.2.0]octadienes in good yields (Scheme 85).[81] In this reaction, more than 1 equivalent of the Cu salt is needed to suppress the [3,3]-sigmatropic rearrangement or other side reactions. *i*-Pr_2NH probably plays three roles in the reaction. First, it likely reduces Cu(II) to Cu(I) and assists the coordination of the 1,4-bisallenes to the Cu(I) center. Second, it dissociates the polymeric precatalyst and also stabilizes the active species. Third, it likely makes the oxidative addition more facile.



Scheme 85 $CuBr_2$-mediated [2 + 2] cycloadditions of 1,4-bisallenes.

Furthermore, the cycloadduct **74a** undergoes [4 + 2] cycloaddition with DMAD followed by a retro-Diels–Alder reaction of the resulting product to produce benzocyclobutene **76** in 78% yield (Scheme 86). However, **74b** readily reacted with *N*-phenylmaleimide to produce the bridged polycyclic compound **78**.

5.07.11 Metal-Catalyzed [2 + 2] Cycloaddition of Allenes and Alkenes



5.07.11.1 Gold-Catalyzed Intermolecular [2 + 2] Cycloaddition of Allenes and Alkenes

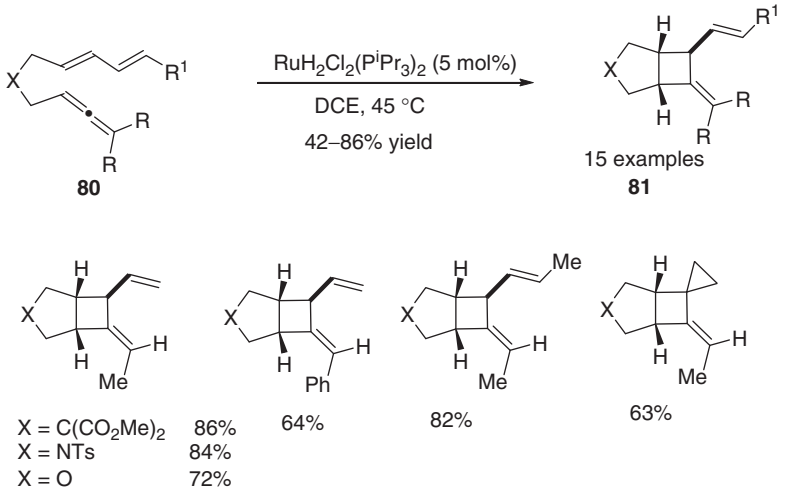
An efficient method for the construction of highly functionalized cyclobutane adducts via (Johnphos)AuCl-catalyzed formal intermolecular cycloaddition of alleneamides with electron-rich alkenes has been developed by Chen et al.[77] The reaction provides a practical entry to cyclobutane derivatives **79**, which were obtained in good yields with excellent selectivities

Scheme 86 [4 + 2] Cycloadditions of cyclobutanes **74** with DMAD.

(Scheme 87). The scope of the reaction is broad with respect to both alleneamides and alkenes (vinyl ethers, amides, and electron-rich styrenes).

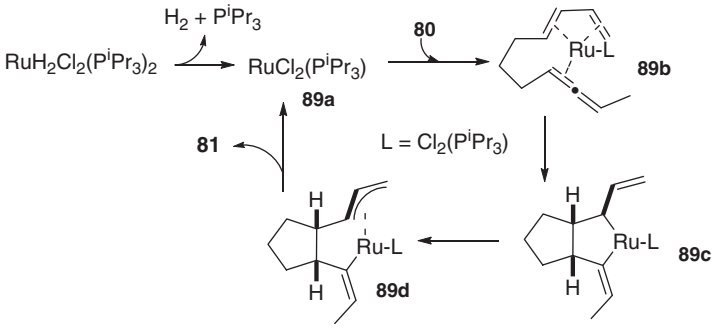
Scheme 87 Gold-catalyzed formal intermolecular cycloadditions of allenamides with electron-rich alkenes.

5.07.11.2 Ruthenium-Catalyzed Intramolecular [2 + 2] Cycloaddition of Allenes and Alkenes



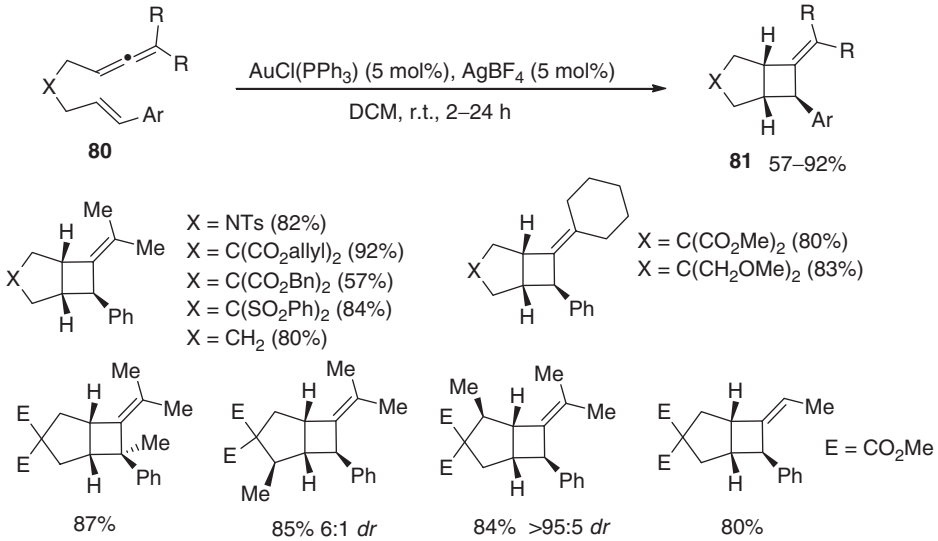
Esteruelas, Mascarenas, and coworkers developed a new type of intramolecular [2 + 2] cycloaddition of allenes and alkenes using $RuH_2Cl_2(P^iPr_3)_2$ as the catalyst.[82] The reaction proceeded under mild conditions and was fully diastereoselective, providing a new practical entry to bicyclic cyclobutanes (Scheme 88). Notably, the internal C═C double bond of the allene moiety participated in the cycloaddition via a possible ruthenabicyclic intermediate.

Based on DFT calculations, the authors suggested that the catalytic cycle is initiated by the unsaturated species $[RuCl_2(P^iPr_3)]$, which comes from the dissociation of molecular hydrogen and one triisopropylphosphine ligand from $RuH_2Cl_2(P^iPr_3)_2$ (Scheme 89). Then, coordination of the conjugated diolefin unit and the internal allenic double bond of the substrate to the Ru center of **89a** generates complex **89b**, which evolves into the ruthenabicycle **89c** by oxidative cyclometalation. Further, σ- to π-allyl rearrangement of **89c** affords **89d**, which enables a subsequent reductive elimination to give the cycloaddition product **81** and regenerates the Ru catalyst.



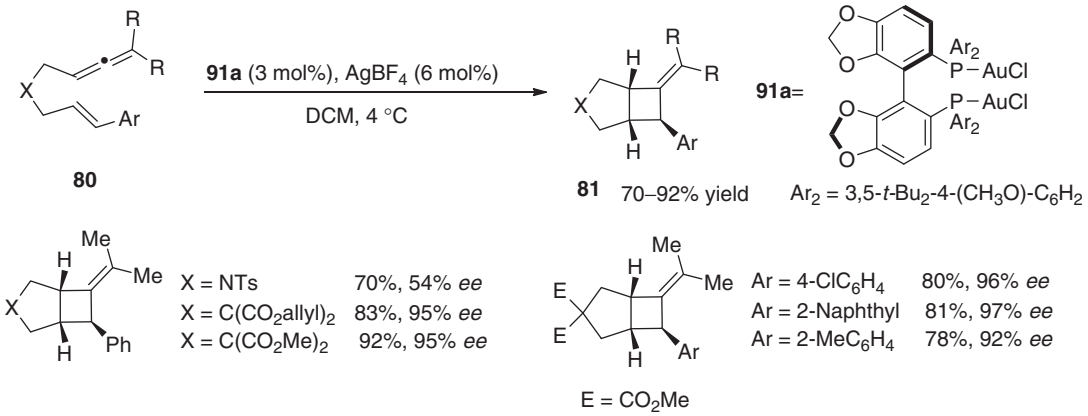
5.07.11.3 Gold-Catalyzed Intramolecular [2 + 2] Cycloaddition of Allenes and Alkenes

Toste et al. demonstrated an intramolecular $AuCl(PPh_3)/AgBF_4$-catalyzed [2 + 2]-cycloaddition reaction of allenes and alkenes affording cyclobutanes in good yield. The reaction proceeds with a high selectivity for the internal C═C bond of the allenene moiety in **80** (Scheme 90).[83a] It is interesting to note that only the internal C═C double bond of the allene moiety participated in the cycloaddition via a possible carbocationic mechanism. Under these conditions, a variety of aryl-substituted alkenes reacted intramolecularly with allenes to furnish cyclobutanes. Interestingly, trisubstituted olefins also participate to give highly substituted cyclobutanes.

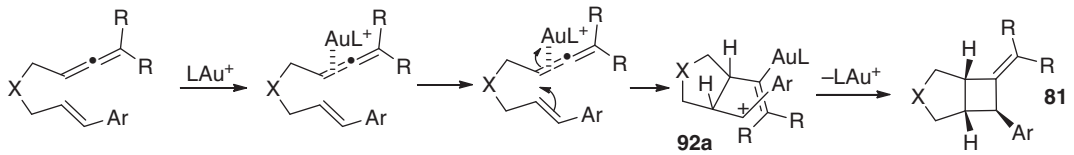


The same group reported an asymmetric [2 + 2] cycloaddition of allene-enes in the presence of (*R*)-(–)-5,5′-bis[di(3,5-di-*tert*-butyl-4-methoxyphenyl)phosphino]-4,4′-bi-1,3-benzodioxole ((*R*)-DTBM-SEGPHOS)$(AuCl)_2$ (**91a**) and 6 mol% of $AgBF_4$ to

Scheme 88 Intramolecular [2 + 2] cycloadditions of allenes and alkenes.

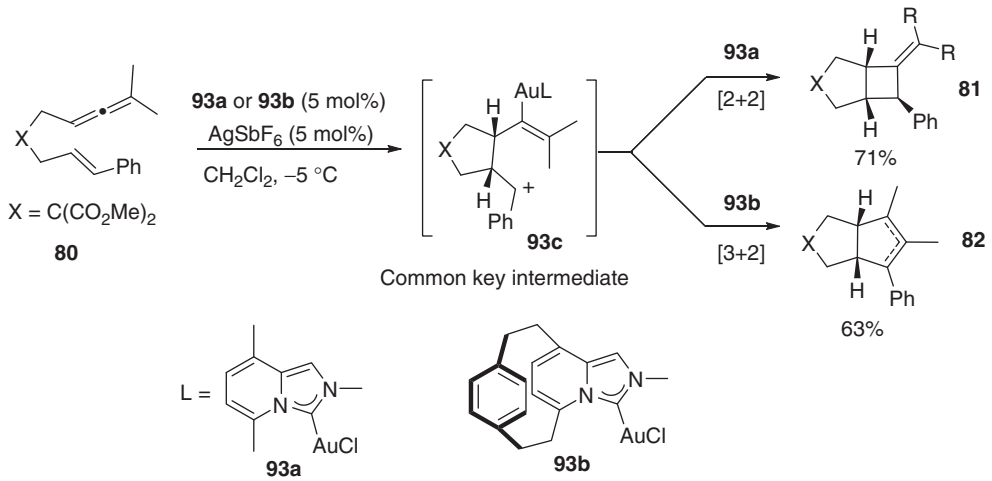


Scheme 89 Proposed mechanism for the formation of the bicyclic cyclobutanes of type **81**.



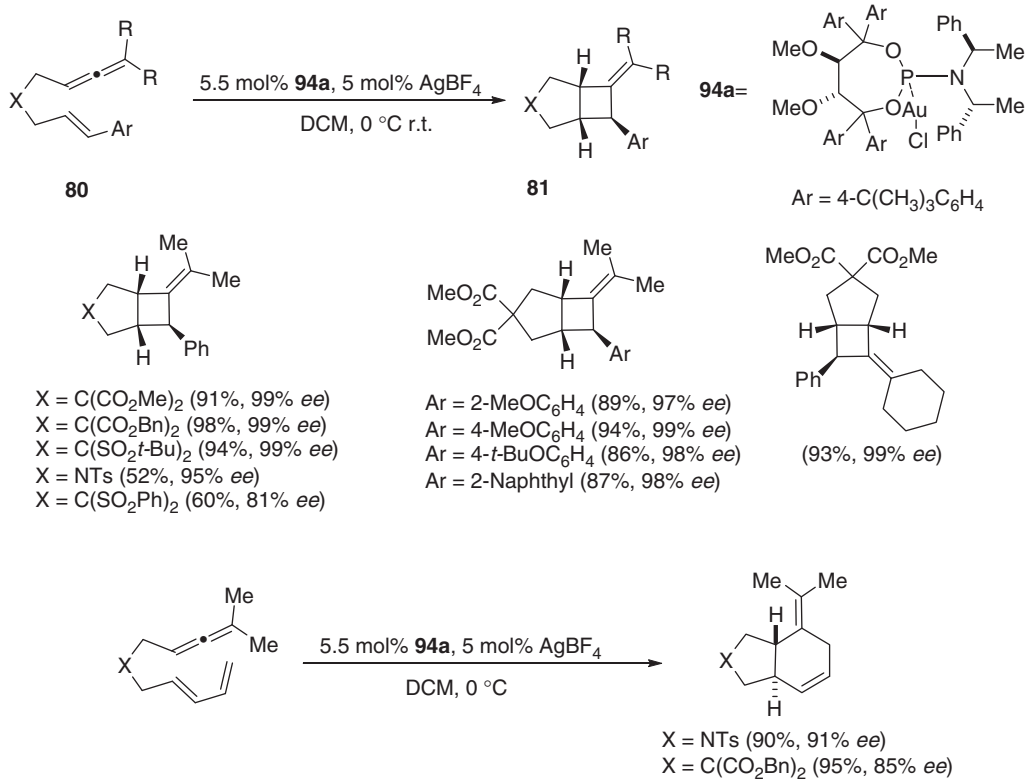
Scheme 90 Gold(I)-catalyzed intramolecular [2 + 2]-cycloaddition reactions of allenes and alkenes.

afford cyclobutanes **81** in 70–92% yields with 54–97% *ee*. A variety of allene-enes containing a styrenyl moiety gave good yields and excellent enantioselectivity (Scheme 91).[83b]



Scheme 91 Gold(I)-catalyzed asymmetric [2 + 2]-cycloadditions.

The proposed mechanism involves the activation of the internal allene double bond by the cationic gold species, which undergoes cyclization to give the benzylic cation **92a** (Scheme 92). A subsequent ring closure through the carbon adjacent to the gold atom provides the final cycloadduct **81**.



Scheme 92 Proposed mechanism for the intramolecular [2 + 2]-cycloaddition leading to bicycles of type **81**.

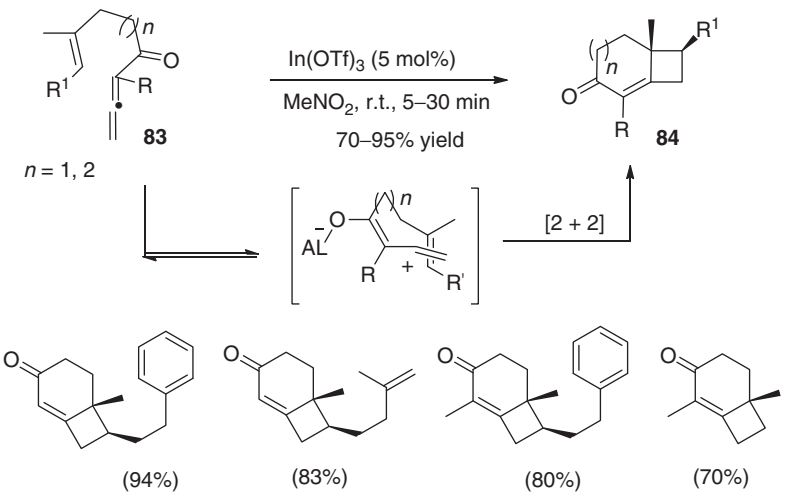
More recently, Fürstner et al. observed a remarkable ligand effect on the course of the cycloaddition. For example, an eneallene treated with the more electron-deficient gold catalyst (**93a**) favors the [2 + 2]-cycloaddition product, whereas the electron-rich gold catalyst (**93b**) affords [3 + 2] products.[84] Mechanistically, the reaction proceeds via the formation of a common intermediate **93c** in the presence of gold complex **93a** or **93b** (Scheme 93).

Scheme 93 Ligand effects on the course of gold-catalyzed cycloaddition reactions of ene-allenes.

Very recently, the Fürstner group demonstrated an asymmetric [2 + 2] cycloaddition of ene-allenes in the presence of 5.5 mol% of the phosphoramidite gold complex (**94a**) and 5 mol% of $AgBF_4$ to afford cyclobutanes **81** in good yields with excellent *ee*. The asymmetric cycloadditions occurred at 0 °C to r.t. with outstanding enantioselectivities of up to 99%. The authors studied an effect of remote substituents on the arene part of the TADDOL-type ligand on the enantioselectivity and reaction rate of gold-catalyzed [2 + 2] cycloaddition. Gratifyingly, the *tert*-butyl group has performed well on the enantioselective [2 + 2] cycloaddition and >99% *ee* was obtained. Under similar reaction conditions, a series of ene-allenes containing a substituted styrenyl moiety gave good yields and excellent enantioselectivity (Scheme 94).[85] However, ene-dienes favored asymmetric [4 + 2] cycloadditions in the presence of 5.5 mol% of the phosphoramidite gold complex **94a** and 5 mol% of $AgBF_4$ furnishing the cycloadducts in good to excellent yields with a high enantioselectivity (Scheme 94).[85]

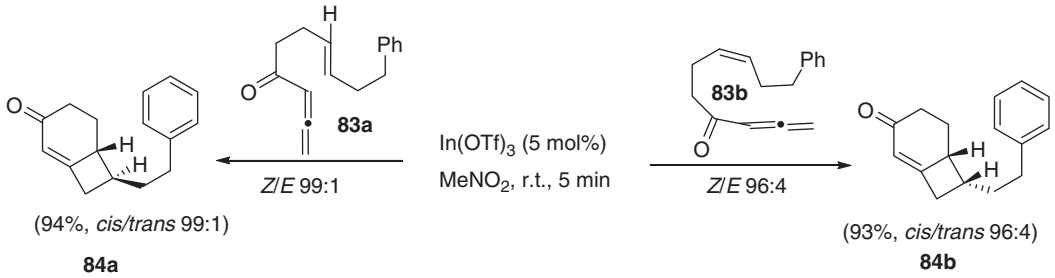
Scheme 94 Gold-catalyzed asymmetric [2 + 2]-cycloadditions of ene-allenes.

5.07.11.4 Indium-Catalyzed Intramolecular [2 + 2] Cycloaddition of Allenes and Alkenes



Loh and coworkers have shown that $In(OTf)_3$ is a versatile catalyst for the intramolecular [2 + 2] cycloaddition between a distal allenic double bond and an unactivated alkene. The cycloaddition reactions provide easy access to strained bicyclo[n.2.0] cyclobutenes under very mild reaction conditions with high yields and excellent diastereoselectivities. This reaction probably proceeds via a $[_{\pi}2_s + _{\pi}2_a]$ concerted mechanism, which involves a vinyl-cation resonance structure, as shown in Scheme 95.[86]

To probe the mechanism of this [2 + 2]-cycloaddition, the stereospecificity of the reaction and the steric effects on the alkene motif were examined. Thus, substrates **83a** and **83b** were treated under the standard conditions (Scheme 96). Both **83a** and **83b** with a methylene group on the alkene motif were smoothly transformed to the [2 + 2]-cycloaddition products **84a** and **84b** with excellent yields and diastereoselectivities. Another interesting observation is that the *cis* and *trans* products were obtained almost exclusively from the *Z* and *E* alkenes, respectively, which demonstrated that this is a stereospecific process.



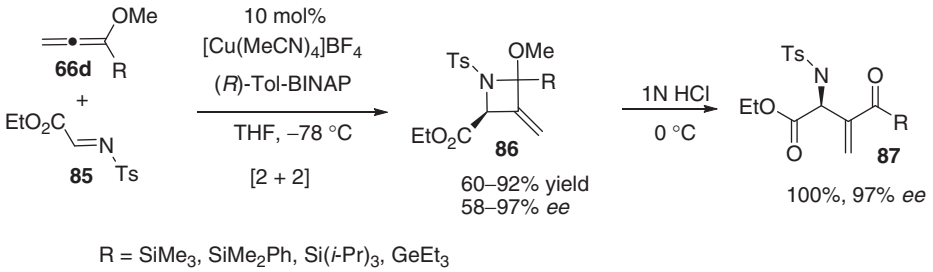
5.07.12 Metal-Catalyzed [2 + 2] Cycloaddition of Imines with Allenes, Alkenes, Allyl Phosphates, and Halides

5.07.12.1 Copper-Catalyzed Intermolecular [2 + 2] Cycloaddition of Imines and Allenes

As described above, alkynes, alkenes, and allenes efficiently participate in the [2 + 2] cycloaddition leading to various four-membered cyclic compounds. However, the cycloaddition of polar unsaturated bonds to give four-membered heterocyclic

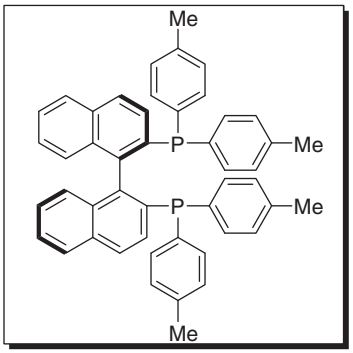
Scheme 95 $In(OTf)_3$-catalyzed intramolecular [2 + 2]-cycloadditions between the distal allenic double bond and inactivated alkenes.

Scheme 96 Investigation of stereospecificity and steric effects of indium-catalyzed [2 + 2] cycloadditions.



compounds catalyzed by metal complexes are less explored. In this respect, Akiyama et al. reported enantioselective [2 + 2] cycloaddition reactions of 1-methoxyallenylsilanes **66** with α-imino ester **85** in the presence of $[Cu(MeCN)_4]BF_4$/(*R*)-(–)-2,2′-bis(*p*-tolyl-phosphino)-1,1′-binaphthyl ((*R*)-Tol-BINAP) as the catalyst system (Scheme 97).[87] The reaction afforded azetidines **86** in good yields with excellent enantiomeric excess at low temperature. Azetidines **86** were cleanly converted to chiral acylsilanes (**87**) by acid-catalyzed ring opening at 0 °C.

5.07.12.2 Silver-Catalyzed Intermolecular [2 + 2] Cycloaddition of Imines and Alkenes



Azetidines are versatile building blocks for a number of naturally occurring products and have attracted much attention due to their unique biological activities.[88] However, the azetidine skeleton has been one of the most difficult amines to synthesize, because of the ring strain. Several methods for the synthesis of azetidines are known. An Ag(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato (fod)) (**98a**) catalyzed [2 + 2] cycloaddition is a simple and efficient method for the synthesis of azetidines from imines with (alkoxymethylene)cyclopropanes (Scheme 98).[89] Various imines performed well. It is important to mention that substrates lacking the *exo*-enol ether group on the cyclopropane ring did not react with the imines under the reaction conditions.

This reaction proceeds through the coordination of the imine nitrogen to the silver catalyst, which certainly enhances the electrophilicity of the imine and hence favors the nucleophilic attack of the carbon–carbon double bond of **21** leading to the *anti*-oriented zwitterion *anti*-**99a**. The latter cyclizes to give azetidine *cis*-**86** or *trans*-**86′** after internal rotation. The *cis* isomer *cis*-**86** is thermodynamically more stable (Scheme 99) and the *trans* isomer can be isomerized to the *cis* product under the reaction conditions.

The utility of the *cis* products was demonstrated by the synthesis of the β-phenylalanine analogue **89**, which is a known biologically active compound.[90] Thus, hydrolysis of *cis*-**86** afforded aldehyde **87** in 86% yield. Subsequent Jones oxidation and removal of the nosyl (Ns) group from **88** gave amino acid **89** (Scheme 100).

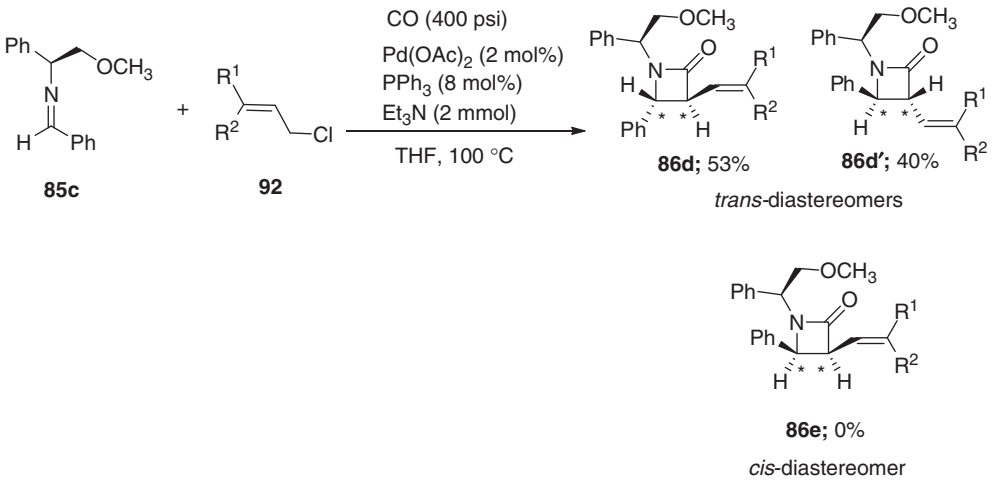
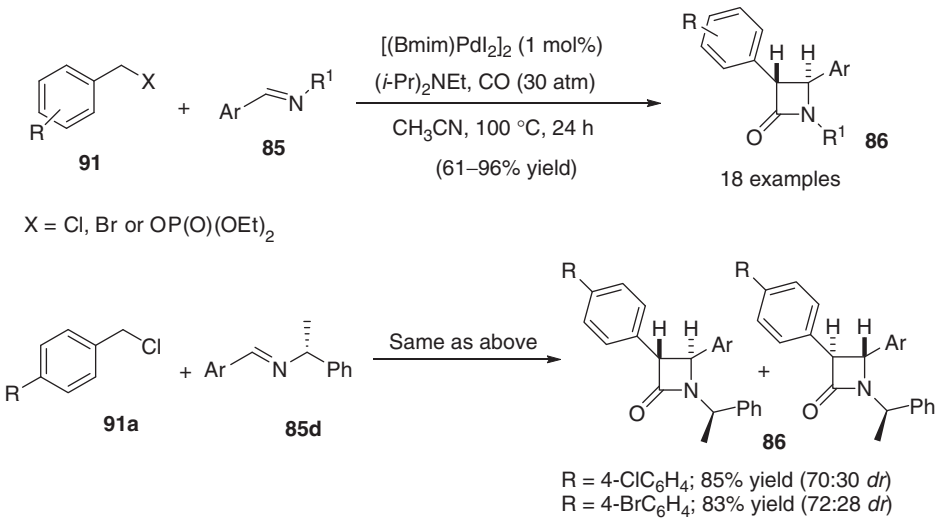
5.07.12.3 Palladium-Catalyzed Carbonylative [2 + 2] Cycloaddition of Imines, Allyl Phosphates, and Halides

Palladium-catalyzed carbonylative [2 + 2] cycloadditions of allyl phosphates with imines under CO pressure lead to either *cis*- or *trans*-β-lactams (**86**) in moderate to high yields.[91] The stereochemical outcome strongly depends on the nature of the imines employed. For example, imines conjugated with a carbonyl such as a ketone or an ester stereoselectively produce *cis*-β-lactams at r.t., whereas imines unconjugated with a carbonyl group exclusively afford *trans*-β-lactams at 70 °C. This reaction was proposed to occur via an enolate of a 3-butenoyl-Pd species **101a** (Scheme 101).

Scheme 101 Pd(0)-catalyzed carbonylative [2 + 2] cycloaddition of allyl phosphates with imines.



Shim et al. observed that Bn and allyl halides react stereoselectively with imines under CO pressure to give the corresponding β-lactams in good yields when the reaction is catalyzed by $PdCl_2(PPh_3)_2$ (Scheme 102).[92]



Scheme 102 Pd-catalyzed carbonylative [2 + 2] cycloadditions of benzyl chloride with imines.

The [2 + 2] carbonylative cycloaddition of chiral imines with various allyl halides, under CO pressure, in the presence of a catalyst system comprising $Pd(OAc)_2$, PPh_3, and Et_3N gives chiral alkenyl-β-lactams in good yields with high *trans* diastereoselection (Scheme 103).[93]

Very recently, Huang, Xia, and coworkers reported an efficient synthesis of β-lactams by carbonylative [2 + 2] cycloaddition of Bn chlorides or allyl derivatives with imines catalyzed by a palladium/NHC complex (Scheme 104).[94] The desired β-lactam derivatives were obtained in good to excellent yields (61–96%) with excellent regioselectivity (*trans*/*cis* > 95:5). Under similar reaction conditions, optically active lactams could be obtained in good yields with moderate diastereoselectivity. Bn acetate, carbonate, and sulfonate are not suitable for this carbonylative [2 + 2] cycloaddition.

Scheme 103 Pd-catalyzed carbonylative [2 + 2] cycloadditions of a chiral imine with various allyl halides for the synthesis of β-lactams.

Scheme 104 Synthesis of β-lactams via the carbonylative [2 + 2] cycloadditions of benzyl or allyl chlorides with imines.

5.07.13 Conclusion

In this chapter, we have compiled various metal-mediated, metal-catalyzed, inter- and intramolecular [2 + 2] cycloaddition reactions of alkyne/alkene, alkyne/allene, alkyne/ketone, alkyne/alkyne, alkene/alkene, allene/allene, allene/alkene, and imine/allene pairs, as well as of alkenes, allyl phosphates, and halides. Mechanistically, most of the reactions proceed via metallacyclopentenes or metallacyclopentanes as key intermediates. These reactions are regio- and stereoselective providing an atom- and step-economical method for the synthesis of various highly substituted cyclobutane or cyclobutene rings in good to excellent yields. These reactions are excellent alternatives to the more traditional methods for making four-membered rings. Overall, we believe that this comprehensive chapter will support the synthetic community in further developing the [2 + 2] cycloaddition chemistry and its application to organic synthesis.

Glossary

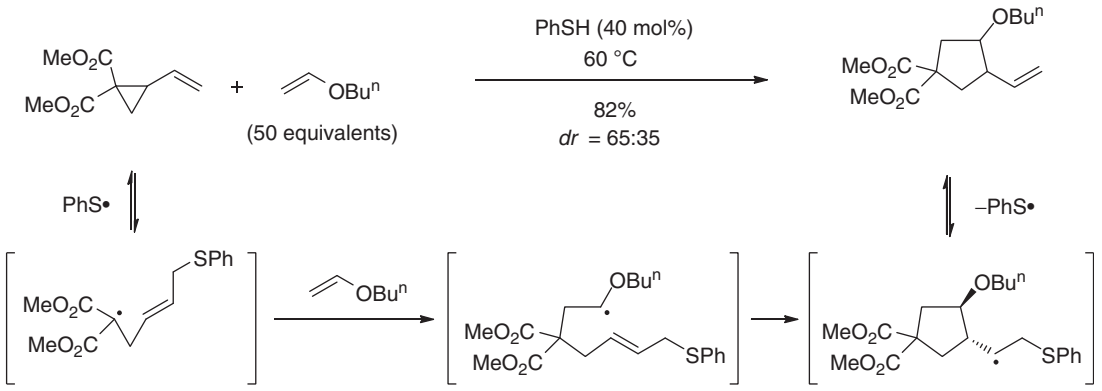
1,3-Bis(2,4,6-trimethylphenyl)imidazole-2-ylidene (IMes) A representative *N*-heterocyclic carbene.

Distal and proximal bond of methylenecyclopropane The 'distal bond cleavage' means cleavage of C2–C3 bond generating a TMM, whereas the 'proximal bond cleavage' means cleavage of C1–C2 bond.

Trimethylenemethane (TMM) 1,3-Diradical or 1,3-dipole species composed of four carbon atoms containing an *exo*-methylene moiety at the central carbon. TMM and its transition metal complexes have been utilized as a useful three-carbon unit in synthetic chemistry.

Tris(2,2′-bipyrazine)ruthenium(II) ($[Ru(bpz)_3]^{2+}$) A photoredox catalyst that absorbs visible light.

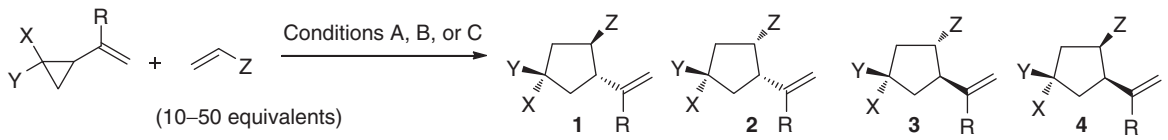
5.08.1 Introduction



This chapter deals with [3 + 2] cycloaddition and related reactions for the formation of five-membered carbocycles. In contrast to the extensively investigated 1,3-dipolar [3 + 2] cycloaddition reactions for the construction of five-membered heterocyclic compounds, the corresponding all-carbon [3 + 2] cycloadditions were rather limited. In the first edition of this book, thermal and transition metal-catalyzed trimethylenemethane (TMM) cycloaddtions (*see* Chapters 3.1 and 3.2), [3 + 2] cycloadditions of allenylsilanes with electron-deficient alkenes (*see* Chapter 3.2), some cyclopropane-related reactions (*see* Chapter 8.1), and photochemical *meta*-cycloadditions of benzene derivatives (*see* Chapter 5.3) were described.[1] Since then, important developments of these reactions have been made and, more importantly, various new approaches for the [3 + 2] cycloaddition or annulation reactions could be realized based on organo- and transition metal-catalyzed processes. This chapter intends to summarize these new aspects of the all-carbon [3 + 2] cycloaddition reaction, along with recent advances in the chemistry already described in the first edition of this book.

5.08.2 Thermal and Photochemical [3 + 2] Cycloaddition Reactions

5.08.2.1 Radical Reactions



Cyclopropylmethyl radicals are well known to isomerize to homoallyl radicals, which add to alkenes followed by further cyclization onto the alkene moiety generated from the cyclopropane precursors to give cyclopentylmethyl radicals. This reaction can be regarded as a [3 + 2] cycloaddition of a cyclopropane ring with alkenes, but it is necessary to devise a system which enables efficient control over the reactivity of the highly reactive intermediates. Several methods to realize such reactions were reported; one common method is the addition of a thiyl radical to vinylcyclopropanes. In the original studies, the necessary thiyl radical

was generated by photoirradiation of a disulfide in the presence of 2,2′-azodiisobutyronitrile (AIBN) or simply by heating a mixture of the substrates with benzenethiol. Addition of this radical to the olefinic moiety of a vinylcyclopropane generates cyclopropylmethyl radicals, which undergo smooth ring opening to give butenyl radicals. These radicals then undergo addition to the alkenes followed by radical cyclization to give cyclopentylmethyl radicals, which finally eliminate the thiyl radical to give the [3 + 2] cycloadducts (Scheme 1).[2] It is necessary to employ 2-substituted vinylcyclopropanes, such as vinylcyclopropyl ethers or vinylcyclopropanecarboxylates, which generate substituted radicals stabilized by these groups. As a 2π unit, both electron-rich and -deficient alkenes along with electron-deficient alkynes were employed in large excess, although the efficiency of the reaction was dependent on the combination of the electronic nature of the substituents. In general, the diastereoselectivity of the reaction was not very good, but in some cases improvements were observed by adding a Lewis acid (Table 1).[3a,b] By using 2,2-dihalovinylcyclopropanes as the substrates, the diastereoselectivity of the products was improved in favor of the 3,4-*cis* isomer, although the reaction with electron-rich alkenes became less efficient.[3c]

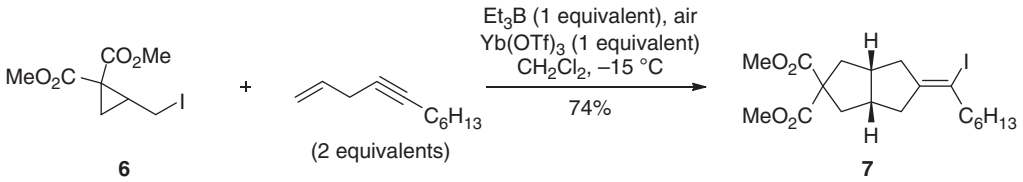
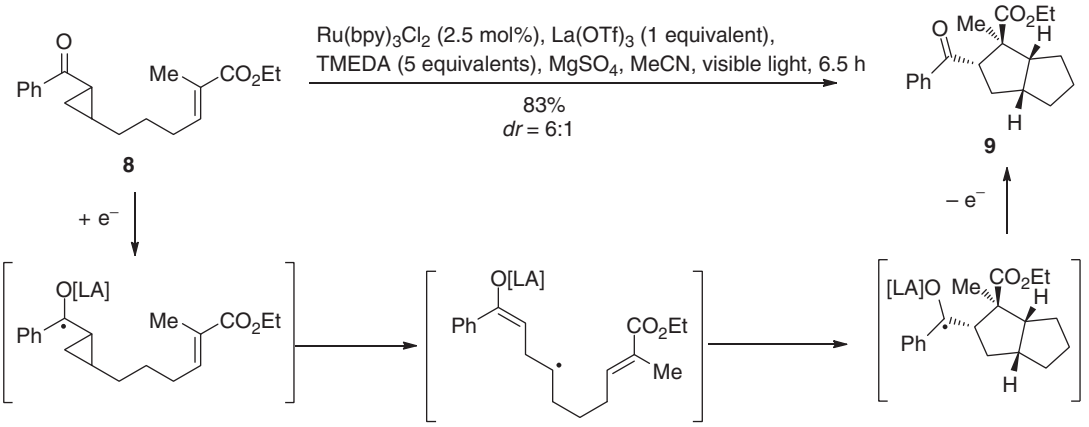
By using bicyclo[3.1.0]hex-2-ene-6-carboxylate **5** as the vinylcyclopropane partner, the reaction with various kinds of alkenes in the presence of di(*n*-butyl) disulfide under photoirradiation conditions gave diquinane or triquinane derivatives in good yields (Scheme 4).[5]



In addition to the thiyl radical addition to vinylcyclopropane derivatives, iodine atom-transfer [3 + 2] cycloadditions were achieved using 2-(iodomethyl)cyclopropane-1,1-dicarboxylate **6** as the precursor of the cyclopropylmethyl radical. The reaction with electron-rich alkenes proceeded smoothly in the presence of Et_3B under O_2 atmosphere, whereas simple alkenes gave good yields of the products in the presence of an equimolar amount of $Yb(OTf)_3$, which was thought to increase the electrophilicity of the generated bis(methoxycarbonyl)methyl radical (equation 1). A one-step construction of bicyclo[3.3.0]octane skeleton **7** could be achieved based on this protocol using dienes or enynes as radical acceptor (equation 2).[6]

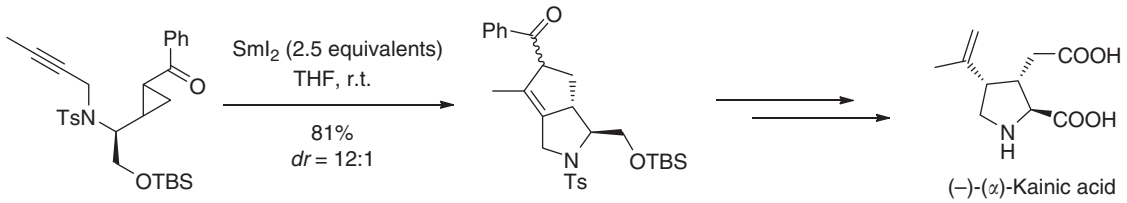
Scheme 4

(1)



(2)

Recently, two related methods for the generation of cyclopropylmethyl radicals were devised for the intramolecular [3 + 2] cycloaddition reaction.[7] One consists in the one-electron reduction of cyclopropyl aryl ketones **8** to the corresponding radical anions, which was accomplished using a photocatalytic system composed of $Ru(bpy)_3Cl_2$, $La(OTf)_3$, and tetramethylethylenediamine (TMEDA). Radical anions of cyclopropyl aryl ketones **8** were generated by one-electron transfer from the $Ru(bpy)_3^+$ on visible light irradiation, which underwent ring opening followed by sequential intramolecular radical additions to give cyclized ketyl radicals, which, on loss of an electron, gave the formal intramolcular [3 + 2] cycloaddition products **9**. Use of $La(OTf)_3$ for the activation of cyclopropyl ketones was essential for the success of the reaction (Scheme 5).[7a]



A similar ketyl radical was generated by SmI_2-mediated reduction of cyclopropyl phenyl ketone **10**. A subsequent diastereoselective intramolecular cycloaddition reaction afforded a key intermediate for the synthesis of (–)-(α)-kainic acid (Scheme 6).[7b]

Radical cations of cyclopropylamines also undergo ring opening to give β-imino radicals, which react with alkenes in a [3 + 2] cycloaddition manner to give cyclopentylamine derivatives. Ceric ammonium nitrate (CAN)-mediated one-electron oxidation of tertiary cyclopropylbenzylamines **11** generated γ-imino radicals, which underwent tandem cyclization to give the debenzylated bicyclic amines **12**. The reaction proceeded with either electron-rich or -deficient alkenes in *N*,*N*-dimethylformamide (DMF) at room temperature (Table 3).[8]

A visible light-mediated intermolecular [3 + 2] cycloaddition of *N*-arylcyclopropylamines with alkenes was achieved using $Ru(bpz)_3(PF_6)_2$ as a photocatalyst. Photoirradiation of mono- or bicyclic *N*-arylcyclopropylamines and styrene derivatives or acrylonitrile in the presence of 2 mol% of $Ru(bpz)_3(PF_6)_2$ using a fluorescent light bulb at room temperature gave the corresponding cyclopentylamine derivatives in good yield. The diastereoselectivity of the monocyclic cyclopropylamines was low, but bicyclic derivatives showed moderate selectivity (Scheme 7). The reaction proceeded in a similar manner as in the above photocatalyzed ketyl radical reaction.[9]

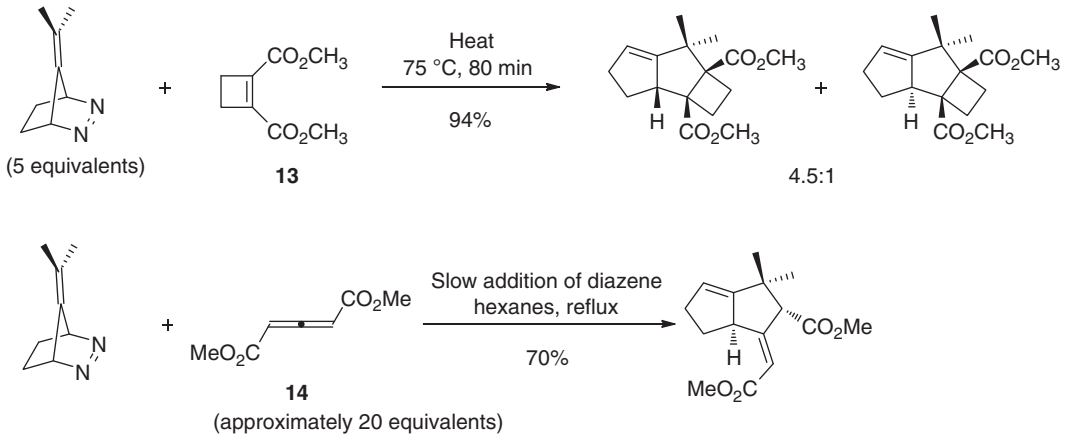
5.08.2.2 TMM Chemistry

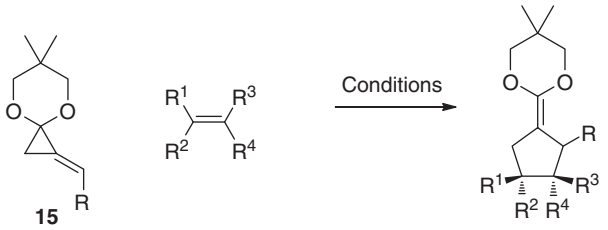


TMM has continued to be a useful three-carbon unit for [3 + 2] cycloaddition reactions. The basic approaches for the generation of TMMs have been categorized mainly into two types, that is, thermal and transition metal (mainly Pd)-catalyzed reactions, each of which is further categorized into several kinds of reactions. This section describes the recent development of thermal reactions since the first edition of this book.[1a,10] The transition metal-catalyzed reactions will be treated in Section 5.08.4.2.1.

Since the first edition of this work, several applications of TMMs, generated from diazenes under thermal conditions, to natural product synthesis, have been reported with an emphasis on the regio- and stereo-selectivity of the reaction. Owing to the competitive dimerization of diyls, most of the examples are intramolecular reactions, which enable the concise construction of synthetically useful polycyclic frameworks. Some representative examples are shown below with the key [3 + 2] cycloaddition step (Scheme 8).[11]

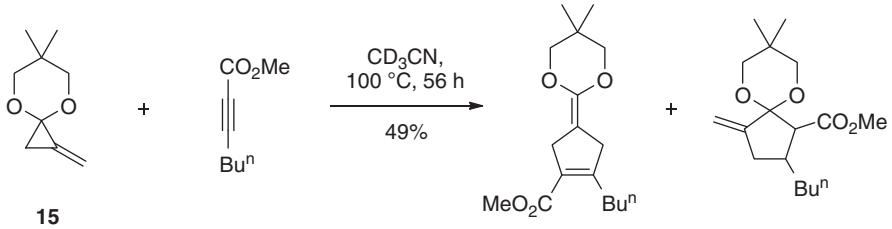
Scheme 8

Intermolecular [3 + 2] cycloadditions were achieved by using highly electron-deficient alkenes **13** or allenes **14**. The former reaction was applied to the preparation of bicyclo[n.3.0] systems by a cycloaddition-fragmentation sequence (Scheme 9).[12] Mechanistic studies suggested that the diyls generated from diazenes have a character of 'dipolar diradical' as they could be trapped either with water or with 1,4-cyclohexadiene.[13]



Scheme 9

Another method for the generation of TMM utilizes methylenecyclopropane derivatives as precursors. The character of the generated TMM differs considerably depending on the kind of substituent on the chosen substrate. For example, TMMs generated from simple methylenecyclopropane derivatives show a diradical character like diyls, which are difficult to trap intermolecularly because of insufficient equilibrium concentration and short life time. In contrast, dialkoxy-substituted methylenecyclopropane derivatives generate an electron-rich TMM, which shows zwitterionic character and is sufficiently stable to undergo nucleophilic



addition or single-electron transfer to electron-deficient alkenes to give [3 + 2] cycloaddition products.[14a] For example, treatment of cyclopropane **15** (R = H), which was prepared from 1,3-dichloro-2-propanone acetal in a few steps and could be stored for a long time, with various electron-deficient alkenes gave the [3 + 2] cycloaddition products by heating the mixture in acetonitrile. A variety of alkenes substituted with a single-electron-withdrawing group (EWG) reacted at 70–80 °C to give ketene acetals of cyclopentanecarboxylates in high yields, in which the geometry of the alkenes was transferred to the stereochemistry of the products, thus suggesting a concerted nature of the reaction.[14b] When a substituted dialkoxymethylenecyclopropane was employed as the substrate, high *endo*-selectivity was attained by carrying out the reaction in nonpolar solvents (Table 4).[14c]

Table 4 Trimethylenemethanes (TMMs) from dialkoxy-substituted methylenecyclopropanes

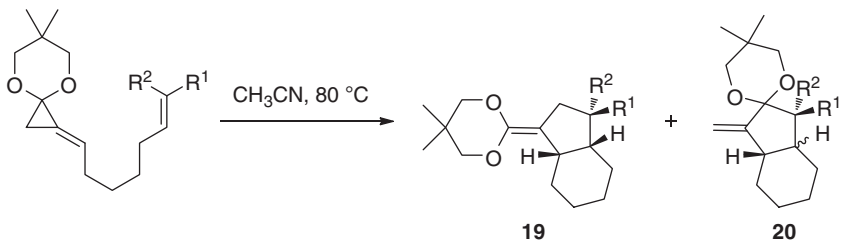
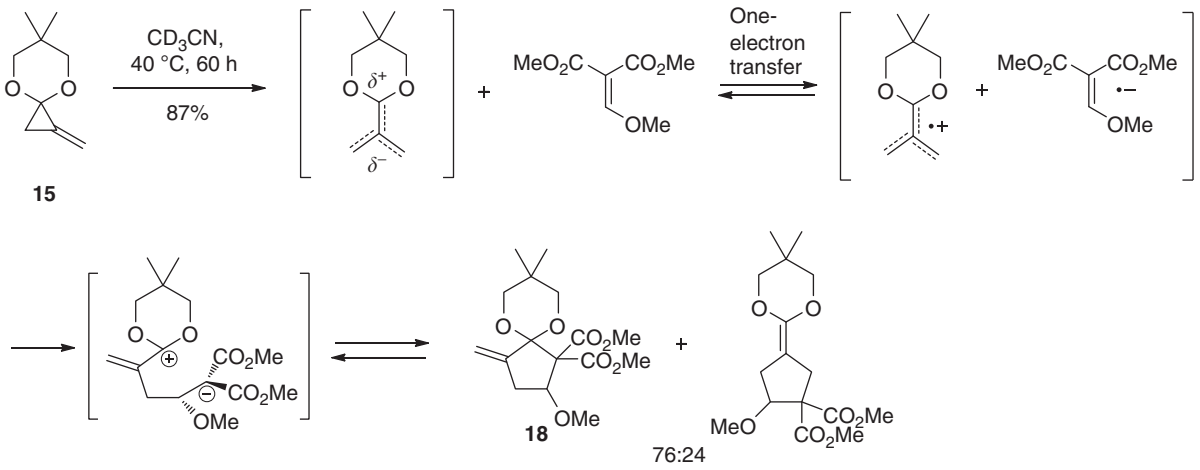
Me	H	COOMe	H	COOMe	Octane, 80 °C	77	97:3 (β-R:α-R)	14c
Me	H	COOMe	H	COOMe	CH_3CN, 80 °C	78	80:20(β-R:α-R)	14c
Me	H	H	Me	COOMe	Toluene, 100–120 °C	72	1:1(β-R, alkene regioisomer)	14c
Pr^i	Me	H	H	COOMe	CD_3CN, 100–120 °C	71	96:4(β-R, alkene regioisomer)	14c



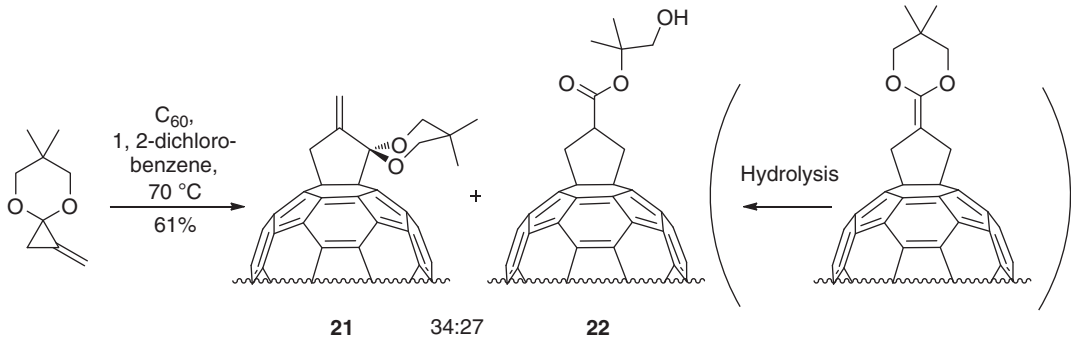
Electron-deficient alkynes also reacted as a 2π unit to give ketene acetals **16** as the major products along with small amounts of methylenecyclopentanes **17**, although alkynes were found less reactive than alkenes and needed higher reaction temperatures (equation 3).[14d]

(3)



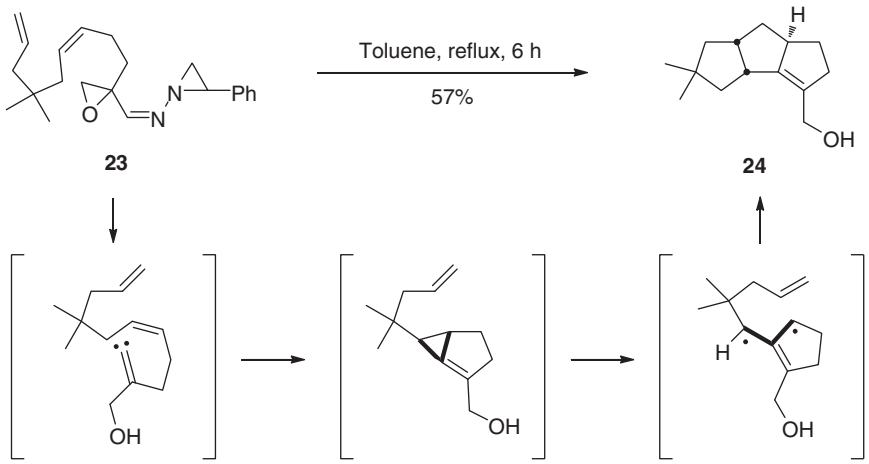
Interestingly, when highly electron-deficient alkenes were employed as substrates, stepwise [3 + 2] cycloadditions occurred to give predominantly the regioisomeric α-alkylidene acetals **18**. The reaction was proposed to proceed through single-electron transfer from the TMM to the electron-deficient alkenes to generate radical ion pairs, which undergo intermolecular radical coupling followed by ring-closure to give the products (Scheme 10).[14e]

The stereochemistry of the intramolecular reaction was shown to be controllable by the choice of the olefinic substituent, owing to the concerted or stepwise nature of the [3 + 2] cycloaddition reaction (equation 4). Monoester derivatives gave ketene acetals **19** selectively as single stereoisomers through a concerted reaction pathway, whereas diesters gave α-alkylidene acetals **20** as a major product as a mixture of stereoisomers.[14f]



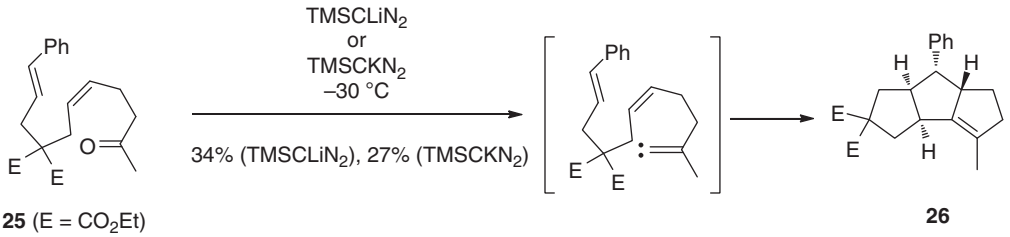
(4)

R^1 = COOMe, R^2 = H: 76% (**19**:**20** = 100:0), **19**: single isomer
R^1 = COOMe, R^2 = COOMe: 81% (**19**:**20** = 36:64), **20**: 17:83



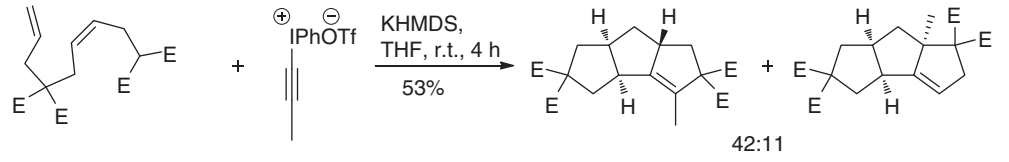
Scheme 10

The [3 + 2] cycloaddition reaction of 1,1-dialkoxymethylenecyclopropane with C_{60} furnished a mixture of the *exo*-methylene product **21** and hydrolyzed ketene acetal **22** in 34 and 27% yield, respectively, after silica gel chromatography. The *exo*-methylene product **21** was isomerized to the ketene acetal by heating at higher temperature (equation 5).[14g,h]



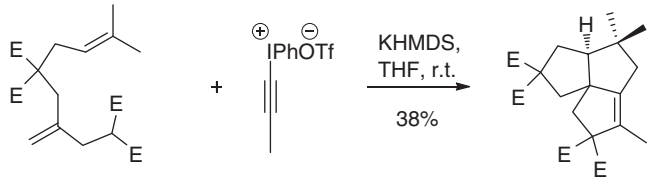
(5)

Several other useful methods for the preparation of methylenecyclopropanes as precursors of TMM have been developed. Most of them utilize intramolecular cyclopropanations of alkenes with vinylidene carbenes, that can be generated by several different methods. For example, the thermal decomposition of epoxyaziridinylimines was utilized to generate vinylidenes, which underwent intramolecular cyclopropanation to give methylenecyclopropanes. On heating in toluene at 110 °C, epoxyaziridinylimine **23** generated TMM diyl to give the intramolecular [3 + 2] cycloaddition product **24** in reasonable yields (**Scheme 11**). Based on this methodology, triquinanes could be prepared in a single operation starting from linear substrates.[15a]



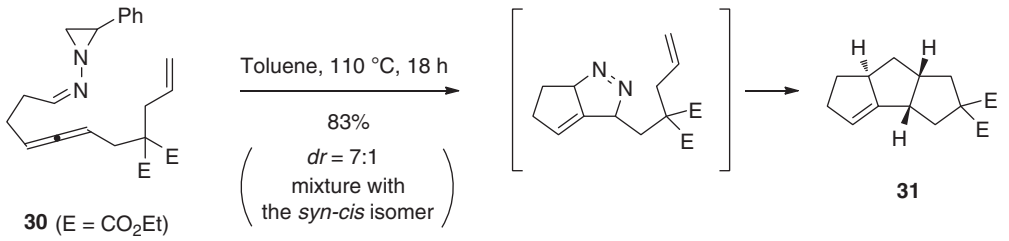
Scheme 11

The reaction of ketones with the anion of trimethylsilyl (TMS)-diazomethane also generated alkylidenes under mild conditions. Treatment of an appropriate dienone, such as **25** with the lithium or potassium enolate of TMS-diazomethane at − 30 °C to room temperature gave the triquinane derivatives **26** in moderate yield through TMM diyl intermediates (equation 6).[15b]

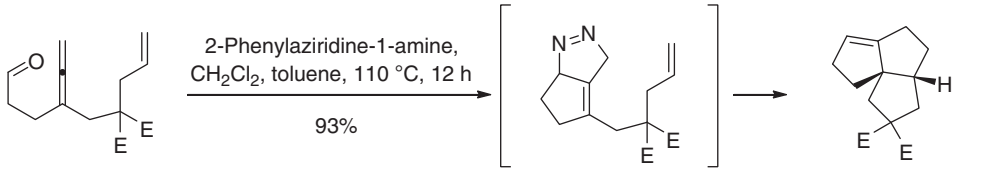


25 (E = CO_2Et) **26** (6)

The addition of nucleophiles to alkynyliodonium compounds is another method for the generation of vinylidenes. Active methylene compounds containing olefinic moieties added to the propynyliodonium salt **27** in tetrahydrofuran (THF) at room temperature gave polycyclic compounds in moderate yields through vinylidene generation, cyclopropanation, TMM diyl generation, and [3 + 2] cycloaddition. All the sequences proceeded at room temperature; either linearly fused or angularly fused triquinanes **28**, **29** were prepared on appropriate choice of the substrates (equations 7 and 8).[15c–f]

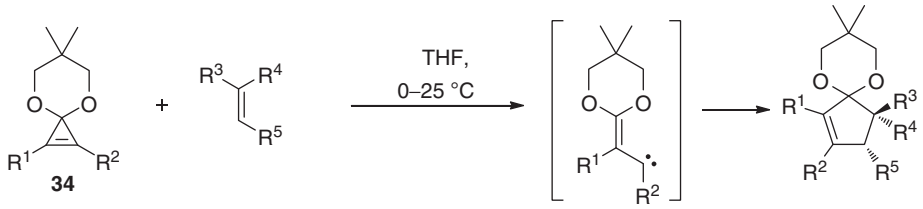


(E = CO_2Et) **27** **28** (7)



(E = CO_2Et) **27** **29** (8)

The reaction of diazo compounds with allenes can also generate TMM diyls. Thermal reaction of the 1,3-disubstituted allene **30** containing an appropriately arranged diazo precursor gave good yields of the triquinane derivative **31** (equation 9). Treatment of 1,1-disubstituted allenyl carbonyl compounds **32** with 2-phenylaziridin-1-amine or tosylhydrazine in toluene at 110 °C gave angularly fused triquinanes **33** in good yields (equation 10).[15g,h]



30 (E = CO_2Et) **31** (9)

32 (E = CO_2Et) **33** (10)

A seemingly related [3 + 2] cycloaddition reaction of cyclopropenone acetals with alkenes is briefly described here. The reversible thermal generation of π-delocalized singlet vinylcarbenes from cyclopropenone acetals and subsequent [3 + 2] cycloaddition with electron-deficient alkenes under mild conditions was described in the first edition of this book (*see* Chapter 3.1). Thereafter, the reactivity of various substituted cyclopropenone acetals was examined and the reaction with highly electron-deficient alkenes was found to proceed even below room temperature by using phenylthio- or alkoxycarbonyl-substituted substrates of type **34** (equation 11).[16a]

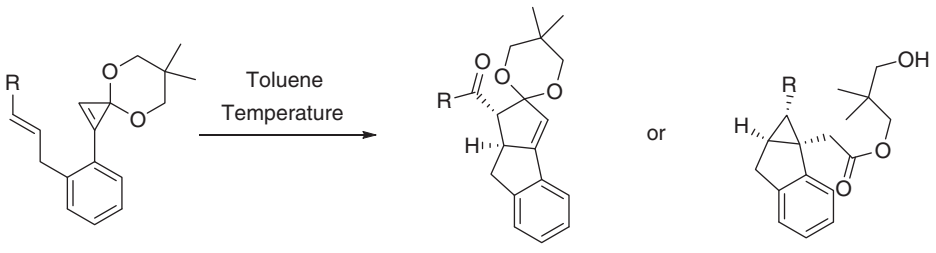
*Stereochemistry of the product was not assigned.

The reaction with C_{60} gave the corresponding [3 + 2] cycloaddition product in moderate yields when 2-ethylcyclopropenone acetal was employed as the substrate. Double cycloaddition was also realized by using a new reagent containing two tethered cyclopropenone acetal units (equation 12).[16b–d]



(12)

A, A = 2, 2-dimethylpropane-1,3-diyl acetal

The reaction was further extended to the intramolecular version. Substrates bearing an aldehyde- or ketone-substituted electron-deficient alkene and an aryl-cyclopropenone acetal moiety built into the linking tether gave the desired products in good yield under mild reaction conditions. Less activated substrates bearing an ester- or nitrile-substituted alkene provided the corresponding [2 + 1] cycloadduct of a singlet π-delocalized vinyl-carbene at lower temperature (80–100 °C); the same reaction at higher temperature (170–180 °C) gave the [3 + 2] cycloadducts formed by vinylcyclopropane rearrangement of the intermediate [2 + 1] cycloadducts (**Table 5**).[17]

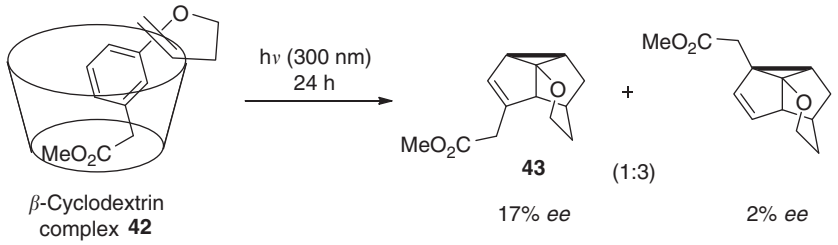
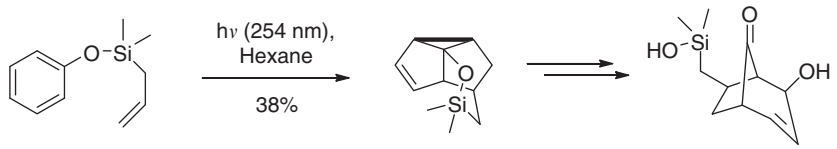
5.08.2.3 Photochemical [3 + 2] Cycloaddition Reactions

Photochemical [3 + 2] cycloaddition reactions of a benzene ring with alkenes (*meta*-cycloaddition) were treated extensively in the first edition of the book.[1c,18] Since then, some advances have been made for this reaction (*see* Chapter 5.15). For example, naphthalene was found to be a good substrate of intramolecular [3 + 2] cycloaddition with alkenes. Irradiation of 1-cyano-2-(4-pentenyl)naphthalene derivatives **37** through a pyrex filter (> 280 nm) afforded the products in good yield. Interestingly, the reaction initially gave [2 + 2] cycloadducts **38**, but prolonged irradiation afforded the [3 + 2] cycloadducts **39** selectively, suggesting that the initial [2 + 2] cycloaddition reaction is reversible (**Scheme 12**).[19]



Scheme 12

Photoirradiation of substrate **40** having phenyl and vinyl groups connected by a chiral 2,4-pentanediol tether was found to give the corresponding [3 + 2] cycloadduct with high diastereoselectivity. Removal of the tether afforded an optically active bicyclo[3.2.1]octane derivative (equation 13).[20]

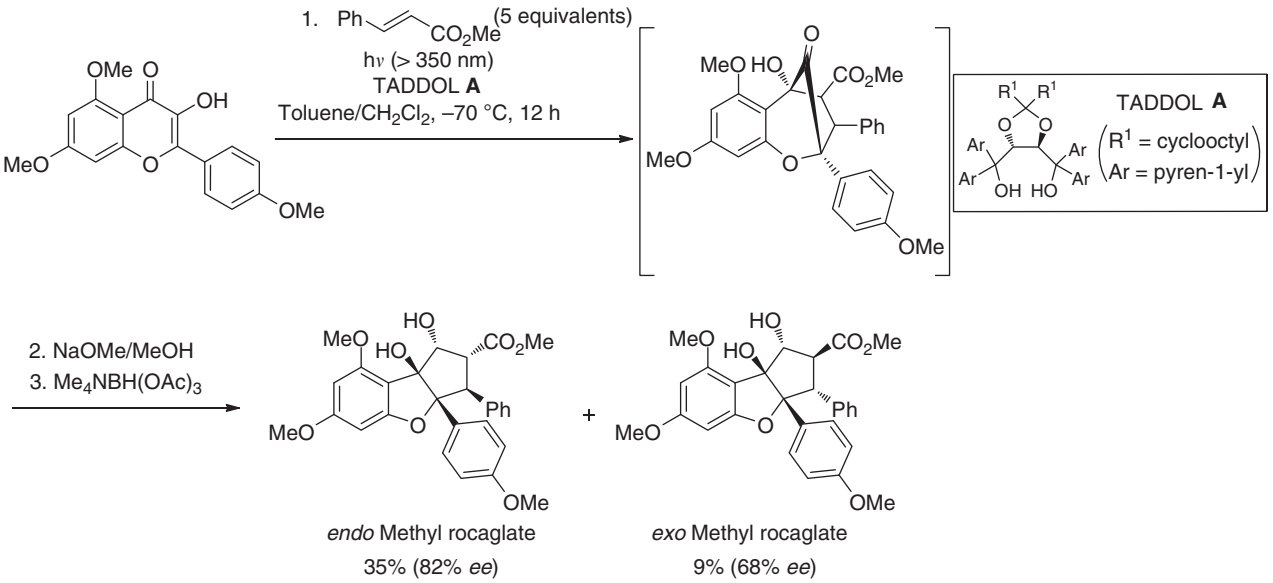


(13)

Asymmetric induction was examined using *β*-cyclodextrin complexes of phenoxyalkenes. Irradiation (300 nm) of the solid cyclodextrin complexes of substituted phenyl butenyl ethers **42** gave the corresponding [3 + 2] cycloadducts **43** in up to 17% *ee* (equation 14). Although the selectivity of the reaction was low, this is a unique example of an enantioselective *meta*-cycloaddition reaction.[21]

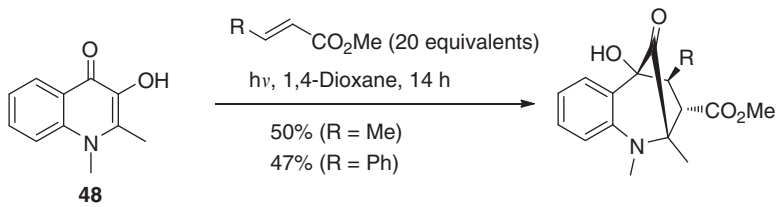
(14)

One serious drawback of this transformation is the formation of several isomeric [3 + 2] cycloadducts (*see* Chapter 5.03). Partial control could be achieved by carrying out the reaction intramolecularly as described above. The use of temporary tethers, in particular silicon tether, was studied for this purpose. For example, a silicon-tethered intramolecular *meta*-cycloaddition gave a photoadduct, which was further transformed into a model for the gelsemine skeleton (equation 15).[22]



(15)

Some applications of the intramolecular variant to the synthesis of polycyclic natural or unnatural products are shown in Table 6.[23]

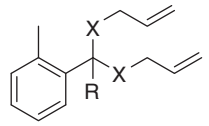


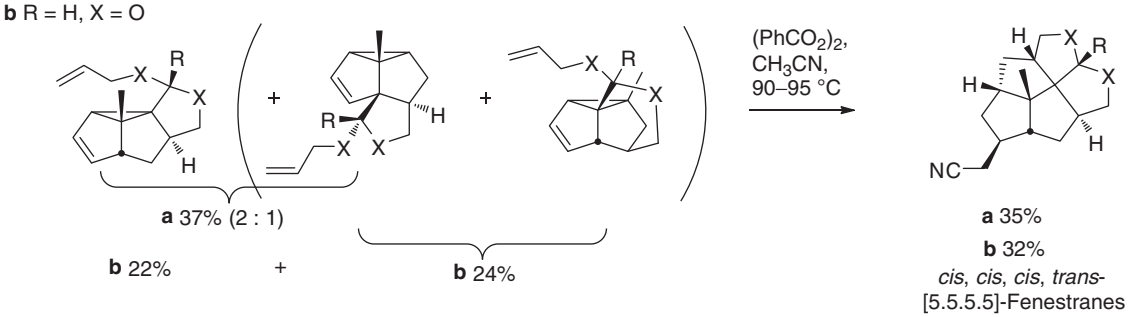
Oxidopyrylium salts usually undergo [5 + 2] cycloaddition with alkenes; however, oxidopyryliums generated photochemically from 3-hydroxyflavones by excited-state intramolecular proton transfer were found to give [3 + 2] cycloadducts with cinnamates as a biomimetic approach toward rocaglamides. Irradiation (> 350 nm) of 3-hydroxyflavone **44** in the presence of cinnamate gave a mixture of the *endo* [3 + 2] cycloadduct **45** and [2 + 2] cycloadduct **46**. Interestingly, an equilibration of these two products was observed during silica gel purification. Another product **47** was also obtained, which derives from the *exo* [3 + 2] cycloadduct by an acyloin rearrangement (Scheme 13).[24a]

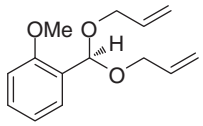
An enantioselective version of this reaction was realized using α,α,α′,α′-tetraaryl-1,3-dioxolan-4,5-dimethanol (TADDOL) derivatives as chiral Brønsted acids and was applied to the synthesis of rocaglates and other natural products (equation 16).[24b–g]

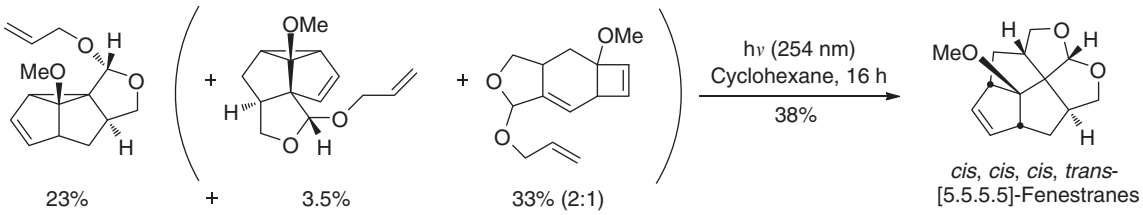
(16)

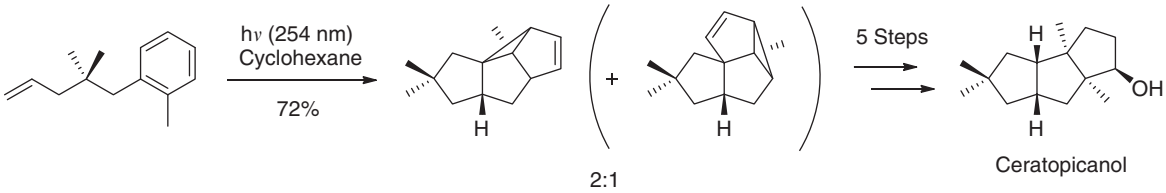
A similar reaction proceeded with 3-hydroxyqunolinones **48** (equation 17).[24h]

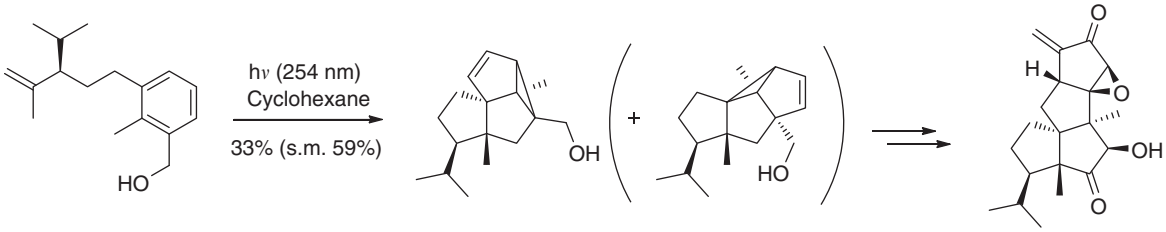


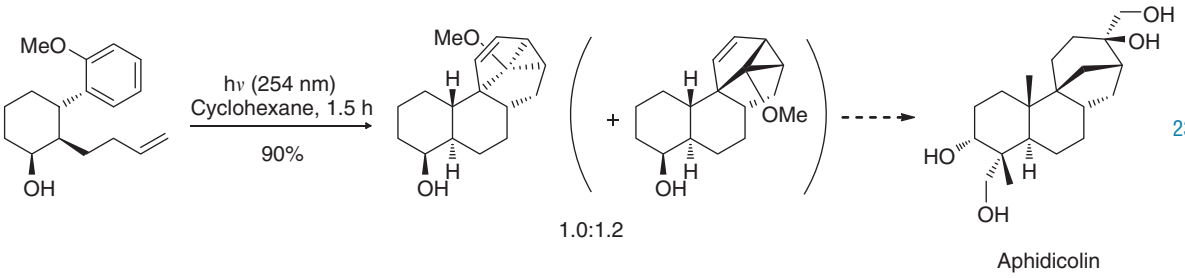






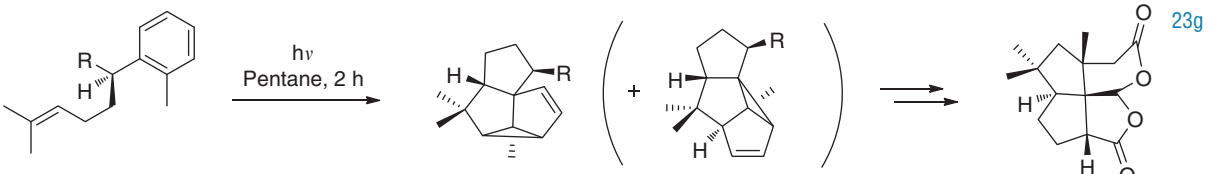






48

(17)



A mechansitically interesting [3 + 2] cycloaddition reaction of 2-(1-alkynyl)cyclohexenones with alkenes was reported to give tricyclic furans in good yield. The reaction was thought to proceed through the photochemically generated diradical intermediate **50**, which undergoes a 5-*exo* cyclization to give the carbene intermediate **51**. Finally, this species undergoes cyclization with the carbonyl group to give the furan derivative **52**. Although the scope of the reaction was quite restricted, a unique transformation was realized (Scheme 14).[25]

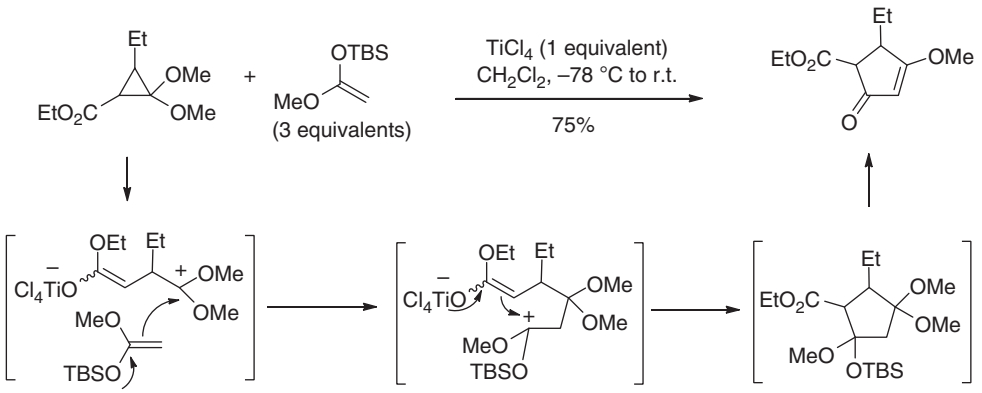
5.08.3 Lewis Acid or Lewis Base-Catalyzed [3 + 2] Cycloaddition Reactions

5.08.3.1 Donor/Acceptor-Substituted Cyclopropanes

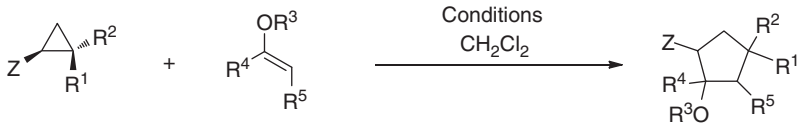


When the first edition of this book was published, Lewis acid-mediated [3 + 2] cycloaddition reactions of cyclopropyl carbonyl compounds without heteroatom substituents on the ring had already been reported.[26] However, the use of cyclopropanes

substituted with both electron-donating and EWGs on neighboring positions, which facilitate the generation of 1,3-dipoles on treatment with Lewis acids, had been limited to rearrangement and ring-opening reactions.[1d] The utilization of donor/acceptor-substituted cyclopropanes as a three-carbon unit in [3 + 2] cycloaddition reactions with electron-rich 2π components has been studied extensively since that time, and representative new results will be described according to the chosen types of substrates (Scheme 15).[27]

Scheme 15

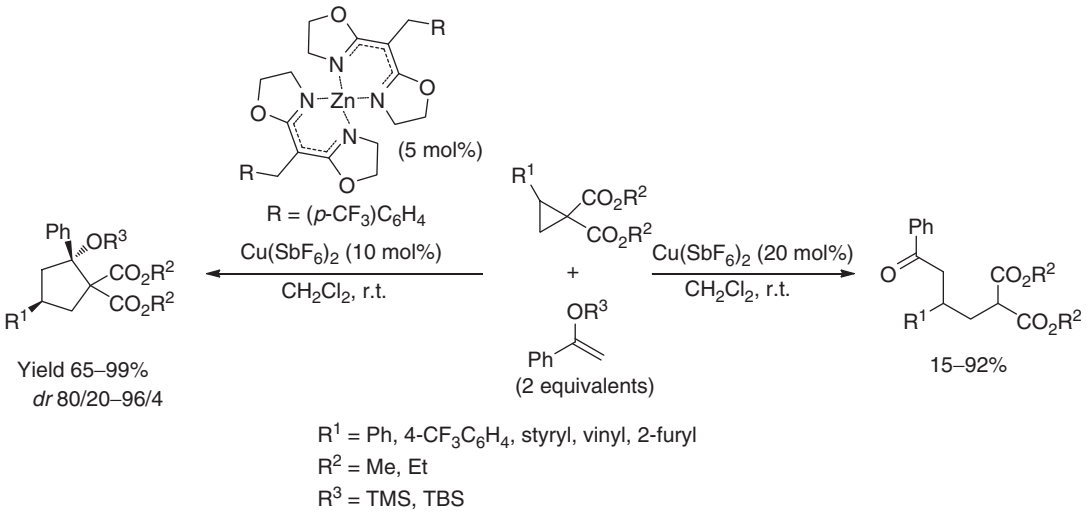
As an early example, the reaction of 2,2-dialkoxycyclopropane carboxylates with ketene silyl acetals was found to proceed smoothly in the presence of a stoichiometric amount of $TiCl_4$ to give cyclopentenone derivatives in good yields. The reaction was sensitive to steric hindrance, and the use of 3,3-disubstituted cyclopropane or disubstituted ketene silyl acetal lowered the yields of the products considerably. The reaction was thought to proceed as follows: Treatment of 2,2-dialkoxycyclopropanecarboxylate with $TiCl_4$ generates a ring-opened zwitterionic intermediate via a retro-aldol type reaction, which was observed by ^1H nuclear magnetic resonance; the ketene silyl acetal then attacks the cationic center, followed by a Dieckmann-type condensation to give a cyclopentanone intermediate. Elimination of alcohol provides the final product (Scheme 16).[28]



Scheme 16

In a similar manner, the reaction of 2-alkoxycyclopropane carboxylates with silyl enol ethers using a stoichiometric amount of $SnCl_4$ afforded highly functionalized cyclopentanes in good yield as a mixture of stereoisomers. Similar reactions of 2-methoxycyclopropyl methyl ketone with silyl enol ethers proceeded even with 3 mol% of $SnCl_4$.[29a] A higher diastereoselectivity was observed for the reaction of 2-phenylthiocyclopropyl methyl ketone with *t*-butyldiphenylsilyl (TBDPS)-enol ethers in the presence of Me_2AlCl as a Lewis acid.[29b] Triflic imide (Tf_2NH) was found to be an active catalyst for this type of reaction. Even 1–2 mol% of the catalyst was sufficient to promote the reaction of 2-butoxycyclopropanecarboxylate or 2-(*p*-methoxyphenyl)cyclopropyl phenyl ketone with various silyl enol ethers even at $-78\ ^\circ C$ (Table 7).[30]

In the reaction of 2-arylcyclopropane-1,1-dicarboxylates with silyl enol ethers, [3 + 2] cycloadducts or the derived ring-opening products were obtained selectively by choosing appropriate reaction conditions or additives. For example, in the $Cu(SbF_6)_2^-$catalyzed reaction, addition of a bisoxazoline–Zn(II) complex gave the [3 + 2] cycloaddition products selectively with high diastereoselectivity, whereas without this additive, further ring opening occurred to give 1,6-dicarbonyl compounds selectively (Scheme 17).[31]



Indoles are also useful partners for this type of reaction as a 2π-component to give synthetically useful cyclopenta[*b*]indoles. $Yb(OTf)_3$-catalyzed reactions of 3-alkylindoles with 1,1-cyclopropane diesters were performed in CH_3CN at room temperature to elevated temperatures or under high pressure, depending on the kind of substituent on the cyclopropane (equation 18).[32a,b] The reaction of 2-arylcyclopropyl ketones and diesters with various indoles in the presence of $BF_3 \cdot OEt_2$ proceeded with perfect diastereoselectivity in most cases to give the products as a single stereoisomer (equation 19).[32c] Highly diastereoselective annulation reaction between indoles and 2-alkoxycyclopropane carboxylates have also been reported using TMSOTf as a Lewis acid. In these cases, a single stereocenter on the cyclopropane allowed the diastereoselective formation of up to four new stereogenic centers to be controlled (equation 20).[32d]

(20)

Silyl ynol ethers were also employable as an electron-rich 2π unit to give cyclopentenone derivatives. Treatment of 2-ethoxycyclopropane carboxylates with silyl ynol ethers in the presence of a stoichiometric amount of Me_2AlCl pretreated with air gave cyclopentenone derivatives in good yield after acid treatment (Table 8). It was postulated that the active catalyst for this reaction was (MeO)AlMeCl, which has sufficient Lewis acidity to promote the reaction but does not decompose the silyl ynol ether.[33a]

Simple aryl alkynes could also be employed as 2π unit in the intramolecular reaction. Cyclopropane dicarboxylates tethered with aryl alkynes through an aromatic ring underwent intramolecular [3 + 2] cycloadditions in the presence of 10 mol% of $Sc(OTf)_3$ to realize an efficient synthesis of cyclopenta[c]chromene skeletons (equation 21).[33b]

(21)

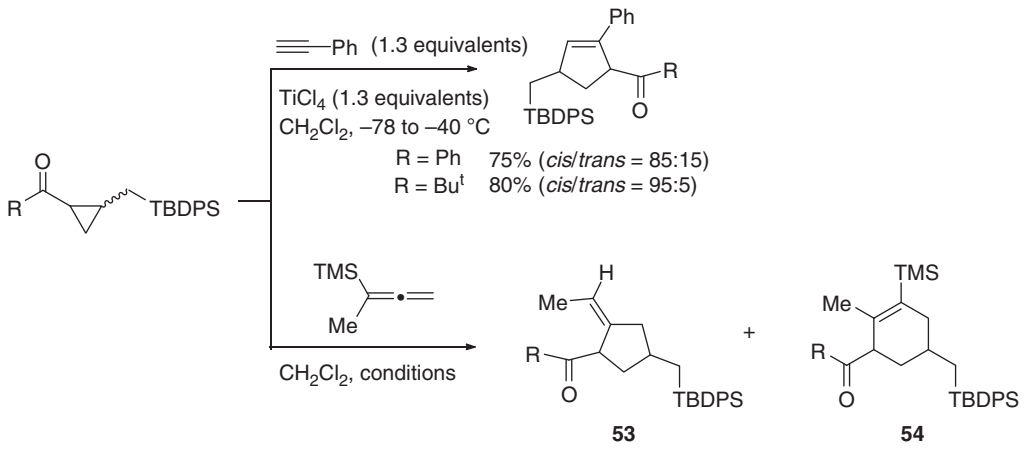
R^3 = Me, Et; Ar = Ph, 4-$MeOC_6H_4$, 3-MeC_6H_4, 2-$MeOC_6H_4$

Methylenecyclopropyl ketones were also used to generate allylcationic intermediates on treatment with $TiCl_4$. The resulting 1,3-dipoles underwent [3 + 2] cycloaddition with allylsilane as a two-carbon unit to give methylenecyclopentane derivatives. Regioisomeric products were obtained depending on the substituents on the cyclopropane (equation 22).[34]



(22)

2-TBDPS-methyl-substituted cyclopropyl ketones were also employed as 1,3-dipole precursors. On treatment with arylacetylenes in the presence of $TiCl_4$, cyclopentenylketones were obtained in good yields as a mixture of *cis* and *trans*-isomers. The intramolecular variant of the reaction also proceeded without problem to give the corresponding products stereoselectively (equation 23).[35a] Allenylsilanes also reacted as a 2π unit in the presence of $TiCl_4$ (− 78 to − 40 °C) or Et_2AlCl (r.t.) to give [3 + 2] or [3 + 3] cycloaddition products, depending on the kind of substrates and the chosen conditions. In most cases, $TiCl_4$ favored methylenecyclopentane formation, whereas Et_2AlCl favored cyclohexene formation (Table 9).[35b]

Recently, cyclopropane dicarboxylates with a phthalimide group at the 2-position of the cyclopropane were found to react with silyl enol ethers or vinyl ethers on treatment with 5 mol% of $SnCl_4$. The choice of the phthalimide group as a nitrogen donor was essential for the success of the reaction. The transformation showed wide generality to give variously substituted cyclopentylamines in good yields with high diastereoselectivity (Table 10). The most unique feature is that the use of optically active cyclopropane dicarboxylates gives substituted cyclopentylamines without loss of optical purity (Scheme 18).[36]

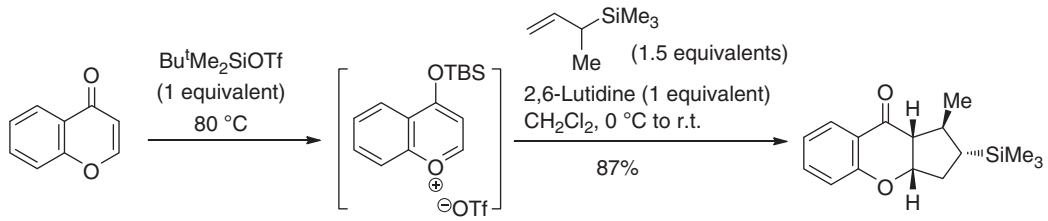
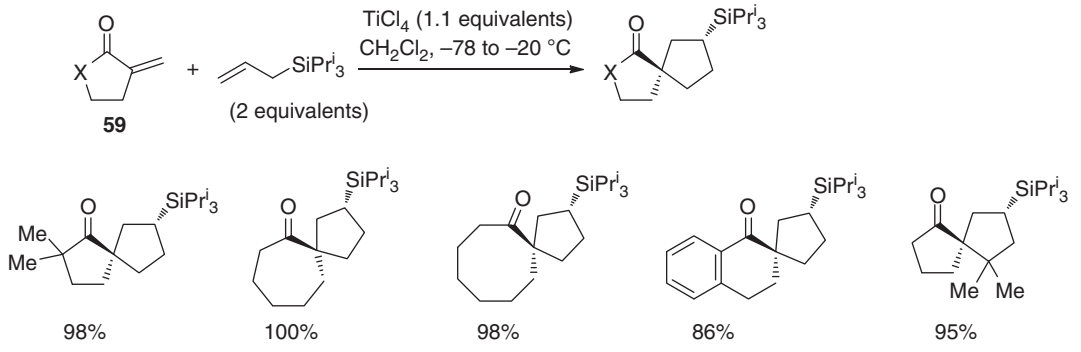
5.08.3.2 Allylsilanes

The reaction of allyl- or allenylmetallic species with α,β-unsaturated carbonyl compounds with 1,2-migration of the metallic moiety to give cyclopentyl- or cyclopentenyl-metallic derivatives as formal [3 + 2] cycloaddition products had been studied since 1970s and the major investigations were described in the first edition of this book (*see* Chapter 3.2).[1b] Early studies include the reaction of allyliron, allyltungsten, and several other allylmetallic species, but applications had been limited until the Lewis acid-promoted reaction of allenylsilanes with α,β-unsaturated carbonyl compounds was reported.[1b,37] The use of allylsilanes as a three-carbon unit for [3 + 2] cycloadditions was discovered by careful analysis of the side products of the Hosomi–Sakurai reaction, and has been extended since then to a useful cyclopentane annulation process, which is mainly summarized in this section.



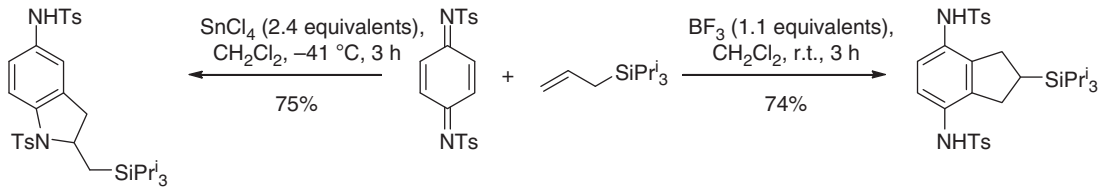
Allylsilanes have been employed as a very useful reagent for the Lewis acid-catalyzed allylation of carbonyl and related compounds (the Hosomi–Sakurai reaction) and extensive investigations have been carried out on this chemistry. During these studies, it was found that (trimethylsilyl)cyclopentanes, formal [3 + 2] cycloadducts, were obtained as side products of the Hosomi–Sakurai reaction when α,β-unsaturated carbonyl compounds were used as the electrophile. Actually the formation of such side products was noted in earlier papers but they were assigned to be cyclobutane derivatives. By careful analysis, the structure was revised to the cyclopentane derivatives. The mechanism of the reaction is as follows: Nucleophilic 1,4-addition of allylsilanes to enones activated by Lewis acid provides zwitterionic intermediate such as **55**, in which the generated carbocation is stabilized by the presence of the silicon atom in the β-position. This cation is in equilibrium with the silacyclopropane intermediate **56** (or 1,2-silicon-migrated carbocation), which is attacked by the enolate so as to make the five-membered ring product.

The ratio of the Hosomi–Sakurai product and the [3 + 2] cycloaddition product strongly depends on the steric hindrance at the silicon atom. For example, the $TiCl_4$-promoted reaction of 1-acetylcyclohexene with allyltrimethylsilane in CH_2Cl_2 at $-20\,^{\circ}C$ gave a simple allylation product **58** and the cyclopentane product **57** in 76 and 18% yield, respectively, whereas the same reaction using allyltriisopropylsilane gave the two products in 2 and 86% yield, respectively (Scheme 19).[38]



Scheme 19

Nearly at the same time, the reaction of chromone derivatives with 3-butenylsilane was reported to give the corresponding [3 + 2] cycloaddition products stereoselectively (equation 24).[39]



(24)

The reaction showed wide generality, and various kinds of α,β-unsaturated carbonyl compounds can be used. For example, 2-alkylidenecycloalkan-1-ones **59** gave spirocyclic ring compounds in high yields (Scheme 20),[40a] and quinones and quinone diimines gave the corresponding [3 + 2] cycloaddition products by choosing appropriate reaction conditions (Scheme 21).[40b,c] Even simple dienes could be employed as a 2π-component by carrying out the reaction with allyltrimethylsilane using $AlCl_3$ as a promoter in the presence of TMSCl (Table 11).[40d] Cyclic allylsilanes gave bicyclo[n.2.1] systems with high diastereoselectivity (equation 26).[40e]

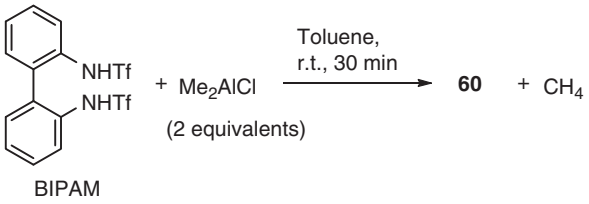
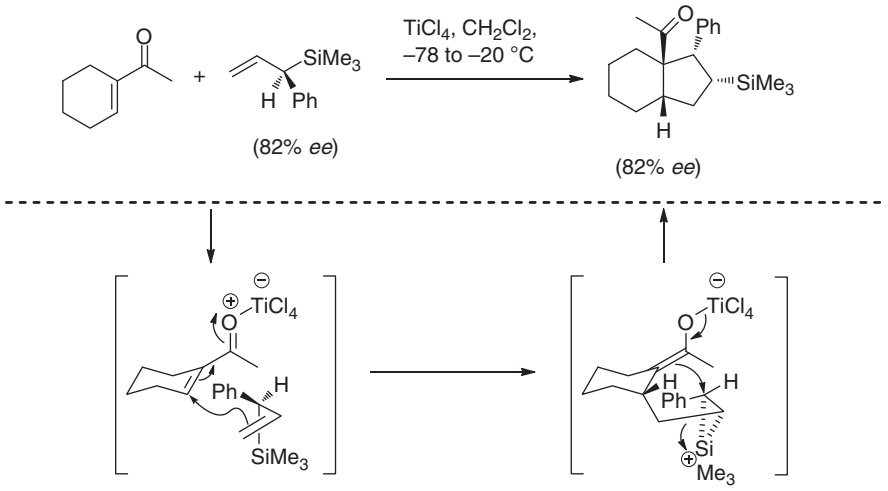
The intramolecular version of the reaction was reported to give bicyclic lactones by using the novel bidentate aluminum Lewis acid **60**. Treatment of 3-(dimethylphenylsilyl)-4-pentenyl alkenoates with a stoichiometric amount of the aluminum reagent prepared from 1.1′-biphenyl-2,2′-di(triflyl)amide (BIPAM) and Me_2AlCl (2 equivalents) in toluene gave the intramolecular [3 + 2] cycloaddition products diastereoselectively in good yields (Table 12).[41]

By using optically active allylsilanes, enantiospecific syntheses of cyclopentane derivatives were achieved. The reactions proceeded with almost perfect chirality transfer to give the corresponding products with high diastereoselectivity (Scheme 22).[42]



In addition to allylsilanes, propargylsilanes containing an alkyl substituent at the silicon-bearing carbon also participated in the $TiCl_4$-mediated [3 + 2] cycloaddition with electron-deficient alkenes when the reaction was carried out in CH_2Cl_2 at −78 °C. In general, however, the diastereoselectivity of the products was low (Table 13).[43]



In order to utilize the remaining silicon group on the cyclopentane ring for further functionalization, the reactions of allyldimethyltritylsilane,[44a,b] allyl(*t*-butyl)diphenylsilane,[44c] allyldiisopropylphenylsilane,[44d] and allylbenzhydryldimethylsilane[44e] were developed. These allylsilanes are not only bulky but also easily convertible into the hydroxy group by Tamao oxidation, thus providing synthetically useful cyclopentanol derivatives. One application of such a reagent in the total synthesis of the triquinane sesquiterpene *β*-isocomene is shown in Scheme 23.

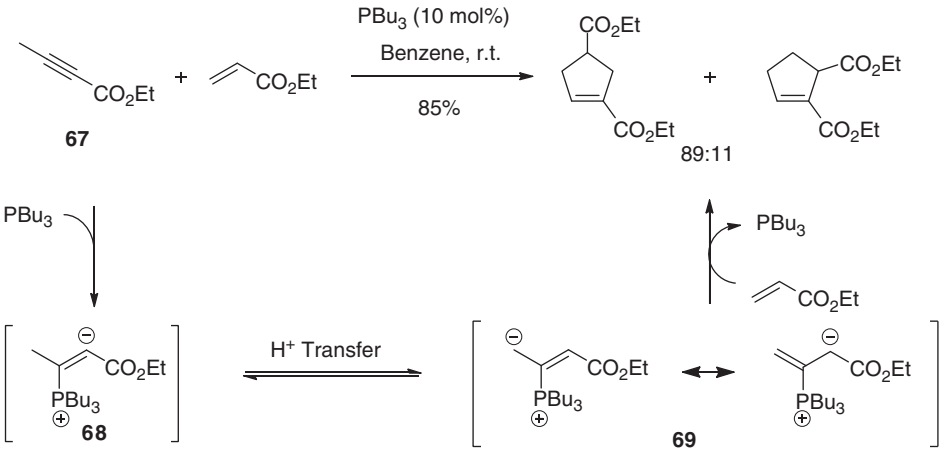
5.08.3.3 Lu Reaction

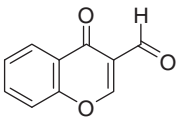
In 1995, the first example of a phosphine-promoted reaction of allenoates with electron-deficient alkenes, now known as the Lu reaction, was reported.[45a] This reaction attracted much attention because of its simplicity, the easy availability of the starting materials, and the utility of the products. Not only electron-deficient alkenes but also aldehydes and imines have been utilized as the 2π component. Triphenylphosphine has been employed in most cases, but tributylphophine has also found some applications. In particular, the development of asymmetric versions of this reaction has recently been extensively studied, with the focus on the design of new chiral phosphines as organocatalysts. In this section, these reactions will be summarized with an emphasis on the scope of the reaction and applications to asymmetric catalysis.[46]

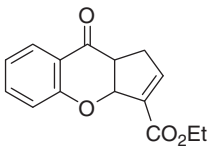


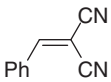
Treatment of ethyl 2,3-butadienoate **61** with ethyl acrylate in the presence of 10 mol% of PPh_3 in benzene at room temperature gave a regioisomeric mixture of the cyclopentenedicarboxylates **62** and **63**, formal [3 + 2] cycloaddition products, in good yield.[45a] The reaction was proposed to proceed as follows: The phosphine attacks the allenoate in a 1,4-manner to generate the zwitterionic enolate intermediate **64**. This species then undergoes a [3 + 2] cycloaddition with the electron-deficient alkene to give cyclopentyl ylides **65** and **66**, which undergo proton transfer followed by elimination of the phosphine to give the products (Scheme 24). The reaction with diethyl fumarate and maleate gave *trans* and *cis* cyclopentenetricarboxylate, respectively, suggesting a concerted nature of the [3 + 2] cycloaddition, although later theoretical analyses by several research groups strongly suggested a stepwise pathway. It should also be noted that the mechanistic analysis suggested that a water molecule plays an important role in this reaction.[47]

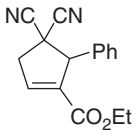
Scheme 24

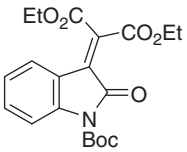
The reaction of 2-butynoate **67** with electron-deficient alkenes catalyzed by tributylphophine also proceeded in a similar manner. The same zwitterionic species **69** was generated by proton transfer from the primary addition intermediate **68** (Scheme 25).[45]

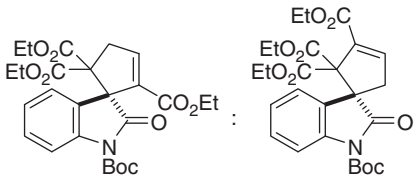


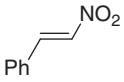


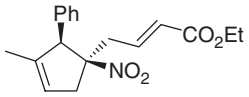


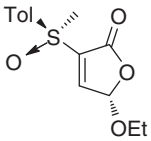


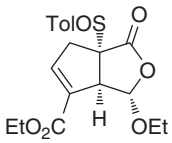


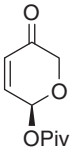


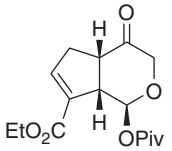












One drawback of the reaction is the regioselectivity concerning the acceptor alkene. Highly electron-deficient alkenes such as 3-formylchromones,[48a] arylidenemalononitriles,[48b] isatine-derived α,β-unsaturated diesters,[48c] nitroalkenes,[48d] and cyclic alkenes[48e,f] gave the corresponding [3 + 2] cycloaddition products regioselectively, whereas β-unsubstituted alkenes such as acrylates and *exo*-methylene ketones often afford mixtures (Table 14).

Scheme 25

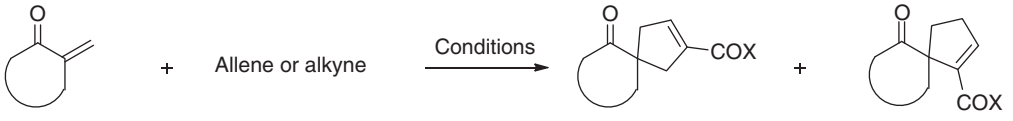


Table 14 Regioselective [3 + 2] cycloadditions of ethyl 2,3-butadienoate with acceptor alkenes

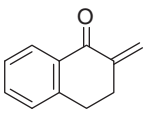
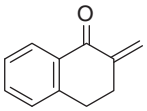
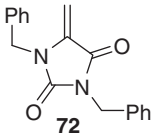
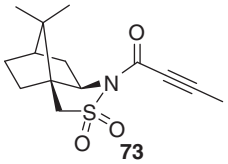
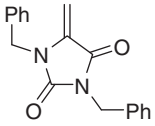
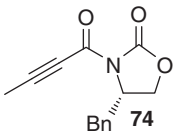












Acceptor alkene	*Conditions*	*Product(s)*	*Yield (%)*	*References*
	PPh_3 (14 mol%) benzene, reflux, 80 h		74	48a
	PPh_3 (9 mol%) toluene, 15 °C		89	48b
	PBu_3 (20 mol%) toluene, r.t., 2 h	 13 : 1	86	48c
	$P(p\text{-}FC_6H_4)_3$ (20 mol%) toluene, 60 °C, 12 h	 *cis/trans* = 3.9 : 1	90	48d
	PPh_3 (30 mol%) benzene, r.t., 3 h		96	48e
	PPh_3 (10 mol%) toluene, 110 °C, 30 min		63	48f

In the reaction with *exo*-methylene ketones, the use of *t*-butyl 2,3-butadienoate instead of the ethyl ester gave higher selectivity in favor of **70**. Furthermore, when *t*-butyl 2-butynoate was used in the tributylphophine-catalyzed reaction, the regioselecitivty was improved in some cases, although the reason is not obvious.[49a,b] Such an influence of the components on the regioselectivity was more pronounced in the reaction of methylenehydantoins **72** with various 2-butynoate derivatives. Camphor sultam **73** gave **70** selectively, whereas the oxazolidinone derivative **74** gave **71** as a major product. The electrostatic interaction was thought to play an important role in determining the regioselectivity (**Table 15**).[49c]

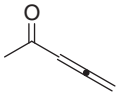
Table 15 Regioselective [3 + 2] cycloadditions with *exo*-methylene carbonyl compounds

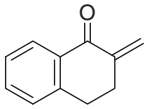
70 **71**

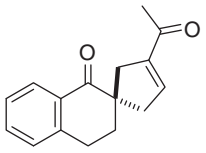
Exo-methylenen carbonyl	*Allene or alkyne*	*Conditions*	*Yield (%) (ratio = **70:71**)*	*References*
		PPh_3 (10 mol%) toluene, r.t., 11 h	93 (79:21)	49a
		PPh_3 (10 mol%) benzene, reflux, 18 h	98 (91:9)	49a
 **72**	 **73**	PBu_3 (10 mol%) benzene, r.t.	74 (100:0)	49c
	 **74**	PBu_3 (10 mol%) benzene, r.t.	54 (11:89)	49c

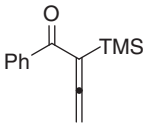
As the electron-deficient allene partners, allenyl ketones,[50a,b] allenylphosphonates,[50c] 3-butynoate,[50d] and allenylsulfones[50e] could also be employed, although the reaction with allenylsulfones was found to proceed through a somewhat different mechanism (**Table 16**).

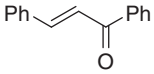
The intramolecular version of this phosphine-catalyzed reaction of electron-deficient 1,7-enynes was found to proceed efficiently to give bicyclo[3.3.0] ring systems diastereoselectively by heating the substrates with 10 mol% of PBu_3 in ethyl acetate at 110 °C.[51a] This reaction was successfully applied to the total synthesis of hirsutene (**Scheme 26**).[51b] A very efficient synthesis of cyclopentene-fused dihydrocoumarins **77** from cinnamyl allenoates **76**, that are easily prepared from salicylaldehyde derivatives **75**, was also achieved (**Scheme 27**).[51c]

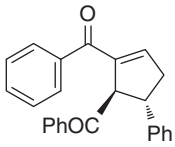


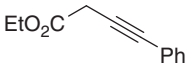


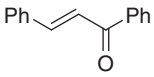


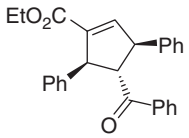


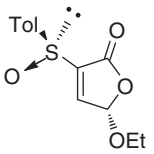


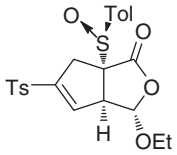




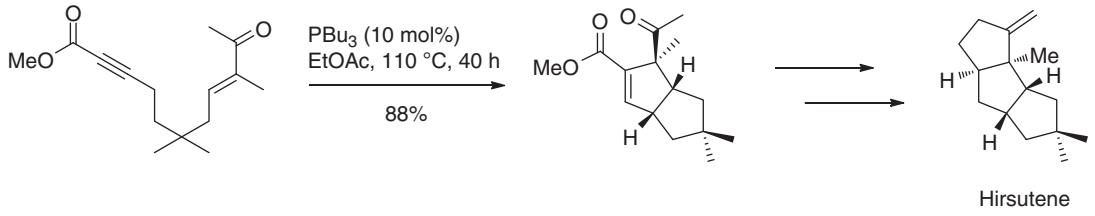








Soon after Lu's original work had been published, the first successful example of the asymmetric version of this reaction was reported. By using the chiral 7-phosphabicyclo[2.2.1]heptane derivatives **78**, which were prepared from 1,4-disubstituted benzenes in a multistep sequence, cyclopentene carboxylate was obtained regioselectively in good yield with up to 93% *ee* on reaction of 2,3-butadienoate with acrylate in the presence of 10 mol% of the phosphine (**Scheme 28**).[52a]



Nearly 10 years passed until the second example of this type of reaction was reported using the binaphthyl type phosphine **79**. By using this phosphine, the reaction of 2,3-butadienoate with chalcone and related α,β-unsaturated ketones proceeded to give functionalized cyclopentene derivatives in nearly 90% *ee*. It should be noted that the regiochemical outcome of this reaction using β-substituted enones was opposite to the reaction with β-unsubstituted α,β-unsaturated carbonyl compounds.[52b] Thereafter, several research groups reported unique chiral phosphine catalysts, which realized good to high enantioselectivity in this reaction. Representative examples are summarized in **Table 17**.[52c–j]

Another type of phosphine-catalyzed formal [3 + 2] cycloaddition reaction of allylic bromides or acetates having an ethoxycarbonyl group at the central carbon with electron-deficient alkenes was reported. The reaction was carried out with 10 mol% PPh_3 and a stoichiometric amount of K_2CO_3 in toluene at 110 °C; slow addition of the reactants to the toluene solution

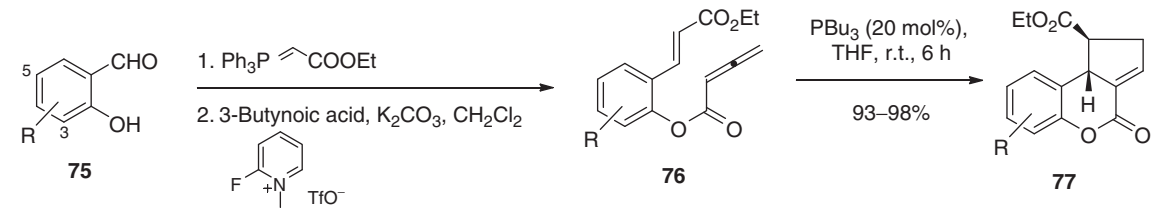


Table 16 Phosphine-catalyzed [3 + 2] cycloaddition with electron-deficient allenes

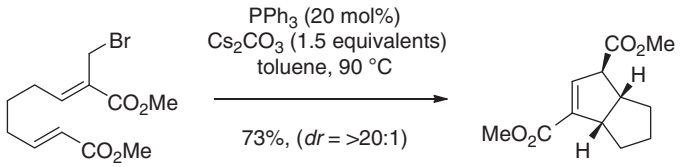
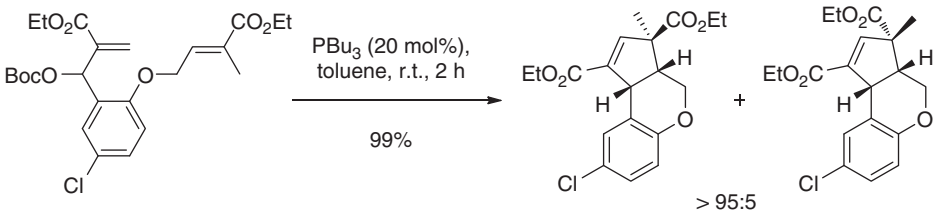


Scheme 27

containing the phophine and K_2CO_3 improved the yield. The reaction was thought to proceed through the phosphonium salts **80** generated by an S_N2 or addition/elimination reaction of PPh_3 to the allylic bromides or acetates. The salts are then deprotonated by the base to afford ylides **81**, which undergo nucleophilic addition to electron-deficient alkenes to yield zwitterionic intermediates **82**. Subsequent cyclization by intramolecular conjugate addition provides betain-like intermediates **83**, which finally undergo elimination of the phosphine to complete the catalytic cycle. By using allylic *t*-butylcarbonate as the substrate, the reaction proceeded without the necessity of adding a base (Scheme 29).[53a]



Scheme 28

An intramolecular variant was developed for the diastereoselective synthesis of bicyclo[n.3.0] compounds, and an asymmetric version was also reported using a chiral phosphine catalyst (equations 28 and 29).[53b]

(28)

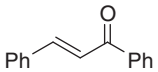
(29)

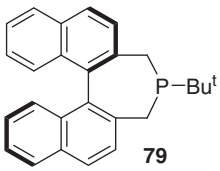
The use of easily available Morita–Baylis–Hillman carbonates instead of the corresponding bromides has expanded the utility of this reaction. It is not necessary to add bases, as *t*-butoxide is generated during the reaction. Various applications to the preparation of synthetically useful cyclopentene derivatives, including enantioselective reactions, have been realized (Table 18).[54]

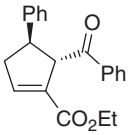
5.08.3.4 Other Acid or Base-Promoted Reactions

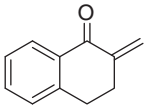
This section briefly describes other types of acid or base-promoted reactions of high utility.

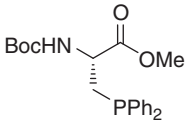
3-Acetoxy-1-(methylthio)-2-(triisopropylsiloxy)-1-propene **84** reacts with various electron-rich alkenes such as enol ethers or vinyl sulfides to afford the corresponding cyclopentanones in good yield, when the reaction is performed in the presence of a stoichiometric amount of $EtAlCl_2$. The reaction of 1-acetoxy-3-(methylthio)-2-(triisopropylsiloxy)-2-butene with vinyl sulfides proceeded with high stereoselectivity and was applied to the total synthesis of (–)-coriolin (Table 19, Scheme 30).[55]

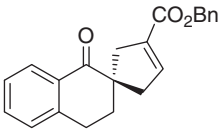


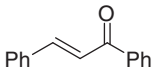


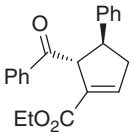


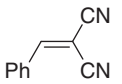


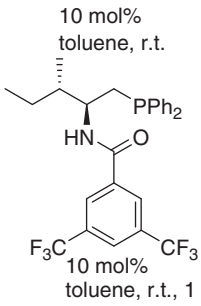


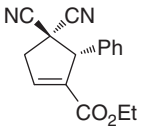


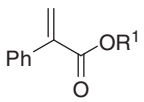


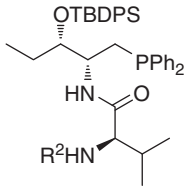


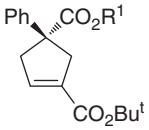


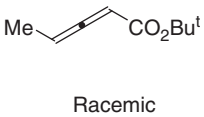


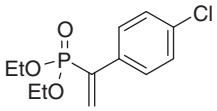


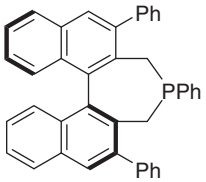


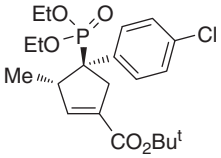








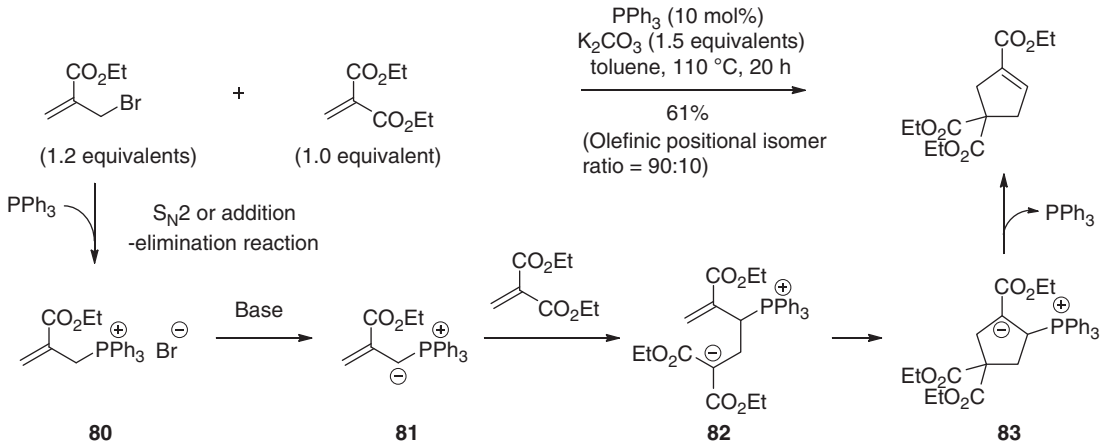




Domino Mukaiyama-aldol reactions of 1,3-bis(trimethylsiloxy)-1,3-dienes **85** with enolizable 1,2-diketones gave substituted cyclopentenones regioselectively. The reaction proceeded smoothly at $-78\ ^{\circ}C$ to room temperature by using 2 equivalents of $TiCl_4$ and showed reasonable generality (Scheme 31).[56]

A unique [3 + 2] cycloaddition of silyl enol ethers with terminal alkynes to give cyclopentenones was realized by using a combination of $SnCl_4$ and Et_3N followed by 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) treatment. It was proposed that $SnCl_4$ and Et_3N promote the addition of silyl enol ethers to the internal carbon of the terminal alkynes to give γ-stannyl α,β-unsaturated ketone intermediates **86**, which undergo intramolecular cyclization by the action of DBU, whereby $SnCl_3$ serves as a leaving group liberating a Sn(II) species (Scheme 32).[57]

Several nucleophilic addition reactions of 1,3-dipole equivalents to electron-deficient alkenes followed by ring-closure were reported. For example, the lithiated 2-(bromomethyl)allyl sulfone **87** reacted with nitroolefins, 2-(phenylsulfonyl)enones, and α,β-unsaturated esters and ketones to give the corresponding methylenecyclopentane derivatives.[58a,b] In particular, the reaction with α,β-unsaturated esters proceeded in good yields with high diastereoselectivity (Table 20).[58c,d]



Addition of nucleophiles to an allenylsulfone or 2,3-bis(phenylsulfonyl)-1,3-butadiene generates 1,3-dipole equivalents, which react with electron-deficient alkenes in a 1,4-addition manner followed by intramolecular addition of the generated anionic species to the vinylsulfone moiety. By using malonates containing an electron-deficient alkene, bicyclic products were obtained in

Table 17 Chiral phosphine-catalyzed enantioselective [3 + 2] cycloaddition

 Racemic		 10 mol% Pr^i_2O. r.t.		82, 99	52j

good yield. It should be noted that this reaction proceeded stereospecifically concerning the alkene geometry, as observed in examples **c** and **d** shown in Scheme 33.[59]

Several anionic methods have also been reported.[60e] For example, β-heteroatom-substituted α,β-unsaturated acylsilanes reacted with ketone lithium enolates to give functionalized cyclopentenol derivatives. The reaction proceeds through 1,2-addtion of the enolates to the carbonyl group of the acylsilanes, followed by a Brook rearrangement to give allyl anionic species containing a ketone carbonyl, which cyclizes to give the products. The use of β-silyl or β-thio-substituted α,β-unsaturated acylsilanes was

Scheme 29

essential for the success of the reaction, as crotonoyl derivative gave cyclopropanol derivatives instead (Scheme 34). The reaction was applied to the synthesis of some natural products.[60]

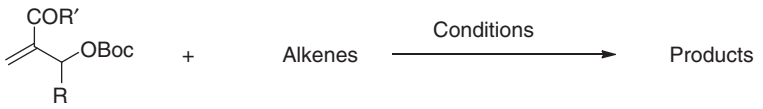
5.08.4 Transition Metal Mediated or Catalyzed Reactions

5.08.4.1 Fischer Carbene Chemistry

Use of α,β-unsaturated Fischer carbene complexes of group 6 metals as a three-carbon unit in the reaction with various alkenes or alkynes has been studied, and several different types of [3 + 2] cycloaddition reactions have been developed, most of which include 1-metalla-1,3,5-trienes as intermediates.[61] These reactions employ preformed carbene complexes and thus are stoichiometric. Therefore, although the reactivity of the carbene complexes is unique, applications to synthetic purposes are rather limited. At the end of this section, recently developed new approaches toward the catalytic generation of α,β-unsaturated carbene complexes for [3 + 2] cycloaddition reactions will be described.

The reaction of {[2-(dialkylamino)alkenyl]ethoxycarbene}chromium complexes **88** with alkynes afforded 5-dialkylamino-3-ethoxycyclopentadiene derivatives **89** in good yield, that are a kind of [3 + 2] cycloadducts. When performed in acetonitrile or pyridine as a donor solvent, the reaction was found to be applicable to various (2-aminoalkenyl)carbene complexes. When terminal alkynes were employed, the regioselectivity was approximately 10:1, favoring the isomer containing the alkyne substituent neighboring the amino group. The ethoxycyclopentadiene products were easily hydrolyzed to cyclopentenone derivatives under acidic conditions. The reaction was thought to proceed as follows: In analogy with the Dötz reaction, a metathesis process occurred between the alkyne and the carbene moiety to give a dienylcarbene complex **90**, which undergoes 6π electrocyclization followed by reductive elimination of the cyclopentadiene product. The CO insertion observed in the Dötz reaction was suppressed probably by coordination of the solvent molecule to chromium (Scheme 35).[62a–d]

By applying this methodology, an angular triquinane was synthesized with an overall yield of 22% from (+)-2-carene (Scheme 36).[62e,f]



An interesting application concerns the synthesis of indanone derivatives by the reaction of the carbene complexes with 1,5-diene-3-ynes. In this case, dialkenylcyclopentadienes **91** were produced as the initial [3 + 2] cycloaddition products, which further underwent 6π-electrocyclization followed by elimination of the amine to give the products (Scheme 37).[62g,h]

Formal [3 + 2] cycloaddition reactions of alkenylcarbene complexes with ynamines or of alkynylcarbene complexes with enamines have also been developed for the preparation of cyclopentadienes. For example, the reaction of an α,β-unsaturated tungsten carbene complex with an ynamine gave 1-tungsta-1,3,5-hexatriene, which underwent a smooth ring-closure at 20 °C to give a cyclopentadiene product (Scheme 38).[63a,b]

The reaction of alkynylcarbene complexes with enamines was more general and highly regioselective and proceeded at room temperature simply by mixing the two compounds. In both reactions, 1-metalla-1,3,5-hexatrienes are formed as key intermediates, the former through the metathesis reaction via a metallacyclobutene intermediate, and the latter through the 1,4-addition of the enamine to the alkynylcarbene complexes followed by 1,3-proton transfer. Final electrocyclization followed by reductive elimination gives the corresponding cyclopentadiene derivatives (Table 21, Scheme 39).[63c]

A related reaction of α,β-unsaturated tungsten carbene complexes with enamines gave cyclopentenyl ethers in good yield with high diastereoselectivity. The regioselectivity can be reversed depending on the chosen kind of enamines. Enamines derived from ketones afforded 4-amino cyclopentenyl ethers **92**, whereas enamines derived from aldehydes afforded 5-amino derivatives **93** with high regioselectivity. Use of chiral pyrrolidino enamines gave optically active products with high selectivity (Scheme 40).

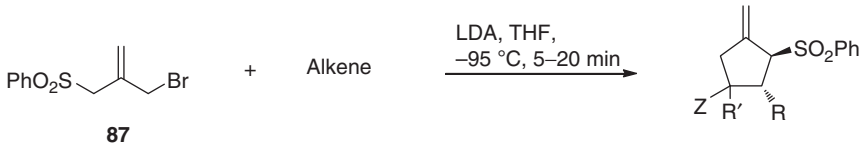
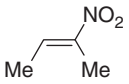
Scheme 30

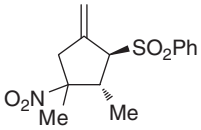
Scheme 31

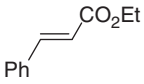
Scheme 32

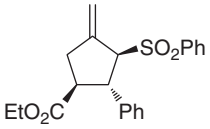


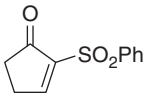
The reaction was proposed to proceed through 1,2-addition (ketone enamines) or 1,4-addition (aldehyde enamines) followed by cyclization with $W(CO)_5$ elimination.[63d]

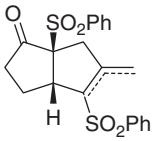


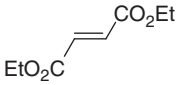


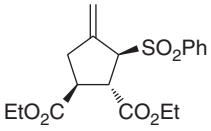


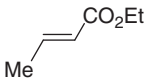


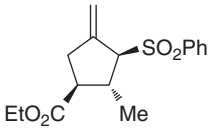


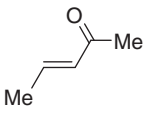


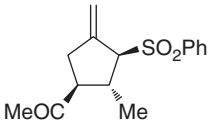


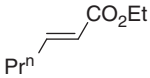


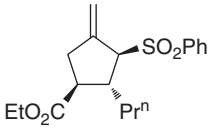


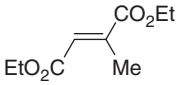


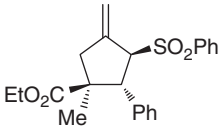












The reaction of α,β-unsaturated carbene complexes with dienes was first realized by using a donor/acceptor-substituted diene in 1,2-dichloroethane (DCE) at 80 °C. It was reported that among several dienes examined, only this diene gave the [3 + 2] cycloaddition product.[64a] Simple dienes were also found to undergo [3 + 2] cycloadditions by choosing appropriate reaction conditions. In these reactions, the choice of the solvent was crucial for the success; by carrying out the reaction in toluene at 80 °C in the presence of 2,6-di-*t*-butyl-4-hydroxytoluene (BHT), cyclopentenyl ethers were obtained in good yield, whereas the reaction in THF at 120 °C in a sealed flask gave [4 + 1] cycloaddition products selectively in moderate yield. Tungsten carbene complex gave higher yields when polysubstituted dienes were employed. An asymmetric version was also presented using menthyloxy carbene complexes. A metalla-Diels–Alder reaction pathway to give metallacyclohexenes followed by reductive elimination was proposed as a possible reaction mechanism (Table 22).[64b]

Reactions of lithium enolates of methyl ketones with α,β-disubstituted alkenyl(methoxy)carbene complexes **96** afforded cyclopentenol derivatives **97** in good yields. Depending on the chosen solvent (Et_2O or THF; or use of pentamethyldiethylenetriamine (PMDTA) as cosolvent), either of two diastereoisomers could be obtained with high selectivity. The reaction proceeded through addition of lithium enolates to the carbene carbon, followed by addition of the generated allyltungsten to the ketone carbonyl with 1,2-$W(CO)_5$ migration. Finally $W(CO)_5$ was eliminated to give the products (Scheme 41).[65]

Additions of alkenyllithiums to alkynyl(methoxy)carbene complexes afforded cyclopentenone derivatives in good yield. The reaction proceeds through 1,4-addition of the alkenyllithiums, followed by protonation to generate $\alpha,\beta,\gamma,\delta$-unsaturated carbene complex intermediates, which undergo cyclization to give cyclopentadienyl ethers. Hydrolysis of the dienyl ethers gave the products. Use of a tungsten carbene complex with a chiral alkoxy group gave optically active products with high selectivity (Scheme 42).[66]

[c]A mixture of diastereo and olefinic positional isomers in a ratio of 9:9:1.

Metal-promoted or -catalyzed reactions of carbene complexes with carbon–carbon double or triple bonds were also reported. A rhodium-catalyzed formal [3 + 2] cycloaddition of α,β-unsaturated chromium carbene complexes with electron-deficient alkynes was developed to give a variety of cyclopentenone derivatives. The reaction was carried out by mixing the chromium carbene complexes and alkynes in the presence of 10 mol% of a cationic Rh(I) complex, and was proposed to proceed through the rhodium carbene complexes generated by transmetallation. The [4 + 2] cycloaddition of the rhodium carbene species with alkynes followed by reductive elimination and hydrolysis gave the cyclopentenone products. The formation of the rhodium carbene complexes was confirmed by X-ray analysis (**Scheme 43**).[67a,b]

Furthermore, the generality of the reaction was greatly expanded by using a stoichiometric amount of $Ni(cod)_2$. In this case, both electron-rich and -deficient alkynes could be employed to give cyclopentenone or cyclopentadiene derivatives in reasonable yield (equation 30).[67c]

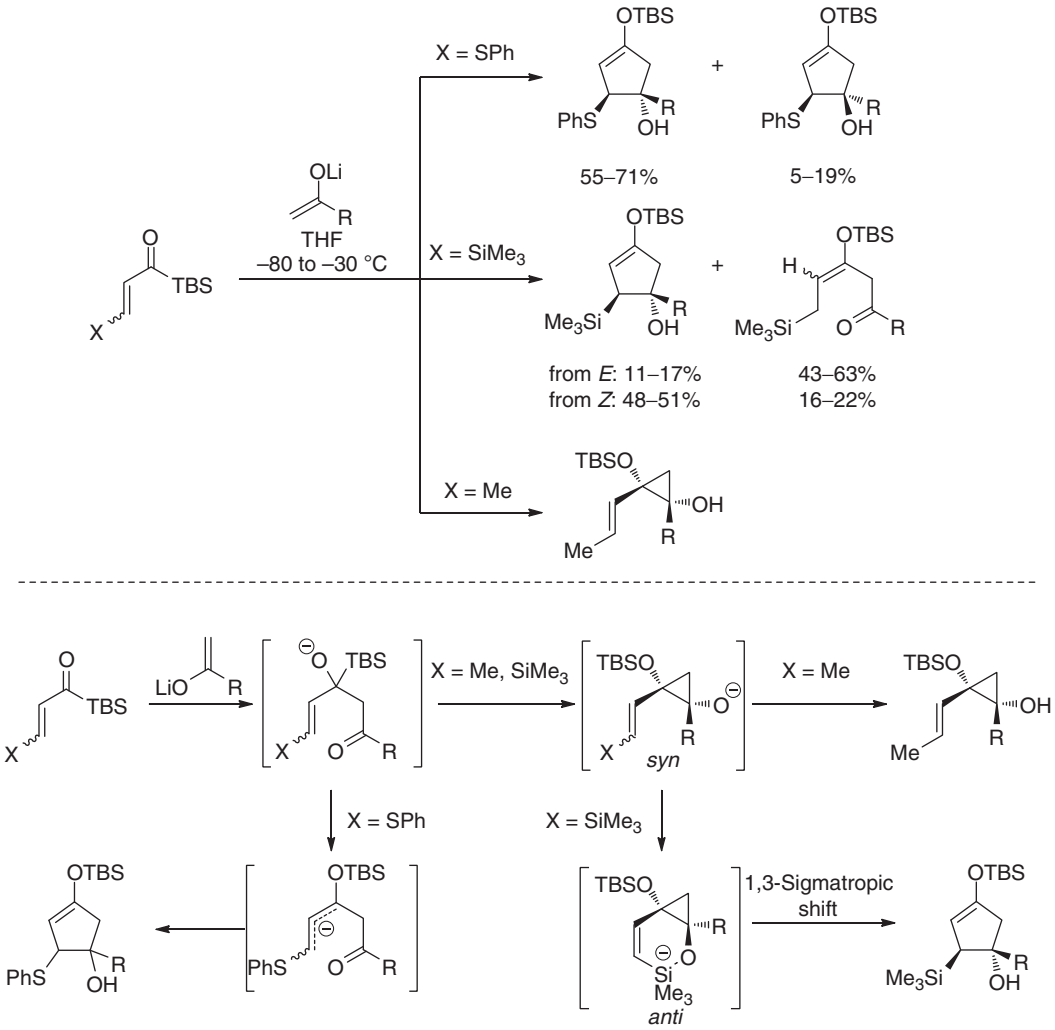
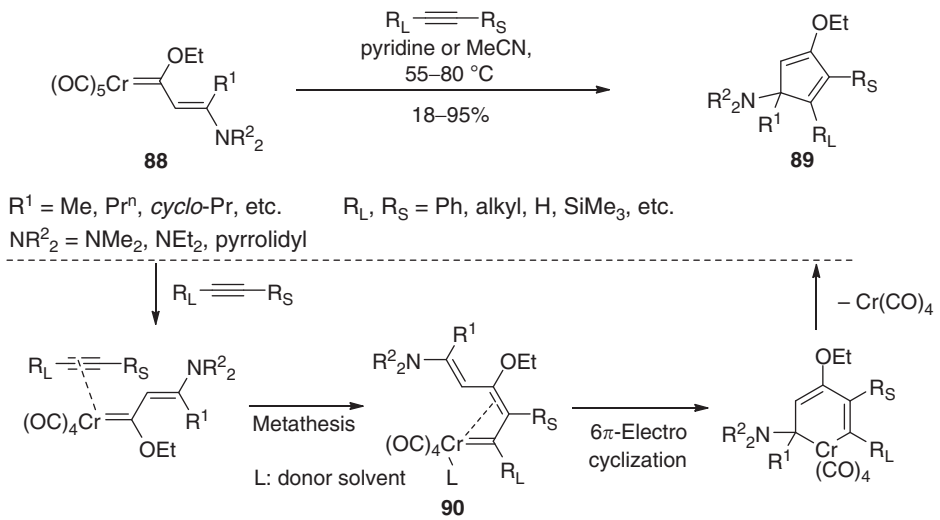
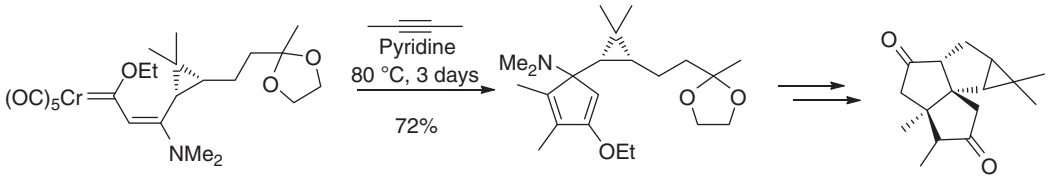


Scheme 33



A similar transition metal-promoted reaction of α,β-unsaturated chromium carbene complexes with allenes gave 4-alkylidene-1-methoxycyclopentenes **98** or 1-methoxy-5-methylenecyclopentenes **99** in moderate to high yield depending on the kind of the metal complex employed. Thus, in the presence of an equimolar amount of $Ni(cod)_2$, the reaction gave 4-alkylidene-1-methoxycyclopentenes **98** by the [2 + 2] cycloaddition of the nickel carbene complex with the allene at the less substituted double bond, followed by 1,3-allylic shift of nickel to give the formal [3 + 2] cycloaddition products. However, the Rh(I)-catalyzed reaction initially gave 1-rhoda-1,3-dienes, which undergo a [4 + 2] cycloaddition with the allenes at the more substituted double bond because of the higher degree of stabilization of the transition structure to give 6-methylene-1-rhoda-2-cyclohexenes. Reductive elimination provides 1-methoxy-5-methylenecyclopentenes of type **99**. Allenamides, phenoxyallene, and allenyl esters were applicable to this Rh(I)-catalyzed reaction and gave the corresponding products with complete regio- and stereoselectivity (Scheme 44).[67d,e]

An interesting [3 + 2] cycloaddition reaction of alkynyl tungsten carbene complexes with indoles was reported to give tricyclic indolines **100** in good yield. By using the (–)-8-phenylmenthyl ester, the reaction gave nearly optically pure products in acceptable yield. The reaction was proposed to proceed through 1,4-addition of the indole to the alkynyl carbene complex, followed by ring-closure of the allenyltungsten to the iminium carbon (Scheme 45).[68]



All the examples described so far employ a stoichiometric amount of preformed carbene complexes. As a method to generate α,β-unsaturated carbene complexes catalytically, the Rh(II)-catalyzed reaction of vinyldiazo compounds was developed. Although the Rh(II)-catalyzed reaction of diazoacetate with alkenes is widely employed as a reliable method for the preparation of cyclopropanecarboxylates, it was found that when vinyldiazocarbonyl derivatives were reacted with vinyl ethers in the presence of Rh_2(S-DOSP)$_4$ catalyst, cyclopentenes **101** were obtained as a single diastereomer with high enantioselectivity (equation 31). Although the details of the reaction mechanism were not presented, a direct [3 + 2] cycloaddition pathway or [4 + 2] cycloaddition including the Rh carbenoid moiety followed by reductive elimination was proposed.[69a] Recently, this method was extended to the reaction with indoles instead of vinyl ethers to give cyclopenta[b]indoles **102** in a highly enantioselective manner, in which a stepwise mechanism including nucleophilic addition of the indoles to the Rh carbenoid carbon followed by ring-closure of the intermediate allylrhodiums to the iminium carbon was proposed (equation 32).[69b]

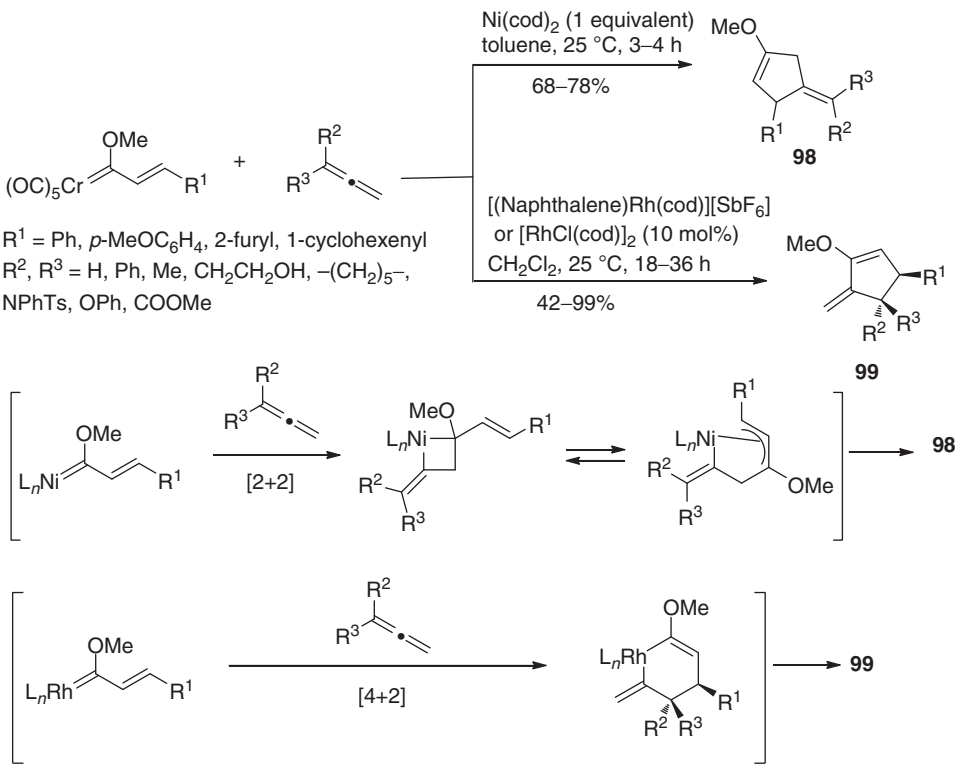
Scheme 43



Copper-catalyzed formal [3 + 2] cycloaddition reactions of α-aryldiazoesters with terminal aryl or alkenyl alkynes gave indene derivatives in reasonable yield. Electrophilic addition of the alkyne to the carbene carbon generates zwitterionic intermediates, which cyclize to the corresponding products (equation 33).[70]

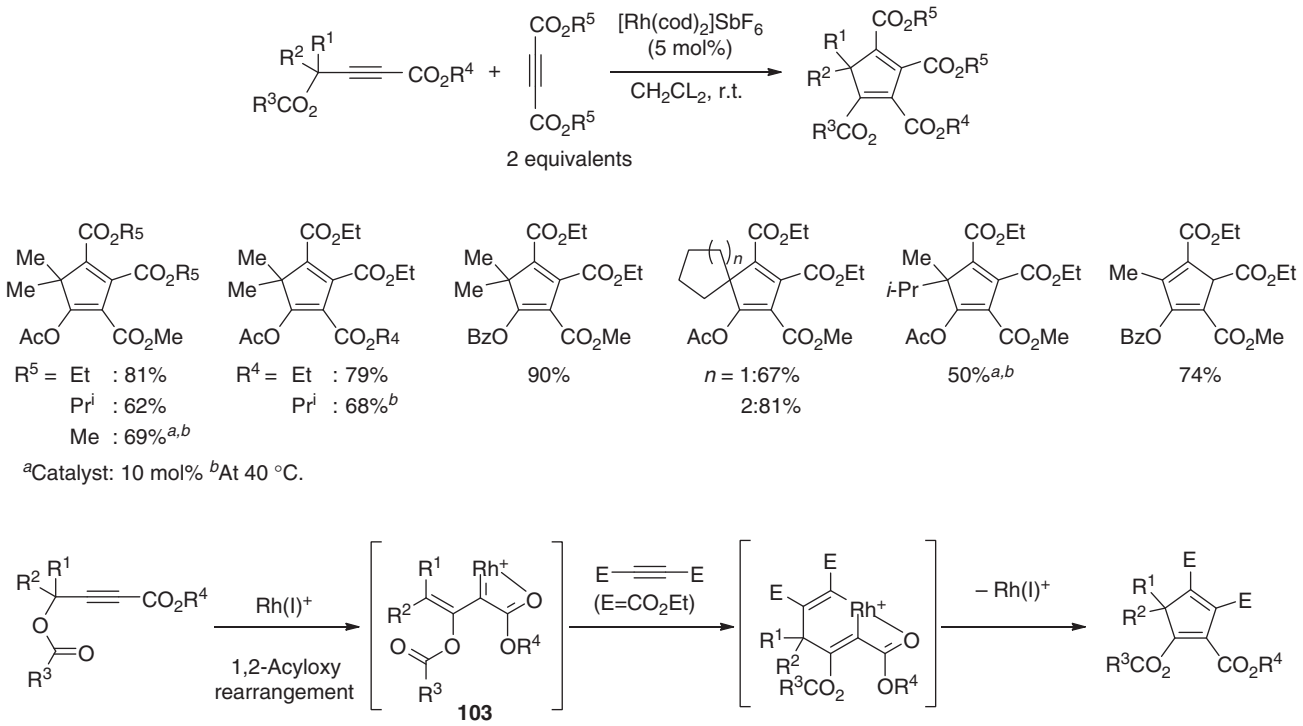
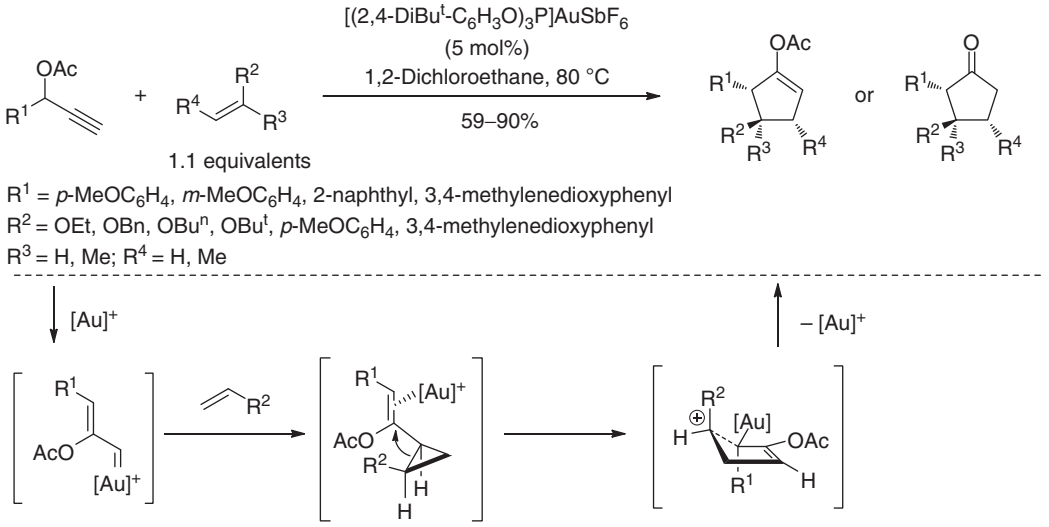
As a new method for the catalytic generation of α,β-unsaturated carbene complexes for [3 + 2] cycloadditions, the cationic Rh(I)-catalyzed reaction of propargyl esters with electron-deficient alkynes was developed. The Rh(I) catalyst worked as an electrophilic reagent; specifically, the reaction of the alkoxycarbonyl-substituted propargylic esters with the Rh(I) complex

Scheme 44



Scheme 45



generated an α,β-unsaturated carbene complex intermediate through 1,2-acyloxy rearrangement, which then reacted with acetylenedicarboxylate to give cyclopentadiene derivatives. The essential part of the pathway is the intermolecular [3 + 2] cycloaddition of the α,β-unsaturated Rh(I) carbene complex intermediates **103** with the electron-deficient alkynes. The method showed reasonable generality concerning the propargyl esters, but the use of electron-deficient alkenes gave cyclopropanes instead of cyclopentene derivatives in good yields (Scheme 46).[71]

Although limited to arylpropargyl esters, a similar reaction with electron-rich alkenes was achieved using a cationic Au(I) complex to give cyclopentenyl acetates in good yields. It was proposed that the Au(I)-catalyzed 1,2-acetoxy migration of the propargyl acetates generates α,β-unsaturated carbene complex intermediates, which react with the alkenes to give vinylcyclopropanes. Subsequent opening of the cyclopropane ring was promoted by coordination of the Au(I) to the adjacent alkenyl moiety, followed by cyclization to give the products (Scheme 47).[72]

Another approach realizing a unique 1,3-dipole generation and subsequent [3 + 2] cycloaddition reaction appeared quite recently. Treatment of α-alkynyl-substituted α,β-unsaturated ketones **104** with 3-alkenylindole in the presence of a cationic Au(I)

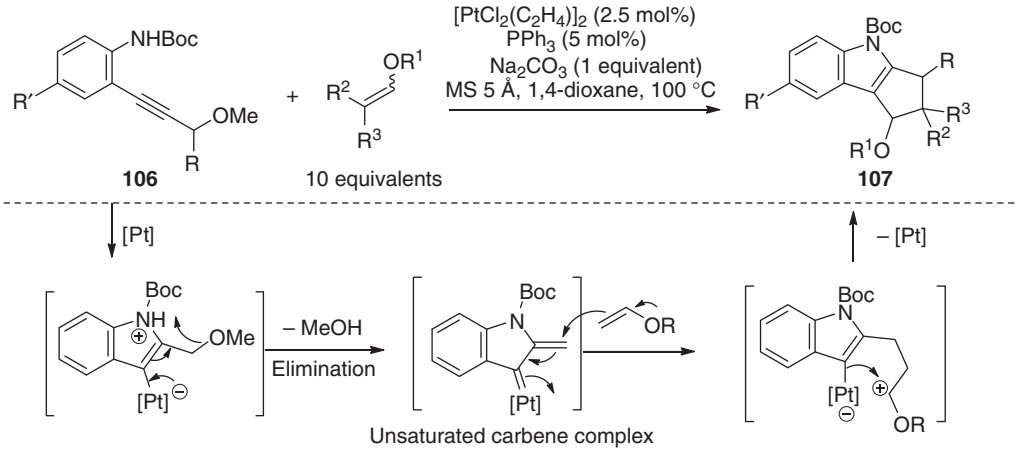
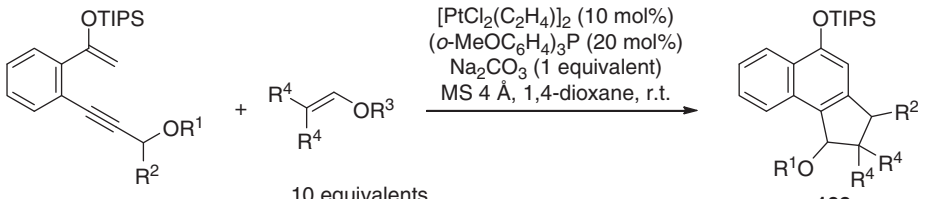
complex gave furan-fused cyclopentane derivatives in good yields with high diastereoselectivity. A furan-containing 1,3-dipole equivalent was generated by the intramolecular cyclization of the carbonyl oxygen to the Au(I)-activated alkyne moiety. Then the nucleophilic attack of the olefin moiety at the C3 position of the indole followed by ring-closure of the furylgold(I) to the cation next to the indole gave the [3 + 2] cycloaddition product (Scheme 48).[73]



Scheme 48



The Pt(II)-catalyzed generation of α,β-unsaturated carbene complex intermediates from various propargyl ether derivatives based on the electrophilic activation of alkynes was employed for [3 + 2] cycloaddition reactions with electron-rich alkenes. Treatment of 2-(3-methoxyprop-1-ynyl)aniline derivatives **106** and vinyl ethers with 2.5 mol% of $[PtCl_2(C_2H_4)]_2$ (5 mol% based on Pt) and 5 mol% of PPh_3 at 100 °C in the presence of Na_2CO_3 as base gave tricyclic indoles in good yield. The reaction was thought to proceed through 5-*endo* nucleophilic attack of the amine nitrogen onto the alkyne, activated electrophilically by Pt(II), to give a zwitterionic intermediate. Then, elimination of the methoxy group triggered by electron-donation from the alkenyl metallic part along with deprotonation from the ammonium nitrogen occurs to give an unsaturated carbene complex. Nucleophilic attack of the vinyl ether to the β-carbon of this α,β-unsaturated carbene moiety generates an alkenyl metallic intermediate, which undergoes intramolecular nucleophilic attack onto the oxonium carbon to afford the final product with regeneration of the catalyst. The efficient formation of indoles, naphthols, and benzofuran fused with a five-membered ring was achieved in high yields based on the same strategy (**Table 23**, equation 34).[74]

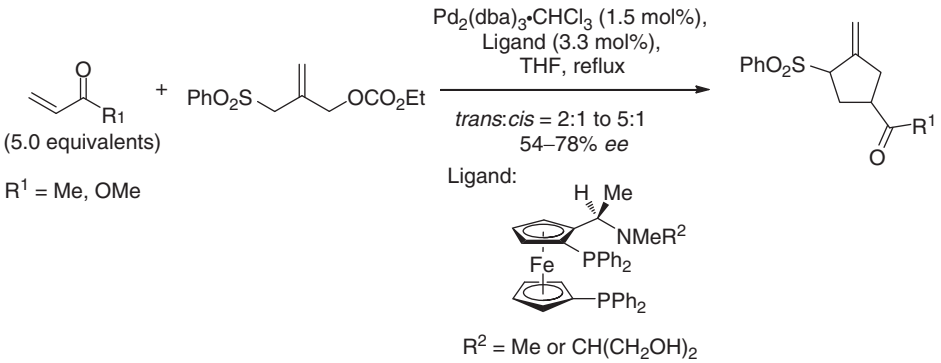
5.08.4.2 Use of Cyclopropane Rings as Three-Carbon Unit in the Transition Metal-Catalyzed Reaction

5.08.4.2.1 Palladium-catalyzed TMM reaction

There are two major approaches for the generation of TMM–transition metal complexes and their further [3 + 2] cycloaddition reactions. The first method employs 2-(trimethylsilylmethyl)-3-acetoxy-1-propenes, whereas the other employs methylenecyclopropanes as precursors. Most of these reactions are catalyzed by palladium complexes, but some other metals such as nickel were also employed. Various aspects of the two methods have been studied, including chemo-, regio- and stereoselectivities, which were already described in the first edition of this book (*see* Chapter 3.2).[1a] Since then, further investigations have been done mainly on the application of this methodology to natural product synthesis and asymmetric catalysis. The recent advances are summarized below.[75]

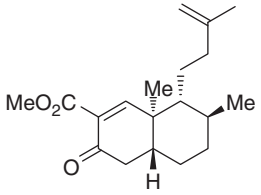
Concerning the first method of employing 2-(trimethylsilylmethyl)-3-acetoxy-1-propenes as precursor of TMM, applications to natural product synthesis were studied, including intramolecular versions of the reaction. For example, the diastereoselectivity of the intramolecular [3 + 2] cycloaddition of substrate **110** having a stereogenic center adjacent to the acceptor was shown to be very high when doubly activated acceptors were employed. This reaction was applied to the total synthesis of (–)-isoclavukerin A (Scheme 49).[76a]

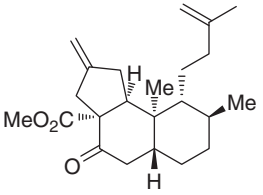


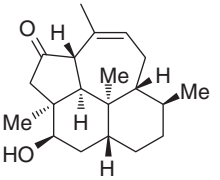
Scheme 49

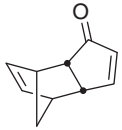
Various other compounds such as kempane diterpenes,[76b] the basic skeleton of the kaurane diterpenes,[76c] (±)-cephalotzxine,[76d] 11-hydroxyjasionone,[76e] (+)-brefeldin A,[76f,g] pinnaic acid,[76h] and several others[76i] have been synthesized utilizing this methodology. By means of a carboxylative TMM-cycloaddition using the silylated TMM precursor **111**,[76j] a concise total synthesis of (±)-marcfortine B was achieved (Table 24).[76k]

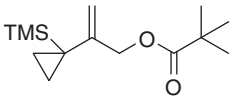
Some additional aspects of this reaction were reported. Several factors were examined in the reaction with α,β-unsaturated ketones. 1,4-Addition reactions occurred as a major pathway when triisopropyl phosphite or tri(*o*-methoxyphenyl)phosphine was employed as ligand, whereas 1,2-addition predominated when the reaction was carried out in the presence of a catalytic amount of $In(acac)_3$ along with PPh_3 as the ligand (Scheme 50).[77]

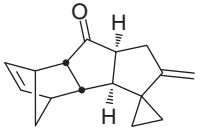


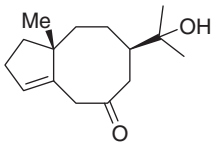


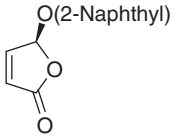


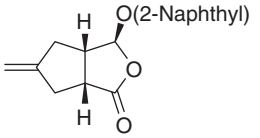


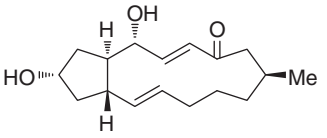




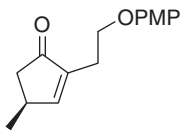








Recently, asymmetric catalytic variants of this reaction have been developed.[78a] The first example of a [3 + 2] cycloaddition of 2-(sulfonylmethyl)-2-propenyl carbonate with methyl acrylate or methyl vinyl ketone catalyzed by a chiral palladium complex was reported to give methylenecyclopentane derivatives in up to 78% *ee* by using a chiral ferrocenylphosphine ligand (equation 35).[78b]



(35)

The second example of this type of reaction appeared more than 15 years later using a phosphoramidite-type ligand containing 1,1′-bi-2-naphthol and 2,5-diphenylpyrrolidine, which realized a wider scope of the reaction with reasonably high enantioselecivity.[78c] For example, treatment of 2-(trimethylsilylmethyl)-3-acetoxy-1-propene and an electron-deficient alkene with 5 mol% of $Pd(dba)_2$ and 10 mol% of the phosphoramidite ligand gave methylenecyclopentane derivatives in high yield with high enantioselectivity. As the electron-deficient alkene, α,β-unsaturated ketones, esters, amides, nitriles, and nitroalkenes could be employed without problem; in particular, α,β-unsaturated acyl pyrroles reacted with a substituted TMM precursor to give highly substituted cyclopentane derivatives in very high diastereo- and enantioselectivity.[78d–f] In these reactions, the use of a bulky

phosphoramidite ligand enabled control of the nucleophilic attack of the zwitterionic intermediates to the alkenes, which occurred distal to the coordinated chiral ligand on the palladium (Table 25).

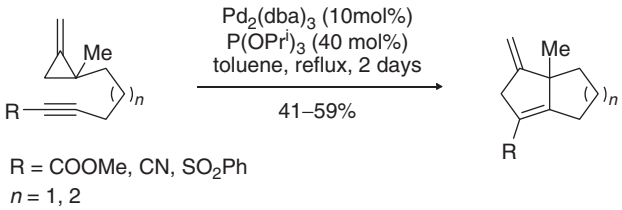
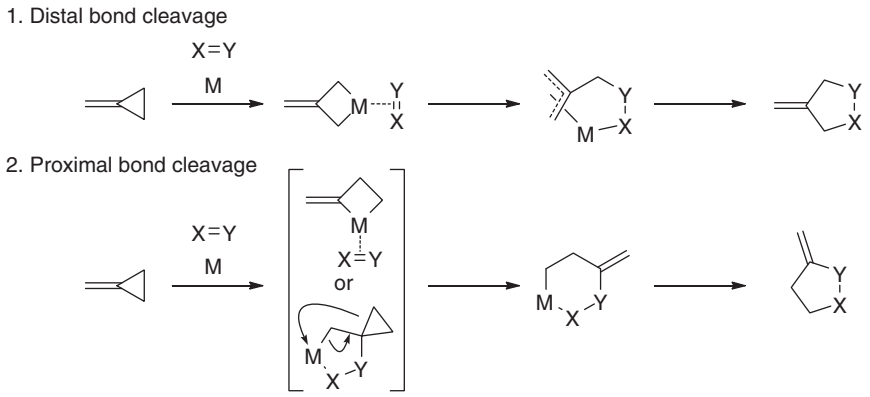
Diamidophosphite ligands derived from chiral *trans*-1,2-cyclohexanediamine and 2,4-pentanediol were employed for the reaction of vinyl-substituted TMMs with α,β-unsaturated acyl imidazoles to give tetra-substituted cyclopentanes bearing three contiguous stereocenters in high yields with good diastereo- and enantioselecitivity (Scheme 51).[78g]

Scheme 51



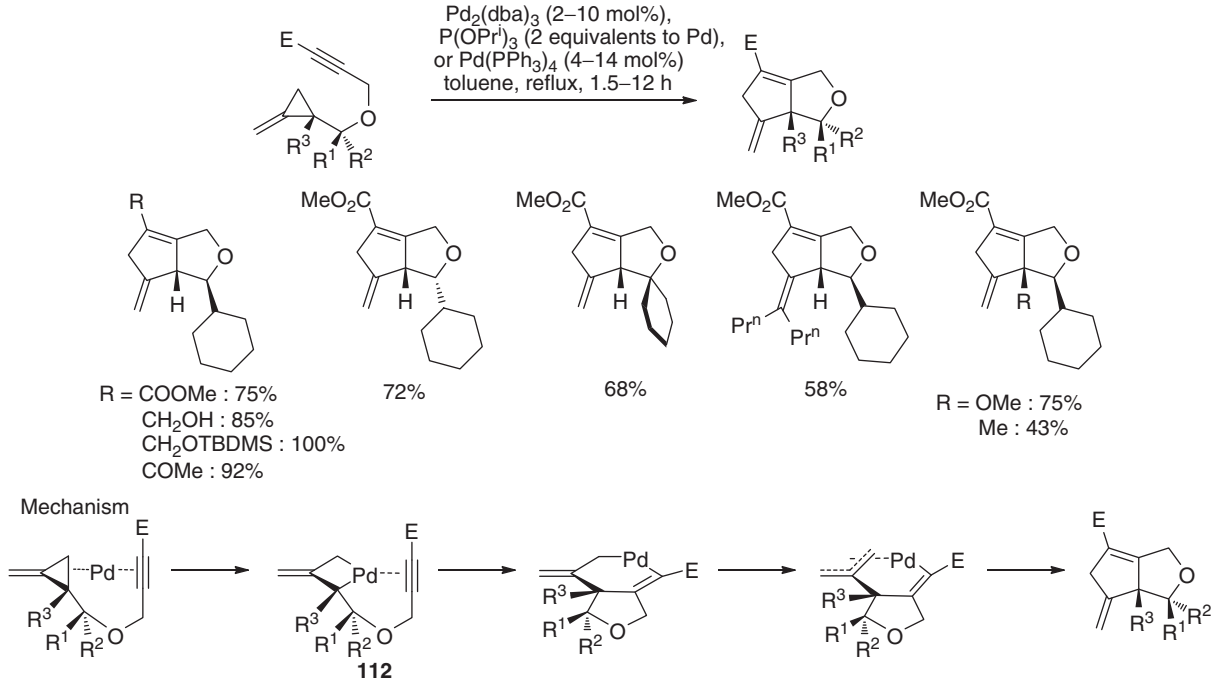
Bis-allylic alcohol could be employed as a 1,3-dipole equivalent in the palladium(0)-catalyzed reaction with α-branched aliphatic aldehydes. Treatment of a mixture of 2-hydroxymethyl-2-propen-1-ol and an aldehyde with 10 mol% $Pd(OAc)_2$, 20 mol% PPh_3, and excess of Et_3B gave methylenecyclopentanol derivatives in good yield. In this reaction, a π-allylpalladium intermediate was generated first by the action of palladium(0) and Et_3B. The aldehyde attacks this intermediate at the α-position to give an addition product, from which a new allylpalladium species is generated that then nucleophilically attacks the carbonyl carbon to give the product. In the palladium-catalyzed TMM chemistry, electron-deficient alkenes are usually employed and the reaction proceeds by a sequence of nucleophilic-electrophilic alkylation. However, the present reaction proceeds in the opposite order: Electrophilic-nucleophilic alkylation (equation 36).[79]

(36)



The use of methylenecyclopropanes in transition metal-catalyzed reactions has been extensively studied, initially with nickel and then with palladium catalysts. In almost all cases, the distal ring opening occurred in the palladium-catalyzed reaction, whereas the nickel-catalyzed reaction gave distal or proximal ring opening depending on the substituent on the cyclopropane ring (Scheme 52). Fundamental aspects of these reactions were described in the first edition of this book (*see* Chapter 3.2).[1b,80]

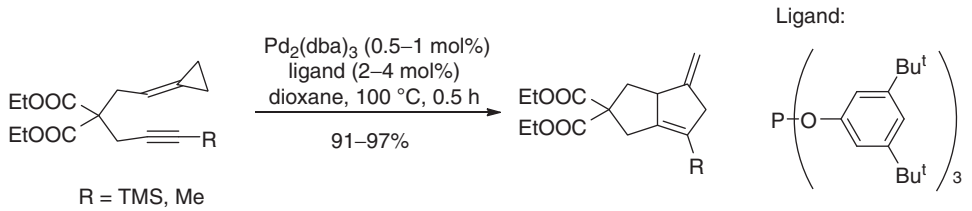
A major advance since the first edition is the intramolecular version of the reaction. Various tether lengths were examined, and substrates with three- or four-carbon tethers and electron-withdrawing substituents at the alkyne terminus gave the products in acceptable yield on heating in the presence of 10 mol% of $Pd(dba)_2$ and 40 mol% of triisopropylphosphite (equation 37).[81a,b]



(37)

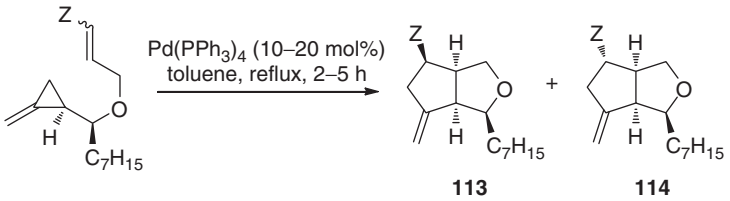
The reaction proceeded with retention of configuration at the substituted cyclopropane to give the products in good yield using $Pd_2(dba)_3$-P(O*i*-Pr)$_3$ with MS 4 Å or $Pd(PPh_3)_4$ as the catalyst. The reaction was proposed to proceed through a metallacyclobutane

Scheme 52



intermediate **112** generated by insertion of palladium(0) into the distal carbon–carbon bond of the cyclopropane, which undergoes carbometallation of the alkyne followed by reductive elimination to give the product stereospecifically (Scheme 53).[81c,d]

Scheme 53



Similar intramolecular reactions using diastereomerically pure methylenecyclopropanes bearing tethers with electron-deficient alkenes proceeded stereospecifically to give the products in good yield, but both geometrical isomers of the alkene moiety gave the same diastereomer, suggesting a stepwise nature of the cycloaddition reaction. The *trans*-bicyclo[3.3.0]octane skeleton was constructed from one of the diastereomeric methylenecyclopropanes (Tables 26 and 27).[81e]

The same type of products was obtained using substrates tethered with alkynes at the *exo*-methylene carbon, which could be synthesized easily from 1-ethenylcyclopropanol. The reaction proceeded under similar conditions. The use of bulky phosphite and phophoramidite ligands was found to accelerate the transformation, such that a lower catalyst loading was sufficient (equation 38).[82a,b]

(38)

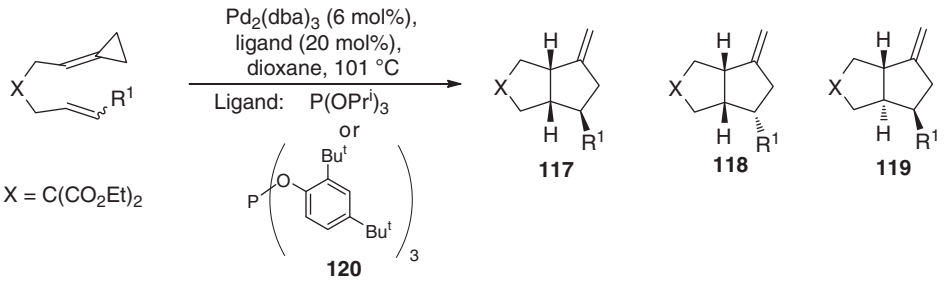
Again, similar reactions with substrates tethered to an alkene (instead of alkyne) occurred smoothly. Even with unactivated alkenes or allenes, the reaction proceeded by using a bulky phosphite ligand. Interestingly the behavior of the geometrical isomers was different when the bulky phosphite **120** was used instead of triisopropyl phosphite (Table 28, equation 39).[82c,d] A mechanistic analysis of the reaction was carried out to reveal that several different pathways are possible for the palladacyclobutane intermediate generated by the oxidative addition of the distal carbon–carbon bond of the cyclopropane to Pd(0) (Scheme 54).[82e,f]



X = $C(CO_2Et)_2$, $NCHPh_2$, O

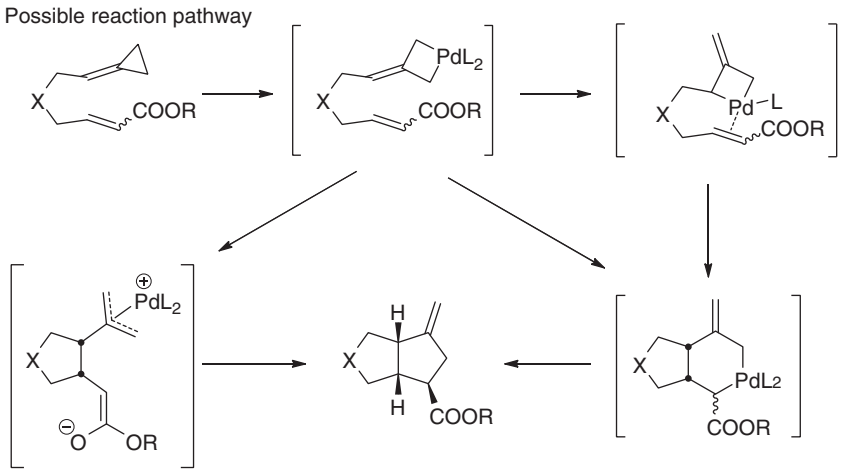
(39)



A ruthenium complex was also found to be effective for this reaction. Heating of a toluene solution of the substrate at 110 °C in the presence of 10 mol% of the first-generation Grubbs catalyst **121** gave the [3 + 2] cycloadducts in reasonable yield instead of the enyne metathesis product. The active catalytic species was thought to be a noncarbene ruthenium complex generated under the reaction conditions (Table 29).[83]

There has been much less work on the cleavage of the proximal bond of methylenecyclopropanes. Just one example of a Ni(0)-catalyzed intramolecular reaction is shown here (Scheme 55).[84]

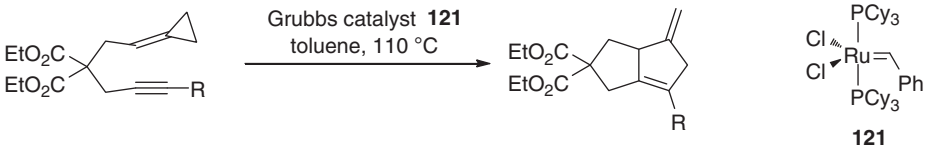
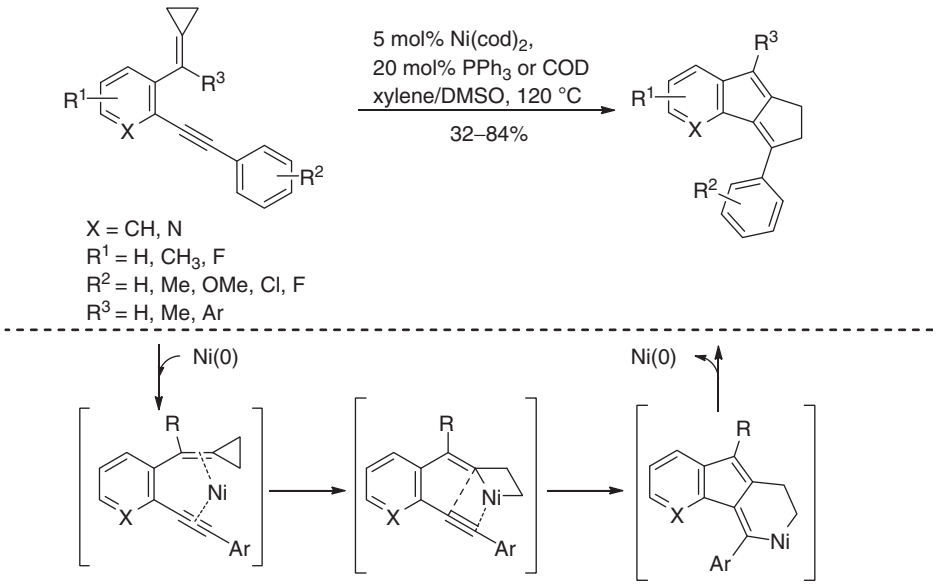
5.08.4.2.2 Pd and Rh-catalyzed reactions of vinylcyclopropanes

Use of simple cyclopropanes as a three-carbon unit in transition metal catalyzed [3 + 2] cycloaddition reactions was rather difficult. However, such reactions become possible by introducing a vinyl group, because of the efficient activation of the cyclopropane by the transition metal coordinated to the neighboring olefin.



It was found that the reaction of 2-vinylcyclopropanedicarboxylate with Pd(0) generates a zwitterionic intermediate containing π-allylpalladium and malonate anion moieties, which can work as a 1,3-dipole (Scheme 56).[85]

This reaction was extended to the asymmetric synthesis of cyclopentane derivatives. A palladium-catalyzed enantioselective formal [3 + 2] cycloaddition between 2-vinylcyclopropane diesters with alkylidene azlactones was developed using **123** as a ligand. The use of the bis(2,2,2-trifluoroethyl)malonate derivative **124** gave higher yields and selectivities, in particular, when aryl-substituted alkylidene azlactones **125** were employed. This reaction provides a concise access to highly functionalized chiral amino acid derivatives (Table 30).[86a]



An efficient synthesis of the cyclopentene core of the *Melodinus* alkaloids was achieved utilizing this method (Scheme 57).[86b]

Allenylboronic esters and electron-deficient alkenes react in the presence of a palladium catalyst to give cyclopentene derivatives in good yield. Allenyl boronic esters undergo transmetallation to give propargyl/allenylpalladium species, which insert electron-deficient alkenes to give allenyl intermediates. *Endo*-carbopalladation of the pendant allene and protodepalladation

afford the cyclopentene products. By using a phosphoramidite ligand, the reaction proceeded smoothly in the presence of 10 mol% $PdCl_2(PhCN)_2$, 50 mol% NaO^tBu, and 1.1 equivalents ^tBuOH. The reaction showed reasonable generality with benzylidene cyanoesters and malononitriles (Scheme 58).[87]

Vinylcyclopropanes had been utilized as a five-carbon unit in the Rh(I)-catalyzed [5 + 2] cycloaddition reaction, but the position of the 2π unit was found to be crucial. Certain substrates undergo [3 + 2] cycloadditions, in which the vinyl group just remains intact. Thus, when 2-alkenyl-vinylcyclopropanes **126** were treated with 5 mol% of $[Rh(CO)_2Cl]_2$ at 80–110 °C, bicyclo[3.3.0]octane derivatives were obtained in reasonable yield as a single diastereoisomer. Use of a cationic complex generated from $[Rh(CO)_2Cl]_2$ and AgOTf promoted the reaction at lower temperature and sometimes gave the corresponding products in

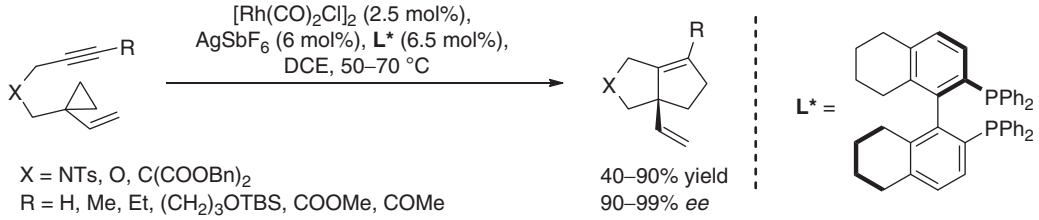
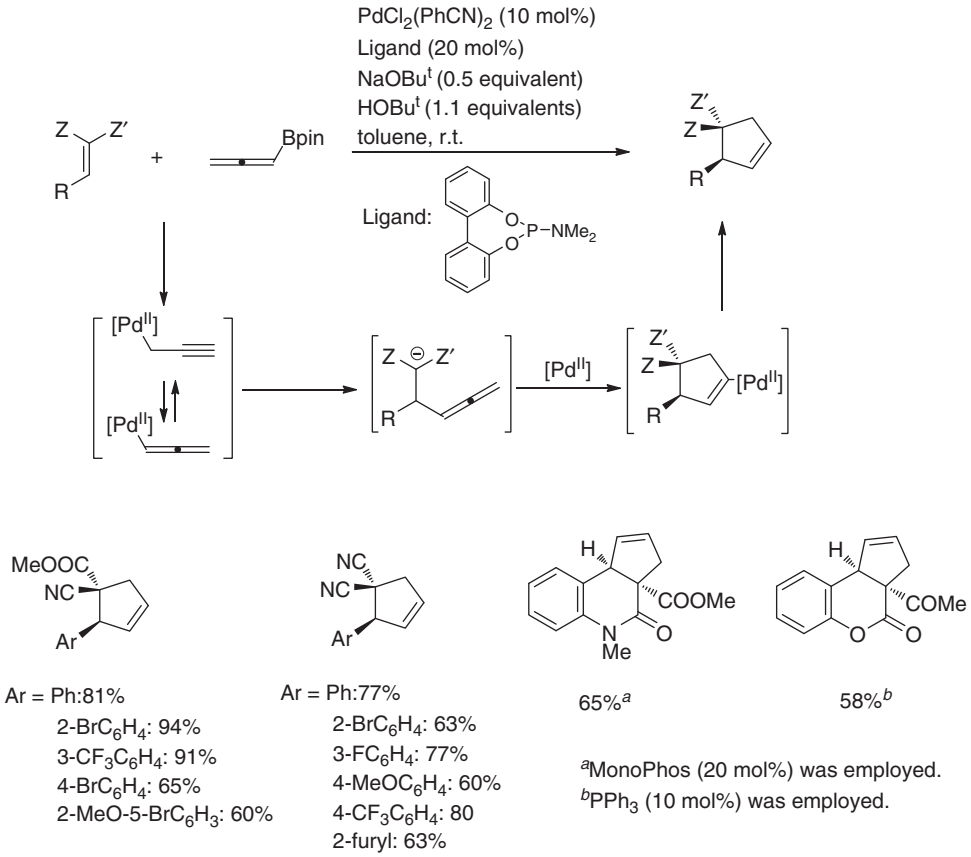


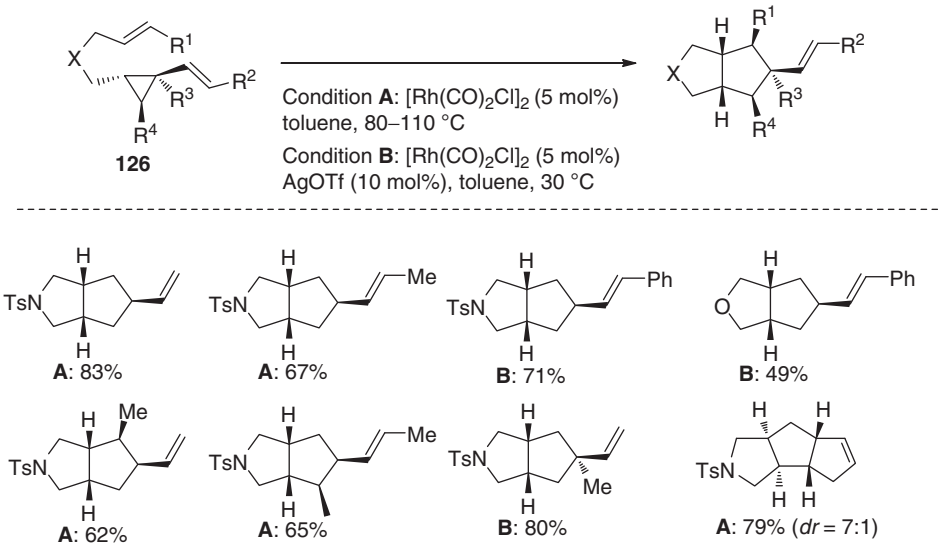
Scheme 57

higher yield. It should be noted that only the *trans*-isomers gave the [3 + 2] cycloadducts, whereas the *cis*-isomers furnished the [5 + 2] cycloadducts exclusively (Scheme 59).[88a]



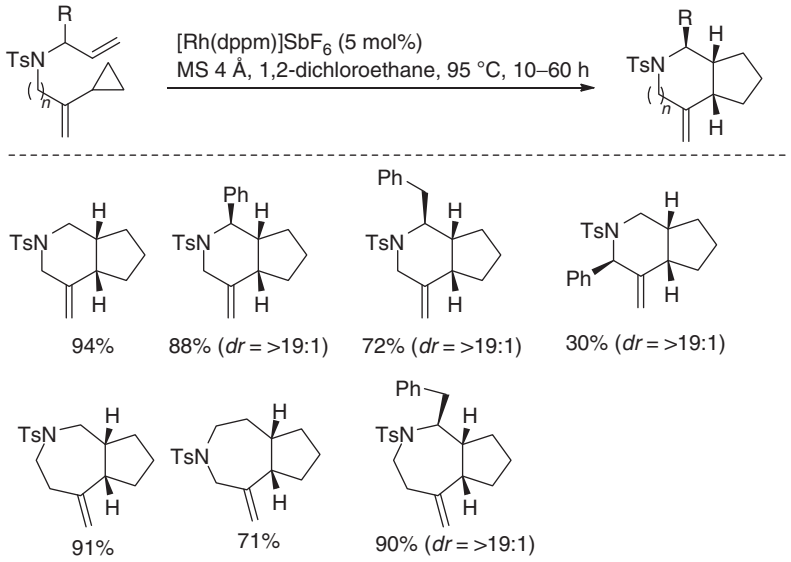
Similar reactions were also achieved with vinylcyclopropanes bearing an alkenyl substituent as 2π component on the vinyl group. In these cases, a cationic Rh(I) complex, [Rh(dppm)]SbF_6, gave good results, and bicyclo[4.3.0]nonane and bicyclo[5.3.0]decane derivatives with an *exo*-methylene group were obtained diastereoselectively. Addition of MS 4 Å improved the yield of the product without accompanying isomerization of the double bond (Scheme 60).[88b]

Furthermore, 1-alkenyl-, 1-alkynyl, and 1-allenyl-vinylcyclopropanes also gave the corresponding [3 + 2] cycloaddition products in good yields by carrying out the reaction in dichloroethane at 80 °C using [Rh(dppm)]SbF_6 as catalyst. A DFT analysis of the reaction supported a catalytic cycle composed of substrate-catalyst complex formation, cyclopropane cleavage, alkene/alkyne insertion, and reductive elimination. The alkene/alkyne insertion step was shown to be the rate-determining step of the reactions (Scheme 61).[88c,d]

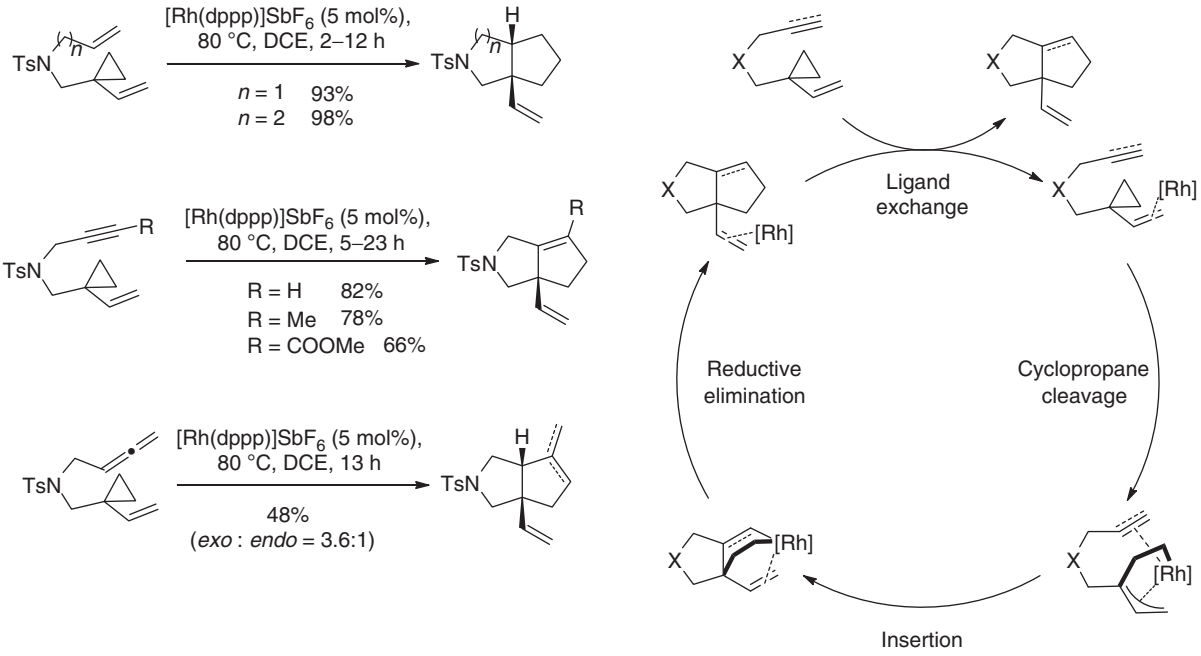


Recently, a highly enantioselective Rh(I)-catalyzed intramolecular [3 + 2] cycloaddition of 1-alkynyl-vinylcyclopropanes to give bicyclo[3.3.0]octene derivatives was achieved using a cationic Rh(I) complex with (*R*)-H_8-BINAP as ligand (equation 40). The enantioselectivity could be explained considering the two diastereomeric transition states of the alkyne insertion step based on DFT calculations.[89]

(40)



Scheme 58



Scheme 59

Another Rh(I)-catalyzed [3 + 2] cycloaddition reaction was achieved using cyclopropenones. Treatment of cyclopropenones and alkynes at 80–110 °C in toluene in the presence of 1 mol% of $[Rh(CO)_2Cl]_2$ gave cyclopentadienones in good yield. The cyclopropenones serve as a three-carbon unit with cleavage of the C1–C2 bond; aryl alkynes selectively afforded products with the aryl substituent neighboring the carbonyl group (Table 31).[90]

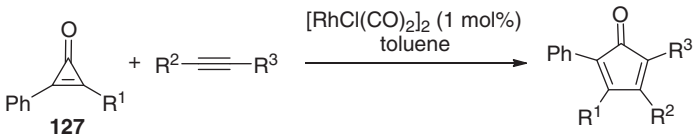
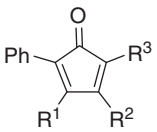
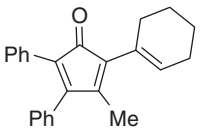
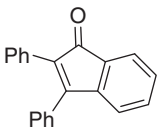
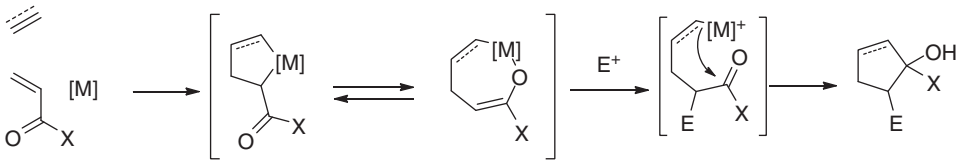








Scheme 61



5.08.4.3 Reductive Coupling Using Low-Valent Transition Metal Complexes

After the publication of the first edition of this book, all-carbon [3 + 2] cycloadditions utilizing the reducing ability of transition metal complexes have emerged as a useful method for the construction of functionalized cyclopentane and cyclopentene derivatives. Most of the reactions utilized the reductive coupling of enals, enones, and enoates with alkynes, wherein the α,β-unsaturated carbonyl compounds served as a three-carbon unit. The basic idea is as follows: Reductive coupling of the above two components generates metallacyclopentene intermediates, which, on treatment with an appropriate electrophile, react like enolates at the α-carbon to give alkenylmetal species containing a carbonyl group. Then the alkenylmetals attack the carbonyl carbon to give cyclopentenol derivatives. Thus, the carbon atoms of the alkynes react with the α,β-unsaturated carbonyl compounds in a 1,4- and 1,2-manner, respectively. Initially, stoichiometric reactions were reported based on the use of low-valent titanium-mediated reactions, followed by Ni(0)-promoted transformations; the latter have been developed into catalytic processes by the combination with appropriate reducing agents (Scheme 62).

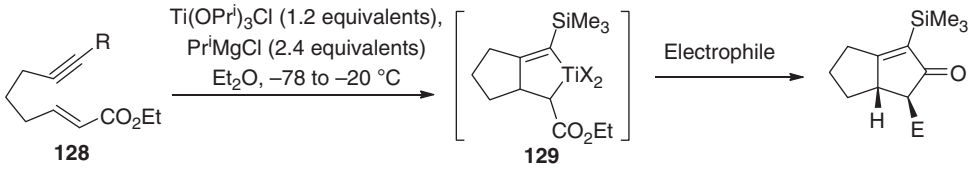
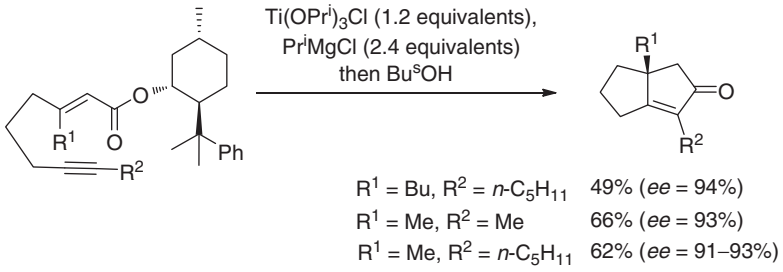
		80 °C, 3 h	88
		120 °C, 3.5 h	69

Scheme 62



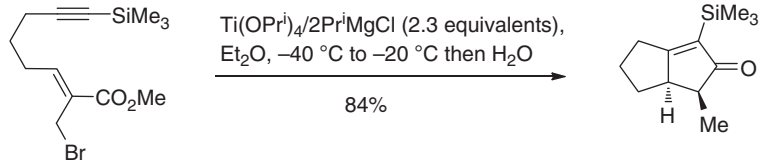
The first example of this type of reaction was achieved using a stoichiometric amount of low-valent titanium complexes. Thus, treatment of a mixture of 8-trimethylsilyl-2-octen-7-ynoate **128** (R=TMS) with (η^2-propene)TiX_2, generated *in situ* from Ti(O-*i*-Pr)$_3$Cl and *i*-PrMgCl in ether, afforded a titanacyclopentene intermediate **129**, which on addition of an equimolar amount of *s*-BuOH gave a bicyclic ketone in good yield. The product was produced by mono-protonation of the titanacyclopentene intermediate at the α-position to the ester functionality, followed by nucleophilic attack of the resulting alkenyltitanium to the ester carbonyl. This reaction can be regarded as a formal [3 + 2] cycloaddition reaction between an alkyne and an α,β-unsaturated ester. More importantly, the electrophile was not limited to protons but carbonyl compounds were also employable, and functionalized cyclopentenones could be obtained by this protocol where the electrophiles had been introduced to the convex face of the bicyclo[3.3.0]octane system with high selectivities. The reaction was applicable to various 2-octen-7-ynoates and 2-nonen-8-ynoate, and the substituent at the allylic position controlled the direction of cyclization to give the product with high selectivity (Table 32).[91a,b]

The reaction was further applicable to 2,7-dienoates having a terminal double bond to give saturated bicyclic ketones, and was applied to an efficient and highly stereocontrolled synthesis of carbacyclin. Treatment of the cyclization precursor **130** with Ti(O-*i*-Pr)$_3$Cl and *i*-PrMgCl, followed by addition of a side-chain aldehyde gave the basic carbon skeleton of carbacyclin with high stereoselectivity in an efficient manner (equation 41).[91c]



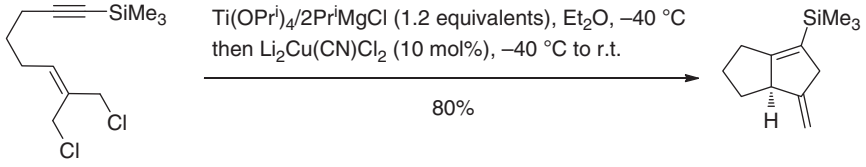
(41)

Table 32 Titanium-mediated reductive coupling



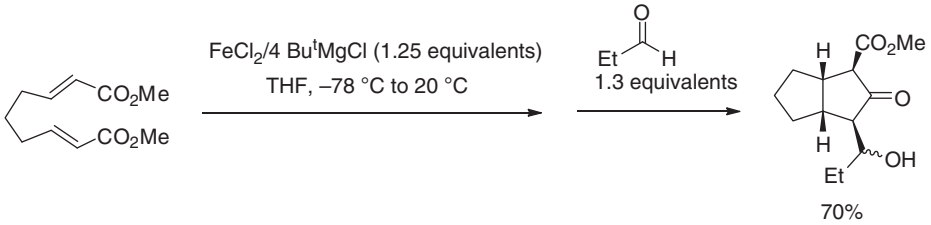
R	*Electrophile*	*E*	*Yield (%)*
TMS	Bu^sOH	H	80
TMS	EtCHO	EtCH(OH)–	78 (*dr* = 63:37)
TMS	Et_2CO	$Et_2C(OH)$–	65
n-C_5H_{11}	Bu^sOH	H	73

This titanium(II)-mediated cyclization was also performed asymmetrically by using 8-phenylmenthyl enynoates as the substrates. Synthetically useful, angularly substituted bicyclic ketones of up to 94% *ee* were obtained by this method (equation 42).[91d]

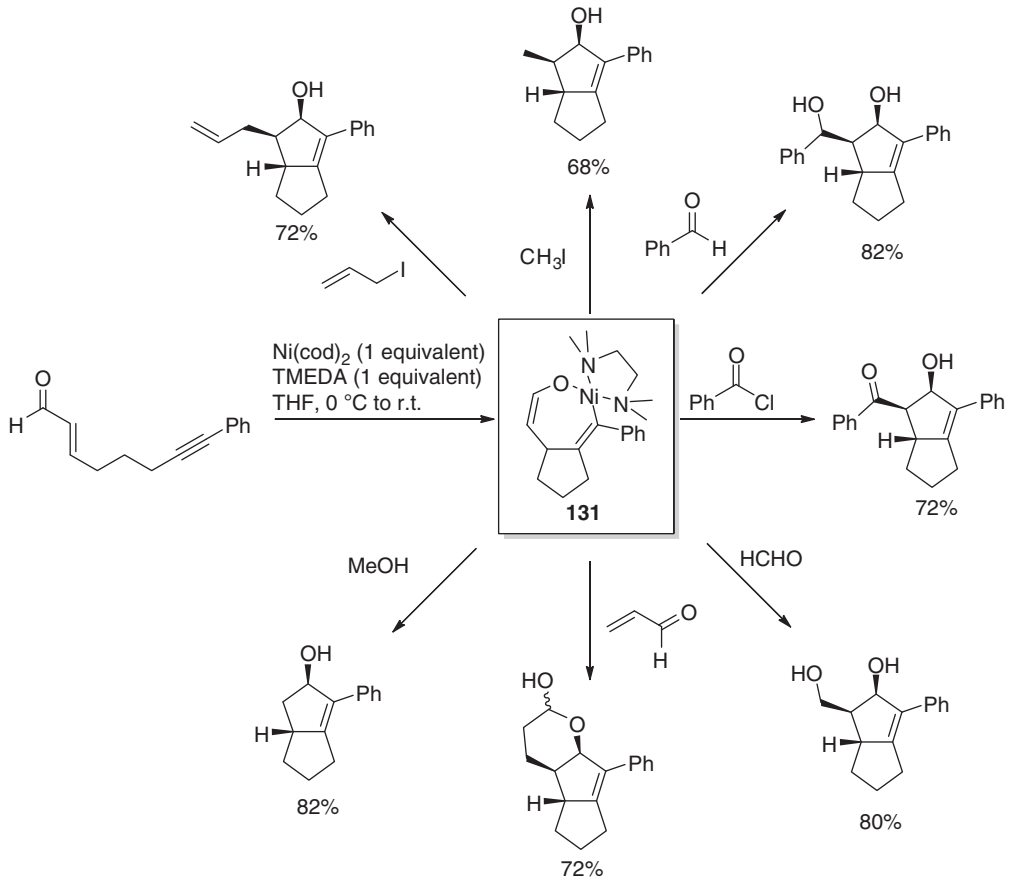


(42)

A further extension of this chemistry was achieved by the reaction of α,β-unsaturated esters containing an allylic chloride or bis(allylic chloride) moiety. Instead of protonation, β-elimination of chloride generated active alkenyltitanium intermediates, which further reacted with the ester or another allylic chloride to give five-membered ring products (equations 43 and 44).[91e]

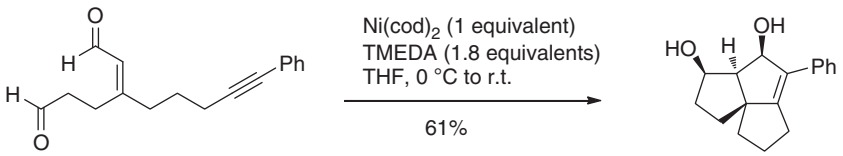


(43)



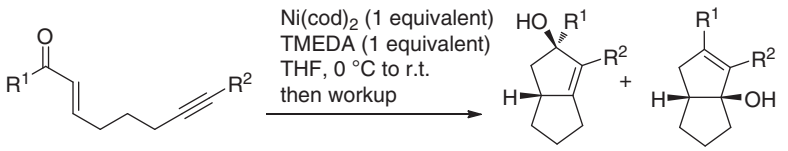
(44)

Recently an iron version of this reaction was also realized. Treatment of 2,7-nonadienedioates with low-valent iron, generated *in situ* from $FeCl_2$ and *t*-BuMgCl in a ratio of 1:4, gave metallacyclic intermediates, which afforded bicyclic keto esters after the addition of *s*-BuOH or carbonyl compounds as electrophiles to trap the iron enolate intermediates (equation 45).[92]



(45)

Nickel-promoted coupling reactions of unsaturated molecules have found abundant application in organic synthesis. Moreover, the combination with appropriate reducing reagents enables such reactions to be performed catalytically, which further expands their utility. Among these reactions is the Ni(0)-catalyzed [3 + 2] cycloaddition of enones or enals with alkynes. Initially, the intramolecular coupling of alkynyl enones and enals was reported using a stoichiometric amount of $Ni(cod)_2$ in the presence of TMEDA to give oxanickellacycloheptadiene intermediates, which afford a variety of synthetically useful compounds by subsequent transformations. Among the reported transformations were the reactions with electrophiles such as water, aldehydes, alkyl and acyl halides, and an α,β-unsaturated aldehyde to give alkenylnickel intermediates containing a carbonyl group, which furnished cyclopentenol derivatives with high stereoselectivity by the addition of the alkenylnickel to the carbonyl group.[93a,b] Concerning the mechanism of the reaction, the key oxanickellacycloheptadiene intermediate **131** was isolated from the reaction of 8-phenylocta-7-yn-2-enal with a stoichiometric amount of $Ni(cod)_2$-TMEDA (1:1) and its structure was determined by X-ray analysis. Further, treatment of this complex with either methanol or dilute aqueous acid actually gave the bicyclo[3.3.0]octene derivative in good yield with high diastereoselectivity. This is the same type of transformation as the Ti(II)-mediated reactions, and the main difference lies in the use of α,β-unsaturated ketones or aldehydes instead of α,β-unsaturated esters as the three-carbon unit (**Scheme 63**).[93c,d]



Scheme 63

Concerning the substituent on the alkyne, aromatic, aliphatic, and silyl groups gave good yields of the products, whereas terminal alkynes and alkynoates were poor substrates. In all cases, a single diastereomer was obtained. The reaction was further extended to the synthesis of more elaborate structures and one example is shown in **Table 33** and equation 46.

This reaction was successfully developed into a catalytic, intermolecular [3 + 2] cycloaddition of enals and alkynes when carried out in the presence of triethylborane as a reductant and MeOH as a proton source. The choice of the reducing agent was crucial: It must be stable under protic conditions and must have a sufficient reducing ability to convert Ni(II) to Ni(0). As such reducing agent, triethylborane has been known to be effective in several related reactions, and it certainly worked well in this system too. Furthermore, the choice of the ligand had a considerable effect on this intermolecular reaction with tributylphosphine giving the best results. Thus, by carrying out the reaction in THF-MeOH (1:8), the formal [3 + 2] cycloaddition reaction of enals and alkynes proceeded in the presence of 10 mol% of $Ni(cod)_2$ and 20 mol% of PBu_3 along with 4 M equivalents of Et_3B to give cyclopentenol derivatives in good yield. As substrate, various enals could be used, and terminal and internal alkynes were applicable. High regioselectivity was achieved when aryl-substituted alkynes were employed (Table 34).[94a,b]

The reaction using triethylborane as a reductant was further extended to enoates instead of enals to give cyclopentenone derivatives. Although simple methyl enoates were unreactive, phenyl enoates and α,β-unsaturated acyl oxazolidinones participated in this reaction. PCy_3 and N-heterocyclic carbene (NHC) ligands (IMes) were found to be optimal; in particular, IMes showed the best generality. Although a variety of alkynes reacted smoothly with β-substituted phenyl enoates with high regioselectivity, α-substituted enoates reacted smoothly only with terminal alkynes, whereas internal alkynes mostly gave acyclic reductive coupling products (Table 35).[94b] Essentially the same reaction was found to proceed in isopropyl alcohol without using Et_3B as a reductant. Treatment of α,β-unsaturated phenyl esters and alkynes in *i*-PrOH at 130 °C in the presence of 10 mol% $Ni(cod)_2$,

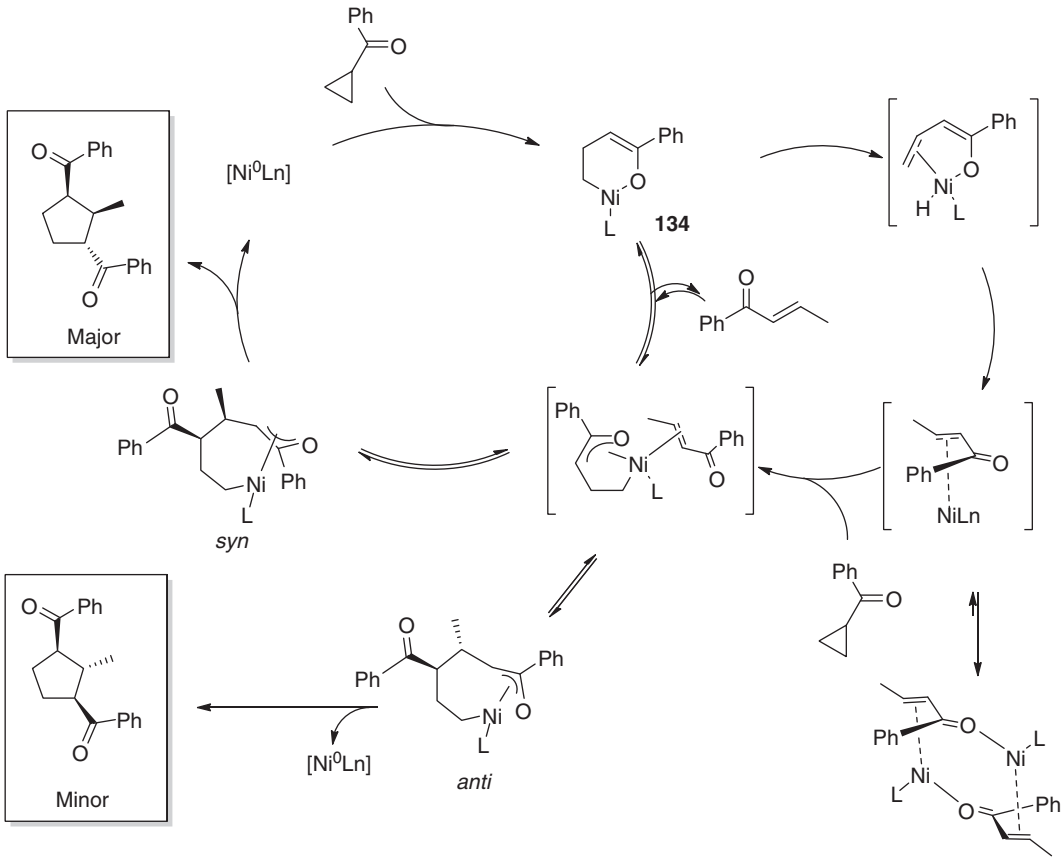
[a]Conditions a = $Ni(cod)_2$ (10 mol%), IMes • HCl, Bu^tOK (10 mol %), Et_3B (5.0 equivalents), THF/MeOH (50:1), 50 °C. Conditions b = $Ni(cod)_2$ (10 mol%), PCy_3 (20 mol%), zinc powder (4.0 equivalents), Pr^iOH, 130 °C.
[b]PCy_3 (20 mol%) was used as ligand.

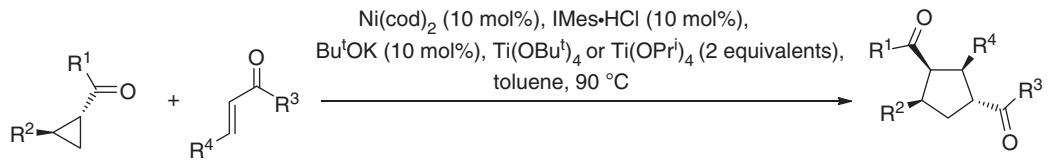
20 mol% PCy_3, and 4 equivalents of Zn powder gave the corresponding cyclopentenones in good yield. It was thought that isopropyl alcohol worked as a reductant through β-hydride elimination in this reaction; the addition of Zn powder improved the yield of the products considerably (Table 35).[94c]

As another type of [3 + 2] cycloaddition utilizing the reducing ability of Ni(0), the reaction of cyclopropyl ketones or imines with enones was developed. Initially, it was found that treatment of cyclopropyl aryl ketones with 5–10 mol% $Ni(cod)_2$ in the presence of an NHC or tricyclohexylphosphine ligand gave dimerized cyclopentane derivatives in good yield. Cyclopropyl alkyl ketones were less reactive in this process and the introduction of a substituent on the cyclopropane ring also lowered the yield. A careful study on the mechanism of this reaction was carried out to reveal that the reaction of Ni(0) with cyclopropyl ketones generated six-membered oxanickelacycles **134**, which isomerized to α,β-unsaturated ketones presumably through β-hydride elimination followed by reductive elimination. The remaining oxanickelacycles reacted with the produced enones in a 1,4-addition manner, followed by reductive elimination of the cyclopentane derivatives with regeneration of Ni(0). These key intermediate complexes were isolated and their structures were determined by X-ray analysis (Schemes 64 and 65).[95a–c]



$Ni(cod)_2$ (10 mol%), PCy_3 (20 mol%), toluene-d_8, 100 °C, 1.5 h — 93 (76:17)

$Ni(cod)_2$ (10 mol%), IMes•HCl, Bu^tOK (10 mol%), toluene, 90 °C — 85 (98:2)



Scheme 64

The crossed reaction of cyclopropyl ketones with α,β-unsaturated ketones was realized by keeping the enone concentration low by syringe-drive addition to suppress the self-dimerization. Addition of Ti(O-*i*-Pr)$_4$ or Ti(O-*t*-Bu)$_4$ improved the yields and increased the reaction rates. The diastereoselectivity was generally good and tri- or tetra-substituted cyclopentane derivatives were obtained with high selectivity. In this reaction, the substrate scope was much improved, and cyclopropyl ketones with a substituent on the ring or cyclopropyl methyl ketone could be employed, whereas α,β-unsaturated ketones seemed to be limited to those having an aryl group on the carbonyl (Table 36).[95d]

Furthermore, cyclopropyl imines could be applied to give trisubstituted cyclopentanecarbaldehyde in good yield, whereas the corresponding reaction of cyclopropanecarbaldehyde was totally ineffective. The reaction showed wide generality and various synthetically useful functionalized cyclopentanes were obtained by this protocol (Table 37).[95e]

Recently, [3 + 2] cycloadditions of cyclopropyl ketones with alkynes were realized using a combination of nickel and aluminum compounds as catalyst. Thus, treatment of a mixture of a cyclopropyl ketone and an alkyne with 10 mol% of $Ni(cod)_2$ and 20 mol% of Me_2AlCl gave a cyclopentenyl ketone in good yield. Addition of the aluminum reagent was crucial for the reaction to proceed, which is supposed to activate the cyclopropyl ketones and stabilize the nickelacyclobutane intermediate **135** in order to inhibit isomerization to an unreactive oxanickelacycle **136**. Various cyclopropyl ketones and internal alkynes were amenable to this reaction, and high regioselectivity was achieved when aryl or silyl alkynes were employed as substrates (Scheme 66).[95f]

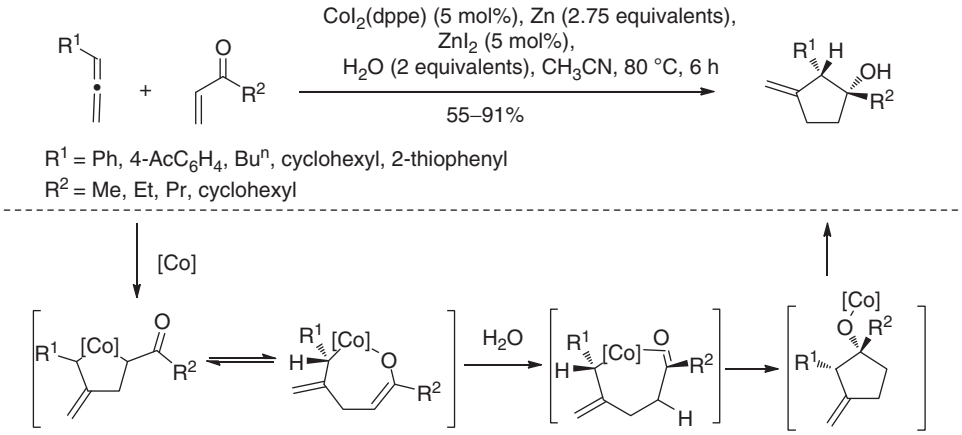
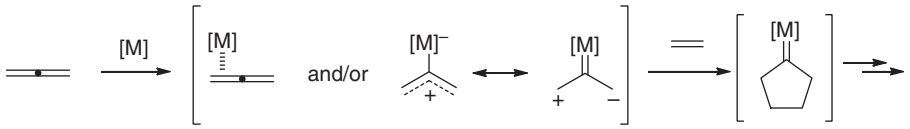


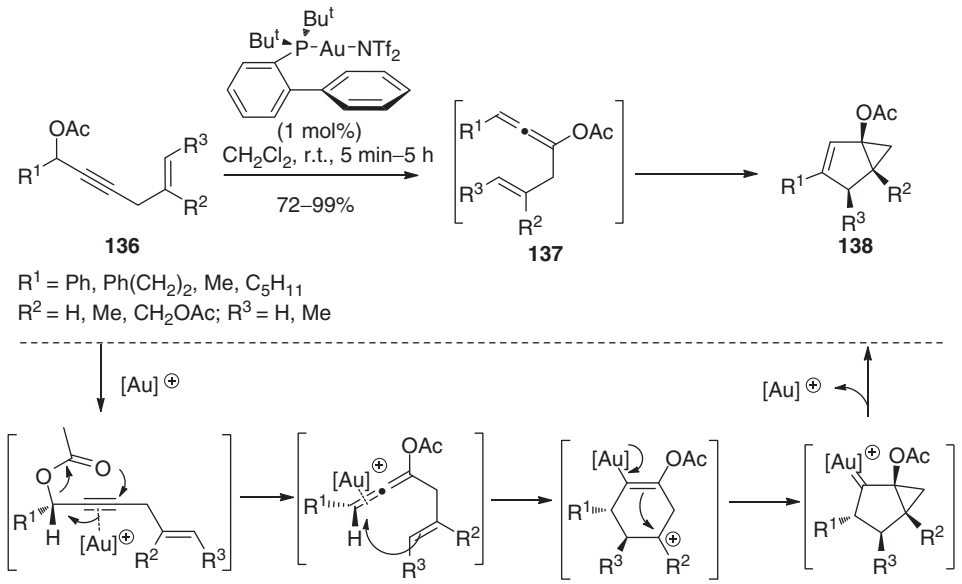
Scheme 66

In a related study, a cobalt-catalyzed reductive [3 + 2] cycloaddition of allenes and enones was realized. In this reaction, the low-valent Co complex, generated from CoI_2 with Zn, gave cobaltametallacycle intermediates from allenes and enones, which on protonation with H_2O, gave allylcobalt species with a ketone moiety. Subsequent intramolecular allylation gave the corresponding methylenecyclopentanols stereoselectively as formal [3 + 2] cycloadducts. The reaction was carried out in the presence of 5 mol% CoI_2(1,2-bis(diphenylphosphino)ethane (dppe)) and stoichiometric amounts of Zn as a reductant and H_2O as a proton source; the addition of a catalytic amount of ZnI_2 was crucial for the success of the reaction (Scheme 67).[96]



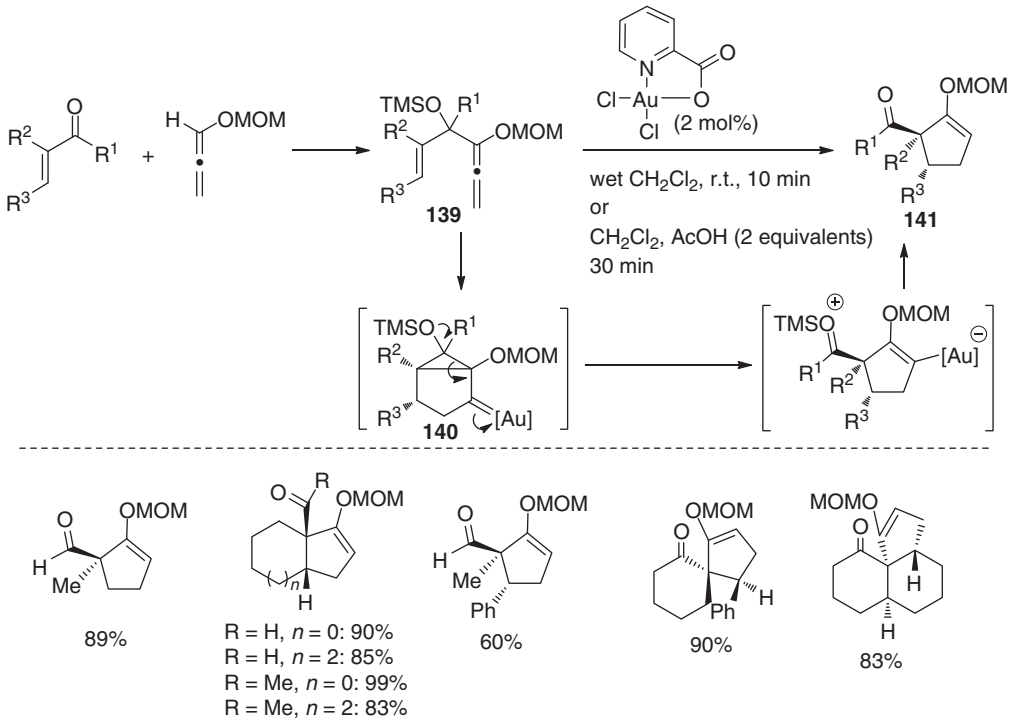
5.08.4.4 Electrophilic Transition Metal Catalyst

The electrophilic activation of alkyne derivatives has attracted tremendous attention of synthetic chemists and a variety of new methodologies has been developed in the last decade. Recently, these investigations have been extended to the activation of allenes. Thus, it was found that the electrophilic activation of allenes can generate all-carbon 1,3-dipoles, which undergo [3 + 2] cycloaddition with an olefinic substrate.[97] The basic concept is as follows: Coordination of the allenes to an electrophilic transition metal complex such as gold(I) or platinum(II) generates a zwitterionic intermediate which can be regarded as an allyl



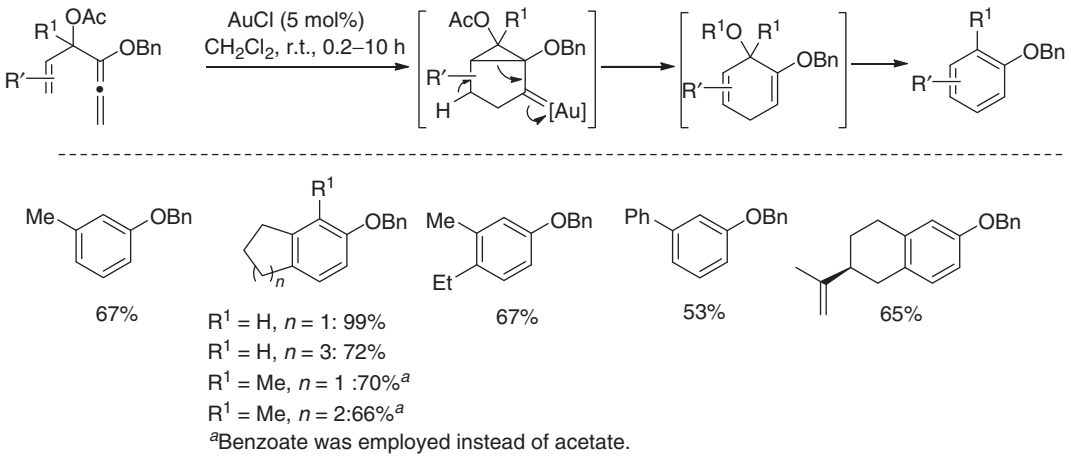
Scheme 67

cation with the anionic (or neutral when the starting complex is cationic) metal attached to the central carbon or, alternatively, as an all-carbon 1,3-dipole with the central carbon coordinated to the metal in a carbene-like fashion. [3 + 2] Cycloaddition reactions with appropriate olefins would give cyclopentylidene carbene complexes, which further undergo typical reactions of metal carbenes such as 1,2-hydrogen migration to give cyclopentene derivatives (Scheme 68).



Scheme 68

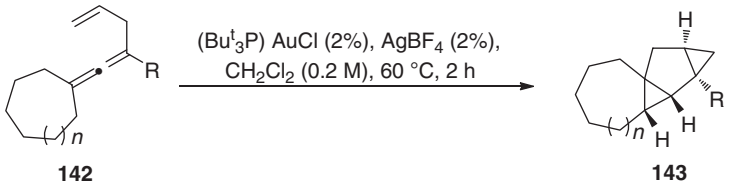
The first example of this type of reaction was realized as an intramolecular process. Specifically, treatment of 5-en-2-yn-1-yl acetates **136** with 1 mol% of a cationic Au(I) catalyst containing a bulky phosphine ligand gave bicyclo[3.1.0]hexene derivatives **138**. The reaction was proposed to proceed through 3,3-sigmatropic rearrangement of the propargyl acetates to give allenes **137**, which undergo formal intramolecular [3 + 2] cycloaddition with the alkene moiety to give bicyclo[3.1.0]hexylidene carbene intermediates. 1,2-Hydrogen shift furnishes the products and regenerates the cationic Au(I) catalyst. Variously substituted 5-en-2-yn-1-yl acetates reacted smoothly at room temperature to give the corresponding products in good yields (Scheme 69).[98a]



Scheme 69

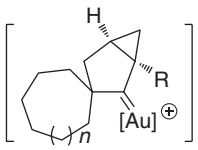
A related reaction of TMS-protected allenyl carbinols **139** also gave cyclopentene derivatives **141** by using a Au(III) catalyst. The reaction was thought to proceed in a similar manner to first give bicyclo[3.1.0]hexane intermediates **140**, which undergo cyclopropane ring opening instead of 1,2-hydrogen shift to give the cyclopentene derivatives. The reaction showed wide generality concerning the olefinic moiety to produce monocyclic, bicyclic, and spirocyclic products in good yields with high stereoselectivity. The starting allenyl carbinols were prepared by the addition of a lithiated allenyl methoxymethyl (MOM) ether to α,β-unsaturated aldehydes or ketones. This method thus corresponds to a formal intermolecular [3 + 2] cycloaddition reaction of allenyl ethers and α,β-unsaturated carbonyl compounds (Scheme 70).[98b]

Scheme 70



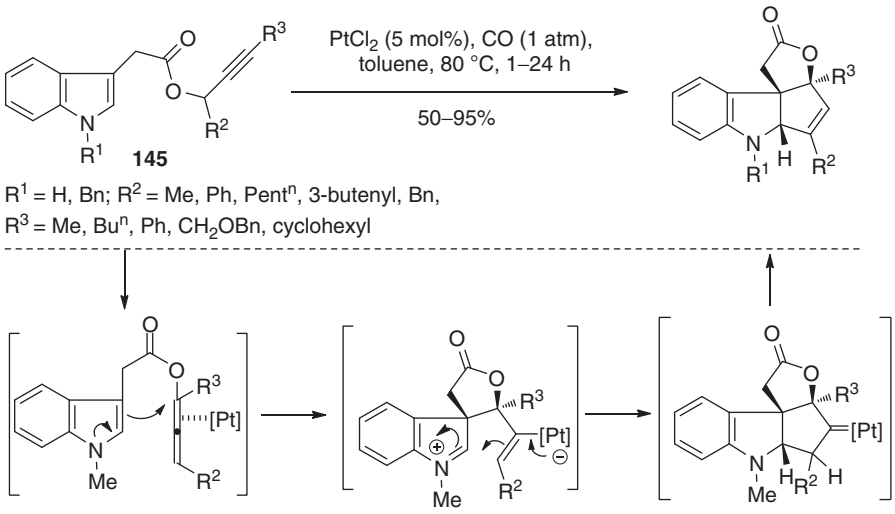
By using acetates or benzoates instead of TMS ethers in the above reaction, the intermediates [3 + 2] cycloadducts underwent another mode of cyclopropane ring opening to give phenol derivatives in good yields. In this case, the use of simple Au(I)Cl gave the best results (Scheme 71).[98c]

Scheme 71



C–H insertion is another typical reaction of carbenoid intermediates. Such a process was exemplified in the Au(I)-catalyzed [3 + 2] cycloaddition of 1,4-enallenes **142**. Treatment of 1,4-enallenes with 2 mol% of a cationic Au(I) catalyst gave bis(cyclopropanes) **143** formed by insertion of the produced Au(I) carbene complex intermediates **144** into a neighboring C–H bond (Table 38).[99]

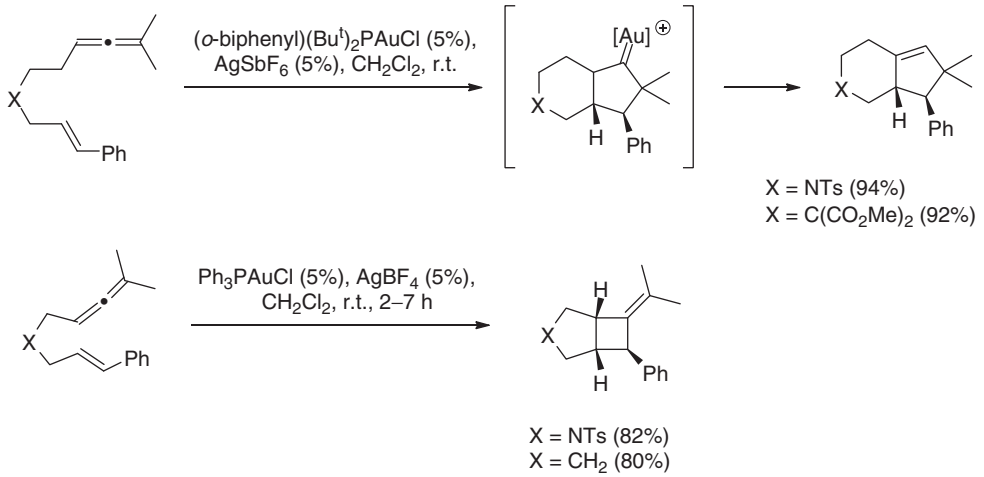
Table 38 Gold(I)-catalyzed cycloisomerization of 1,4-enallenes



142 **143**

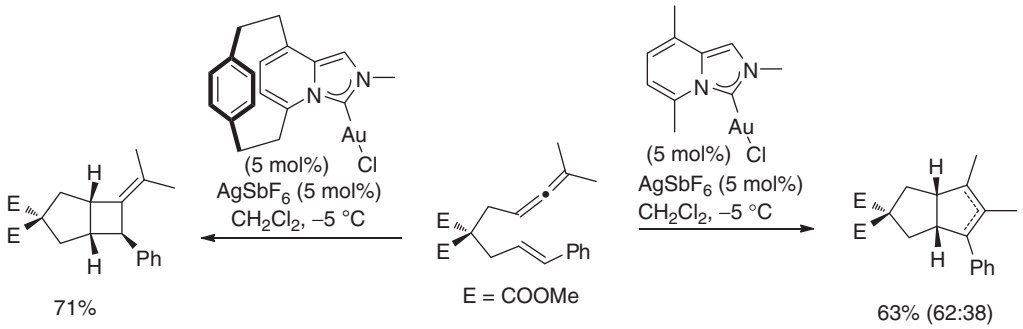
n	R	Yield (%)
1	H	73
1	Bn	83
2	Bn	62
1	Ph	88
2	Ph	85
2	*p*-CF$_3$C$_6$H$_4$	63

144



The concept was extended to indole derivatives **145** using a Pt(II) catalyst. In this reaction, allenyl esters were again generated by 3,3-rearrangement of propargyl esters of indole-3-acetic acid and reacted with the C2–C3 double bond of the indole moiety to give polycyclic indoles containing a cyclopentene ring in good yields. It is also noted that the use of the cationic Au(I) complex gave an intramolecular [2 + 2] cycloadduct selectively. Thus, by appropriate choice of the catalyst, either [3 + 2] or [2 + 2] cycloadducts could be obtained selectively (Scheme 72).[100]

145

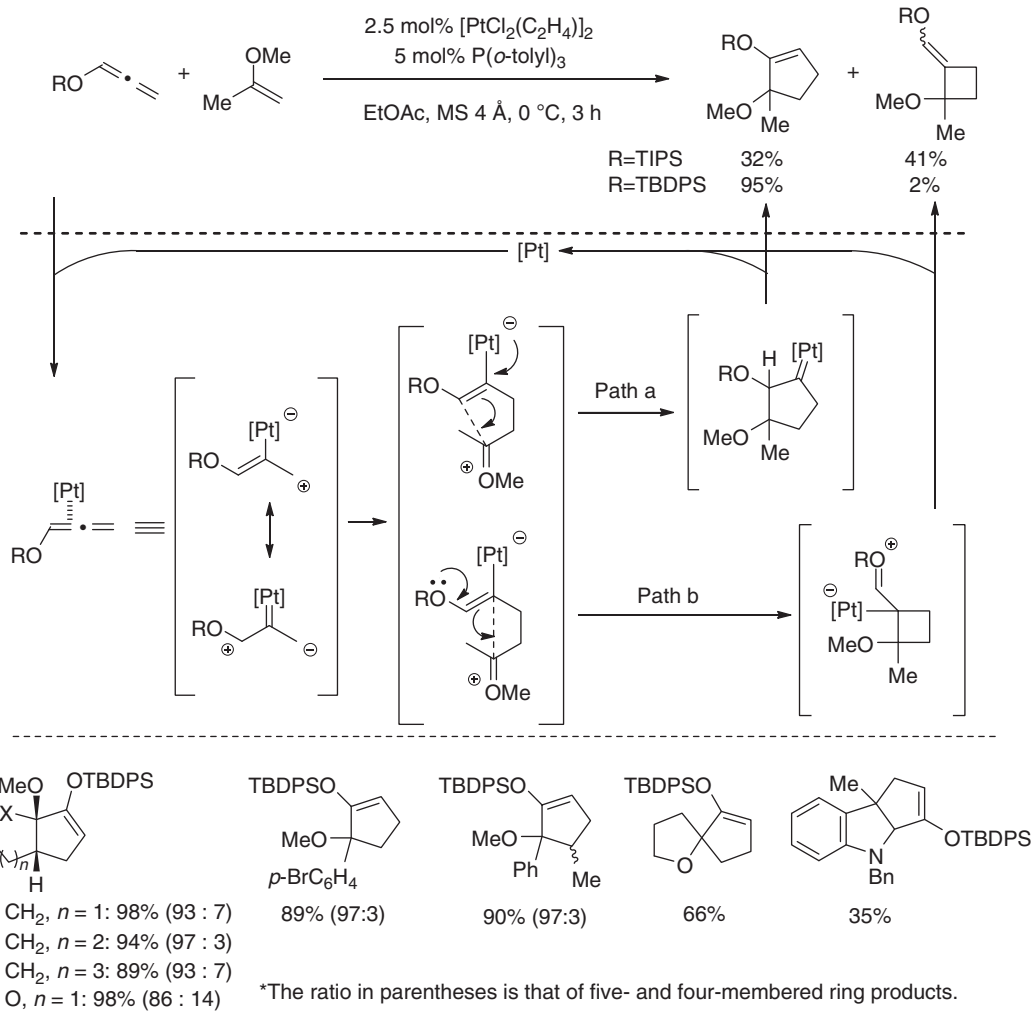


Scheme 72

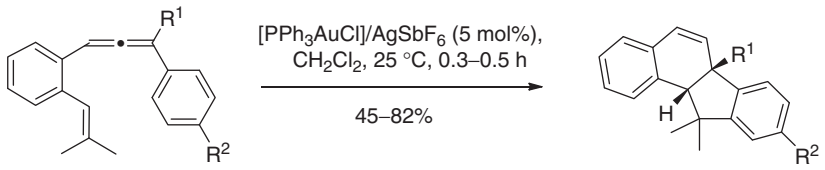
Simple intramolecular [3 + 2] cycloaddition reactions of 1,2,7-trienes were reported as an extension of Au(I)-catalyzed [4 + 2] and [4 + 3] cycloadditions of allene-dienes. By using a cationic Au(I) catalyst containing a bulky phosphine ligand, 1,2,7-trienes gave bicyclo[4.3.0]nonene derivatives in high yield.[101a] In contrast, the use of a cationic Au(I) complex containing PPh_3 as the ligand gave the [2 + 2] cycloadduct selectively under similar reaction conditions (Scheme 73).[101b]

Scheme 73

A unique ligand effect was observed for the cationic Au(I) complex containing NHC ligands in a similar cyclization of 1,2,7-trienes. An electron-rich NHC–Au(I) complex favored the [3 + 2] pathway, whereas an electron-deficient catalyst delivered the [2 + 2] cycloadduct selectively. The π-acceptor ability of the ligand was thought to play an important role in this reaction (Scheme 74).[101c]



Scheme 74



Intermolecular [3 + 2] cycloaddition reactions of silyl propadienyl ethers and alkenyl ethers was achieved by using platinum(II) catalysts. Treatment of a mixture of a TBDPS–propadienyl ether and alkenyl ether with 2.5 mol% of $[PtCl_2(CH_2{=}CH_2)]_2$ (5 mol% based on Pt) and 5 mol% P(o-tol)$_3$ gave synthetically useful oxygenated cyclopentanone derivatives in good yield. When a triisopropylsilyl (TIPS)–allenyl ether was employed instead, the reaction gave a mixture of [2 + 2] and [3 + 2] cycloadducts, whereas cyclopentene derivatives were formed with high selectivity by using TBDPS–allenyl ether as the three-carbon unit. It was postulated that the lower electron-donating ability of the TBDPS group rendered the [2 + 2] cycloaddition reaction less favorable. The method showed wide generality for the electron-rich alkenes and is therefore complementary to the phosphine-catalyzed [3 + 2] cycloaddition of electron-deficient allenes with electrophilic 2π components (Scheme 75).[102]

Intramolecular [3 + 2] cycloadditions of arenyne-yne functionalities was realized based on electrophilic alkyne activation using cationic Au(I) catalysts. Treatment of diyne **146** with 2 mol% of Ph$_3$PAuSbF$_6$ gave the formal [3 + 2] cycloadduct **147**. Various aryl-substituted diynes, endiyne, and alkenyl-substituted diynes were applied to this reaction to give the corresponding products in good yields. The reaction was thought to proceed through the nucleophilic attack of the aromatic ring to the electrophilically activated alkyne at the benzylic position to give the nine-membered alkenylgold intermediate **148**. This intermediate was further protonated at the alkyne moiety to give a cationic intermediate, which undergoes 5-*exo*-*dig* or Nazarov cyclization to give the product (Table 39).[103a]

This reaction was further developed into the intramolecular [3 + 2] cycloaddition of 1-aryl-1-allene-6-enes to give dihydrobenzo[a]fluorene derivatives in good yields using the same cationic Au(I) catalyst under similar conditions (equation 47).[103b]

Scheme 75

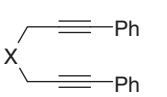
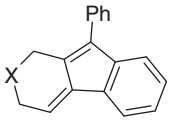
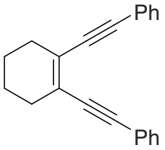
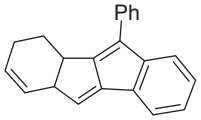
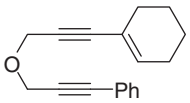
5.08.4.5 Use of Aryl Carbonyl and Related Derivatives as a Three-Carbon Unit

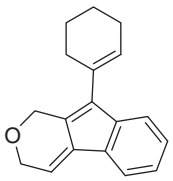


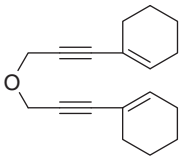


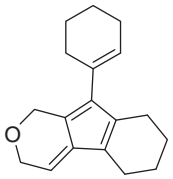






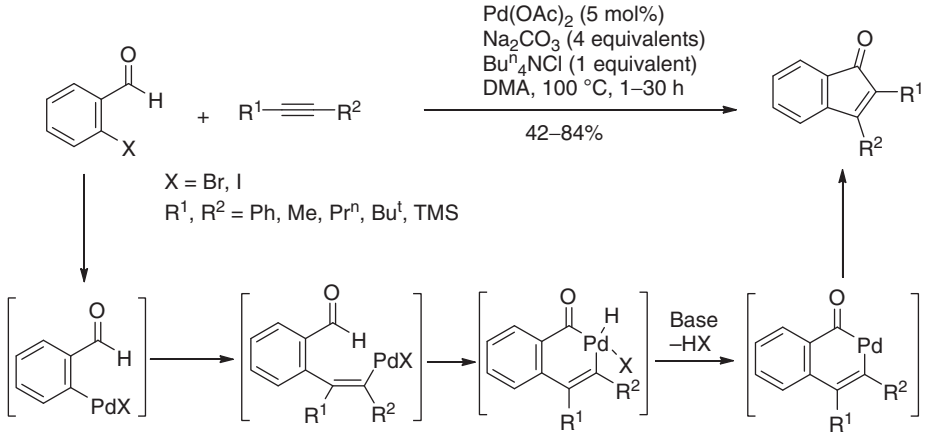






This section summarizes recent progress in the annulation of aryl carbonyl and related compounds as a three-carbon unit via transition metal-catalyzed reactions with alkynes or alkenes.

Initially, transition metal-catalyzed [3 + 2] cycloadditions of *o*-haloarylcarbonyl and related derivatives with alkynes have been developed. *o*-Bromo and *o*-iodobenzaldehyde were employed as substrate for the reaction with alkynes using 5 mol% of $Pd(OAc)_2$, 4 equivalents of Na_2CO_3, and 1 equivalent of n-Bu_4NCl. The reaction worked well with internal alkynes and the regiochemistry was sterically controlled.[104a] The cycloaddition was proposed to proceed through a palladium(IV) intermediate generated by oxidative addition of the aldehyde C–H bond to a primary alkenylpalladium(II) intermediate (Scheme 76).[104b,c]



Interestingly, when carried out using 5 mol% $Pd(OAc)_2$ and 2 equivalents KOAc, indenol derivatives were obtained in good yield. In this case, the reaction was thought to proceed via nucleophilic addition of alkenylpalladium intermediates to the aldehyde. This process worked well even with *o*-bromophenyl ketone derivatives (Table 40).[104d,e]

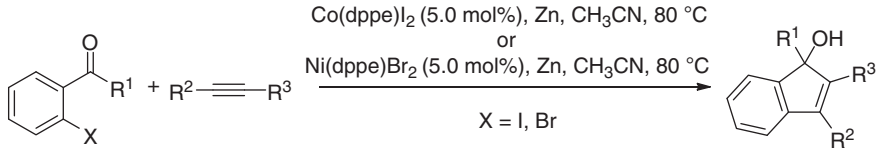
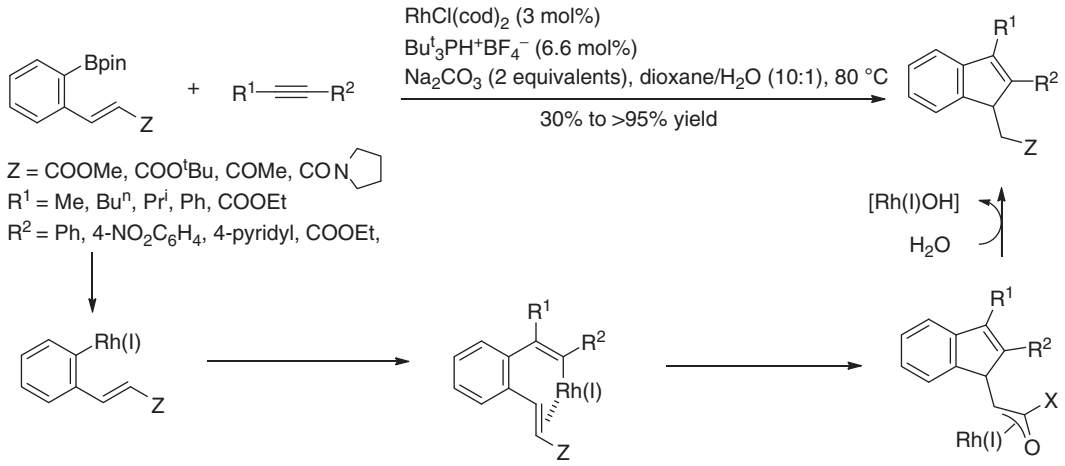
Note: A: None, B: PPh_3 (10 mol%), C: PPh_3 (10 mol%), EtOH (equivalent), and D: EtOH (10 equivalents), 60 °C.

Since these early studies, various investigations have been carried out concerning the electrophilic moieties that participate in the reaction, such as ketone carbonyls, cyano-, and imine groups. Various metal catalysts have also been developed; for example, even benzynes, generated *in situ* from 2-(trimethylsilyl)aryl triflate and CsF, could be employed as a two-carbon unit to give fluoren-9-ones (Scheme 77).[105a,b]



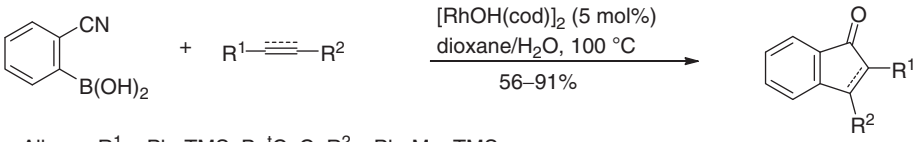
Scheme 77

Similar nucleophilic additions of alkenylpalladium species to nitriles were found to proceed with *o*-iodobenzonitrile and alkynes or alkenes, although the efficiency of the reaction was not necessarily good. Diaryl alkynes and norbornene derivatives gave better results (Scheme 78).[105c,d]



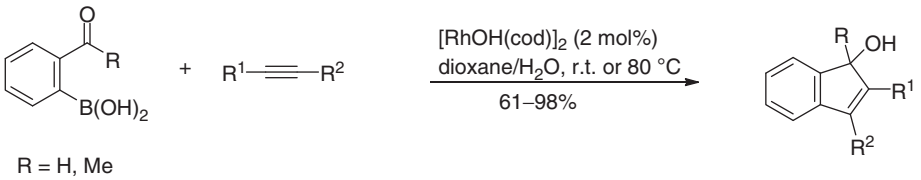
Scheme 78

Furthermore, nickel- and cobalt-catalyzed reactions were also realized (equation 48).[106]



(48)

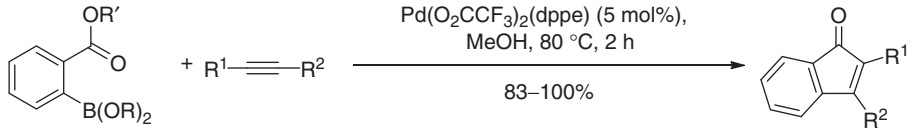
Phenylboronic acids with an electrophilic *ortho* substituent were also employed for this type of reaction using rhodium(I) or palladium(II) catalysts. In these cases, redox processes are not involved in the catalytic cycle but the reaction proceeds through arylrhodium(I) or arylpalladium(II) species generated by transmetallation. These intermediates insert alkynes or alkenes to give alkenyl- or alkyl-metallic species, which then add to the electron-deficient carbon to give the formal [3 + 2] annulation products. For example, arylboronates bearing a pendant electron-deficient alkene reacted with alkynes to give indene derivatives in good yield using a rhodium(I) catalyst with a bulky, electron-rich phosphine ligand (Scheme 79).[107]



Scheme 79

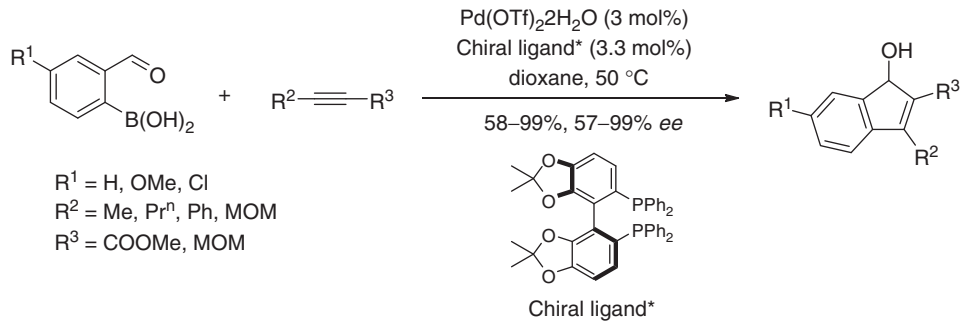
As for the electrophilic moiety, cyano and formyl functionalities have been utilized in such rhodium-catalyzed reactions. Some representative examples are shown in equations 49 and 50.[107c,d]

(49)



Alkyne: R^1 = Ph, TMS, $Bu^tC{\equiv}C$; R^2 = Ph, Me, TMS
Alkene: norbornene

(50)

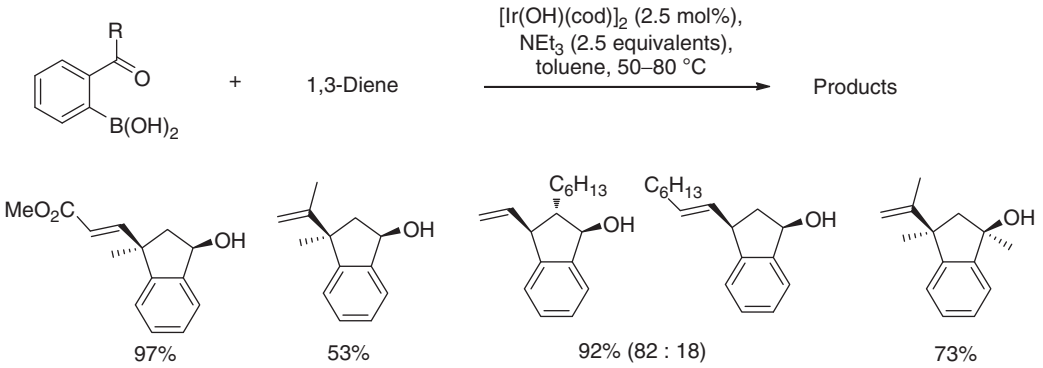


R = H, Me
R^1 = Ph, Et, CH_2OAc, COOEt, COMe
R^2 = Ph, Me, Et, CH_2OAc, TMS

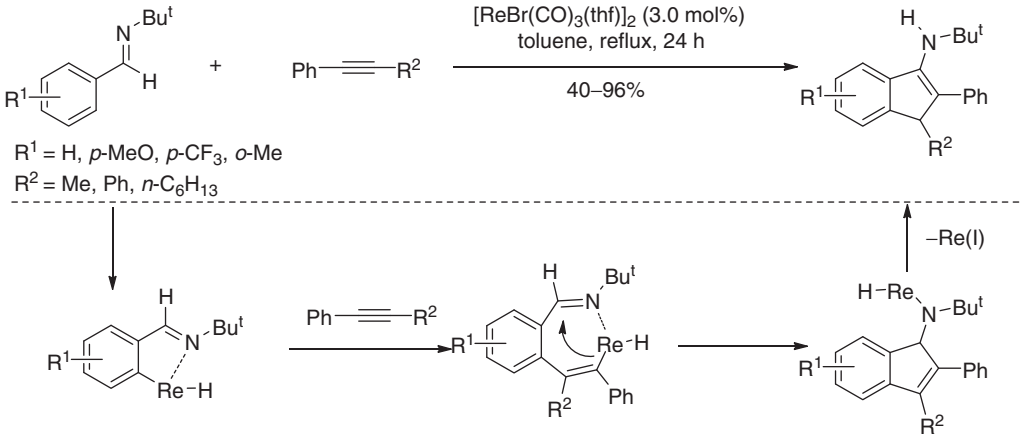
Palladium complexes have also been employed for similar reactions. For example, treatment of a mixture of *o*-alkoxycarbonylphenylboronic acid and an internal alkyne with 5 mol% of $Pd(O_2CCF_3)_2$(dppe) gave indenone derivatives in good yield. Not only aryl alkynes but also dialkyl alkynes were applicable to this reaction (equation 51).[108a] *o*-Formylarylboronic acids furnished indenol derivatives. Cationic palladium complexes were effective catalysts, and optically active products have been prepared by using a chiral palladium complex (equation 52).[108b,c]

(51)

$B(OR)_2$ = $B(OH)_2$ or Bpin; R′ = Me, Et, Pr^i
R^1 = Ph, 4-$MeOC_6H_4$, Pr; R^2 = Ph, 4-$MeOC_6H_4$, Me, Pr

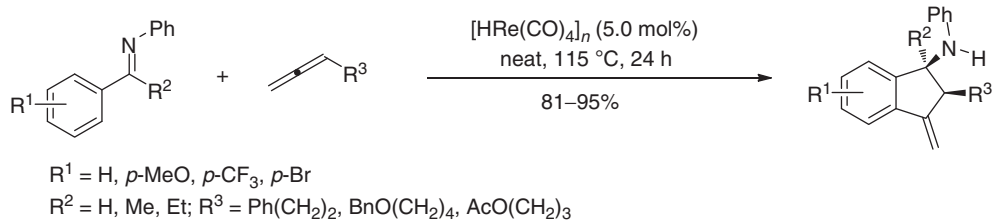


(52)



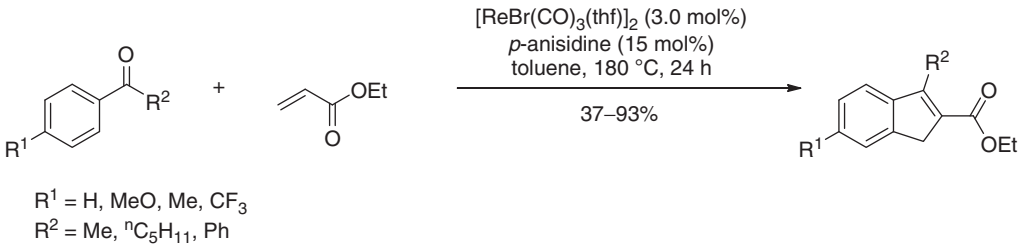
R^1 = H, OMe, Cl
R^2 = Me, Pr^n, Ph, MOM
R^3 = COOMe, MOM

Furthermore, *o*-carbonylated phenylboronic acids reacted with 1,3-dienes to give indanol derivatives in the presence of an iridium(I) catalyst (**Scheme 80**).[109]



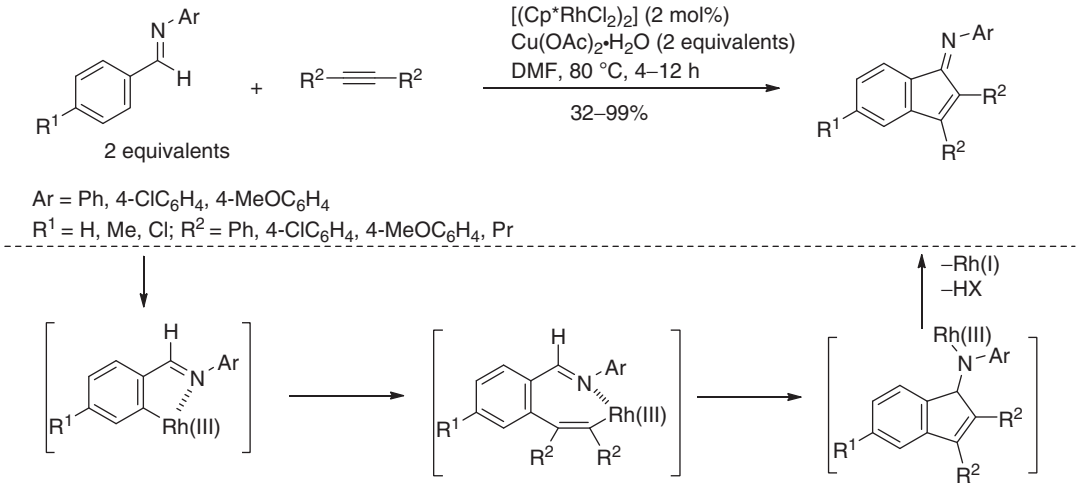
Recently, this type of reaction was combined with C–H activation chemistry. Thus, simple aryl carbonyl derivatives, in particular, arylimines could be employed as a three-carbon unit in reactions with alkenes and alkynes. Treatment of a mixture of benzaldehyde imines and arylalkynes with 3 mol% of $[ReBr(CO)_3(thf)_2]_2$ afforded aminoindene derivatives in good yield. The reaction proceeded with arylalkynes regioselectively, with the aryl substituent getting positioned next to the amino group. Arylrhenium species are generated by C–H activation; insertion of the alkyne followed by nucleophilic addition of the generated alkenylrhenium to the imine moiety and subsequent reductive elimination gave the product with regeneration of the Re(I) catalyst (**Scheme 81**).[110a,b] Allenes could also be employed in a similar process; specifically, aniline-derived ketimines gave the corresponding methylene aminoindane derivatives diastereoselectively on heating with the allenes in the presence of a catalytic amount of $[HRe(CO)_4]_n$ (equation 53).[110c]

Scheme 80



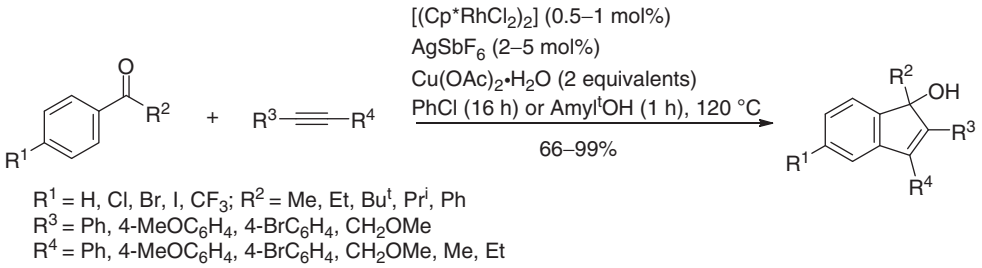
Scheme 81

(53)



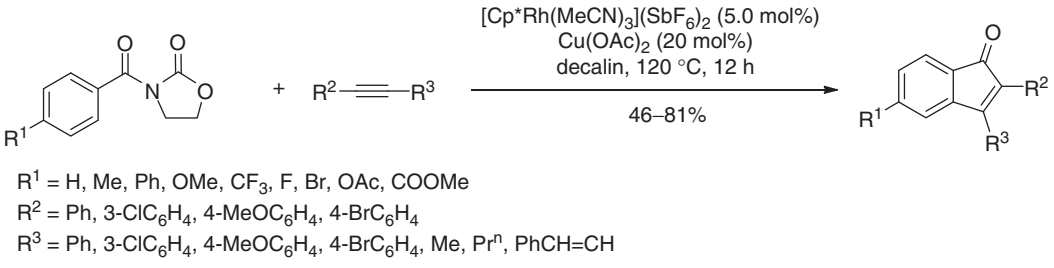
A similar reaction using acrylate instead of alkynes or allenes gave indene derivatives by elimination of aniline from the initial product. A rhenium- and aniline-cocatalyzed annulation of aromatic ketones with acrylate was achieved in good yield (equation 54).[110d]

(54)



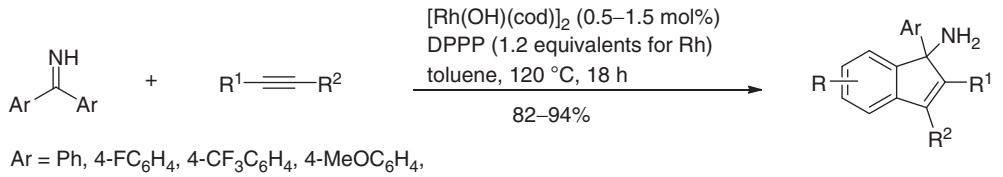
Rhodium-catalyzed reactions have also been accomplished recently, and these are classified into three reaction types, that is, (1) oxidative couplings using a Rh(III) catalyst with a stoichiometric Cu(II) reoxidant, (2) Rh(III)-catalyzed reactions in combination with a stoichiometric Cu(II) reagent, although no obvious reoxidation process is involved, and (3) Rh(I)-catalyzed

reactions based on a redox cycle. The first type of reaction employs $[Cp*RhCl_2]_2$ with $Cu(OAc)_2$ as a reoxidant. The reactions of aromatic aldimines with internal alkynes proceeded at 80 °C in DMF to give the corresponding [3 + 2] coupling products in good yield (Scheme 82).[111]

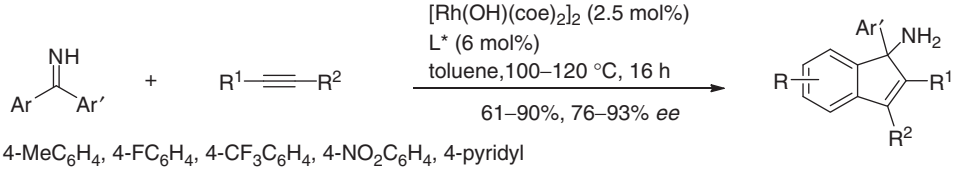


Scheme 82

The second type of reactions employs cationic Rh(III) catalysts in combination with $Cu(OAc)_2$ for the reactions of aromatic ketones or aroyl imides with internal alkynes. Almost all examples employed arylalkynes as substrates. Treatment of the aryl ketones or aroyl imides with aryl alkynes in the presence of cationic Rh(III) catalysts and $Cu(OAc)_2/H_2O$ gave indenol or indenone derivatives. Although the reason is not obvious, the use of $Cu(OAc)_2$ was essential to obtain the products in good yield. Representative examples are shown below (equations 55 and 56).[112]

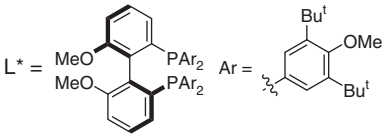


(55)



(56)

The third type of reactions employs Rh(I) complexes with phosphine ligands without further additives. For example, in the presence of 0.5–1.5 mol% $[Rh(OH)(cod)]_2$ and dppp, N-unsubstituted diaryl ketimines and internal alkynes were coupled to give tertiary 1*H*-inden-1-amines in good yield. In this reaction, oxidative addition of C–H bonds to Rh(I) and reductive elimination of the products from the Rh(III) metalacycle intermediates are involved.[113a,b] This reaction was extended to an enantioselective version using a chiral phosphine ligand (equations 57 and 58).[113c]



(57)

Ar = Ph, 4-FC_6H_4, 4-$CF_3C_6H_4$, 4-$MeOC_6H_4$,
$R^1 = R^2$ = Ph, Et, Pr^n, $MeOCH_2$
R^1 = Ph, R^2 = Me, Et

(58)

Ar = Ph, 4-MeC_6H_4, 4-FC_6H_4, 4-$CF_3C_6H_4$, 4-$NO_2C_6H_4$, 4-pyridyl
Ar′ = Ph, Ph, 4-MeC_6H_4, 4-FC_6H_4,
$R^1 = R^2 = MeOCH_2$
R^1 = Ph, Me, R^2 = $MeOCH_2$, $AcOCH_2$, $PhthNCH_2$

Glossary

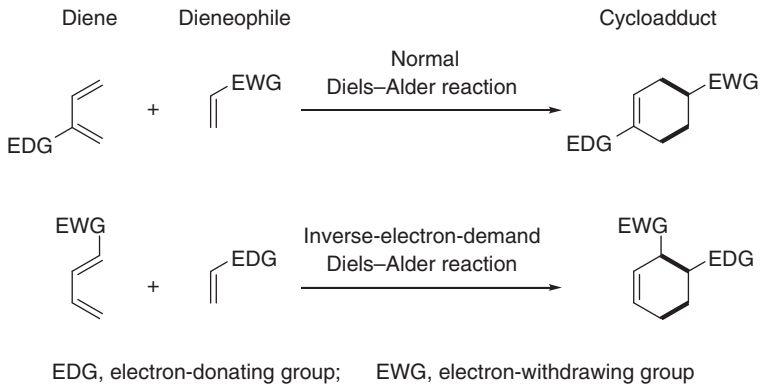
Biomimetic synthesis Biomimetic synthesis is an attempt to assemble natural products using a specific reaction or a sequence of reactions that mimic a proposed biological pathway without recourse to the full enzymatic machinery of nature.

CH–π interaction CH–π interaction is a weak attractive noncovalent interaction between CH groups and π-systems. For example, intramolecular CH–π interaction is used to stabilize the conformation of some proteins.

Cinchona alkaloid Cinchona alkaloids are an important subgroup of the polycyclic β-carboline alkaloids, which include (dihydro)cinchonine, (dihydro)cinchonidine, (dihydro)quinidine, and (dihydro)quinine. These alkaloids are isolated from cinchona, a genus of approximately 38 species in the family Rubiaceae, native to tropical South America.

Endo*, *exo The Diels–Alder reaction of cyclopentadiene with 2-propenal can produce two possible diastereomers, the *endo*- and the *exo*-adducts. The prefix *endo* refers to the isomer with the substituent located closest, or *syn*, to the longest bridge. The prefix *exo* is reserved for the isomer with the substituent located farthest, or *anti*, to the longest bridge. Here 'longest' and 'shortest' refer to the number of atoms that comprise the bridge. *Endo* and *exo* are also used to describe the stereochemistry of transition-state assemblies that lead to the *endo*- and the *exo*-adducts, respectively.

HOMO, LUMO HOMO and LUMO are acronyms for highest occupied molecular orbital and lowest unoccupied molecular orbital, respectively. HOMO and LUMO are sometimes referred to as frontier orbitals. Electron-rich dienes have high-energy HOMOs and interact strongly with the LUMOs of electron-poor dienophiles.



π–π Interaction π–π Interaction refers to attractive, noncovalent interactions between π-systems. In general, electron-rich π-systems (π-electron donor) interact with electron-deficient π-systems (π-electron acceptor) in parallel orientation.

s-cis*, *s-trans The spatial arrangement of two conjugated double bonds about the intervening single bond is described as *s-cis* if synperiplanar and *s-trans* if antiperiplanar. This term should not be applied to other systems such as *N*-alkyl amides (use *E*/*Z* or *sp*/*ap*).

5.09.1 Introduction

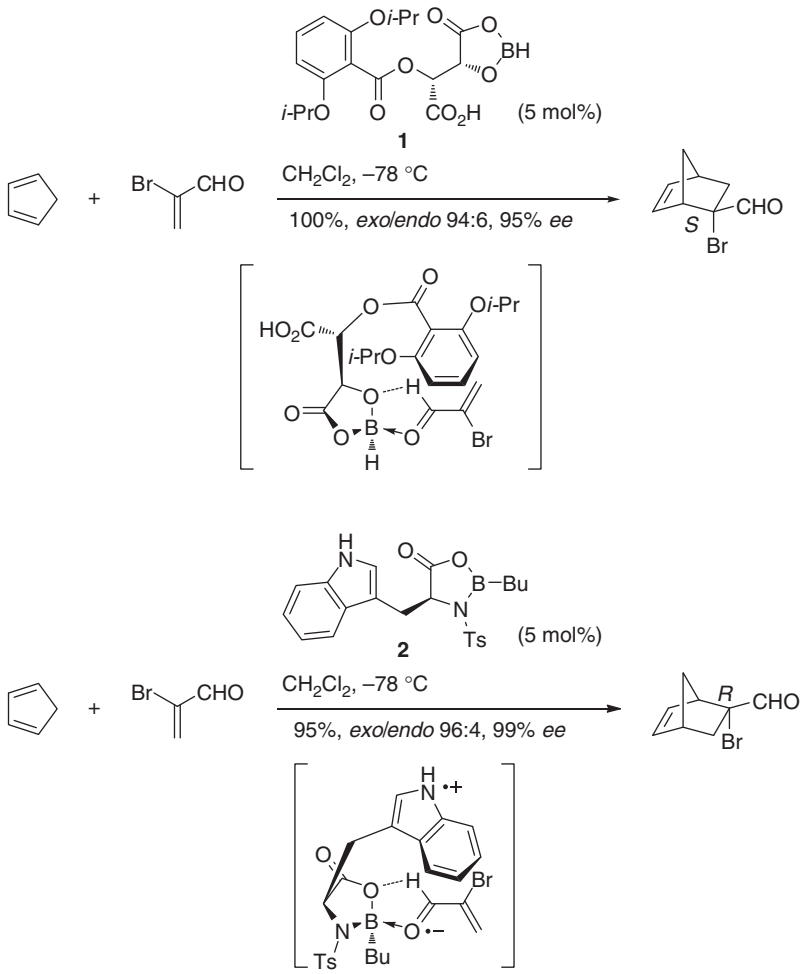
The cycloaddition reaction of a diene with a dienophile (alkene or alkyne) generates a cyclohexene derivative. This concerted [4 + 2] cycloaddition is known as the 'Diels–Alder reaction.' The Diels–Alder reaction has significant synthetic utility since it generates two new σ-bonds and a π-bond with the selective construction of multiple stereogenic centers in a single operation. In general, electron-deficient alkenes, such as quinones and α,β-unsaturated aldehydes, are more reactive toward electron-rich dienes

(Scheme 1). However, for the reaction with electron-poor dienes, electron-rich alkenes, such as vinyl ethers, are more reactive. This type of reaction is called an 'inverse-electron-demand' Diels–Alder reaction. An excellent review of intermolecular Diels–Alder reactions was presented in the first edition of Comprehensive of Organic Synthesis in 1991: 'Intermolecular Diels–Alder Reactions' by W. Oppolzer.[1]

Scheme 1 Conceptual Diels–Alder reactions.

Since the discovery of the Diels–Alder reaction, stereoselective versions of the reaction have been widely investigated. In 1960, the Diels–Alder reactions of anthracene with maleic anhydride, benzo-1,4-quinone, or dimethyl fumarate were shown to be markedly accelerated by the presence of aluminum trichloride.[2] This catalytic effect is the result of the coordination of the Lewis acid with the dienophile, which lowers the energy of the lowest unoccupied molecular orbital (LUMO), thereby allowing the Diels–Alder reaction to be conducted under mild conditions with enhanced regio- and diastereoselectivity. Furthermore, enantioselectivity in the reaction can be achieved with the use of chiral Lewis acid catalysts. This chapter focuses on recent advances in the diastereo- and enantioselective Diels–Alder reaction using chiral Lewis acid catalysts or chiral organocatalysts.

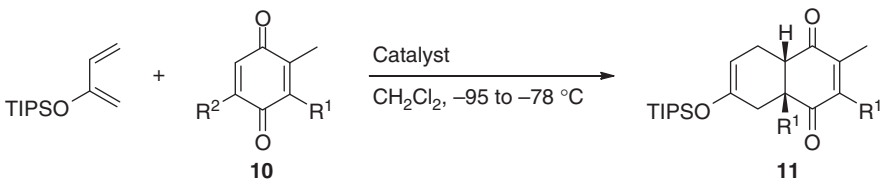
5.09.2 Catalysis Using Chiral Boron Compounds



5.09.2.1 Chiral Cationic Oxazaborolidines

Early examples of chiral boron catalysts for the enantioselective Diels–Alder reaction include the chiral acyloxyborane (CAB) catalyst **1** derived from *O*-[2,6-di(isopropoxy)benzoyl]-L-tartaric acid[3–6] and the chiral oxazaborolidine **2** derived from *N*-tosyl-L-tryptophan and butylboronic acid (Scheme 2).[7–9] Catalyst **1** is effective for the Diels–Alder reaction with acrylic acids, α,β-alkenals and α,β-alkynals. Effective shielding of the *Si* face of α,β-alkenal coordinated to **1** arises from π–π stacking between the electron-rich 2,6-diisopropoxybenzene ring and the coordinated aldehyde. The high enantioselectivity in the Diels–Alder reaction of α,β-alkenals catalyzed by **2** is induced by attractive interactions between the π-donor indole ring and the coordinated aldehyde. Based on the bright orange-red color of the complex of **2** with 2-methylpropenal, this attractive interaction may be due to charge-transfer complexation, which is stronger than a π–π attractive interaction.

Activation of oxazaborolidines through coordination with a strong acid on nitrogen generates highly Lewis acidic cationic oxazaborolidines.[10,11] Thus, cationic oxazaborolidines **3**–**7** have been developed as powerful catalysts for the enantioselective Diels–Alder reaction. Oxazaborolidines **3** (X=TfO, Tf_2N) and **4**, derived from an α,α-diphenyl-L-prolinol and tri-2-tolylboroxin, are activated by superacids such as trifluoromethanesulfonic acid (TfOH),[12,13] trifluoromethanesulfonimide (Tf_2NH),[14,15] or strong Lewis acids such as aluminum tribromide.[16] Oxazaborolidines **3** and **4** show excellent catalytic activities for the Diels–Alder reactions of various α,β-alkenals, α,β-unsaturated ketones, and α,β-unsaturated esters (Table 1) (Figure 1).

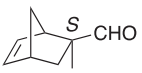


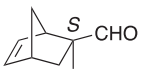
As shown in Table 1, the face selectivities of the enantioselective Diels–Alder reactions of α,β-unsaturated ketones and esters are opposite to those observed for α-substituted propenals. This reversal in face-selectivity can be explained in terms of the pretransition-state complexes **8** and **9** (Figure 2).[13] In pretransition-state complex **8** for α,β-alkenals, the oxygen of the oxazaborolidine catalyst interacts with the formyl CH proton (formyl CH–O interaction), whereas for other α,β-unsaturated carbonyl compounds, the oxygen interacts with the α-CH proton (α-CH–O interaction) in pretransition-state complex **9**. In the Diels–Alder reactions of α,β-unsaturated esters, an alternative mode of coordination that does not involve an α-CH–O interaction has also been proposed on the basis of computational investigations.[17]

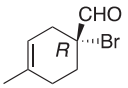
In general, quinones are highly reactive dienophiles and the scope of their reactions is broad. The Diels–Alder reaction of quinones is very useful for the synthesis of natural products and other complex molecules. For example, oxazaborolidines **3b** and **4** successfully catalyze the Diels–Alder reaction of quinones **10** to afford the corresponding adducts **11** with high regio- and enantioselectivities (equation 1, Table 2).[15,16] In particular, aluminum tribromide-activated oxazaborolidine **4** shows excellent

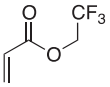
Scheme 2 Early examples of chiral boron catalysts for the enantioselective Diels–Alder reaction.

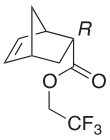
catalytic activity and can promote the reaction of quinones **10** with low catalyst loading (4 mol%). The sense of the enantioselectivity of the Diels–Alder reaction of quinones **10** is consistent with pretransition-state complex **9**.

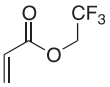


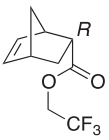


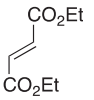


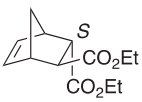


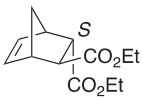


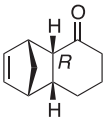


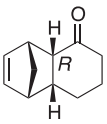












(1)

The following set of selection rules for the Diels–Alder reaction of unsymmetrical 1,3-butadienes with unsymmetrical 1,4-benzoquinones has been proposed.[15]

1. For a quinone carbonyl flanked by Cα–H and Cα–R, the major product will result from catalyst coordination preferentially at the oxygen lone pair on the C–H side rather than the C–R side because the C–H side is sterically more accessible (Figure 3).
2. Catalyst coordination at the more basic of the two 1,4-quinone oxygens will predominate, and this mode will lead to the preferred Diels–Alder adduct (Figure 3).
3. If a double bond of the quinone in a 1,3-diene addition bears two hydrogens, it will be more reactive than that bearing substituent(s), especially one or two π-electron-donating groups.
4. For monosubstituted 1,4-quinones (or *p*-benzoquinone itself), the major product pathway will involve coordination of the catalyst at the C=O *syn* to the HC=CH subunit that undergoes [4 + 2]-cycloaddition (Figure 3).
5. C-1 of 2-triisopropylsilyloxy-1,3-butadiene, the more nucleophilic end of the diene, will attach to the carbon β to the carbonyl group that coordinates with the catalyst, that is, the more electrophilic carbon.

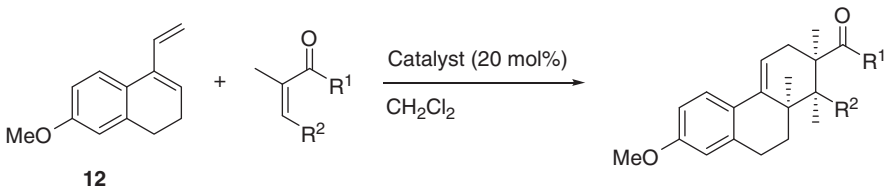


Table 1 Enantioselective Diels–Alder reactions of α,β-unsaturated carbonyl compounds catalyzed by oxazaborolidines **3** and **4**[a]

		**4** (4)		98	97:3	99	16
		**3b** (20)		99	–	>99	14
		**4** (4)		95	–	98	16
		**3a** (20)		97	91:9	93	13
		**4** (4)		99	94:6	95	16

[a]Conditions: diene (1.1 equivalents), catalyst (4–20 mol%), CH_2Cl_2.

6. The preferred three-dimensional transition state corresponds to the *endo* arrangement of the diene and catalyst-coordinated quinone.

Another type of chiral Lewis acid with an oxazaborolidine core is the *N*-methyloxazaborolidinium salt **5**,[18] which generally affords better results than catalyst **4**. For instance, the *ent*-**5**-catalyzed Diels–Alder reaction of Dane's diene **12** with 2-methylcyclopent-2-enone gives the corresponding *endo*-adduct **13** in 98% yield with 82% *ee* (equation 2, **Table 3**). However, the corresponding reaction with catalyst **4** provides *ent*-**13** in lower yield (50%) with lower enantioselectivity (75%).

(2)

The stereoselective construction of halogenated quaternary stereogenic centers is an important synthetic task because they are important structures in drug candidates and/or their synthetic intermediates. The asymmetric Diels–Alder reaction of halogenated dienophiles is an attractive approach for the stereoselective formation of halogenated quaternary carbons. Lewis acid-activated

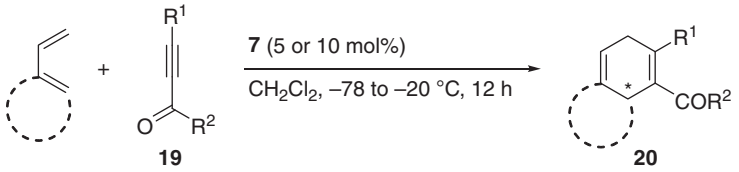
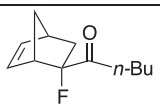
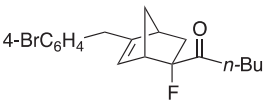
	**4**	−20, 48	 **13**	50	75	18

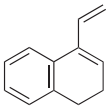


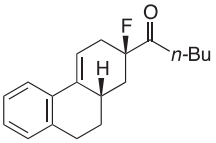
chiral oxazaborolidine **6** is an efficient catalyst for the enantioselective Diels–Alder reaction of 2-fluorohept-1-en-3-one **14** and gives the corresponding adducts **15** with high optical purity (equation 3, Table 4).[19] Notably, the reaction of **14** with cyclopentadienes catalyzed by **6** preferentially gives the *exo*-adducts, whereas the same reaction of ethyl vinyl ketone gives the corresponding nonfluorinated adducts with high *endo* selectivities.

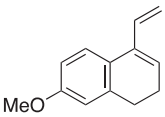
Catalyst **6** can also promote the enantioselective Diels–Alder reaction of 2-halocycloalken-1-ones. For example, the reaction of 2-bromocyclopenten-1-one **16** with diene **12** affords the corresponding *endo*-adduct **17** with high enantioselectivity (Scheme 3). The adduct **17** can be converted to a *trans*-fused CD ring system **18** via a three-step sequence that includes *trans*-selective reductive alkylation as a key step.

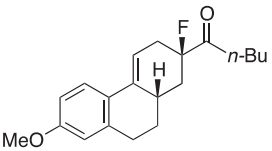




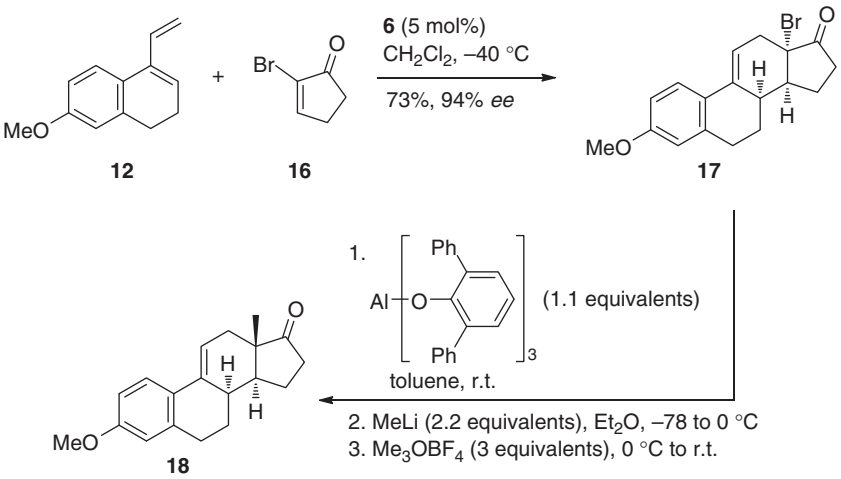








(3)



Despite advances in asymmetric catalysis, only a few methods have been reported for the enantioselective Diels–Alder reactions of alkynes. The L-valine-derived cationic oxazaborolidine **7** shows good catalytic activity for regio- and enantioselective Diels–Alder reactions of α,β-ynones **19** (equation 4, Table 5).[20] Both cyclic and acyclic dienes provide the corresponding adducts **20** in high yields with high enantioselectivities. In the reaction with cyclopentadiene, the use of dienophile **19** bearing a *tert*-butyldimethylsilyl (R^1=TBDMS) group improves the enantioselectivity, whereas the reaction of **19** bearing a trimethylsilyl (R^1=TMS) group shows moderate enantioselectivity. Importantly, a high level of asymmetric induction is observed with dienophiles that lack the hydrogen-bonding motif required for cationic oxazaborolidine-catalyzed Diels–Alder reactions.

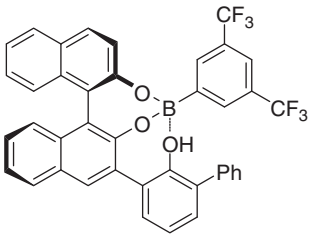
5.09.2.2 Boric or Boronic Acid Esters of Chiral 1,1′-bi-2-naphthols (BINOLs)



Chiral boric or boronic acid esters of binaphthols, e.g., **21** and **22** (Figure 4), can serve as Brønsted acid-assisted chiral Lewis acid (BLA) catalysts for the enantioselective Diels–Alder reactions of α,β-alkenals.[21–24] For example, in the presence of (*R*)-**21a** (R^1 = H, 10 mol%), the Diels–Alder reaction of 2-substituted propenals **23** ($R^2 \neq H$) with cyclopentadiene gives the corresponding *exo*-adduct **24** with high enantioselectivity, whereas the reaction of 2-unsubstituted propenals **23** (R^2 = H) preferentially gives the *endo*-**24** with moderate enantioselectivity (equation 5, Table 6). For the Diels–Alder reaction of propenal ($R^2 = R^3 = H$), the use of (*R*)-**21b** (R^1 = Ph) improves the enantioselectivity to 92% *ee*.[24] However, the scope of dienophiles that are suitable for use with less-reactive dienes is rather limited.

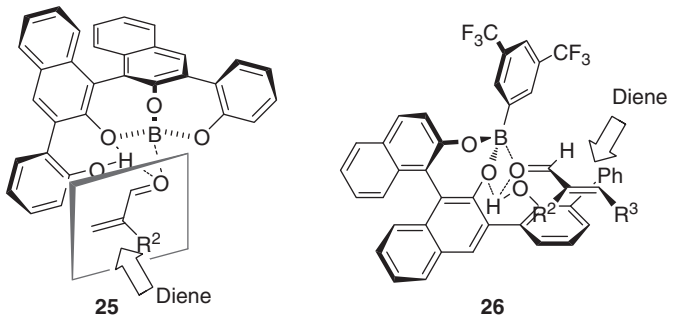
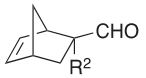
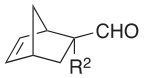
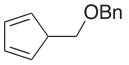
The asymmetric induction in the (*R*)-**21**-catalyzed Diels–Alder reaction can be understood in terms of the most favorable transition-state complex **25** (Figure 5). It is conceivable that the coordination of a proton of the 2-hydroxyphenyl group with an oxygen of the adjacent B–O bond in complex **25** plays an important role in face selection. Hydrogen bonding through the Brønsted acid presumably causes the Lewis acidity of boron and the π-basicity of the phenoxy moiety to increase, which stabilizes the transition state. In transition state **25**, the hydroxyphenyl group blocks the C*α-Re* face of the carbon–carbon double bond in the 2-substituted propenals, which leaves the *Si* face open to an approach by the diene.

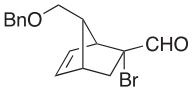
(5)

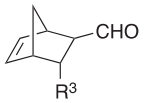


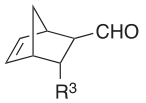


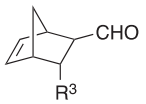


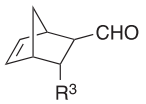


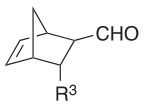


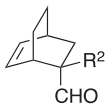


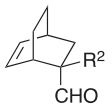


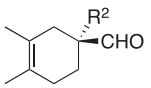


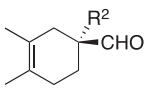


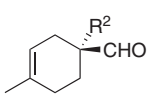












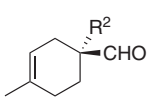


Figure 5 Proposed transition-state complexes **25** and **26**.

The chiral BLA catalyst (*R*)-**22** shows excellent activity for the Diels–Alder reaction of α,β-alkenals **23** with both α-unsubstitution ($R^2 = H$) and α-substitution ($R^2 \neq H$) with a variety of dienes (Table 7).[22,24] The BLA (*R*)-**22** is prepared *in situ* by reaction of the corresponding chiral (*R*)-triol with commercially available 3,5-bis(trifluoromethyl)phenylboronic acid in dichloromethane. In the presence of 5–20 mol% of (*R*)-**22**, the Diels–Alder reaction proceeds smoothly to afford the corresponding adducts with excellent diastereo- and enantioselectivities. The asymmetric induction in the (*R*)-**22**-catalyzed Diels–Alder reaction is opposite that in the reaction catalyzed by (*R*)-**21a**. This means that the presence of the 3,5-bis(trifluoromethyl)phenyl group greatly affects the asymmetric induction of (*R*)-**22**, which can be understood in terms of transition state **26** (Figure 5).

The chiral BLA **21** and **22** are also efficient catalysts for the enantioselective Diels–Alder reaction of acetylenic dienophiles **19** ($R^2 = H$).[23] The reaction of cyclic dienes with acetylenic dienophiles in the presence of (*R*)-**21a** or (*R*)-**22** (10–20 mol%) proceeds smoothly to afford the corresponding cycloadducts with a range of enantioselectivities (Table 8). Interestingly, (*R*)-**21a** generally gives higher enantioselectivity than (*R*)-**22**. As in the reaction with α,β-enals, the absolute configurations of the adducts with (*R*)-**21a** are opposite to those with (*R*)-**22**. The absolute configuration of the products of this reaction can be explained in terms of an *anti-exo* transition-state model **27** (Figure 6), and this view is strongly supported by theoretical studies. The frontier molecular-orbital theory explains *exo* selectivity in terms of the secondary antibonding interaction between the lobes on C-2 of cyclopentadiene and the carbonyl oxygen of propynal in the *endo*-transition state (TS) (Figure 6).

Because the *endo*/*exo* selectivity in the Diels–Alder reaction strongly depends on the substrates, it is quite difficult to control both the enantioselectivity and anomalous *endo*/*exo* selectivity by conventional chiral catalysts, which can only discriminate the enantiofaces of the dienophiles. For example, in the reaction of cyclopentadiene with propenal, an *endo* preference is observed with regard to second-order orbital interactions without significant steric interactions (Scheme 4). In sharp contrast, in the reaction

with 2-methylpropenal (R^1 = Me), an *exo* preference is observed with regard to steric interactions between the methylene moiety of cyclopentadiene and the substituent R^1 at the 2-position of the dienophile. In the reaction with 2-unsubstituted propenal, the thermodynamically more stable and enantiomerically enriched *exo*-**28** can be generated by the epimerization of *endo*-**28**. In contrast, enantiomerically enriched *endo*-**29** with a quaternary carbon center cannot be generated by the epimerization of *exo*-**29**. Therefore, the only approach for the synthesis of *endo*-**29** should be the enantioselective, anomalous *endo*-selective Diels–Alder reaction (Scheme 4).

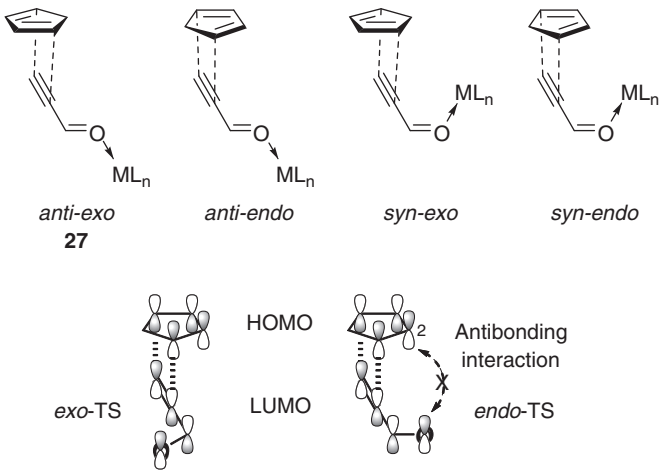

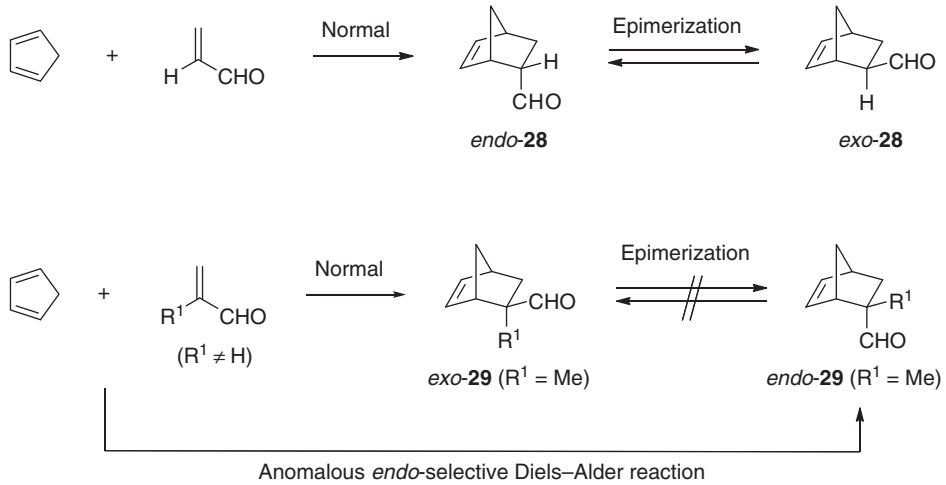

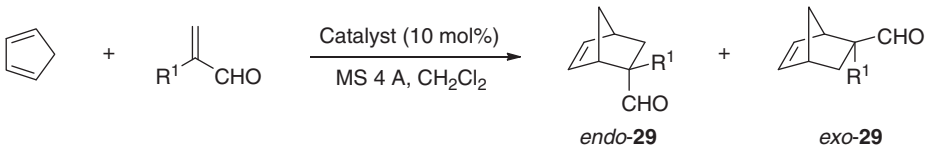

Figure 6 Four possible transition structures, and the secondary antibonding interaction in *endo*-TS. ML_n = Lewis acid.

Chiral supramolecular catalysts **32**–**35** are readily prepared *in situ* from the corresponding chiral diol **30** (10 mol%), an electron-deficient arylboronic acid **31** (10 mol%) and *tris*(pentafluorophenyl)borane (20 mol%) (Scheme 5).[25,26] Intermolecular acid–base coordinative bonds in the two P=O–B$(C_6F_5)_3$ moieties are critical for the design of the conformationally flexible complexes **32**–**35**. *Tris*(pentafluorophenyl)borane acts as a bulky functional group to form a chiral, narrow, and deep cavity around the Lewis acidic boron center. In addition, the strong electron-withdrawing nature of tris(pentafluorophenyl)borane increases the Lewis acidity of the central boron through conjugated bonds. Catalysts **32**–**35** can catalyze the anomalous *endo*-selective, enantioselective Diels–Alder reaction of cyclopentadiene with 2-substituted propenals ($R^1 \neq H$, equation 6). For example, the reaction with 2-methylpropenal (R^1 = Me) catalyzed by the chiral supramolecular catalyst **32** preferentially affords *endo*-(2*S*)-**29** as the major product (99% yield, *endo*/*exo* = 83:17) with 99% *ee* (Table 9). In contrast, the use of 3,5-*bis*(trifluoromethyl)phenylboronic acid **31** ($R^4 = CF_3$) or *tris*(pentafluorophenyl)borane as a catalyst gives the expected *exo*-**29** as the major product (*endo*/*exo* = 6–12:94–88). The chiral supramolecular catalysts **33**–**35** promote the Diels–Alder reaction with 2-bromopropenal, 2-chloropropenal, and 2-fluoropropenal, respectively, to give the corresponding adduct **29** (R^1 = Br, Cl, and F) with anomalous *endo* selectivities (*endo*/*exo* = 93–82:7–18) and excellent enantioselectivities (96–99% *ee*).

Scheme 4 Normal versus anomalous *endo*/*exo* selectivity in Diels–Alder reaction with 2-substituted propenals.

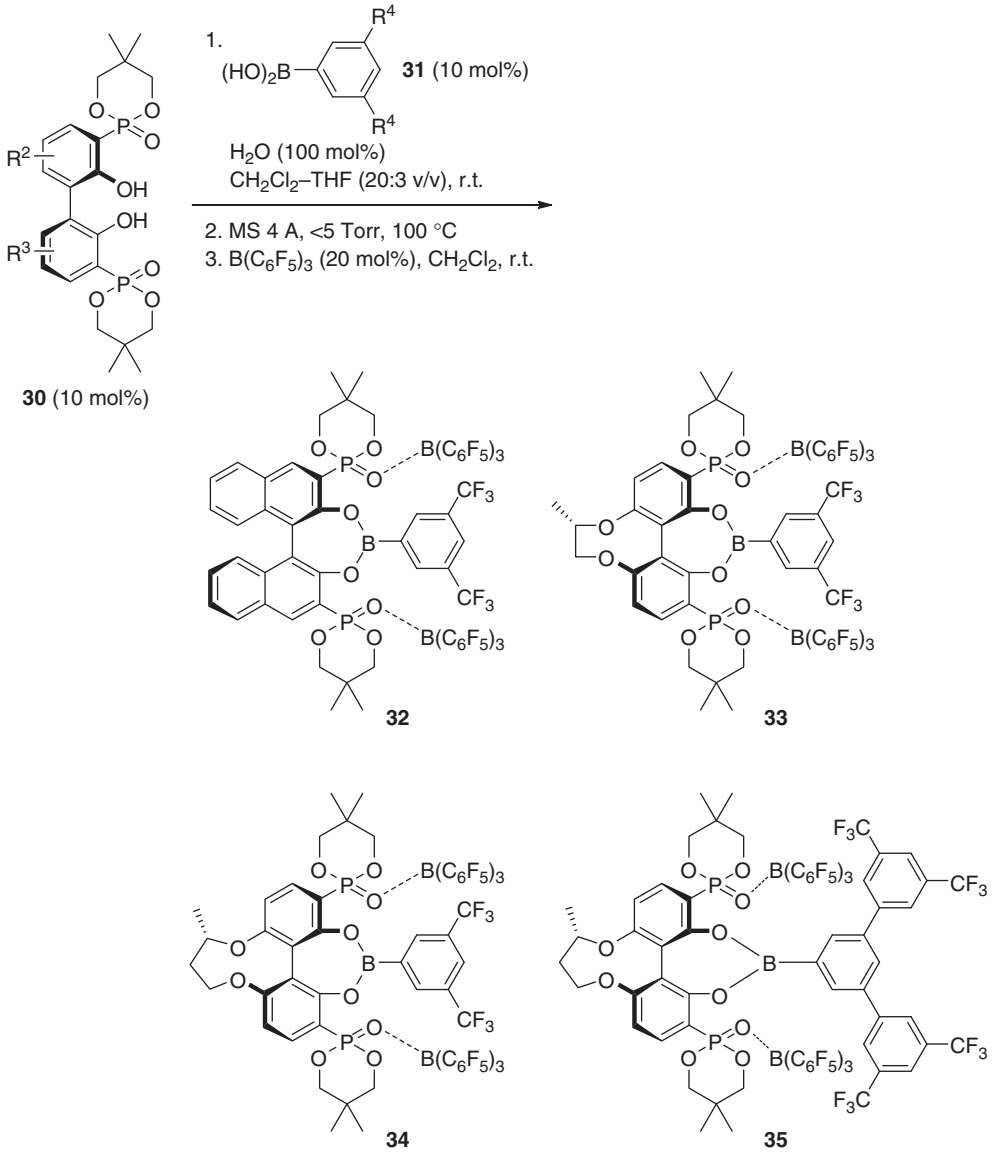
5.09.3 Catalysis Using Chiral Copper(II) Complexes



5.09.3.1 Chiral Copper(II)–*Bis*(oxazoline) Complexes

During the course of a synthetic study on prostaglandins, Corey and colleagues discovered that copper(II) tetrafluoroborate catalyzes the Diels–Alder reaction with α-chloroacrylonitrile.[27–29] The use of $Cu(BF_4)_2$ accelerates the Diels–Alder reaction at 0 °C without the isomerization of 5-(methoxymethyl)cyclopentadiene. Since then, various copper(II) salts have been used as Lewis acid catalysts for the Diels–Alder reaction.[30]

Bis(oxazoline) ligands are a major class of chiral ligands for asymmetric catalysis, among which **36** (R^1 = Bu^t, Pr^i, and Ph), **37**, and **38** (R = Bu^t and Ph) are representative examples (Figure 7).[31–33] The copper(II) complexes of these ligands are efficient catalysts for enantioselective Diels–Alder reactions. The C_2-symmetric copper(II) complexes of *bis*(oxazoline) **36a** (R^1 = Bu^t) show high catalytic activity for the enantioselective Diels–Alder reaction of dienes with *N*-alkenoyloxazolidinones **39** (Scheme 6).[34–37] The salts of copper(II) are the most effective among those of the first-row transition metals, since they offer both strong Lewis acid activation and rapid ligand-exchange. Representative results for enantioselective Diels–Alder reactions catalyzed by the copper(II) salt of **36a** are summarized in Table 10. Most acyclic and cyclic dienes afford the corresponding *endo*-adducts **40** in high yields with high enantioselectivities, whereas 2-substituted buta-1,3-dienes, such as isoprene and 2,3-dimethylbuta-1,3-diene, provide moderate enantioselectivities. The absolute configuration of the adducts **40** is consistent with activation through bidentate coordination of the dienophile **39** to a distorted square-planar copper(II) center (Scheme 6). A diene can approach the C*α*-*Re* face of the activated *s-cis* dienophile via an *endo*-transition state to afford the corresponding cycloadduct **40** with excellent enantioselectivity.

In contrast to 2,3-unsubstituted dienes, 3-methylbuta-1,3-dienyl acetate shows a significant *exo* preference (*endo*/*exo* 73:27). This diastereoselectivity could be explained by the steric hindrance of the 3-methyl substituent (R^3 = Me, Figure 8). The steric effect of the 3-methyl substituent could also explain the low enantioselectivity observed in the reaction of isoprene (59% *ee*). Isoprene is presumed to approach the activated dienophile largely via an *exo* transition-state **42**. The disfavored *exo* approach **43** of isoprene to the C*α*-*Si* face of the activated dienophile does not involve substantial steric interaction with the ligand to decrease the enantioselectivity. In contrast, the acetoxy group of 3-methylbuta-1,3-dienyl acetate contracts the ligand substituent in the disfavored *exo* approach **44** to generate high enantioselectivity (Figure 9).

The chiral copper(II) trifluoromethanesulfonimide complex of the *bis*(oxazoline) **37** produces a high degree of enantioselectivity in the Diels–Alder reaction of dienophile **39** with a variety of cyclic and acyclic dienes, including 2-substituted buta-1,3-dienes (Scheme 7, Table 11).[38,39] The reaction of acyclic dienes with *β*-substituted dienophiles, which is one of the most challenging reactions, successfully affords the corresponding adducts with high enantioselectivities. For example, the $Cu(NTf_2)_2$•**37**-catalyzed Diels–Alder reaction of isoprene with dienophile **39** (R^2 = $CH_2OTBDMS$) gives the corresponding *endo*-adduct with 95% *ee*; this product is a key intermediate for synthesis of the decahydrofluorene core of hirsutellones.[40]

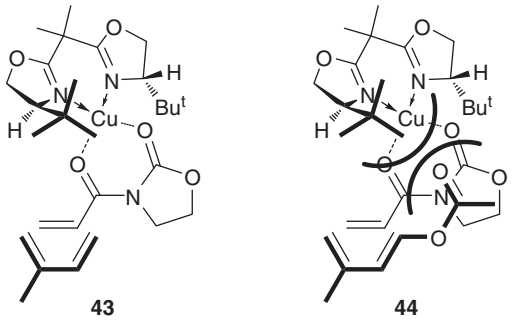
A theoretical study suggests that the *n* electrons of the 4,4′-sulfonamide groups interact with the copper(II) cation (*n*–cation interaction), and the counteranions interact with the sulfonamidyl protons (Scheme 7).[38,39] This coordination is thought to be essential for high catalytic activity, because it results in the formation of a cationic but stable catalyst. It is conceivable that dienes predominantly approach the C*α*-*Si* face side of *s*-*cis*-**39**, because a sulfonamide group and a trifluoromethanesulfonimide anion preferentially shield the *Re* face of the acrylimide moiety. The flexible but highly efficient asymmetric environment created by the secondary interactions provides a broad substrate scope and a high level of asymmetric induction.



The *n*-cation catalyst also promotes the Diels–Alder reaction of diene **45** with *N*-alkenoyloxazolidinones **39** (R^2 = CO_2Et) to give the corresponding *endo*-adduct **46** in 97% yield with 95% *ee* (Scheme 8).[41] This procedure is scalable with a minimal

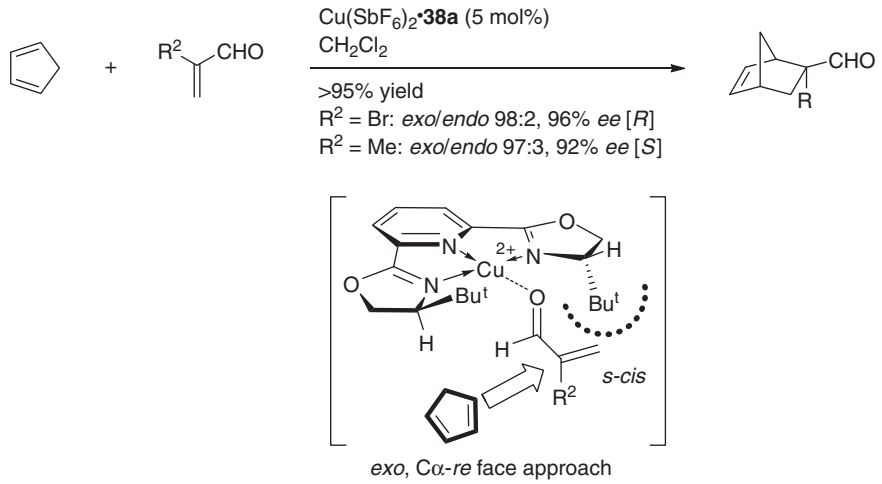
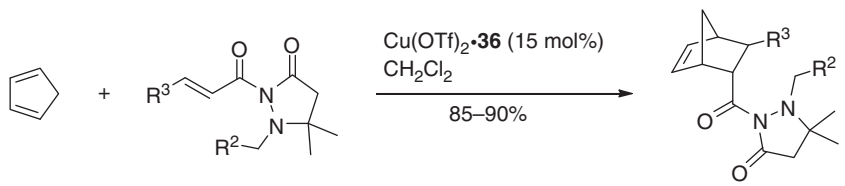
Scheme 8 Synthesis of spiro compound **47**, a key common precursor for the synthesis of pyrrole-imidazole alkaloids, (–)-palau'amine, (–)-axinellamines and (–)-massadines.



The *N*-Cbz-protected lactams **49** and **52** are also good dienophiles for the Diels–Alder reaction catalyzed by the copper(II) hexafluoroantimonate complex of the *bis*(oxazoline) **36a** (Scheme 9). In this context, the diene **48** reacts with the six-membered lactam **49** via an *exo*-transition state, to afford the spirolactam **50**, which is a key intermediate in the synthesis of the spirocyclic imine core of (–)-gymnodimine.[42] In a related example, the $Cu(SbF_6)_2$•**36a**-catalyzed cycloaddition of the diene **51** with the

Scheme 9 Enantioselective Diels–Alder reaction of *N*-Cbz-protected lactams **49** and **52**.

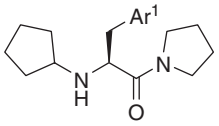


seven-membered lactam **52** gives the spirolactam **53**, which is useful as an intermediate in the synthesis of the azaspiro[5.6]dodec-9-ene system in the marine toxins pinnatoxin A and pteriatoxin A.[43]

For the enantioselective Diels–Alder reaction of α-substituted α,β-alkenals, such as 2-methylpropenal and 2-bromopropenal, the copper(II) complex of a tridentate *bis*(oxazolinyl)pyridine (pybox) **38a** ($R^1 = Bu^t$) is among the most efficient catalysts and gives the corresponding *exo*-adducts with high diastereo- and enantioselectivity (Scheme 10).[36,44] It is presumed that α-substituted α,β-alkenals coordinate to the copper(II) center in a square-planar geometry. Cyclopentadiene predominantly approaches the Cα-*Re* face of the *s-cis*-dienophile via an *exo*-transition state.

Scheme 10 Enantioselective Diels–Alder reaction of α-substituted propenals catalyzed by $Cu(SbF_6)_2$•**38a**.

N-Alkenoylpyrazolidinones **54** can also act as dienophiles in the copper(II)-catalyzed enantioselective Diels–Alder reaction to give the corresponding cycloadducts **55** (equation 7).[45,46] Although the copper(II) complex of *bis*(oxazoline) **36b** ($R^1 = Pr^i$) generally shows poor enantioselectivity for the reaction of cyclopentadiene with *N*-alkenoyloxazolinones **39**,[35] the reaction of **54** (R^2 = 1-naphthyl) provides a high enantioselectivity (Table 12). Interestingly, this dienophile provides higher enantioselectivity when Lewis acids with relatively small chiral ligands are used; this has been attributed to the size of the fluxional group (R^2 = Me < Ph < 1-naphthyl) and the ability of the pyrazolidinone template to relay stereochemical information from the ligand to the reaction center.



54 **55** (7)

5.09.3.2 Chiral Copper(II)–3-Arylalanine Amide Complexes

The enantioselective Diels–Alder reaction of cyclopentadiene with 3-phenyl-1-(2-pyridyl)prop-2-ene-1-one is catalyzed by copper(II) nitrate and the sodium salt of L-abrine (*N*-methyl-L-tryptophan) or *N*-methyl-L-tyrosine in water (equation 8).[47,48] In this reaction, water enhances the enantioselectivity to give a product with up to 74% *ee*. However, the enantioselectivity is reduced to 17–44% *ee* in organic solvents, such as acetonitrile, tetrahydrofuran (THF), ethanol, and chloroform. The asymmetric induction may originate from the intramolecular π–cation interaction between the indole ring of L-abrine and the copper(II) cation. On the basis of such intramolecular π–cation interactions, chiral copper(II)-3-aryl-L-alanine amide complexes CuX_2•**56** have been designed as efficient catalysts for the enantioselective Diels–Alder reaction of 1-alkenoyl-3,5-dimethylpyrazoles **57** (Figure 10).[49,50] In particular, the copper(II) complex of **56a** (Ar^1 = 3,4-$(MeO)_2C_6H_3$) bearing an electron-rich aromatic group shows excellent catalytic activity (Scheme 11). In the presence of 2–10 mol% of the complex of this ligand with copper(II) trifluoromethansulfonimide, cyclic, and acyclic dienes undergo Diels–Alder reactions with various β-substituted dienophiles **57** to afford the corresponding *endo*-adducts **58** with high enantioselectivities (Table 13).

[a]The molar ratio of the 4- and 3-substituted diastereomers is shown.

The stereochemical outcome for the $Cu(NTf_2)_2$•**56a**-catalyzed Diels–Alder reaction can be understood in terms of the *trans*, *s-cis*-transition-state complex (Scheme 11).[49,50] Furthermore, the *N*-cyclopentyl and pyrrolidinyl groups in the ligand **56** sterically assist the π–cation interaction, whereas the 3- and 4-methyl groups on the pyrazole moiety sterically control the coordination environment around the copper(II) complex [*cis* (disfavored) versus *trans* (favored)] and the conformation of **35** [*s-cis* (favored) versus *s-trans* (disfavored)], respectively. Interestingly, the catalytic activity of $Cu(NTf_2)_2$•**56a** is slightly higher than that of $Cu(NTf_2)_2$. The π–cation interaction promotes the release of counteranions from the copper(II) center, thereby increasing the Lewis acidity and catalytic activity.

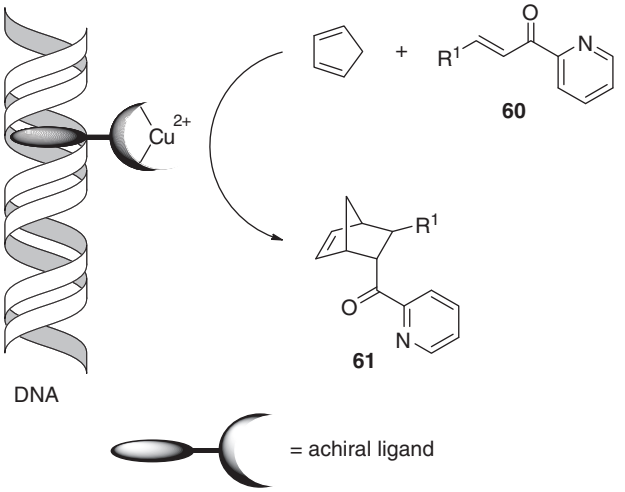
Scheme 11

In general, alkynes are less reactive as electron-deficient dienophiles than the corresponding alkenes. Furthermore, alkynes are more challenging substrates for asymmetric induction with a chiral Lewis acid due to the presence of the linear sp–sp bond, which orients the alkynyl moiety away from the metal center and the cylindrical orbital symmetry of the alkyne. However, propiolamides **59** undergo a catalytic and highly enantioselective Diels–Alder reaction with cyclic dienes in the presence of the chiral copper(II) complex $Cu(NTf_2)_2$•**56b** (Ar^1 = 2-naphthyl) (10 mol%) to afford the corresponding cycloadducts **60** (Scheme 12, Table 14).[51] Complex $Cu(NTf_2)_2$•**56b** (Ar^1 = 2-naphthyl) shows higher enantioselectivity than $Cu(NTf_2)_2$•**56a** (Ar^1 = 3,4-$(MeO)_2C_6H_3$) for the Diels–Alder reaction of propiolamides **59**. The expanded asymmetric environment created by π–cation interaction between the copper(II) center and the 2-naphthyl group may be effective for high-level asymmetric induction. The absolute configuration of the cycloadducts **60** can be explained in terms of the *exo*-transition-state complex (Scheme 12). Due to a secondary antibonding interaction between the lobes at the C2-position of cyclopentadiene (HOMO) and the carbonyl oxygen of **59** (LUMO) in the *endo*-transition state, cyclopentadiene predominantly approaches the *Si*-face side of **59** via an *exo*-transition-state. Since the 3-iodo adducts **60** (R^3 = I) can be readily transformed into 3-nonsubstituted and 3-alkyl derivatives by known methods, the propiolamide **59** (R^3 = I) represents the synthetic equivalent of alkyl- or aryl-substituted alkynes.

Scheme 12



5.09.3.3 Copper(II)–Deoxyribonucleic acid (DNA) Complexes

The chirality of the DNA double helix can be transferred directly to the copper(II)-catalyzed Diels–Alder reaction. DNA from salmon testes (st-DNA) in combination with the achiral copper(II) complex of an achiral ligand catalyzes the enantioselective

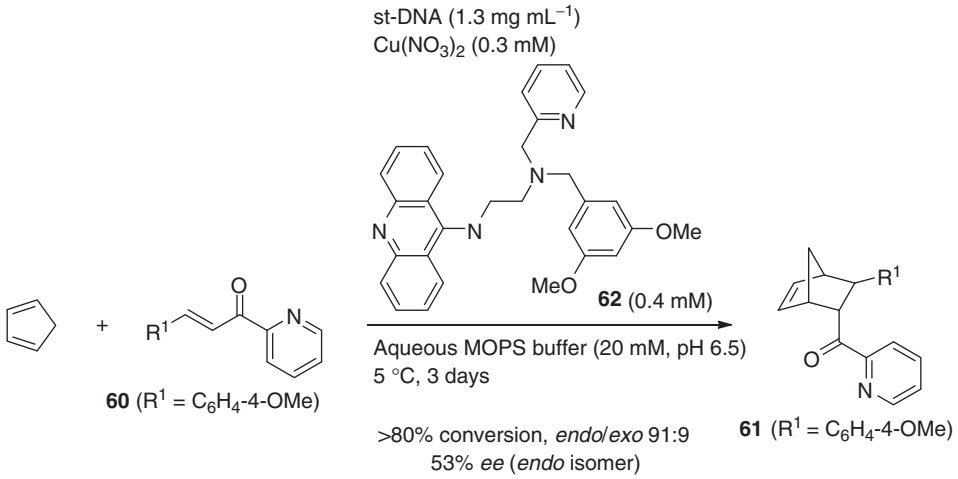
Diels–Alder reaction of cyclopentadiene with azachalcones **60**[52,53] and α,β-unsaturated 2-acyl-1-methylimidazoles[54] in water (Scheme 13). Two generations of DNA-based catalysts that differ in the type of ligand used have been reported. In the first design, the achiral ligand **62** is composed of aminomethylpyridine, a metal-binding domain, which is linked through a short spacer to 9-aminoacridine, a DNA intercalator (equation 9).[52] With this design, up to 53% *ee* can be achieved in the Cu(II)-catalyzed Diels–Alder reaction of cyclopentadiene with **60** ($R^1 = C_6H_4$-4-OMe). However, no rate-acceleration is observed in the presence of DNA in this catalytic system.[56]



Scheme 13 DNA-based asymmetric catalysis of Diels–Alder reaction.

In the other design, the DNA-binding moiety is integrated into the metal-binding domain without any spacer.[53] DNA in combination with the Cu(II) complex of 4,4′-dimethyl-2,2′-bipyridine shows high enantioselectivity in the Diels–Alder reaction of cyclopentadiene with azachalcones **60** (Scheme 14). In this approach, DNA is more than a chiral scaffold; rate-accelerations of up to two orders of magnitude have been observed in the presence of DNA.[55] In addition, both the enantioselectivity and the rate-enhancement are dependent on the DNA sequence.

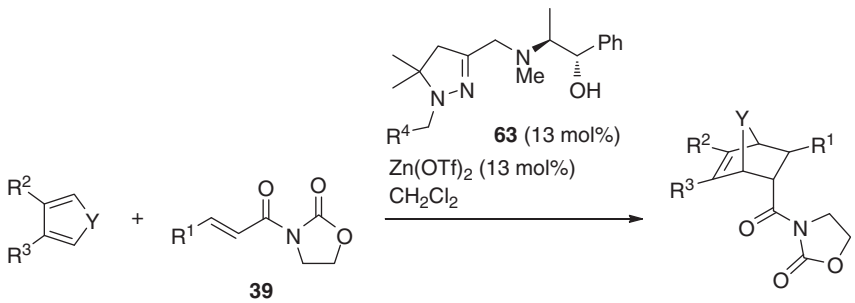
5.09.4 Catalysis Using Other Chiral Lewis Acids



Several other chiral Lewis acid catalysts, including compounds of chromium(III), magnesium(II), aluminum(III), scandium(III), titanium(IV), zinc(II), and the lanthanides, have also been used in enantioselective Diels–Alder reactions.

Zinc(II) complexes of the chiral ligands **63** (equation 10) catalyze the enantioselective Diels–Alder reaction.[57] For example, the chiral complex derived from zinc(II) trifluoromethanesulfonate and a chiral ligand **63** (13 mol%) catalyzes the Diels–Alder reaction of *N*-alkenoyloxazolidinones **39** to afford the corresponding *endo*-(*S*)-adducts with high enantioselectivity (Table 15). The copper(II) complex of **63** also catalyzes the Diels–Alder reaction of **39** and shows high enantioselectivity, which is similar to that of the zinc(II) complex. The level of selectivity depends on the size of the fluxional group (R^4 = Me < Ph < 1-naphthyl), where a larger group provides higher selectivity for both the *endo*- and *exo*-isomers. Based on the requirement of a hydroxy group in the chiral ligand for achieving high selectivity, an octahedral environment around the metal center is proposed, in which the naphthyl group shields the *Re* face of **39**.

(10)

In the same context, additive **64** bearing a benzyl group as a fluxional substituent improves the enantioselectivity of the chiral Lewis acid-catalyzed Diels–Alder reaction of cyclopentadiene with **39** (R^1 = H) (equation 11).[58] In the presence of 10 mol% of **64**, high

enantioselectivity is achieved in the Diels–Alder reaction catalyzed by Lewis acid complexes with chiral *bis*(oxazoline) **36c** (R^1 = Ph), whereas the same reaction in the absence of **64** shows moderate enantioselectivity (Table 16). The level of selectivity depends on the size of the fluxional group in **64** (R^2 = Me < Ph < naphthyl). The fluxional additive may aid in the formation of a well-defined octahedral complex in which the ligand phenyl group is compressed closer to the substrate, which results in enhanced face shielding.

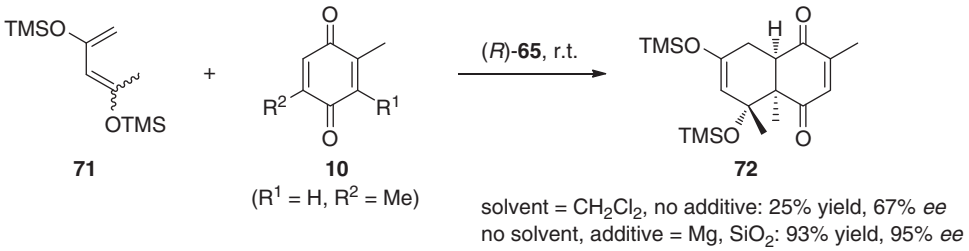
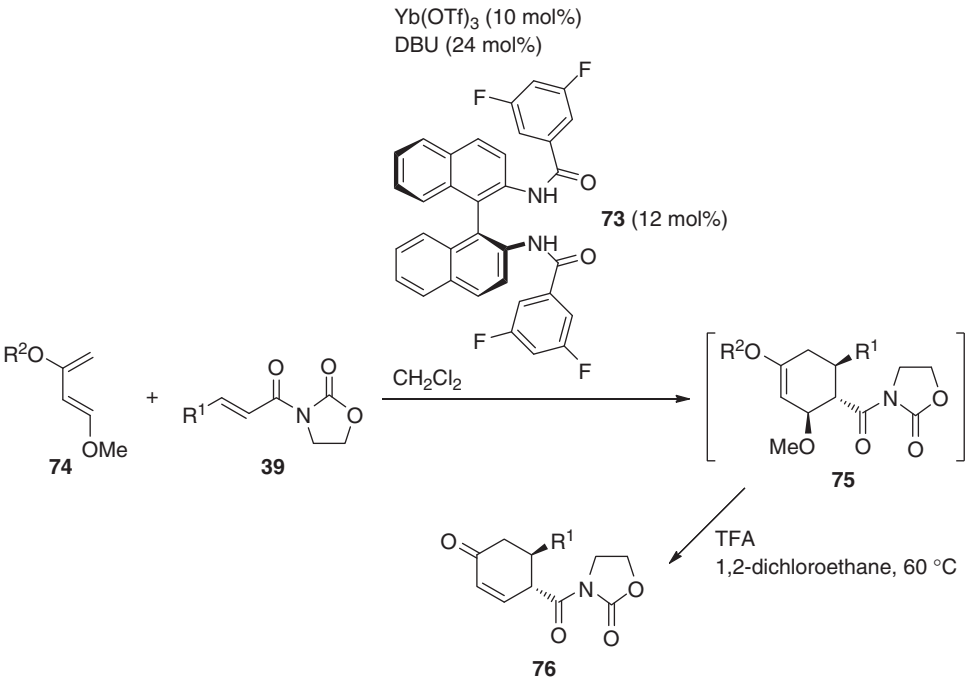
A chiral titanium(IV) complex **65**, prepared *in situ* from the reaction of (*R*)-BINOL and $TiCl_2(OPr^i)_2$ in the presence of molecular sieves 4 Å and H_2O, also acts as a Lewis acid catalyst for enantioselective Diels–Alder reactions (equation 12).[59,60] Although the structure of **65** is not entirely clear, it appears to be chloride-free and to involve μ-oxo bridges between at least two Ti units. The (*R*)-titanium(IV) complex **65** catalyzes the reaction of naphthoquinone with 1-methoxybuta-1,3-diene to give the corresponding *endo*-adduct **66** (Scheme 15). Because the 1,4-quinone adducts are readily aromatized and difficult to handle, the adduct **66** is stereoselectively converted to the more stable derivative **67** in 76% yield (two steps from naphthoquinone) with 85% *ee*. The enantioselective Diels–Alder reaction of 1,4-quinone monoketal **68** is also catalyzed by (*S*)-**65** to give stable *endo*-adduct **69** in 97% yield with 98% *ee* (Scheme 15).[61] Methoxide-catalyzed epimerization of **69** gives the corresponding *cis*-fused ketone **70** without the complication of aromatization.



Scheme 15 Enantioselective Diels–Alder reaction of 1,4-quinones catalyzed by chiral titanium(IV) complex **65**.



(12)

Although several methods are available for the enantioselective hetero-Diels–Alder reactions of Danishefsky-type dienes, only a limited number are known for the carbo-Diels–Alder reaction, presumably due to their sensitivity to Lewis acids. For example, the reaction of Danishefsky-type diene **71** (Scheme 16) with quinone **10** (R^1 = H and R^2 = Me) catalyzed by cationic oxazaborolidine **2b** (20 mol%) gives no Diels–Alder adduct because of the decomposition of diene **71**. For the enantioselective Diels–Alder reaction of Danishefsky-type diene **71** with quinone **10** (R^1 = H, R^2 = Me), the chiral titanium(IV) complex (*R*)-**65** efficiently gives the corresponding adduct **72** with good enantioselectivity (Scheme 16).[62] Importantly, the addition of Mg powder and silica gel increases the stability of **71** and improves the yield and enantioselectivity of **72**. Cycloadduct **72** is a key intermediate for the synthesis of cyathin A_3, a bioactive natural product.

Scheme 16 Enantioselective Diels–Alder reaction of Danishefsky-type diene **71** catalyzed by chiral titanium(IV) complex **65**.

Ytterbium(III) complexes of chiral 1,1′-(2,2′-bisacylamino)binaphthalene (**73**, BINAMIDE) catalyze the highly enantioselective Diels–Alder reaction of Danishefsky-type dienes with *N*-alkenoyloxazolidinones **39** (Scheme 17, Table 17).[63] In the presence of the ytterbium(III)–BINAMIDE complex prepared from ytterbium(III) trifluoromethanesulfonate, BINAMIDE (**73**), and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), Danishefsky-type dienes **74** undergo cycloaddition with **39** to afford the corresponding

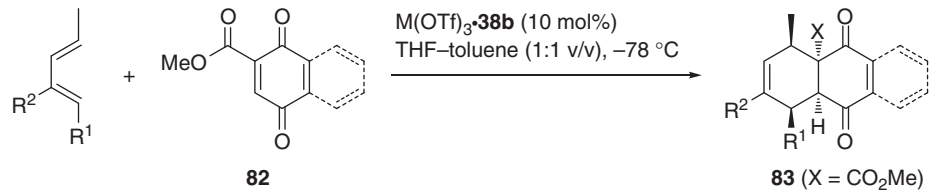
exo-adducts **75**. Acid treatment of adducts **75** gives the corresponding cyclohexenones **76** quantitatively with high enantioselectivity. In the reaction of **39** (R^1 = H), the diene bearing a sterically hindered triisopropylsilyl group (R^2 = triisopropylsilyl (TIPS)) provides the optimal enantioselectivity (71% *ee*). In contrast, when the substituent on **39** is larger ($R^1 = Bu^i$), the diene bearing a sterically less-hindered trimethylsilyl group (R^2 = trimethylsilyl (TMS)) provides the optimal enantioselectivity (87% *ee*). Apparent (+)-nonlinear effects between asymmetric induction and the enantiomeric composition of **73** suggest the possible formation of a reservoir of nonreactive aggregates.

In addition to the Danishefsky-type dienes, 1-amino-3-siloxy-1,3-butadienes are also multiply heteroatom-substituted acyclic dienes, which are useful for Diels–Alder reactions. The enantioselective catalysis of 1-amino-3-siloxybutadienes in Diels–Alder reactions is promising, because uncatalyzed cycloadditions with 2-substituted propenals are known to proceed with excellent regio- and diastereoselectivities. Thus, a chiral catalyst must select between two enantiomeric *endo* adducts. Chiral chromium(III)–salen complex **77** catalyzes the enantioselective Diels–Alder reaction of 1-amino-3-siloxybutadiene **78** with 2-substituted propenals to give the corresponding *endo*-adducts **79** with high enantioselectivity (**Scheme 18**, **Table 18**).[64] The benzyl substituent on the nitrogen of **78** is crucial for obtaining high enantioselectivity. A consideration of the stereochemical outcome and a careful analysis of the salen scaffold suggest transition-state assemblies **80** and **81**. The diene **78** can approach the dienophile from the more open surface on the scaffold, which is believed to be over the imine linkages, away from bulky *tert*-butyl groups. Transition state **80** seems to be more favorable than **81**, which suffers from steric interaction between the benzyl group and the axial hydrogens (**Scheme 18**).



Scheme 18

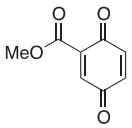
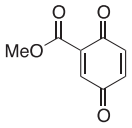
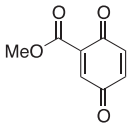
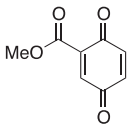
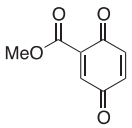
The enantioselective formation of all-carbon quaternary centers is an area of intense research in which Diels–Alder reactions play a major role. For this purpose, 2-methoxycarbonylated quinones **82** are highly active as dienophiles.[65] Chiral Lewis acid complexes derived from the pybox ligand **38b** (R = Ph) with lanthanide(III) triflates are effective catalysts in the enantioselective Diels–Alder reaction of quinones **82**. In the presence of 10 mol% of the samarium(III) and gadolinium(III) trifluoromethanesulfonate complexes with **38b**, the cycloaddition of various acyclic dienes with quinones **82** in THF–toluene (1:1 v/v) gives the corresponding *endo*-adducts **83** with high enantioselectivity (equation 13, Table 19). The reaction between **82** and dienes possessing different alkyl substituents in the 1- and 4-positions is regioselective. For example, the reactions with *trans*-2,4-heptadiene (R^1 = Et and R^2 = H) and *trans*-2,4-octadiene (R^1 = Pr and R^2 = H) give 5:1 and 15:1 mixtures, respectively, of regioisomers with 98% *ee*.

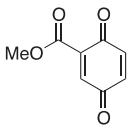


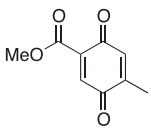


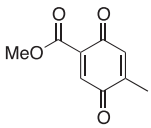


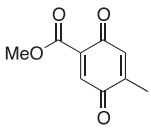


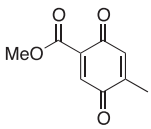






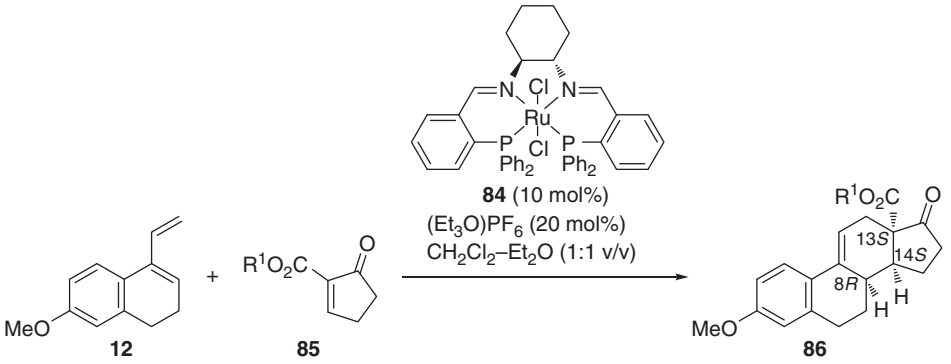






82 **83** (X = CO_2Me) (13)

For the enantioselective construction of all-carbon quaternary centers, α-methylene β-ketoesters are possible alternatives as dienophiles. However, bulkier unsaturated β-ketoesters, such as cyclic carboxypentenones, are much less reactive due to their tendency to undergo polymerization and keto–enol tautomerization. A dicationic ruthenium(II) catalyst, prepared *in situ* from the chiral ruthenium(II) complex **84** and 2 equivalents of $(Et_3O)PF_6$ in dichloromethane, efficiently promotes the enantioselective Diels–Alder reaction of α-methylene β-ketoesters **85** with Dane's diene **12** to give the corresponding (8*R*,13*S*,14*S*)-adducts **86** with high enantioselectivity (Scheme 19).[66] Because the use of a *tert*-butyl ester improves the *exo*/*endo* ratio and enantioselectivity, the *tert*-butyl ester moiety on **85** is pivotal for achieving excellent diastereo- and enantioselectivity. Enantiomerically pure adduct **86** (R = Bu^t) is obtained in 85% yield after recrystallization from 2-propanol, and the *exo*/*endo* ratio is improved to 145:1.



The inverse-electron demand Diels–Alder reaction of tropones provides direct access to bicyclo[3.2.2] ring structures, which can be further developed into more complex molecular architectures through selective manipulation of their preexisting functional groups. The chiral dinuclear BINOL–aluminum complex **87**, a Lewis acid-assisted Lewis acid catalyst prepared from the *tris*(*m*-xylyl)silyl-substituted BINOL ligand and two equivalents of diisobutylaluminum hydride at ambient temperature in dichloromethane, catalyzes the Diels–Alder reaction of 2-substituted tropones **88** with ketene diethyl acetal (Scheme 20).[67] The reaction exclusively gives the corresponding Diels–Alder adducts **89** without other types of cycloadducts, such as [8 + 2] adducts. Although the reaction of unsubstituted tropone shows modest enantioselectivity (46% *ee*), 2-substituted tropones **88** (X ≠ H) generally give high enantioselectivity.

Although several Lewis acid-catalyzed asymmetric Diels–Alder reactions have been reported to date, including those using ketone-derived siloxy dienes such as Danishefsky's diene, none of them use 1-siloxybutadiene **91** because of the lability of **91** under acidic conditions. However, the acid-sensitive diene **91** can be activated by barium alkoxides, which are prepared *in situ* from barium isopropoxide and a chiral diol, through the transmetalation or formation of a hypervalent silicate (HOMO-raising mechanism). Under these conditions, **91** reacts with dimethyl fumarate to give the corresponding Diels–Alder adduct **92** (equation 14).[68] The use of chiral diol **90** as a ligand gives the best results in terms of diastereoselectivity and enantioselectivity (Table 20). The addition of cesium fluoride significantly improves the reactivity and the reaction is complete within 30 min. It is conceivable that the silicon transfer step is accelerated by the formation of a pentavalent silicate with the fluoride ion. In addition, the enantioselectivity also increases to 96% *ee*. This reaction is practical, and the catalyst loading is reduced to 2.5 mol% under more concentrated conditions. On a 58-g scale, both the enantiomeric excess and the diastereomeric ratio are constant, though the reaction is slower. The resulting Diels–Alder adduct **92** is an important chiral building block for the synthesis of (−)-oseltamivir (Tamiflu).[68]

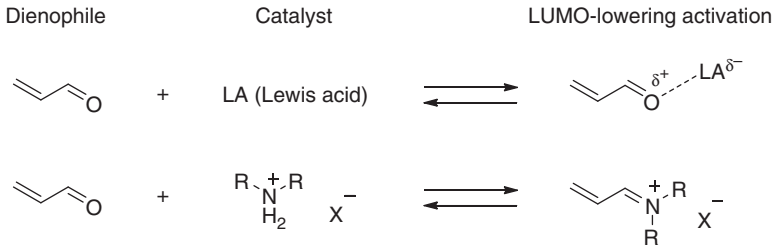
[a]$Ba(OPr^i)_2$ (2.5 mol%), **90** (2.5 mol%), 0.67 M of dimethyl fumarate.
[b]58-g scale.

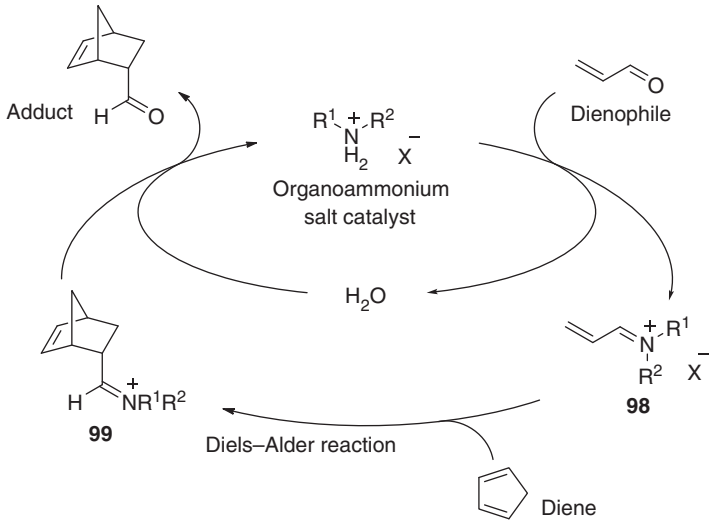
The following reaction mechanism is proposed for the Diels–Alder reaction of **91** with dimethyl fumarate catalyzed by barium(II)-**90** complex (**Scheme 21**).[68] Based on electrospray ionization mass spectrometry studies, the active catalyst is considered to be the 3:3 complex **93**. Chiral barium dienolate **95** is generated through transmetalation between catalyst **93** and siloxydiene **91**. Cesium fluoride may facilitate the generation of **95** through the formation of pentavalent silicate **94**. The cyclization of the barium dienolate **95** with dimethyl fumarate occurs in either a concerted manner (Diels–Alder pathway) or a stepwise manner (Michael-aldol pathway). It is possible that the catalyst promotes the reaction through an intramolecular transfer of the barium dienolate to an activated dienophile by a Lewis acidic barium center, as shown in **96**. Finally, the product barium alkoxide in **97** attacks the trimethylsilyl group attached to the ligand, and catalyst **93** is regenerated, whereas the silylated product **92** is liberated from the catalytic cycle. Alternatively, **97** reacts with another molecule of siloxy diene **94**, liberating product **92** whereas regenerating the active barium dienolate **95**.



Scheme 21 Proposed catalytic cycle of barium(II)-**90** complex-promoted Diels–Alder reaction.

5.09.5 Chiral Organocatalysis

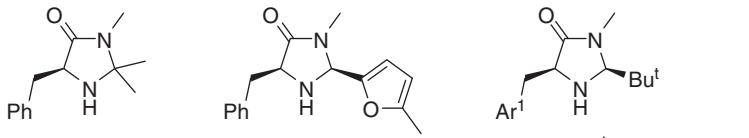
5.09.5.1 LUMO-Activation Using Organoammonium Salts



5.09.5.1.1 Secondary ammonium salt catalysts

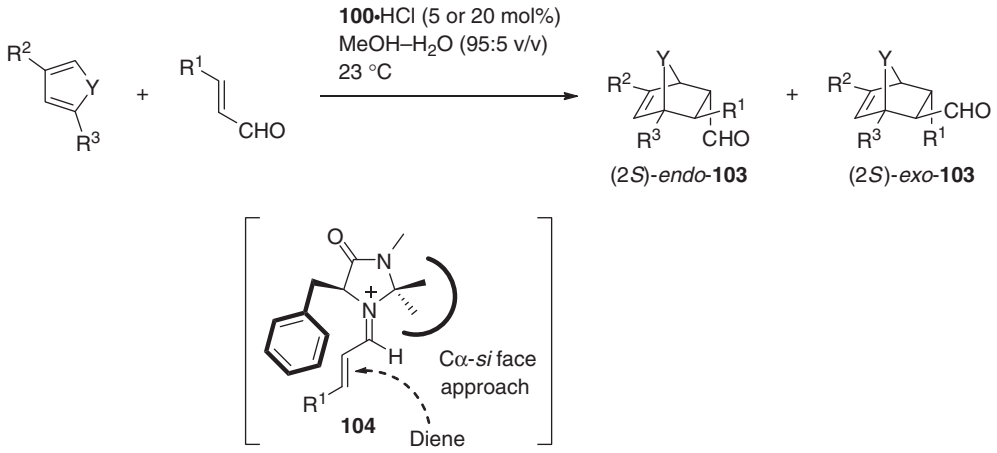
As shown in the above sections, the catalytic effect of Lewis acids (LA) in the Diels–Alder reactions is the result of coordination with α,β-unsaturated carbonyl compounds (dienophile), which lowers the LUMO energy, thereby allowing Diels–Alder reactions to be conducted under mild conditions with enhanced regio-, diastereo-, and enantioselectivity (Scheme 22).

Scheme 22 LUMO-lowering activation of α,β-unsaturated carbonyl compounds.



Organocatalysts have been successfully used as alternatives to Lewis acid catalysts in enantioselective Diels–Alder reactions.[69–71] The first highly enantioselective organocatalytic Diels–Alder reaction was developed by MacMillan and colleagues, who used secondary organoammonium salts of α-amino acid-derived imidazolidinones as catalysts.[72–74] They also described the concept of iminium catalysis by using the term 'LUMO-lowering activation' (Scheme 22). The principle of the reaction mechanism for the organoammonium salt-catalyzed Diels–Alder reaction is shown in Scheme 23. This concept is based on the hypothesis that the reversible formation of iminium cations **98** from α,β-unsaturated aldehydes and chiral ammonium salts might emulate the equilibrium dynamics and π-orbital electronics that are found in Lewis acid catalysis.

Scheme 23



The ammonium salts of chiral imidazolidinones such as **100**–**102** (Figure 11) are efficient organocatalysts for enantioselective Diels–Alder reactions, including those of β-substituted propenals.[72–74] In the presence of imidazolidinone salt **100**•HCl (5 mol%), the reaction of cyclopentadiene with various β-substituted propenals is conducted in MeOH–H_2O (95:5) to give an approximately 1:1 diastereomeric mixture of the corresponding (2*S*)-*exo*- and (2*S*)-*endo*-adducts **103** with high enantioselectivity (Scheme 24, Table 21). A range of α,β-unsaturated aldehydes are exposed to a variety of dienes using the organoammonium salt catalysts **100**•HCl to give the corresponding *endo*-adducts **103** with high enantioselectivity, although the diastereoselectivity is low. Remarkably, the presence of water has beneficial effects on both the reaction rates and selectivities by facilitating the hydrolysis of iminium ion **99** in the catalytic cycle.

A mechanism has been proposed for the asymmetric induction observed in the **100**•HCl-catalyzed Diels–Alder reaction of β-substituted propenals (Scheme 24).[72,74] The sense of asymmetric induction observed in all cases is consistent with the

intermediacy of iminium cation **104**. This mechanism includes two salient stereocontrol elements: (1) the selective formation of the (*E*)-iminium isomer to avoid nonbonding interactions between the substrate olefin and the geminal methyl substituents on the catalyst framework and (2) effective shielding of the *Re*-face of the olefinic π-system of the iminium cation by the benzyl group on the catalyst. Dienes can then preferentially approach the Cα-*Si* face of *s-trans*-iminium cation **104**.

The ability to use simple α,β-unsaturated ketones as dienophiles in the Diels–Alder reaction remains a challenge in the field of asymmetric catalysis. The coordination of LA to ketone dienophiles is normally a nonselective process because the participating lone pairs are positioned in similar steric and electronic environments (Scheme 25). The diastereomeric activation pathway in this case often leads to poor levels of enantiocontrol and ultimately has almost completely precluded the use of simple ketone dienophiles in the catalytic asymmetric Diels–Alder reaction. In contrast, organoammonium catalysts might enable simple ketone dienophiles to function as useful substrates for enantioselective Diels–Alder reactions. In this case, the capacity to perform substrate activation through specific lone-pair coordination is replaced by the requirement for selective π-bond formation (Scheme 25).[73]

An organoammonium salt of imidazolidinone **101** catalyzes the Diels–Alder reaction of simple α,β-unsaturated ketones (Scheme 26, Table 22),[73] whereas the organoammonium salts of **100** and **102** give the adduct in racemic form. Importantly, whereas methyl ketones are usually poor substrates, higher homologs (ethyl, butyl, and isoamyl ketones) give good levels of

Scheme 25 Activation of α,β-unsaturated ketones.

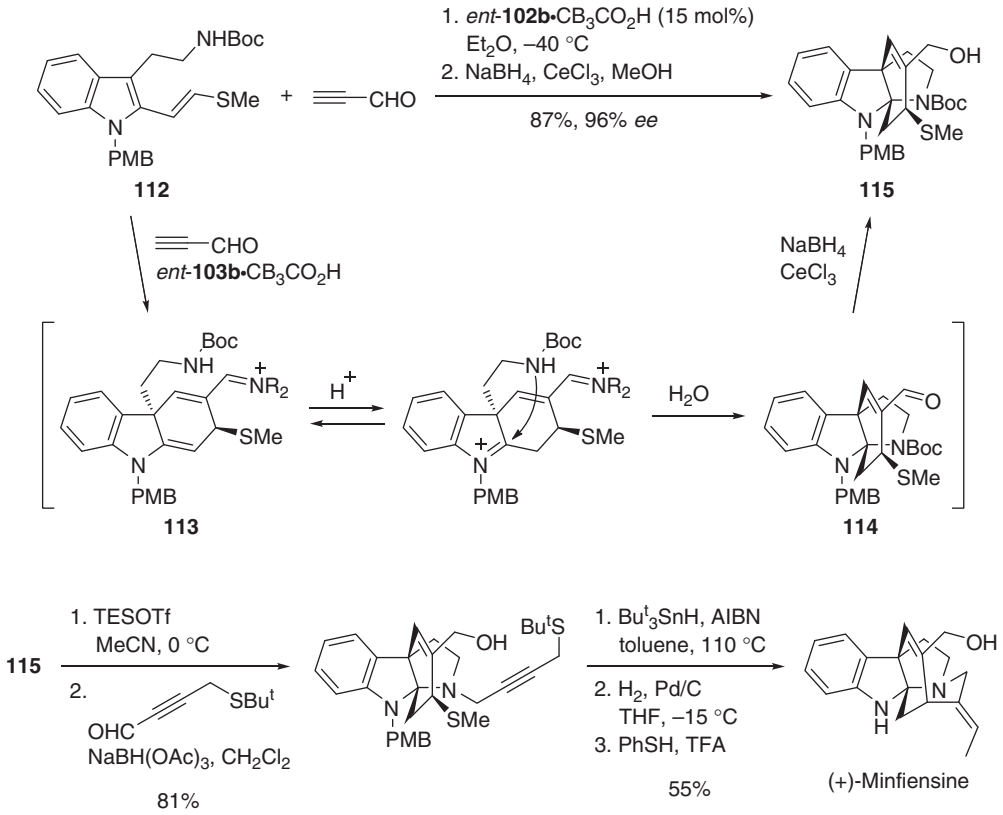
enantiocontrol and high *endo*-selectivities. The present Diels–Alder reaction is also quite general with respect to the diene structure, and thus allows enantioselective access to a range of alkyl-, aryl-, alkoxy-, and amino-substituted cyclohexyl ketones as single diastereomers ($dr > 100{:}1$). The sense of asymmetric induction observed in all cases is consistent with selective engagement of the diene substrate with the *Si*-face of the *cis*-iminium cation intermediate **105**, in which the olefin *Re*-face in the iminium intermediate is shielded by the benzyl group in **101**. The computational models provide supporting evidence that the *trans*-iminium isomer **106** is energetically disfavored based on nonbonding interactions between the benzyl and R^2 substituents.

The Diels–Alder reaction catalyzed by secondary organoammonium salts has been used for the synthesis of key intermediates in the total synthesis of bioactive natural compounds. For example, the **100**•HCl-catalyzed Diels–Alder reaction of 1,3-dimethylcyclohexadiene with α,β-enal **107** is conducted in DMF–MeOH (1:1 v/v) containing 5% water to give *endo*-adduct **108**, which is a key intermediate for the synthesis of (+)-hapalindole Q, in 35% yield with 93% *ee* (Scheme 27).[75] Pinnick oxidation of **108** gives the corresponding carboxylic acid, which undergoes Curtius rearrangement with diphenylphosphoryl azide (DPPA) to give carbamate **109**, which can be converted to (+)-hapalindole Q in six steps.



Scheme 27 Synthesis of (+)-hapalindole Q.

In a practical synthesis of (–)-oseltamivir, the **100**•HCl-catalyzed Diels–Alder reaction of a dihydropyridine derivative with propenal gives azabicyclo[2.2.2]compound **110** as a key intermediate (Scheme 28).[76] Subsequent oxidation of the aldehyde, followed by bromolactonization produces bromolactone **111** in 26% yield (four steps) with >99% *ee*. Importantly, neither tedious chromatographic separations nor expensive reagents are needed in this synthetic sequence. Oseltamivir phosphate can be synthesized in 22% yield (11 steps) from the bromolactone **111**.

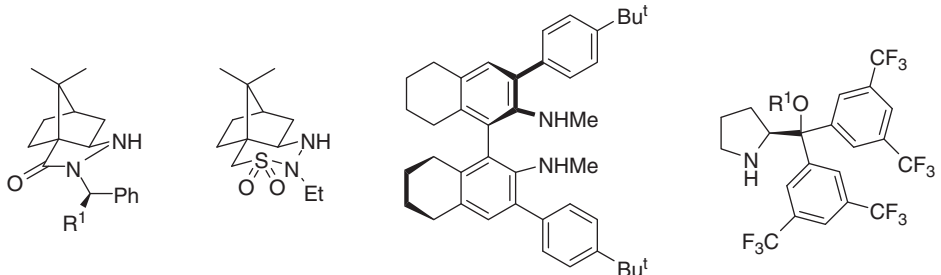
Scheme 28 Synthesis of (–)-oseltamivir.

In a related study, an organoammonium salt of 1-naphthylmethyl-substituted *ent*-**102b** with tribromoacetic acid is used to construct the central tetracyclic pyrroloindoline framework of (+)-minfiensine through an elegant organocascade sequence starting with the Diels–Alder reaction between **112** and propynal (Scheme 29).[77] In the presence of *ent*-**102b**•CBr_3CO_2H (15 mol%), the Diels–Alder reaction regioselectively gives the corresponding adduct **113** via the *endo*-transition state. Simultaneous protonation of the enamine moiety of **113**, followed by a 5-*exo* amine heterocyclization affords the tetracyclic pyrroloindoline **114**. Subsequent reduction of **114** with $NaBH_4$ and $CeCl_3$ produces allylic alcohol **115** in 87% yield with 96% *ee*. In general, acetylene derivatives with a linear sp–sp bond make asymmetric induction with a chiral catalyst difficult because the alkynyl moiety is far from the chiral center of the catalyst. The extended chiral environment created by the naphthyl group in **102b** might be crucial for the high

Scheme 29 Synthesis of (+)-minfiensine.

level of asymmetric induction. Actually, the use of **102a** bearing a phenyl group decreases the enantioselectivity (88% *ee*). The allylic alcohol **115** can be converted into (+)-minfiensine in five steps (nine overall steps, 21% overall yield).

Several types of chiral secondary ammonium salt catalysts are available for use in the enantioselective Diels–Alder reactions of *β*-substituted propenals. Representative chiral secondary amines **116** (R^1 = H and Me), **117**, **118**, and **119** (R^1 = TMS and TES) are shown in Figure 12.



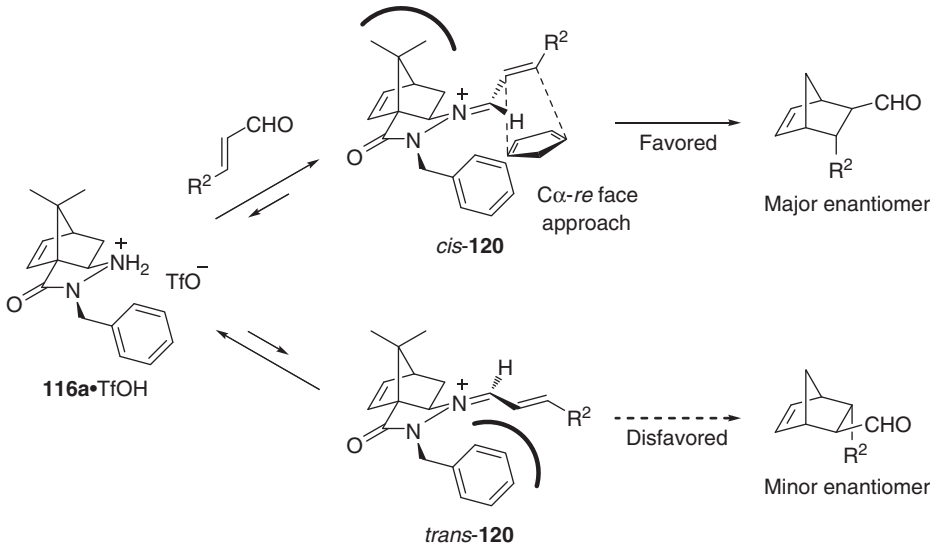


Figure 12 Representative chiral secondary amines **116**–**119**.

Organoammonium salts of chiral secondary amine **116** with trifluoromethanesulfonic acid are efficient catalysts for the Diels–Alder reaction of cyclopentadiene with *β*-substituted propenals (equation 15, Table 23).[78–80] The secondary ammonium salt catalysts **116**•TfOH function best in water. The reaction catalyzed by **116**•TfOH (20 mol%) in water gives the corresponding adducts with high enantioselectivities, although the diastereoselectivities are low. Mechanistic studies indicate that the cycloaddition step of an iminium cation intermediate with a diene is rate-limiting in the hydrazide-catalyzed Diels–Alder reaction.[79] Iminium formation is extremely rapid and the equilibrium heavily favors the iminium cation intermediate, thus maximizing the effective concentration of the reactive dienophile. Based on the sense of asymmetric induction, the **116**•TfOH-catalyzed Diels–Alder reaction proceeds via the C*α*-*Re* face approach of a diene to *cis*-iminium cation intermediate **120** (Scheme 30). The phenyl

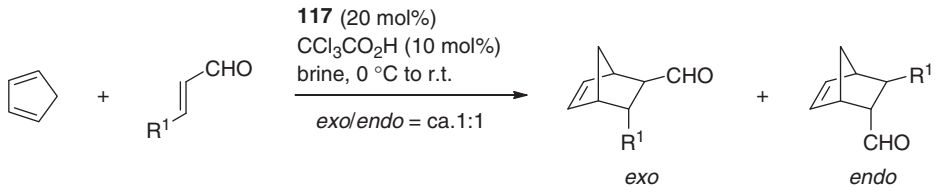
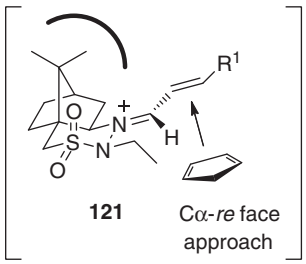
Scheme 30



group of **116** interferes with the formation of an undesired *trans*-iminium cation intermediate. Hydrazine **116b** yields better diastereo- and enantioselectivities than **116a**.[80] The introduction of a methyl group makes the phenyl group properly positioned to interfere with the formation of the *cis*-iminium cation intermediate **120** to improve both the diastereo- and the enantioselectivity.



(15)

A related study showed that an organoammonium salt of chiral camphor sulfonyl hydrazine **117** could catalyze the enantioselective Diels–Alder reaction of cyclopentadiene with β-substituted propenals (Scheme 31).[81] The use of less acidic trichloroacetic acid (CCl_3CO_2H, 0.5 equivalent/**117**) improves the enantioselectivity of the *endo*-adducts. Both the reactivity and enantioselectivity are higher in brine than in water. The reaction is proposed to proceed via iminium ion intermediate **121**. As in the case of *cis*-**120**, the top face of **121** is blocked by the dimethyl groups of the camphor scaffold. Cyclopentadiene approaches from the bottom face.

In general, the Diels–Alder reactions with β-substituted propenals yield the corresponding *endo*-adducts as major products. In contrast, the opposite *exo*-selectivity, particularly in the catalyst-controlled *exo*-selective Diels–Alder reaction, is not readily attainable. However, a highly *exo*-selective, enantioselective Diels–Alder reaction with β-substituted propenals occurs in the presence of the ammonium salt of binaphthyl-substituted secondary diamine **118** (10 mol%) when the reaction is conducted in (trifluoromethyl)benzene ($PhCF_3$) (equation 16, Table 24).[82,83] The reaction gives the corresponding *exo*-adducts with up to >20:1 diastereoselectivity. The presence of two methylamino groups in **118** is essential for rate-acceleration. One methylamino group promotes the reaction of the other methylamino group with an α,β-unsaturated aldehyde to give the iminium cation intermediate **122** and the protonated aminal **123** (Scheme 32). The more reactive iminium cation intermediate **122** reacts with cyclopentadiene to yield the *exo*-adduct under the influence of the sterically hindered octahydrobinaphthyl moiety. The observed

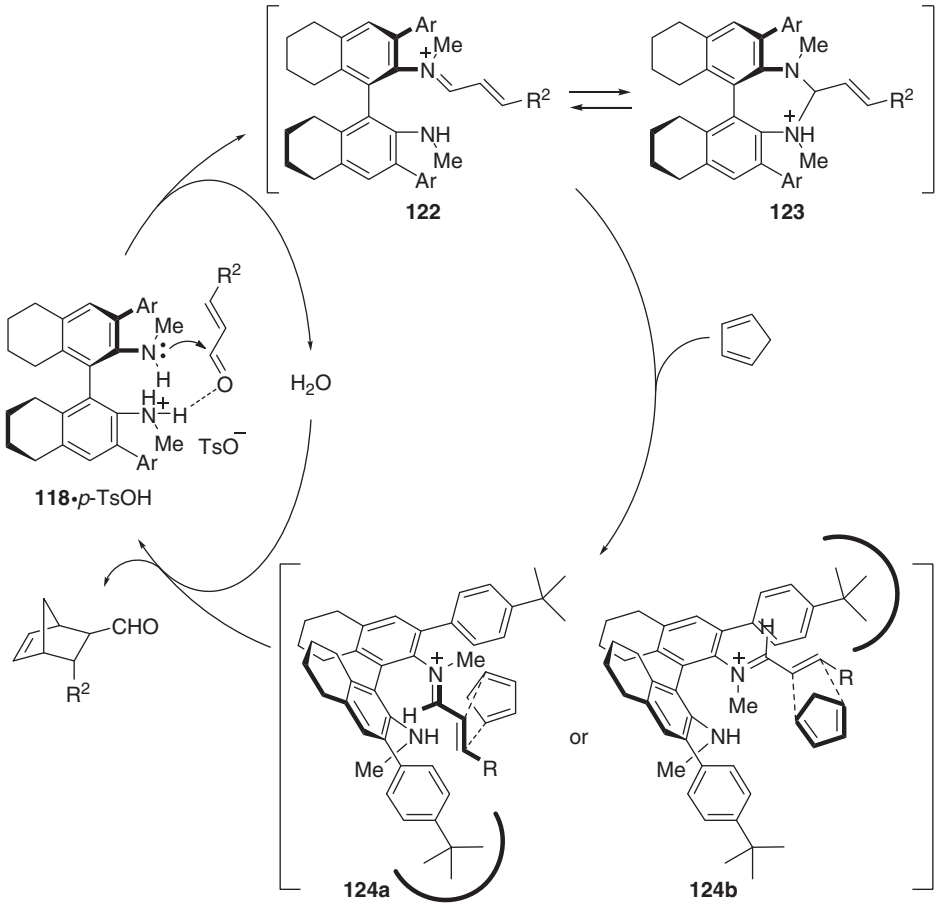
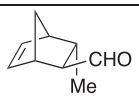
sense of asymmetric induction can be explained by two possible transition-state models, **124a** and **124b**. In both cases, the Cα-*Si* face of the iminium cation moiety is blocked by a 4-*tert*-butylphenyl substituent and the Cα-*Re* face is open for the approach of cyclopentadiene, in accordance with the experimental results.

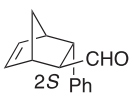


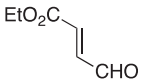
(16)

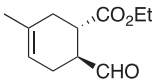
Another *exo*-selective, enantioselective Diels–Alder reaction uses diarylprolinol silyl ether **119** (Table 25).[84,85] For example, the hydroperchlorate salt **119a**•$HClO_4$ (5 mol%) catalyzes the Diels–Alder reaction with β-substituted propenals in water to give the corresponding *exo*-adducts (*exo*/*endo* 2:1 to 6:1) with excellent enantioselectivities. The use of water as a solvent accelerates the reaction and increases the enantioselectivity. Ammonium salts of **119** can catalyze the enantioselective Diels–Alder reaction of not only cyclic dienes but also acyclic dienes such as isoprene. Although butadiene is a useful diene component in the Diels–Alder reaction, its reaction is rather limited as a result of its low reactivity. The present method can provide the cycloadduct of butadiene with propenal with high enantioselectivity. The multigram-scale preparation of the Diels–Alder adduct of cyclopentadiene with cinnamaldehyde can be conducted under completely organic solvent-free conditions, including the purification step.

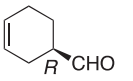
5.09.5.1.2 Primary ammonium salt catalysts











Although secondary ammonium salt catalysts can promote the Diels–Alder reactions with α-unsubstituted propenals, it is difficult to activate α-substituted propenals with these sterically hindered secondary ammonium salts, presumably because of the problems associated with the generation of the corresponding iminium cation intermediates. The greater bulkiness of the secondary amines is thought to be unfavorable for generating an iminium cation intermediate with an α-substituted propenal. In this context, chiral primary ammonium salt catalysts[86,87] have been developed for the Diels–Alder reaction with α-substituted propenals. Representative chiral primary amines **125**–**129** for the enantioselective Diels–Alder reaction are shown in Figure 13.

The primary ammonium salt of a dipeptide-derived triamine **125** and that of 1,1′-binaphthyl-2,2′-diamine **126** are efficient catalysts for the enantioselective Diels–Alder reaction with 2-(acyloxy)propenals **130**.[88–91] 2-(Acyloxy)propenals **130**[92] are among

Scheme 32 Proposed catalytic cycle of **118•***p*-TsOH-catalyzed Diels–Alder reaction.

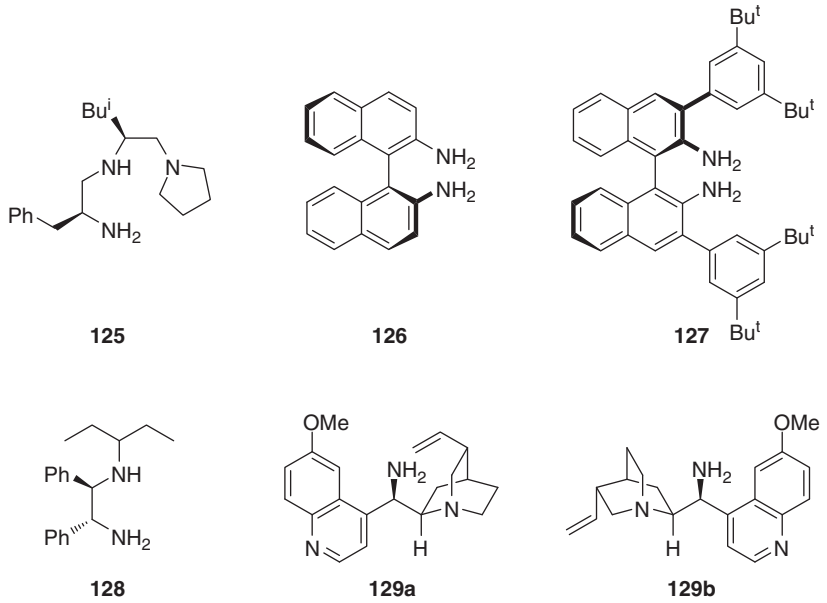
the most promising alternatives to 2-halopropenals,[7,8] which are outstanding dienophiles in catalytic Diels–Alder processes because of the high reactivity and the exceptional synthetic versatility of the resultant adducts. However, 2-halopropenals are irritants and are unstable at ambient temperature. In contrast, 2-(acyloxy)propenals **130** are relatively stable and their reactivity can be controlled by switching the acyloxy group. The ammonium salt (10–20 mol%) of triamine **125** with pentafluorobenzenesulfonic acid ($C_6F_5SO_3H$) can catalyze the reactions of various acyclic dienes and cyclopentadienes with **130a** ($R^1 = C_6H_4$-4-OMe) with excellent enantioselectivity to give the corresponding (2*S*)-adducts (equation 17, Table 26).[88] The reaction of 5-(benzyloxymethyl)cyclopentadiene with **130a** in THF gives the corresponding (2*S*)-*exo*-adduct with 83% *ee*. The adduct of 5-(benzyloxymethyl)cyclopentadiene is an important intermediate for the enantioselective synthesis of prostaglandins.



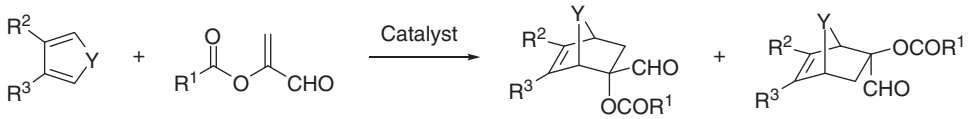


Figure 13 Representative chiral primary amines **125**–**129**.

exo-(2*S*) *endo*-(2*S*) (17)

Although the enantioselectivity in the **125**•2.75 $C_6F_5SO_3H$-catalyzed Diels–Alder reaction of cyclopentadiene is slightly low (83% *ee*), the ammonium salt of **126** with trifluoromethanesulfonimide (Tf_2NH) shows higher catalytic activity than the ammonium salt of **125** (94% *ee*, Table 27).[89,90] Both enantiomers of **126** are commercially available, and the ammonium salt catalysts can be easily prepared *in situ* by mixing **126** and Tf_2NH. Since **126** is an aromatic diamine, the catalytic activity of the ammonium salt of **126** is greater than that of **125,** and the reaction can be conducted at a lower reaction temperature (−75 °C) with a lower catalyst loading (5–10 mol%). 2-(Acyloxy)propenal **130c** ($R = C_6H_4$-4-OTIPS) is suitable as a dienophile for the **126**•1.9 Tf_2NH-catalyzed Diels–Alder reaction, due to the electron-donating nature of the acyloxy group and good solubility under the reaction conditions. The adducts of cyclopentadiene and cyclohexadiene with 2-(acyloxy)propenals **130** can be readily converted into bicyclo[2.2.1]hept-5-en-2-one and bicyclo[2.2.2]oct-5-en-2-one, which are promising synthetic intermediates for the total synthesis of several bioactive natural compounds.

A possible mechanism that accounts for the observed absolute stereochemistry of the adducts is shown in Figure 14. Because **125**•2 $C_6F_5SO_3H$ is much less active than **125**•2.75 $C_6F_5SO_3H$ as a catalyst for the Diels–Alder reaction with **130**, it is conceivable that **125**•3 $C_6F_5SO_3H$ is the actual active catalyst, which activates **130** as (*Z*)-iminium salt **131** with **125**•3 $C_6F_5SO_3H$.

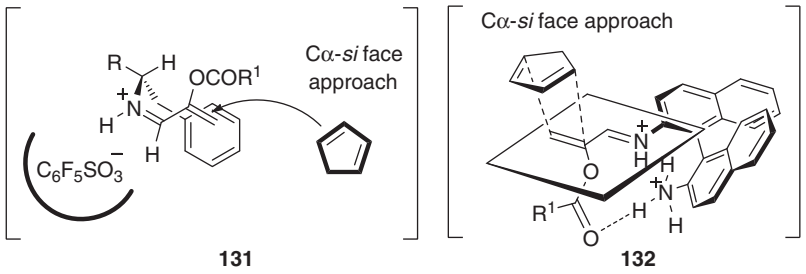

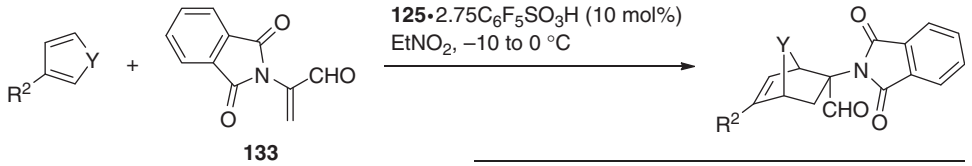

Figure 14 Proposed transition-state assemblies.

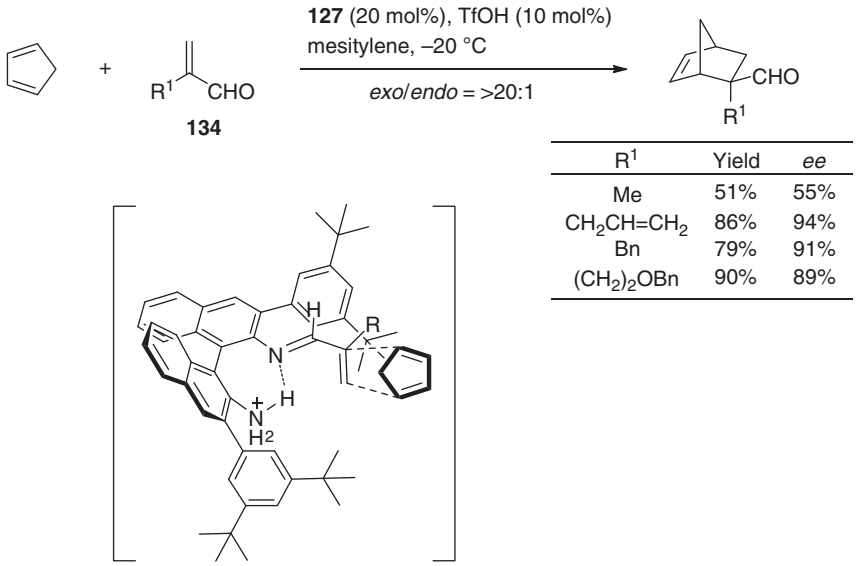
The Diels–Alder reaction may proceed via the (*Z*)-iminium intermediate **131**, where the phenyl group of **125** shields the Cα-*Re* face of the α,β-unsaturated iminium moiety.[88,91,93] However, the mechanism for asymmetric induction for the reaction catalyzed by **125**•2.75 $C_6F_5SO_3H$ is still unclear.[93] Based on the result that the use of the ammonium salt of **126** (5 mol%) and Tf_2NH (5 mol%) as a catalyst produces a lower yield and enantioselectivity, **126**•2 Tf_2NH should be the actual active catalyst for the reaction catalyzed by **126**•1.9 Tf_2NH. The reaction may proceed via an (*E*)-iminium intermediate **132**, in which the acyloxy group interacts with the other ammonium group through hydrogen bonding.[89,90] The electron-donating nature of the 4-(triisopropylsilyloxy)benzoyloxy group presumably enhances the hydrogen bonding between the acyl group and the ammonium proton to stabilize the conformation of the (*E*)-iminium intermediate **132**. In both cases, dienes should approach the Cα-*Si* face of an electron-deficient alkene enantioselectively.



The ammonium salt of chiral triamine **125** can also be used for the Diels–Alder reaction with 2-(phthalimido)propenal **133** to give cyclic α-quaternary α-amino acid precursors.[93] In the presence of **125**•2.75 $C_6F_5SO_3H$ (2.5–10 mol%), the cycloaddition reaction of cyclic and acyclic dienes with **133** is conducted in $EtNO_2$ to give the corresponding *endo*-adducts with high enantioselectivities. For example, cyclopentadiene, isoprene, 2-phenylbutadiene, and myrcene react smoothly with **133** to give the desired 4-alkylsubstituted cyclohex-3-enecarboxaldehydes with 88–94% *ee* (**Scheme 33**). In contrast, another candidate **126**•1.9 Tf_2NH as a catalyst does not catalyze the Diels–Alder reaction with **133** because **126** irreversibly reacts with **133** even at –78 °C in the presence of Tf_2NH.

Scheme 33 Enantioselective Diels–Alder reaction with 2-(phthalimido)propenal **133** catalyzed by the ammonium salt of chiral triamine **125**.

All-carbon quaternary stereocenters, that is, carbon atoms bearing four different carbon substituents, pose a particular challenge in organic synthesis. At present, few methods have been reported for the catalytic enantioselective construction of all-carbon quaternary stereocenters. The Diels–Alder reaction with α-alkyl-substituted propenals **134** is a promising candidate for the preparation of compounds with one all-carbon quaternary stereocenter. For example, the salt of the binaphthyl-based primary diamine **127** with TfOH is an efficient catalyst for the enantioselective Diels–Alder reaction of cyclopentadiene with **134** (Scheme 34).[94] The enantioselectivity of the reaction with **134** highly depends on the reaction solvent and the acid cocatalyst. The reactions in mesitylene and toluene give good results, whereas the use of other solvents significantly decreases the enantioselectivity. In addition, the use of TfOH as an acid cocatalyst is crucial for obtaining high reactivity and enantioselectivity. Although the reaction of 2-methypropenal gives the corresponding adduct (R^1 = Me) with moderate enantioselectivity (55% *ee*), the introduction of longer alkyl substituents at the α-carbon of the propenal significantly improves the level of asymmetric induction.[94]

$(CH_2)_2OBn$	90%	89%

Scheme 34 Enantioselective Diels–Alder reaction with α-alkyl-substituted propenals **134** catalyzed by the salt of binaphthyl-based primary diamine **127**.

The observed stereochemistry in the asymmetric reaction catalyzed by the salt of **127** can be explained by the possible transition-state model shown in Scheme 34.[94] In this model, the aldimine moiety is activated by internal hydrogen bonding with the ammonium proton. A 3,5-di-*tert*-butylphenyl group of **127** effectively blocks one face of *s-cis*-aldimine, while leaving the other face open for the approach of cyclopentadiene. In the case of 2-methylpropenal, due to the small size of the methyl group, it may be difficult to discriminate between *s-cis*- and *s-trans*-aldimine with the 3,5-di-*tert*-butylphenyl group, and this induces moderate enantioselectivity.

An ammonium salt of primary diamine **128** is also an effective organocatalyst for the enantioselective Diels–Alder reaction.[95] The **128**•2HCl-catalyzed reaction with 2-unsubstituted propenals yields the corresponding *endo*-adducts with high enantioselectivities (Scheme 35). Although **128** is a chiral primary amine, the ammonium salt of **128** shows poor catalytic activity and enantioselectivity for the Diels–Alder reaction with 2-substituted propenals.

Cinchona alkaloids have been widely used in asymmetric organocatalysis.[96,97] They are abundant natural products that exist as *pseudo*-enantiomeric pairs, as exemplified by quinine and quinidine. They are readily accessible amine catalysts that can be used to generate either enantiomer of a chiral product of interest. Accordingly, numerous efforts have been devoted to the development of cinchona alkaloid-catalyzed enantioselective reactions. For example, ammonium salts of cinchona alkaloid-derived primary amines **129** with trifluoroacetic acid (TFA) are efficient catalysts for the enantioselective Diels–Alder reaction of 2-hydroxy-2-pyrones **135** with simple α,β-unsaturated ketones.[98] In the presence of **129a**•4 TFA (5 mol%), the reaction of **135** with α,β-unsaturated ketones gives the corresponding *exo*-adduct **136** with excellent enantioselectivities (equation 18, Table 28). However, the same reaction catalyzed by *pseudo*-enantiomeric **129b**•4 TFA preferentially affords *ent*-**136**. The present method catalyzed by **129a**•4 TFA can be applied to various β-aryl, β-alkyl, and β-unsubstituted α,β-unsaturated ketones. Catalyst **129**•4 TFA also tolerates substituted 2-pyrones. The primary amine functionality in **129** is critical to its activity, which is abolished when the amine is replaced with a thiourea group. The presence of TFA is essential for the selectivity of **129**, although TFA itself does not promote the Diels–Alder reaction. Moreover, electron-rich dienes that do not bear either a hydrogen-bonding acceptor or donor such as cyclopentadiene and cyclohexadiene are inactive for the present Diels–Alder reaction in the presence of **129** and TFA. These results indicate that the activation of **135** by **129**•4 TfOH is also required for the Diels–Alder reaction to occur.

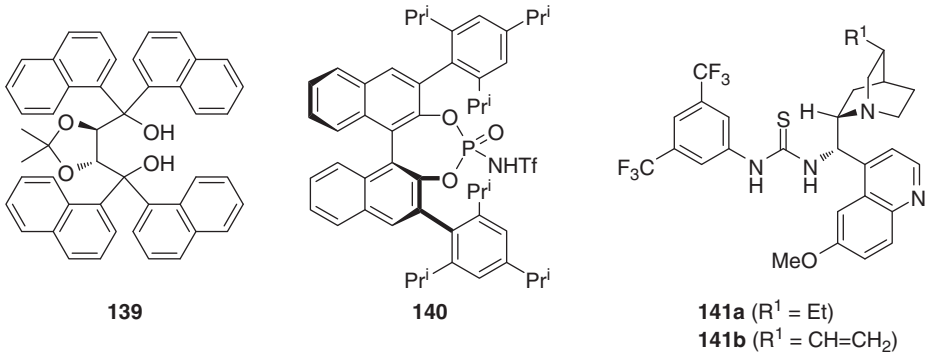
5.09.5.2 Hydrogen-Bonding Catalysis

Some small organic molecules capable of forming hydrogen-bonding interactions can catalyze the Diels–Alder reaction.[99–102] Rate-acceleration by these hydrogen-bonding donors results from the decrease in energy of the electron-deficient dienophile's LUMO, as in Lewis acid activation. For example, electron-deficient diaryl thiourea **138** can promote the Diels–Alder reaction of but-3-en-2-one with cyclopentadiene via the simultaneous donation of two hydrogen bondings.[103] The electron-withdrawing substituents at the *meta*-positions aid in reducing the flexibility of the catalyst, thereby minimizing the decrease in entropy on complexation with carbonyl compounds. The hydrogen atoms at the *ortho*-positions are more positively polarized. The hydrogen-bonding donor ability of these C–H bonds leads to internal interactions between the Lewis basic sulfur and the *ortho*-hydrogen atoms, which prevent rotation of the phenyl groups (Scheme 36).

Some chiral hydrogen-bonding donors are useful tools as catalysts for the asymmetric Diels–Alder reaction. Representative chiral Brønsted acid catalysts **139**–**141** for the enantioselective Diels–Alder reaction are illustrated in Figure 15.



The commercially available chiral diol **139**, α,α.α′,α′-tetraaryl-1,3-dioxylane-4,5-dimethanol (TADDOL, aryl = 1-naphthyl) considerably accelerates the reaction of electron-rich aminosiloxydiene **143** with α-substituted propenals to give the intermediate *endo*-adducts **144** (Scheme 37).[104,105] Treatment of **144** with excess HF in acetonitrile produces aldehydes **145** in yields of 77–85% (Table 29). Alternatively, reduction of **144** with an excess of $LiAlH_4$ followed by acidic hydrolysis gives alcohols **146** with high enantioselectivities of up to 92% *ee*. Interestingly, the enantioselective Diels–Alder reaction with propenal itself is less enantioselective than the analogous reaction with α-substituted propenals, probably due to the greater conformational flexibility of propenal.

As the temperature of the reaction is decreased from ambient temperature to –80 °C, the enantiopurity of the cycloadduct increases steadily. This is attributed to the formation of more persistent hydrogen bonding and a better-organized TADDOL–substrate hydrogen bond complex as the available thermal energy is decreased. TADDOL **139** is expected to exist in a

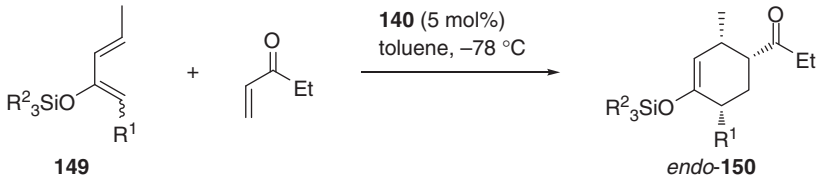
well-defined, internally hydrogen-bonded arrangement **147** in the reaction mixture at –80 °C (Figure 16).[104] An α-substituted acrolein may interact with **139** through hydrogen bonding with the free hydroxyl group and π–π interaction with the proximal equatorial 1-naphthyl group, which selectively shields the Cα-*Re* face of the dienophile. However, a theoretical study for the **139**-catalyzed hetero-Diels–Alder reaction of diene **143** with benzaldehyde showed that the complex of **139** and benzaldehyde is stabilized by CH–π interaction between the aldehyde CH and the pseudoequatorial naphthalene ring of **139** instead of π–π interaction.[106] The present **139**-catalyzed Diels–Alder reaction of α-substituted acroleins may also proceed via transition-state **148** with a CH–π interaction.



147 **148**

Figure 16 Proposed transition-state assemblies **147** and **148**.

Binaphthyl-based axially chiral phosphoric acids have become an important class of chiral Brønsted acid catalysts,[107–109] especially for the activation of relatively Brønsted-basic imine substrates. However, the relatively low acidity of phosphoric acid makes this excellent catalyst of rather limited use in future applications. For example, it is difficult to apply chiral phosphoric acids to the Diels–Alder reaction of simple α,β-unsaturated ketones. The binaphthyl-based *N*-(trifluoromethanesulfonyl)phosphoramide **140**, which is more acidic than phosphoric acids, can catalyze the Diels–Alder reaction of 1-substituted 2-siloxybutadienes **149** with α,β-unsaturated ketones, for example, pent-1-en-3-one, to give the corresponding *endo*-adducts **150** with high enantioselectivities (equation 19, Table 30).[110] An aromatic solvent, such as toluene, is suitable for the **140**-catalyzed enantioselective Diels–Alder reaction of **149** with pent-1-en-3-one, whereas the use of dichloromethane as a solvent significantly decreases the yield, probably due to the dimerization of diene. Although the bulkiness of the silyl group (SiR_3^2) in **149** does not affect the enantioselectivity, the yields of the reactions are quite sensitive to the stability of siloxydienes due to the protonation of the diene and the deactivation (silylation) of the catalyst. For the same reason, α-unsubstituted **149** ($R^1 = H$) produces a relatively low yield. The acid-sensitive TBS ether is tolerated in this reaction. The Lewis basic benzoyl group does not affect either the reactivity or the enantioselectivity.

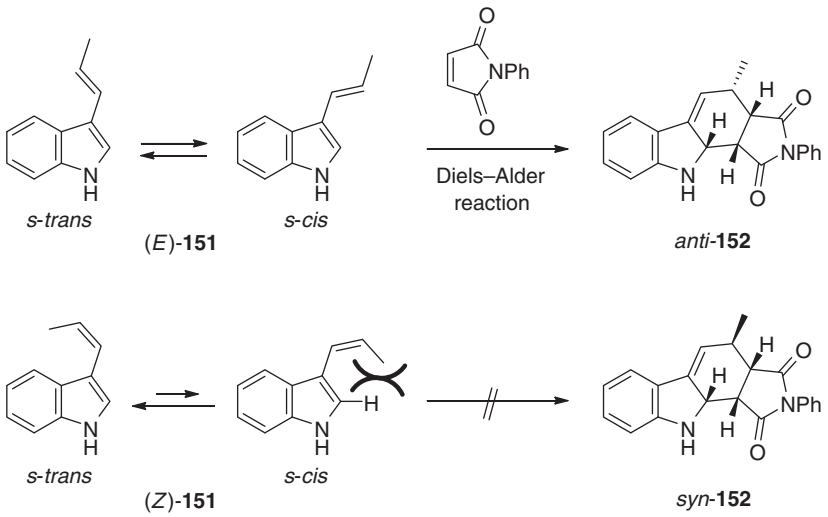
(19)



The cinchona alkaloid-derived bifunctional organocatalyst **141a** promotes the enantioselective Diels–Alder reaction of 3-vinylindoles **151** (Scheme 38, Table 31).[111] In the presence of **141a** (20 mol%), the reaction of **151** with *N*-substituted maleimides in CH_2Cl_2, followed by treatment with trifluoroacetic anhydride, produces the *endo*-adducts **152** in good yields with excellent enantioselectivities. The bifunctional catalyst **141a** can simultaneously activate **151** with the tertiary amine moiety and *N*-substituted maleimides with a thiourea moiety through hydrogen bonding. The fact that 1-tosyl and 1-*tert*-butoxycarbonyl derivatives of **151** give the corresponding **152** in racemic form supports the proposed double activation through hydrogen bondings. The rather low enantioselectivity in the reaction with *N*-unsubstituted maleimide can be attributed to possible interference by the hydrogen-bonding interaction between the catalyst and the imide hydrogen. When 3-vinylindole **151** (R^2, R^3 = H, and R^4 = Me) bearing a methyl group on the exocyclic vinyl substituent is used as a 1:1 *E*/*Z* mixture, the *E*-isomer exclusively undergoes the Diels–Alder reaction to give the corresponding *anti*-adduct **152** with 92% *ee* as a single diastereomer. The preferential reactivity of the *E*-isomer relative to the *Z*-isomer can be explained by the easier accessibility to the *s-cis*-conformation, which is the key structural feature for the Diels–Alder reaction to occur (Scheme 39). *Endo*-**152** (R^2, R^3, and R^4 = H and R^5 = Ph) is successfully converted into the known intermediate **153** of a synthesis of a Strychnos alkaloid, tubifolidine[112] (Scheme 40). Benzoquinone and naphthoquinone, another well-known class of dienophiles for Diels–Alder reactions, are also used to give the corresponding adducts with high enantioselectivities.

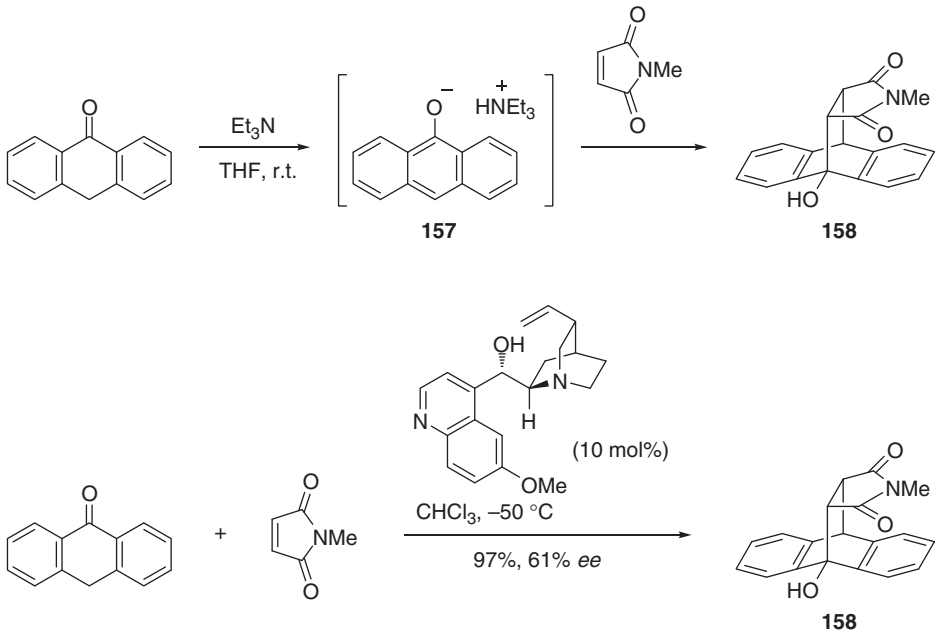
2-Vinylindole (**154**), the olefin moiety of which is considerably less electron-rich, is less reactive than 3-vinylindoles **151** in the Diels–Alder reaction. When the Diels–Alder reaction of **154** with *N*-benzylmaleimide is conducted in the presence of a cinchona alkaloid-derived catalyst **156** (20 mol%) at 0 °C, tetrahydrocarbazole **155** is obtained via the spontaneous 1,3-hydrogen shift in the cycloadduct (Scheme 41). Although the yield of **155** is low (15%), it was isolated with 72% *ee*.[113]

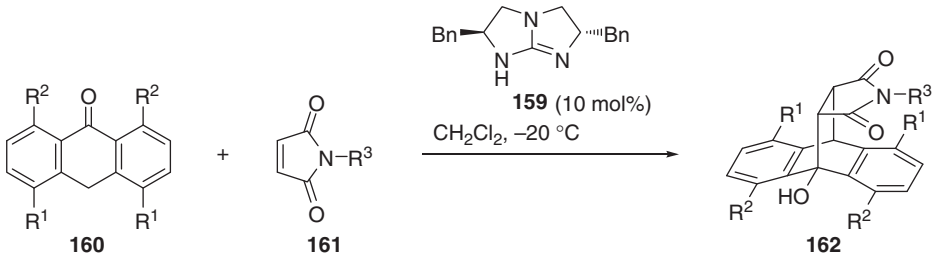


5.09.5.3 HOMO-Activation Using Brønsted Bases

In the presence of a Brønsted base, anthrone functions as a reactive diene. For example, when the reaction of anthrone with *N*-methylmaleimide is conducted in the presence of triethylamine, the corresponding adduct **158** is quantitatively obtained within 15 min (Scheme 42).[114] The reaction proceeds $\geq 10^4$ faster than the reaction in the absence of a Brønsted base. The results of mechanistic investigations are consistent with a concerted [4 + 2] process. A Brønsted base activates anthrone through the formation of an oxyanion intermediate **157**. In contrast to the organoammonium salt catalysis and hydrogen-bonding catalysis (LUMO-lowering activation) described above, the Brønsted base activates anthrone by raising the HOMO energy (HOMO-raising activation), thereby allowing it to react with an electron-deficient dienophile.

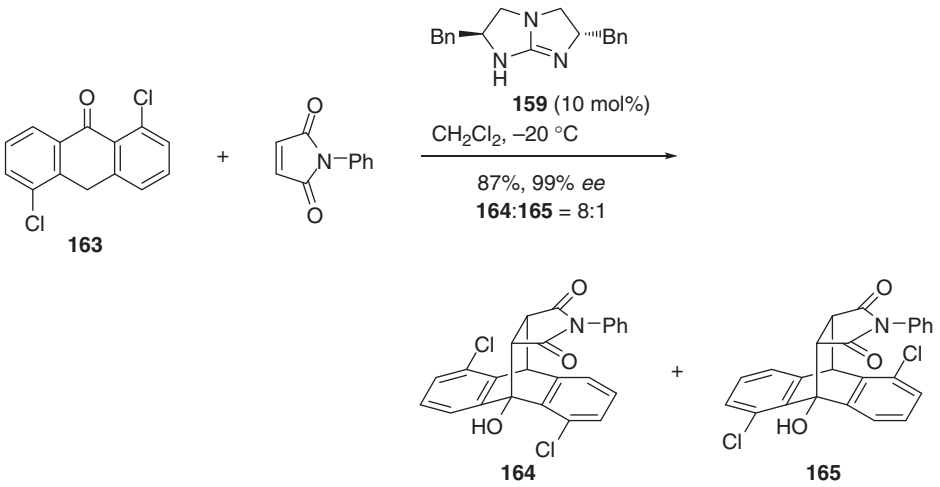
This HOMO-raising activation of anthrone can also be used in an asymmetric Diels–Alder reaction using a chiral Brønsted base catalyst. For example, a catalytic amount of quinidine can catalyze the enantioselective Diels–Alder reaction of anthrone with *N*-methylmaleimide to give **158** in 97% yield with 61% *ee* (Scheme 42).[115,116] The free hydroxy group in quinidine is essential for achieving a high optical yield. When quinidine is replaced by dihydroquinidine *O*-*p*-chlorobenzoate, the adduct **158** is obtained

Scheme 41 Enantioselective Diels–Alder reaction of 2-vinylindole (**154**).



Scheme 42 HOMO-raising activation of anthrone.

in racemic form. A lower reaction temperature and the use of a less polar solvent are also important for achieving high enantioselectivity.



The enantioselectivities of the anthrone Diels–Alder reaction are improved with the bicyclic guanidine catalyst **159** (equation 20, Table 32).[117] The reaction of a series of substituted anthrones **160** and *N*-substituted maleimides **161** is conducted under mild conditions and gives the corresponding adducts **162** in high yields with high enantioselectivities. Excellent regioselectivity is also observed when 1,5-dichloro-9-anthrone **163** is used as the diene. The Diels–Alder reaction of **163** with *N*-phenylmaleimide gives the corresponding adducts **164** in an 8:1 ratio with the regioisomer **165** (equation 21). The guanidine catalyst **159** is proposed to generate the active diene *in situ* through deprotonation.

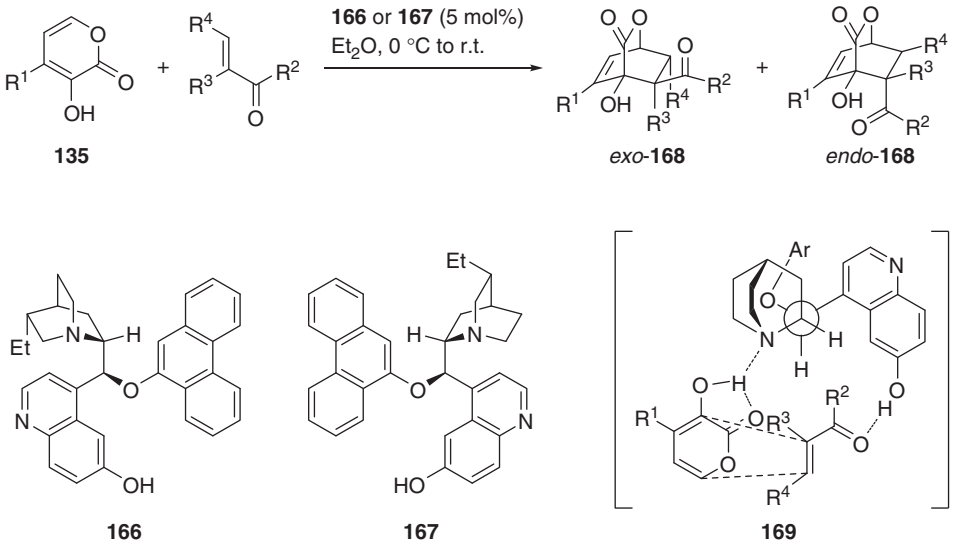
(20)

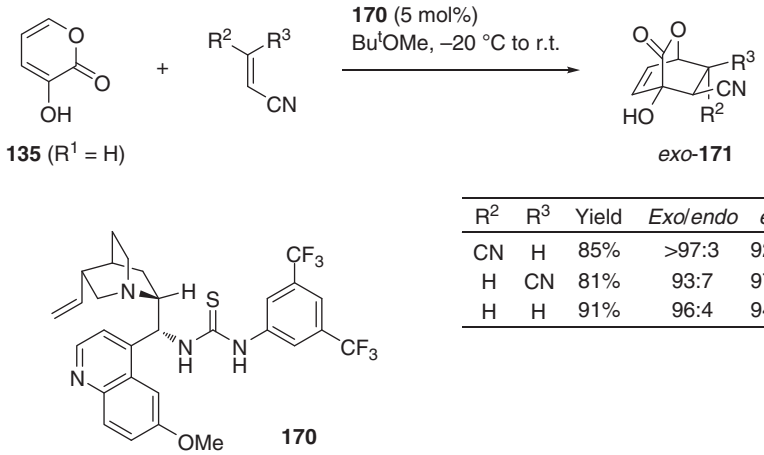
(21)

3-Hydroxy-2-pyrones **135** are also reactive dienes that can be activated by a Brønsted base. For example, the enantioselective Diels–Alder reactions of 3-hydroxy-2-pyrones are promoted by the cinchona alkaloid-derived catalysts **166** and **167** (Scheme 43, Table 33).[118] Cinchona alkaloids bearing an active proton can act as acid–base bifunctional catalysts. The tertiary amino group in **166** and **167** acts as a Brønsted base to activate 3-hydroxy-2-pyrones by raising the energy of the HOMO. Simultaneously, the 6′-hydroxyl group acts as a Brønsted acid to activate the dienophiles by lowering the energy of the LUMO. The use of **166** gives the corresponding *exo*-adducts **168** with high diastereo- and enantioselectivities.



Although catalyst **166** tolerates a significant degree of alterations in both pyrones **135** and dienophiles, catalyst **170** bearing a thiourea group gives low diastereo- and enantioselectivity (73:27 *dr*, 37% *ee*) for the reaction of **135** (R^1 = H) with ethyl 4-oxo-4-phenylbut-2-enoate (R^2 = Ph, R^3 = H, and R^4 = CO_2Et). In contrast, catalyst **166** is ineffective for reactions with fumaronitrile, whereas the use of **170** drastically improves the diastereo- and enantioselectivity (Scheme 44).[118] These reactions are stereospecific with respect to the geometry of the double bond, which is consistent with a concerted cycloaddition mechanism.

Furthermore, the *endo*/*exo*-selectivity can be successfully controlled using cinchona alkaloid-derived bifunctional catalysts (Scheme 45).[118] Thus, in the Diels–Alder reaction of **135** (R^1 = H) with 2-chloroacrylonitrile, the use of **166** selectively gives the *endo*-adduct **172**, whereas the use of **170** affords the *exo*-adduct **173**. Consequently, each of the four possible stereoisomers can be obtained stereoselectively.



As described in Section 5.09.5.1, organoammonium salts of chiral amines with strong Brønsted acids can activate α,β-unsaturated carbonyl compounds through the generation of iminium intermediates **174** (LUMO-lowering activation) (Scheme 46). However, free amines or organoammonium salts with weak Brønsted acids can activate α,β-unsaturated ketones

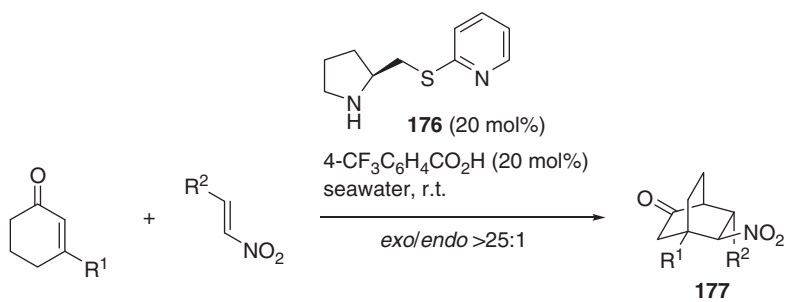
through the formation of 2-dienamine **175**. This electron-rich diene reacts with electron-deficient alkenes to give the corresponding Diels–Alder adducts.[119,120] This catalytic strategy involving HOMO-raising activation is called enamine catalysis.

Recently, chiral amine-catalyzed enantioselective Diels–Alder reactions involving *in situ* enamine activation have been reported. A chiral secondary amine **176** (20 mol%) catalyzes the enantioselective Diels–Alder reaction of cyclohexadienes with nitroalkenes in the presence of 4-$CF_3C_6H_4CO_2H$ (20 mol%) in seawater or brine to give the corresponding cycloadducts **177** with

Scheme 45 High-level diastereo- and enantiocontrol in Diels–Alder reaction of **135** with 2-chloroacrylonitrile.



Scheme 46 HOMO-raising activation of α,β-unsaturated carbonyl compounds: Enamine catalysis.

high diastereo- and enantioselectivity (equation 22, Table 34).[121] Although R^2 is limited to aryl groups, the electronic properties and the position of the substituents on the aryl group have little influence on the diastereo- and enantioselectivity of the reaction. Interestingly, the best result is obtained when seawater, taken from the East China Sea, is used as the solvent. The reaction in boiled seawater gives results similar to those in untreated seawater, which suggests that salts, rather than microorganisms, play an important role in the reaction. The concentration of aqueous NaCl evidently affects the performance of the reaction. Due to the good dispersion of the reactants in aqueous salt solutions and the salting-out effect, conversions of approximately 100% and high diastereo- and enantioselectivities are obtained with seawater or a 7.5% NaCl aqueous solution.

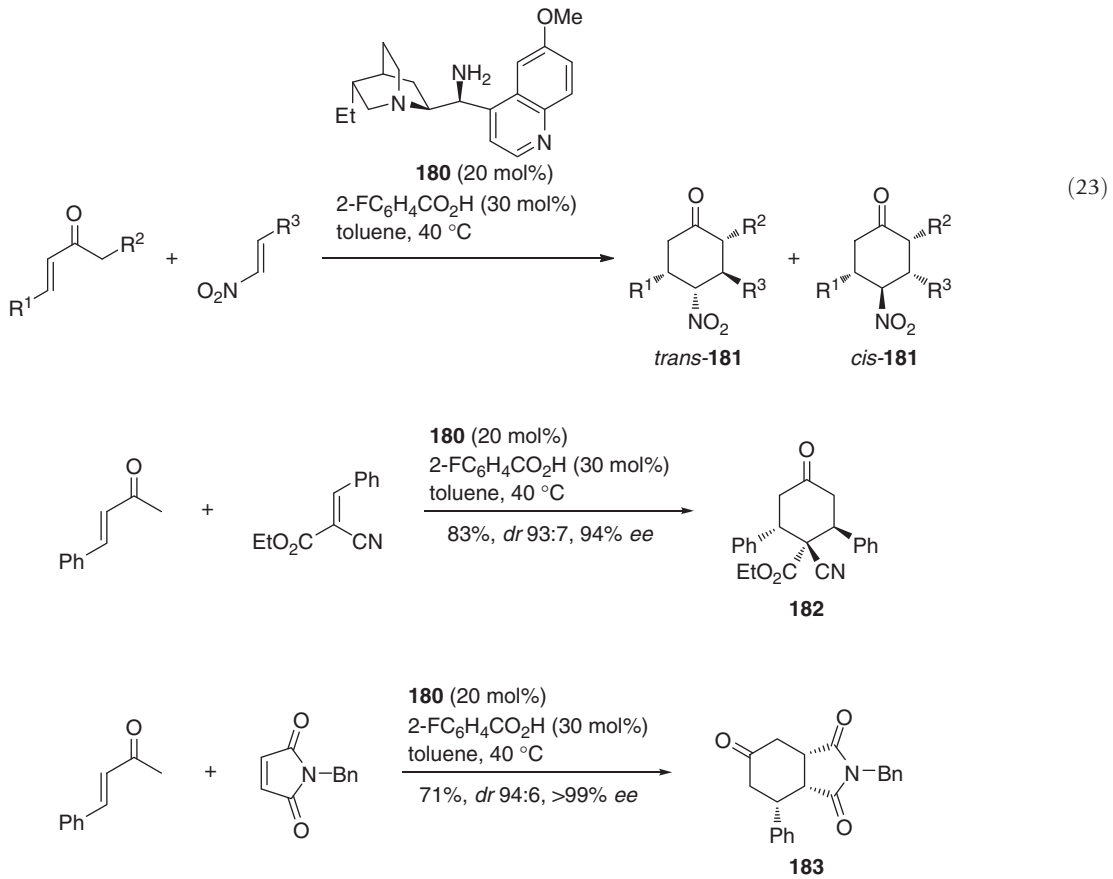
(22)

The reaction proceeds via a chiral dienamine intermediate **178**, which is generated from the catalyst **176** and cyclohexenones (Scheme 47).[121] A nitroalkene is activated by the pyridinium proton of dienamine intermediate **178** to approach the *Si* face of **178**. The fact that seawater or brine significantly enhances the catalytic performance of the Diels–Alder reaction suggests that they play other roles in the process besides the salt effect, which may stabilize transition state **179** through a hydrogen-bonding interaction with 4-$CF_3C_6H_4CO_2H$ and favor the hydrolysis step to close the catalytic cycle. Interestingly, the corresponding Michael adducts of cyclohexenones with nitroalkenes are not found during the transformation, which suggests that the cyclization proceeds via the one-step concerted addition pathway rather than a sequential Michael/Michael mechanism in the present catalytic system.

Scheme 47 Catalytic cycle of Diels–Alder reaction of cyclohexenones with nitroalkenes catalyzed by **176**.



Although chiral secondary amine catalysis has been shown to be efficient in promoting the stereoselective Diels–Alder reactions of cyclic α,β-unsaturated carbonyl compounds via *in situ* dienamine activation, the reaction proceeds with essentially no enantioselectivity. However, a chiral primary amine **180** (20 mol%) catalyzes the formal Diels–Alder reaction of acyclic α,β-unsaturated ketones with nitroalkenes in the presence of 4-$FC_6H_4CO_2H$ (30 mol%) in toluene (equation 23, Table 35).[122] The reaction preferentially gives *endo* products *trans*-**181** with high enantioselectivities. The nature of the acidic cocatalyst strongly influences both the reactivity and the stereochemical outcome of the reaction. For example, the use of salicylic acid (30 mol%) as a cocatalyst improves the diastereoselectivity and the reaction rate, albeit with slightly lower enantioselectivity. The primary amine-catalyzed reaction is proposed to proceed via a stepwise double-Michael sequence. The formal Diels–Alder reaction of acyclic

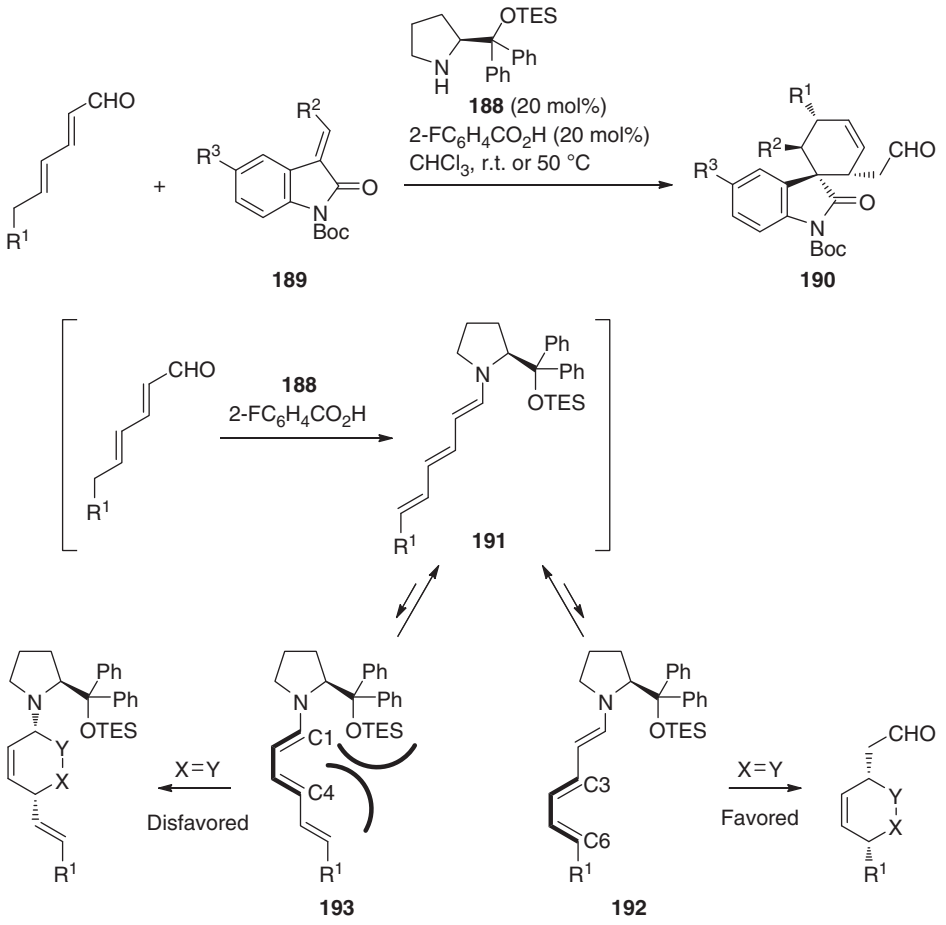
α,β-unsaturated ketones can also be performed with other electrophiles (Scheme 48). For example, the reaction with *trans*-α-cyanocinnamate gives the corresponding cyclohexanone **182** in 83% yield with 94% *ee*. The reaction of *N*-benzylmaleimide affords the bicyclic cyclohexanone **183** in 71% yield with >99% *ee*.

(23)

Scheme 48



The inverse-electron-demand Diels–Alder reaction of α,β-alkenals with electron-deficient dienes is also promoted by the HOMO-raising activation using chiral amines. When the reaction of (*E*)-2-butenal with electron-deficient dienes **185** is conducted in the presence of the chiral secondary amine **184** (10 mol%) and benzoic acid (10 mol%), the corresponding *endo*-adducts **186**

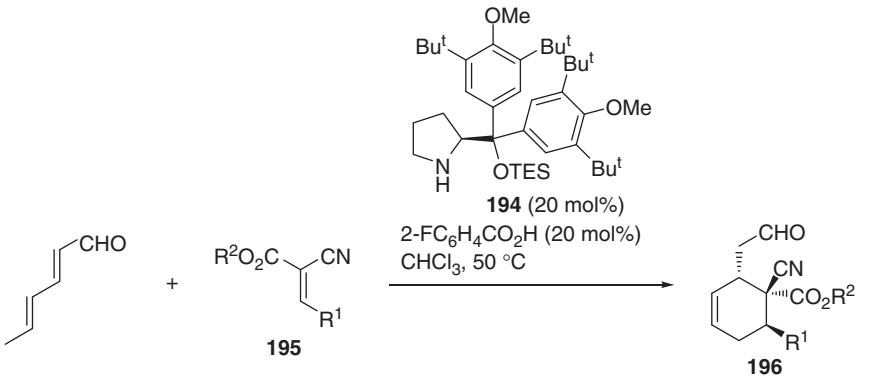

Scheme 50 Inverse-electron-demand Diels–Alder reaction of α,β,γ,δ-dienals based on HOMO-raising activation.

are obtained with high diastereo- and enantioselectivity (Scheme 49, Table 36).[123] Chiral amine **184** activates (*E*)-2-butenal with the aid of benzoic acid through the formation of chiral dienamine **187** (HOMO-raising activation).

The inverse-electron-demand Diels–Alder reaction of α,β,γ,δ-dienals with 3-olefinic oxindoles **189** is catalyzed by chiral secondary amine **188** (20 mol%) and 2-fluorobenzoic acid (20 mol%) to give spirocyclic indoles **190** with high enantioselectivity (Scheme 50, Table 37).[124] It has been shown that the merger of α,β,γ,δ-dienals, **188** and 2-fluorobenzoic acid generates trienamines **191** as active intermediates. In the HOMO-raising activation of **191**, both C3–C6 of **192** and C1–C4 of **193** may act as a diene. However, a computational study suggested that the bond-rotation barrier for the formation of **192** is 1.8 kcal mol^{-1} lower than that of **193**. In addition, the location of the energetically important frontier molecular orbital points to **192** as more reactive intermediate than **193**: the HOMO of **192** is 2.17 eV higher in energy than that of **193**, and the LUMO of **192** is 4.41 eV lower in energy than that of **193**. Thus, both the rotation barrier and the energy of the orbitals suggest that **192** should be the more reactive intermediate for the Diels–Alder reaction with electron-deficient alkenes.

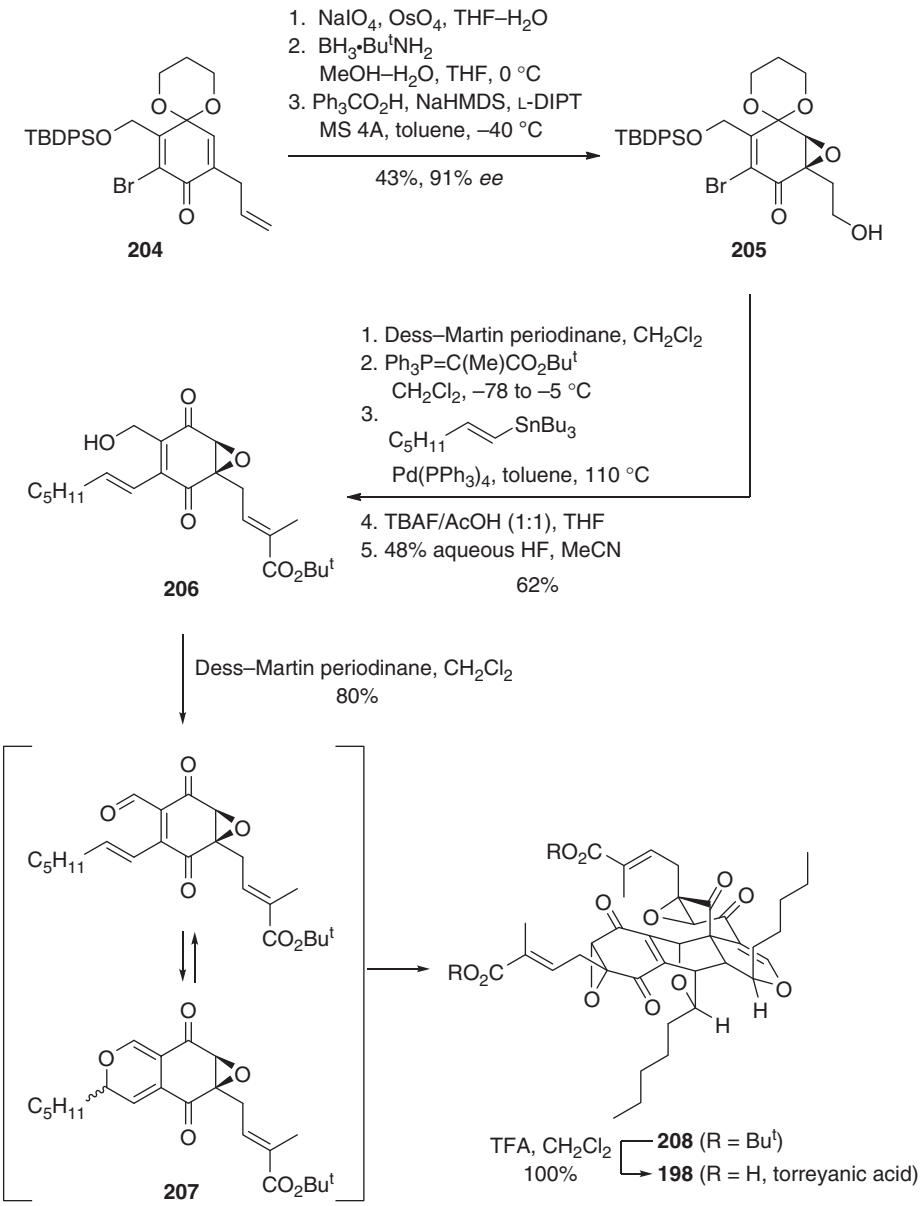
Scheme 52 Dimeric epoxyquinoid natural products.

Scheme 53 Biomimetic Diels–Alder dimerization of epoxyquinol monomer **201**.



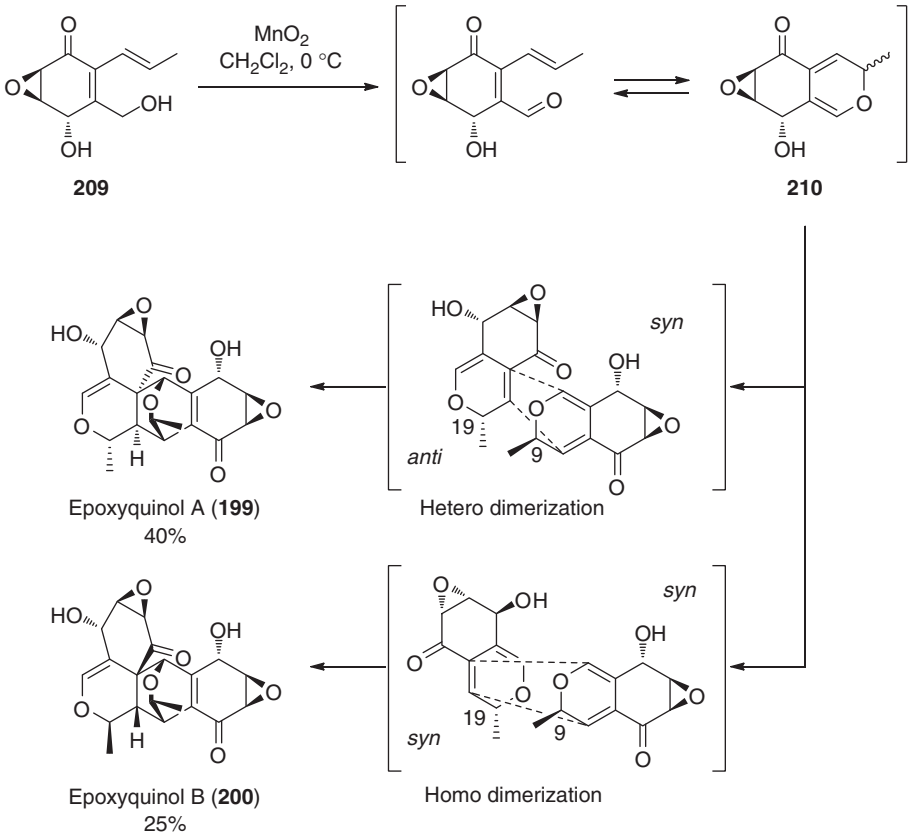
Scheme 54 Torreyanic acid (**198**), a dimeric quinone epoxide.

The trienamine-Diels–Alder reaction can also be used with electron-deficient alkenes **195** (Scheme 51).[124] The sterically more-demanding secondary amine **194** catalyzes the reaction to give the corresponding *endo*-adducts **196** with high diastereo- and enantioselectivity.

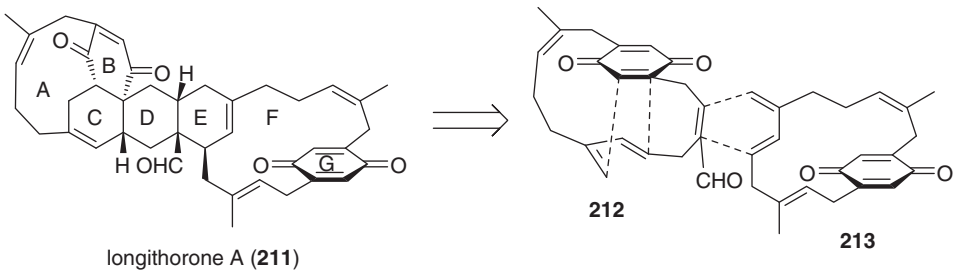
5.09.6 Biomimetic Synthesis of Natural Compounds Using Intermolecular Diels–Alder Reactions

Biomimetic chemistry has become an integral part of organic chemistry, especially in the field of natural compound synthesis.[125,126] In many cases, a biomimetic approach can give the stereoselective production of highly complex carbon skeletons from rather simple precursors. This section focuses on the biomimetic synthesis of bioactive natural compounds using intermolecular Diels–Alder reactions.

Epoxyquinones are one of the main classes of polyketide-based metabolites and originate from a variety of natural sources. For example, panepophenanthrin (**197**, Scheme 52) is an inhibitor of the ubiquitin-activating enzyme (E1), which was isolated from the fermented broth of the mushroom strain *Panus rudis* Fr. IFO8994.[127] This molecule falls into a general class of epoxyquinoid natural products produced by Diels–Alder-type dimerization, along with torreyanic acid (**198**)[128] and epoxyquinols A (**199**)[129] and B (**200**).[130] The biomimetic Diels–Alder dimerization of epoxyquinol monomer **201** proceeds under solvent-free conditions at 25 °C to give panepophenanthrin (**197**) in 80% yield (Scheme 53).[131] Two plausible mechanistic pathways can be proposed for the Diels–Alder reaction. In the first pathway (path a), the tertiary hydroxyl group of one monomer adds to the carbonyl group of the second to form a hemiacetal intermediate **202**. An intramolecular, inverse-electron-demand Diels–Alder reaction gives the dimeric structure. In the alternative pathway (path b), a normal 'pseudo-transannular' Diels–Alder reaction takes place through a transition state **203** involving hydrogen-bonding interactions between the monomers.



Scheme 55 Biomimetic total synthesis of torreyanic acid (**198**).

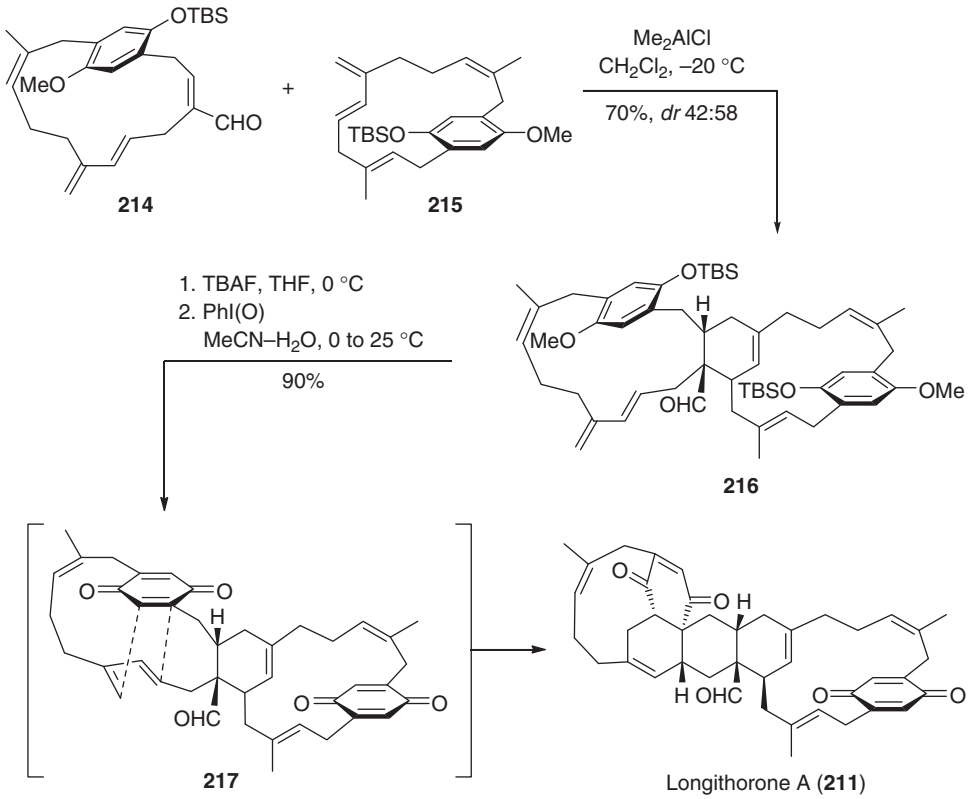


Torreyanic acid (**198**) is a dimeric quinone epoxide that is produced by the endophytic fungus *Pestalotiopsis microspora* associated with the Florida torreya tree.[128] The biosynthesis of torreyanic acid has been proposed to involve the Diels–Alder dimerization of 2*H*-pyrane monomers that are epimeric at C9 (C9′) (Scheme 54). In this *endo*-Diels–Alder reaction, the two pentyl side chains are oriented away from one another in the transition state.

Based on the proposed biosynthetic pathway, torreyanic acid (**198**) was synthesized through the biomimetic Diels–Alder dimerization of diastereomeric 2*H*-pyran monomers **207** (Scheme 55).[132] Oxidative cleavage of monosubstituted alkene of **204** followed by asymmetric nucleophilic epoxidation gives epoxide **205** with high enantioselectivity (91% *ee*). Subsequent transformations of **205**, involving a Wittig and a Stille reaction, give quinone epoxide **206**, which is a precursor of **207**. Dess–Martin oxidation of **206** initiates the tandem oxidation/electrocyclization/Diels–Alder dimerization process to give adduct **208** as a single diastereomer in 80% yield. The stereochemistry is consistent with the biosynthetic pathway. Treatment of **208** with TFA effects the removal of the *tert*-butyl ester to give torreyanic acid (**198**).

The same strategy has been applied to the biomimetic synthesis of epoxyquinols A (**199**) and B (**200**) (Scheme 56).[133,134] The oxidation of quinone epoxide **209** with excess MnO_2 in CH_2Cl_2 gives 2*H*-pyranes **210** as a diastereomeric mixture. The hetero-dimerization of **210** through the *endo*-Diels–Alder reaction gives epoxyquinol A (**199**) in 40% yield. In contrast to the biomimetic synthesis of torreyanic acid (**197**), the homo-dimerization of **210** also proceeds to give epoxyquinol B (**200**) through the

Scheme 56 Biomimetic synthesis of epoxyquinols A (**203**) and B (**204**).



Scheme 57 Proposed biosynthesis of longithorone A (**211**).

exo-Diels–Alder reaction. In the case of the biomimetic dimerization of **201**, steric hindrance by the unsaturated ester moiety may prevent homo-dimerization.

Longithorone A (**211**) is a cytotoxic compound that was isolated from freshly thawed specimens of *Aplydium longithorax* (Monniot) collected in Palau (Scheme 57).[135] This compound has an unusual heptacyclic structure, the biosynthesis of which may involve an intermolecular Diels–Alder reaction between [12]-paracyclophanes **212** and **213** to form the E ring, and a transannular Diels–Alder reaction of **212** to form the A, C, and D rings.

Based on a proposed biosynthesis, longithorone A (**211**) can be synthesized from [12]-paracyclophanes **214** and **215**, which are single atropisomers (Scheme 58).[136,137] An intermolecular Diels–Alder reaction between **214** and **215** proceeds with the aid of Me_2AlCl at -20 °C to give cyclohexene **216** in 70% yield as a 42:58 diastereomeric mixture. Although the present cycloaddition is completely *endo*-selective, the reaction shows only moderate facial selectivity. The lack of substrate-based diastereoselectivity in the cycloaddition suggests that this step is promoted by enzymatic catalysis. Deprotection of **216** followed by oxidation generates bisquinone **217**, which undergoes a transannular Diels–Alder reaction at room temperature to give longithorone A (**211**) in 90% yield.

Scheme 58 Biomimetic total synthesis of longithorone A (**211**).

5.09.7 Conclusion and Outlook

The ultimate goal of organic synthesis is a stereoselective assembly of a given chiral organic compound from readily available starting achiral materials and reagents in the most efficient way. In modern multistep organic synthesis, the word 'efficient' should include high yield and selectivity of each step as well as the reduction of the total number of steps and the improvement of the overall atom economy. In this context, the enantioselective Diels–Alder reaction has been one of the most powerful tools for short-step synthesis of bioactive natural products as described in this chapter. The stereoselective construction of multiple carbon –carbon bonds in a single operation is one of the ideal methods. However, there still is much more to study with respect of the extension of substrate generality, the reagent-control of diastereoselectivity, the decrease of catalyst loading and the determination of mechanistic details. The extension of substrate generality and the reagent-control of diastereoselectivity should allow us to make highly efficient synthetic strategies. The decrease of catalyst loading improves the atom economy. The determination of mechanistic details would result in the development of new catalytic systems that can promote the reaction of less active substrates. Further development of stereoselective Diels–Alder reactions can lead us to achieve 'efficient' synthesis of complex bioactive natural products.

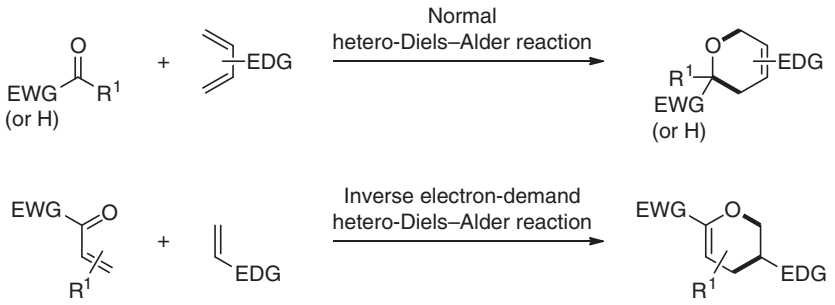
Glossary

CH–π Interaction CH–π Interaction is a weak, attractive, noncovalent interaction between CH groups and Q-systems. For example, intramolecular CH–π interaction is used to stabilize the conformation of some proteins.

endo*, *exo The Diels–Alder reaction of cyclopentadiene with 2-propenal can produce two possible diastereomers: *endo*- and *exo*-adducts. The prefix *endo* refers to the isomer with the substituent located closest, or *syn*, to the longest bridge. The prefix *exo* is reserved for the isomer with the substituent located farthest, or *anti*, from the longest bridge. Here, 'longest' and 'shortest' refer to the number of atoms comprising the bridge. *Endo* and *exo* are also used to describe the stereochemistry of transition-state assemblies that lead to the *endo*- and *exo*-adducts, respectively.



π–π Interaction π–π Interaction refers to attractive, noncovalent interactions between π-systems. In general, electron-rich π-systems (π-electron donor) interact with electron-deficient π-systems (π-electron acceptor) in a parallel orientation.

s-*cis*, s-*trans* The spatial arrangement of two conjugated double bonds about an intervening single bond is described as s-*cis* if they are *syn*periplanar and s-*trans* if they are *anti*periplanar. This term should not be applied to other systems such as *N*-alkyl amides (use *E*/*Z* or *sp*/*ap*).

5.10.1 Introduction

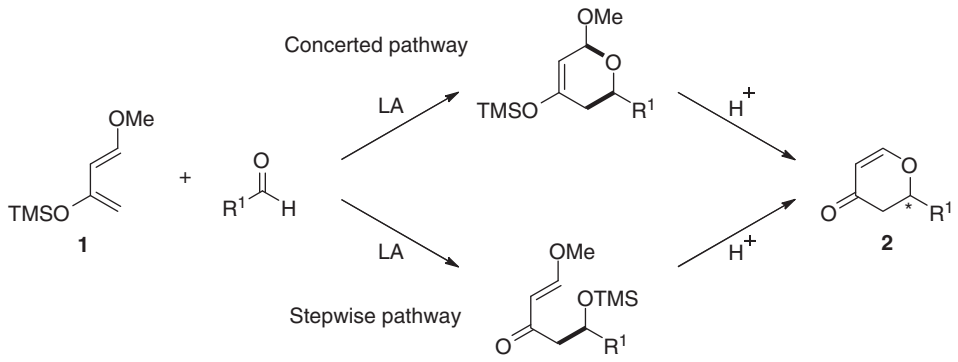
The hetero-Diels–Alder reaction is an important variant of the Diels–Alder reaction in which either the diene or the dienophile contains a heteroatom, most often nitrogen or oxygen. The asymmetric hetero-Diels–Alder reaction of carbonyl compounds is among the most powerful methods for the construction of optically active heterocycles, and has been extensively used in the synthesis of bioactive natural and synthetic compounds.[1–8] The two concepts that underlie the hetero-Diels–Alder reactions of carbonyl compounds are illustrated in **Scheme 1**. In the normal electron-demand reaction, a carbonyl compound reacts with an electron-rich diene. To promote this reaction, an acid catalyst activates the carbonyl compound by lowering its lowest unoccupied molecular orbital (LUMO) energy. In the inverse electron-demand reaction, however, an α,β-unsaturated carbonyl compound reacts with an electron-rich dienophile. This type of reaction can also be promoted by using acid catalysts to lower the LUMO energy of the α,β-unsaturated carbonyl compound. Therefore, the introduction of additional electron-withdrawing groups (EWG) should provide additional activation for both types of hetero-Diels–Alder reaction.

The hetero-Diels–Alder reaction of imines or related compounds (the aza-Diels–Alder reaction) is also a useful method for constructing nitrogen-containing cyclic compounds.[4,6,9–12] Due to the fundamental importance of nitrogen-containing natural compounds, much attention has been given to the development of asymmetric aza-Diels–Alder reactions. In addition to carbonyl

EDG, electron-donating group; EWG, electron-withdrawing group

Scheme 1 Hetero-Diels–Alder reactions of carbonyl compounds.

compounds and imines, various heterodienes and heterodienophiles, which include nitroso compounds, *ortho*-benzoquinones, and so on, also undergo diastereo- and enantioselective Diels–Alder reactions. This chapter focuses on recent advances in diastereo- and enantioselective hetero-Diels–Alder reactions using chiral Lewis acid (LA) catalysts or chiral organocatalysts.

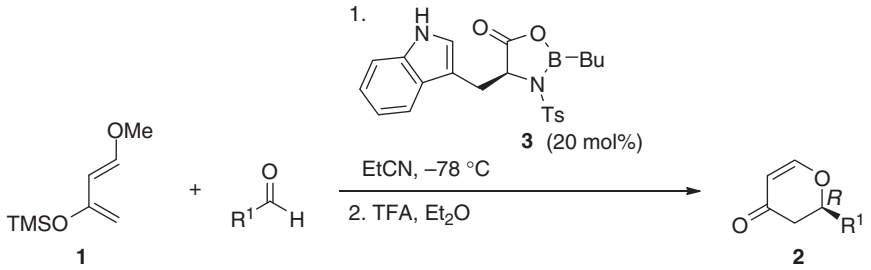


5.10.2 Oxo-Diels–Alder Reactions

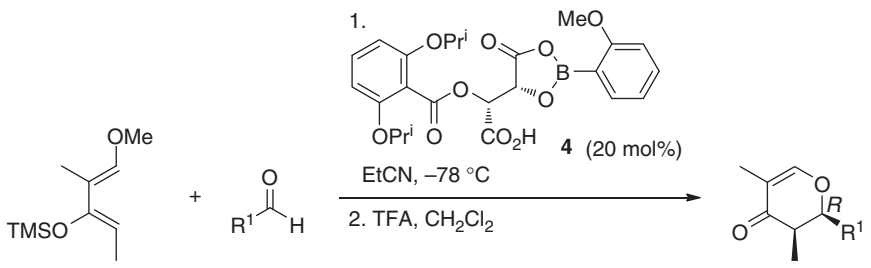
5.10.2.1 Reactions of Carbonyl Dienophiles

5.10.2.1.1 Chiral LA catalysts

As described in the Introduction, the normal electron-demand oxo-Diels–Alder reaction is promoted by an LA catalyst through the activation of the carbonyl dienophiles. Several chiral LA catalysts, including compounds of boron(III), chromium(III), titanium(IV), zirconium(IV), rhodium(II or III), or indium(III), have been used in enantioselective hetero-Diels–Alder reactions of carbonyl compounds.



Electron-rich 1-methoxy-[(trimethylsilyl)oxy]-1,3-butadiene (**1**, Danishefsky's diene) is a highly reactive diene for the hetero-Diels–Alder reaction that can react with unactivated aldehydes. Two hetero-substituents of **1** increase the highest occupied molecular orbital (HOMO) energy, which results in a reduction of the energy-difference between the HOMO of **1** and the LUMO of the dienophile. With the aid of LA catalysis, the hetero-Diels–Alder reaction of **1** with aldehydes provides useful access to 2,3-dihydro-4*H*-pyran-4-one derivatives **2**, a class of compounds with extensive utility in organic synthesis. For the hetero-Diels–Alder reaction of **1** with aldehydes, two mechanistic pathways have been considered (Scheme 2): a concerted [4 + 2] cycloaddition pathway and a stepwise pathway (Mukaiyama aldol and cyclization).[13]



Scheme 2 Two mechanistic pathways for the oxo-Diels–Alder reaction.

Chiral boronic acid derivatives **3** and **4** are efficient catalysts not only for the carbo-Diels–Alder reaction but also for the oxo-Diels–Alder reaction of Danishefsky-type dienes (Scheme 3). Chiral oxazaborolidine **3** derived from *N*-tosyl-L-tryptophan and butylboronic acid catalyzes the Mukaiyama aldol reaction of **1** with aldehydes.[14] Subsequent acid treatment of the Mukaiyama aldol products gives the formal hetero-Diels–Alder adducts **2** with good enantioselectivities. The chiral acyloxyborane (CAB) catalyst **4** derived from *O*-[2,6-di(isopropoxy)benzoyl]-L-tartaric acid and 2-methoxyphenylboronic acid also catalyzes the reaction of Danishefsky-type diene **5** with aldehydes to give the hetero-Diels–Alder adducts **6** with high enantioselectivities.[15]

Chiral chromium(III) complexes, such as **7** (X = BF_4, Cl) and **8** (X = Cl, SbF_6) (Figure 1), are highly efficient catalysts for the hetero-Diels–Alder reactions of Danishefsky-type dienes **9** with unactivated aldehydes.[16–18] The chiral salen–chromium(III)

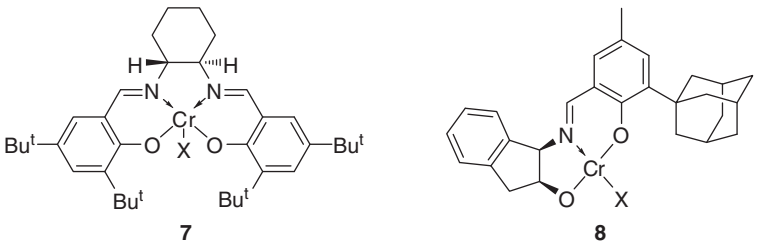

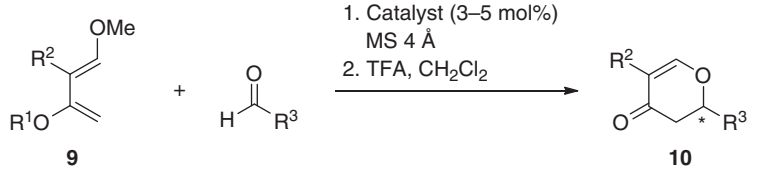

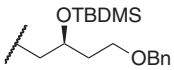

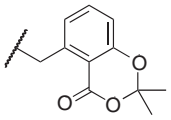

Figure 1 Chiral chromium(III) complexes **7** and **8**.

complex **7** (X = BF_4) catalyzes the hetero-Diels–Alder reaction of **1** with various aldehydes to give the corresponding cyclohexenones with high enantioselectivity (equation 1, Table 1).[16–22] The addition of oven-dried powdered molecular sieves (MSs) 4 Å to the reactions increases the yield and enantioselectivity. The present reaction is proposed to proceed via a concerted [4 + 2] mechanism. The cycloadducts shown in Table 1 are key intermediates for the total synthesis of the polyene macrolide RK-397,[20] the marine ladder toxin gambierol,[21] and the macrocyclic salicylate apicularen A.[22]

The chiral tridentate Schiff base chromium(III) complexes **8** are the most efficient catalysts for the reactions of less nucleophilic dienes bearing fewer than two oxygen substituents with unactivated aldehydes.[17,18] This class of asymmetric hetero-Diels–Alder reaction provides a direct route to enantiomerically enriched dihydropyran derivatives from simple achiral starting materials. In the presence of complex **8** (X = Cl, SbF_6) (3 mol%), the reaction of a 2-siloxy-1,3-diene **11** with a nonactivated aldehyde gives the corresponding 2,3-*cis*-adduct **12** with excellent diastereo- and enantioselectivity (equation 2, **Table 2**).[17] The reaction is performed at room temperature and requires the presence of MS for optimal results. Whereas the use of acetone as a solvent is generally beneficial, and is critical in the case of aromatic aldehydes, the use of solvent-free conditions is satisfactory for some substrates.

(2)

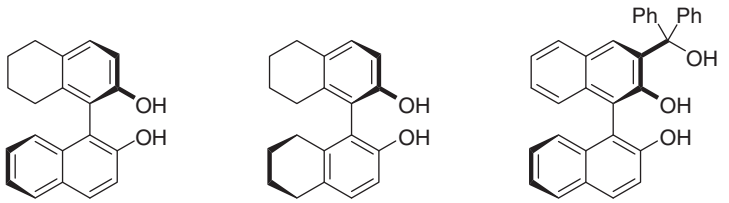
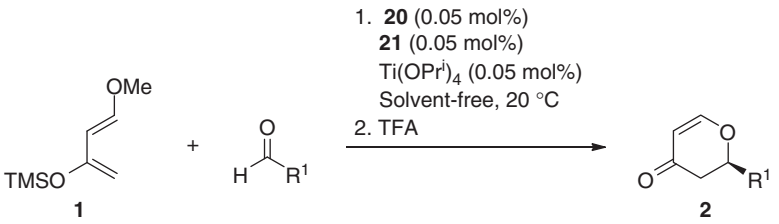
The chromium(III) complex **8** also catalyzes the hetero-Diels–Alder reaction of 1-alkoxydienes **13** and **15** with aldehydes to give the corresponding cyclic acetals **14** and **16** with excellent enantioselectivities; the products can be subjected to hydrolysis and oxidation to afford the corresponding lactones (**Scheme 4**).[17] This method provides highly efficient access to several interesting natural product structures; for example, desilylation of adduct **16** followed by acidic workup and recrystallization gives **17**, a key intermediate in a total synthesis of fostriecin (CI-920), with >99% *ee*.[23]

A titanium(IV) complex of chiral 1,1′-bi-2-naphthol (BINOL) is an efficient catalyst for the hetero-Diels–Alder reaction of carbonyl compounds. The catalytic activity of the Ti(IV)–BINOL complex closely depends on the preparation method. For example, a Ti(IV)–BINOL complex prepared from $Ti(OPr^i)_4$ (10 mol%) and (*R*)-BINOL (20 mol%) in the presence of trifluoroacetic acid (TFA) (0.3 mol%) and MS 4 Å catalyzes the reaction of Danishefsky's diene **1** with unactivated aldehydes to give the adducts **2** with high enantioselectivities (**Scheme 5**).[13] In contrast, a complex prepared from $Ti(OPr^i)_4$ (10 mol%) and (*R*)-BINOL (10 mol%) in the presence of MS 4 Å gives lower enantioselectivity.

A Ti(IV)–BINOL complex prepared from $TiCl_2(OPr^i)_2$ (10 mol%) and (*R*)-BINOL (10 mol%) in the presence of MS 4 Å catalyzes the hetero-Diels–Alder reaction of 1-methoxybutadienes **18** with methyl glyoxylate to give the corresponding adducts *cis*-**19** with high diastereo- and enantioselectivities (**Scheme 5**).[24] Use of the Ti(IV)–BINOL complex under MS-free conditions improves the *cis*-selectivity and enantioselectivity.



Scheme 4 Hetero-Diels–Alder reaction of 1-alkoxydienes **13** and **15**.



Scheme 5 Hetero-Diels–Alder reactions catalyzed by Ti(IV)–BINOL complexes.

Titanium(IV) complexes of the chiral BINOL derivatives **20**–**22** (Figure 2) are also efficient catalysts for the hetero-Diels–Alder reaction of Danishefsky-type dienes with aldehydes. For example, a chiral Ti(IV) complex prepared from $Ti(OPr^i)_4$, (*R*)-tetrahydro-BINOL **20**, and (*R*)-octahydro-BINOL **21** (1:1:1 ratio) shows high catalytic activity for the reaction of **1** under solvent-free conditions (equation 3, Table 3).[25,26] Catalyst loadings of only 0.1–0.05 mol% are sufficient for obtaining the corresponding adducts **2** in quantitative yields and with high enantioselectivities.

A 1:1 complex of Ti(IV) and the chiral triol **22** also promotes the hetero-Diels–Alder reaction of the Danishefsky-type diene **23** with aldehydes (Scheme 6).[27] The present reaction can be applied to a variety of aldehydes and the corresponding adducts **24** are obtained in high yields with high enantioselectivities. Triol **22** acts as a tridentate ligand for the titanium(IV) cation, and the 3-diphenylhydroxymethyl group of **22** is critical for increasing the catalytic activity. Since an unusual nonlinear effect is observed in this reaction, a variety of aggregated catalyst species may be involved in the catalytic system. In contrast to the reaction catalyzed by the Ti(IV)–BINOL complex, the present reaction is proposed to proceed via a concerted Diels–Alder pathway.

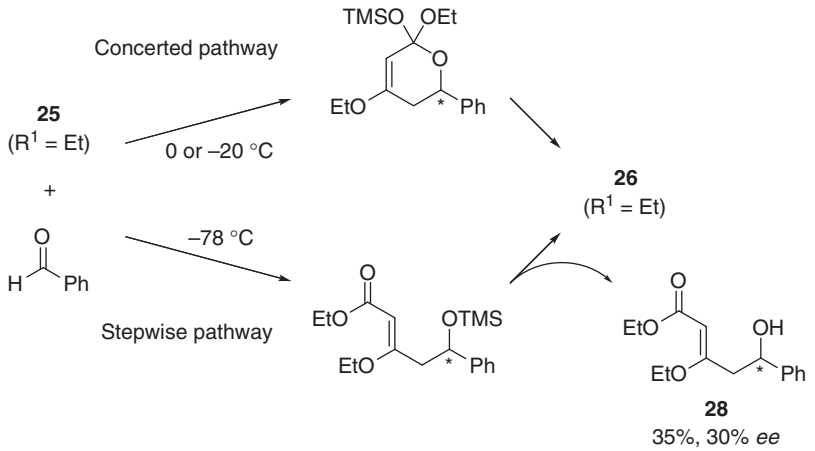

Scheme 6 Hetero-Diels–Alder reaction catalyzed by the Ti(IV) complex of chiral triol **22**.

Brassard's diene **25** is a highly useful substrate for the hetero-Diels–Alder reaction and provides a convenient access to δ-lactones **26**. A chiral titanium(IV) complex of the tridentate Schiff base ligand **27** catalyzes the hetero-Diels–Alder reaction of Brassard diene **25** (R^1 = Et) with aromatic aldehydes to give the corresponding δ-lactones **26** with high enantioselectivities (Scheme 7).[28,29] However, the reaction shows poor enantioselectivity for aliphatic aldehydes. In the present reaction, the temperature influences the reaction pathway (Scheme 8). When conducted at 0 or −20 °C, the reaction proceeds via the concerted pathway, and the silylated intermediate is hydrolyzed by purification through a silica gel column at the end of the reaction to give **26** without TFA treatment. However, when the reaction is conducted at −78 °C by the same procedure, the Mukaiyama aldol product **28** is obtained in 35% yield with 30% *ee*. The reaction mostly follows the Diels–Alder pathway at higher temperature (0 or −20 °C), but the Mukaiyama aldol pathway at lower temperature (−78 °C).

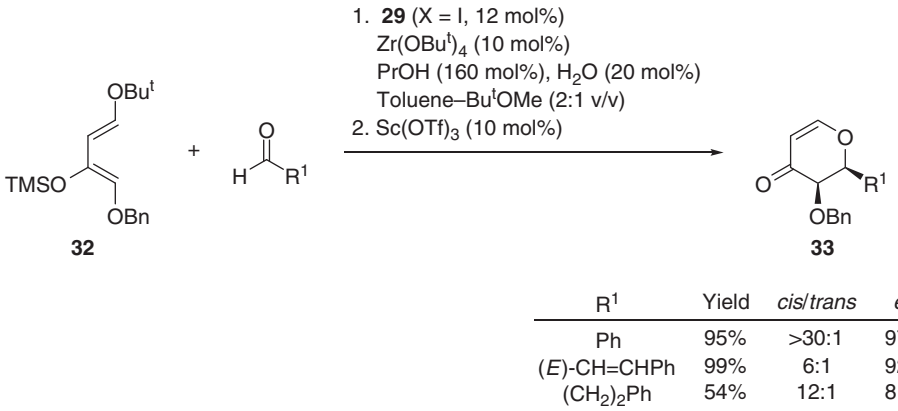
Scheme 8 Proposed mechanism for the hetero-Diels–Alder reaction of Brassard's diene **25** (R^1 = Et).

Chiral zirconium complexes, prepared from zirconium(IV) *tert*-butoxide and the (*R*)-3,3′-disubstituted binaphthol derivatives **29** (X = CF_2CF_3, I) in aqueous propan-1-ol, catalyze the hetero-Diels–Alder reaction of Danishefsky-type dienes with nonactivated aldehydes (equation 4, Table 4).[30] In contrast to the chromium(III)-complex-catalyzed reaction, the zirconium-complex-catalyzed reactions of Danishefsky-type dienes **30** give the corresponding 2,3-*trans*-adducts **31** with high diastereo- and enantioselectivity. The cycloadducts **31** can be used in syntheses of biologically important pyranone-containing natural products. The hetero-Diels–Alder reaction of the 4-oxygenated Danishefsky-type diene **32** is also promoted by the chiral zirconium(IV) complex to give the



corresponding 3-oxygenated pyranone derivatives **33** with high enantioselectivity (Scheme 9).[30] Interestingly, the present reaction gives the 2,3-*cis* product **33** as the major diastereomer, whereas the reaction of **30** predominantly gives the 2,3-*trans* product **31**.

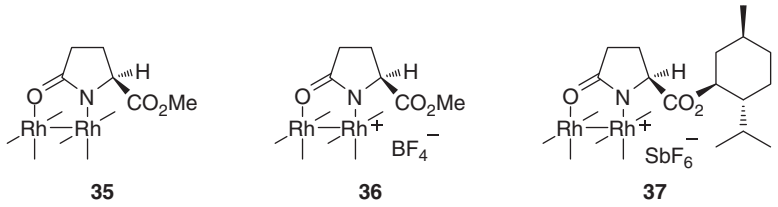
Scheme 9 Hetero-Diels–Alder reaction of the 4-oxygenated Danishefsky-type diene **32**.

In general, a favored transition state in the concerted pathway would be the *endo*-type cycloaddition to afford a 2,3-*cis* product. Therefore, the zirconium(IV) complex-catalyzed hetero-Diels–Alder reaction of **30**, which predominantly gives 2,3-*trans* product **31**, is proposed to proceed via a stepwise pathway (Scheme 10).[30] When the reaction of **30** is conducted without treatment with TFA, the *anti*-aldol adduct **34** (*anti*/*syn*=92:8) is obtained. In addition, TFA treatment of **34** gives the *trans*-product **31** (*trans*/*cis*=92:8). These results support the proposal that the reaction proceeds via a stepwise Mukaiyama aldol-cyclization pathway. The anti-preference in the Mukaiyama aldol step is explained by the steric hindrance between the Zr(IV) catalyst and the 4-methyl group, which prevents the formation of a *syn*-aldol adduct.However, the *cis*-selectivity observed in the reaction of **32** is explained by the interaction of the benzyloxy group with the zirconium center of the catalyst.

The chiral dirhodium(II) carboxamidate Rh_2(5*S*-mepy)$_4$ (**35**) (Figure 3) is an efficient catalyst for the hetero-Diels–Alder reaction of Danishefsky's diene **1** (equation 5, Table 5).[31–33] Although **35** has high catalytic activity, the use of the cationic dirhodium(II) carboxamidate [Rh_2(5*S*-mepy)$_4$]BF_4 (**36**), which is prepared by the oxidation of **35** with $NOBF_4$, further improves the catalytic activity and enantioselectivity (Table 5).[34] With **36**, the rate is estimated to increase by at least a factor of 10. In its use

Scheme 10 Proposed origin of *trans*- and *cis*-selectivity.



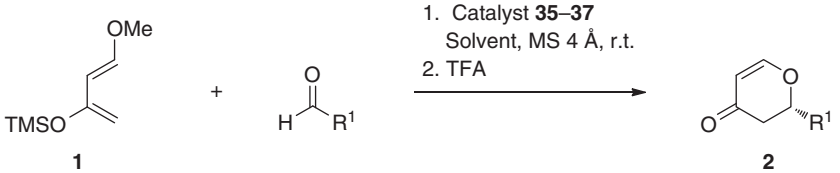


Figure 3 Chiral dirhodium(II) carboxamidate complexes **35–37**.

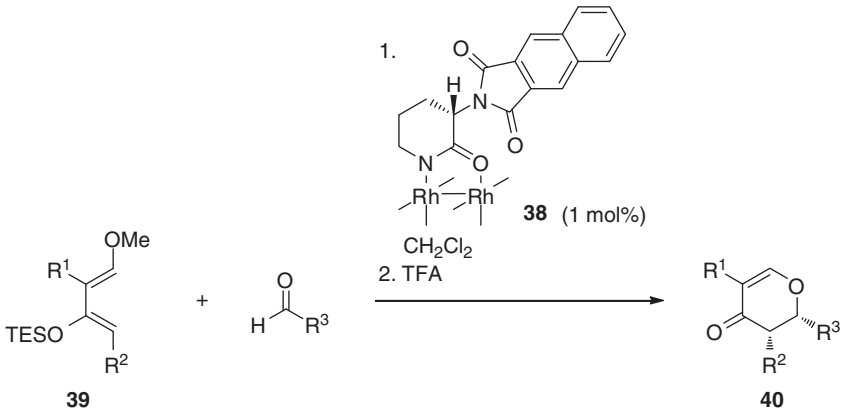
as an LA catalyst, coordination of the cationic rhodium complex with water is expected to produce a protic acid. To circumvent this problem, this reaction can be performed in the presence of a noncoordinating base such as 2,6-di-*tert*-butylpyridine. The use of a less polar solvent such as toluene further improved the reactivity and enantioselectivity (Table 5).[35] This enhancement is attributed to diminished or absent association of toluene with the catalyst, which lessens the relative importance of the uncatalyzed background reaction.

(5)



For the enantioselective hetero-Diels–Alder reaction of Danishefsky-type dienes **39**, the dirhodium(II) carboxamidate complex Rh_2(*S*-BPTPI)$_4$ (**38**) shows higher catalytic activity than **35–37** (equation 6, Table 6).[36] Dirhodium(II) catalyst **38** promotes the reaction with a variety of aldehydes to give 2,3-*cis*-dihydropyranones **40** in high yields with high enantioselectivities. Importantly, complex **38** can catalyze the reaction with sterically less-hindered α,β-acetylenic, α,β-olefinic and aliphatic aldehydes with excellent enantioselectivities. The present method can be applied to a large-scale synthesis without compromising the yield or

enantioselectivity: when the reaction of **39** ($R^1=R^2=H$) with 4-nitrobenzaldehyde (10 mmol) is conducted in the presence of **38** (0.0075 mol%), the corresponding adduct **40** ($R^1=R^2=H$, $R^3=C_6H_4$–4-NO_2) is obtained in 96% yield with 94% *ee*. The **38**-catalyzed hetero-Diels–Alder reaction proceeds though a concerted [4 + 2] cyclization mechanism in an *endo* mode, since the crude reaction mixture obtained without TFA treatment does not include the Mukaiyama aldol adduct, and no detectable cyclization of the Mukaiyama aldol adduct prepared independently is observed under the present reaction conditions.

[a]The reaction is conducted on a 10 mmol scale in the presence of 0.0075 mol% of **38**.

The dirhodium(II) catalyst **38** also promotes the reaction of 2-siloxybutadienes **41**, which are less nucleophilic than the Danishefsky-type dienes, to give the corresponding tetrahydropyranones **42** with high diastereo- and enantioselectivity (Scheme 11).[36] Rawal's diene **43** is known to exhibit significantly higher reactivity than Danishefsky dienes in the Diels–Alder reaction under mild conditions. In the presence of the dirhodium(II) complex **38** (1 mol%), Rawal's diene **43** reacts with a variety of aldehydes at quite a low reaction temperature to give dihydropyranone **44** with high enantioselectivities (Scheme 11).[37]

The indium(III) complex of the chiral *N*,*N*-dioxide ligand **45** shows high catalytic activity for the hetero-Diels–Alder reaction of Danishefsky-type dienes **46** (Scheme 12, Table 7).[38] In the presence of the chiral indium(III) complex (5 mol%), a variety of aldehydes, including aromatic, heterocyclic, α,β-olefinic, and aliphatic aldehydes, are converted to the corresponding 2,3-*cis*-dihydropyranones with excellent enantioselectivity. The use of anisole as a solvent is crucial for obtaining high diastereo- and enantioselectivity. Based on a theoretical calculation, it has been proposed that the reaction proceeds through a concerted pathway in an *endo* mode (Scheme 12).[39] In the transition state **48**, a *Si* face approach is preferred over a *Re* face approach, since there is no distinguishable repulsion between the diene and the ligand in this case.

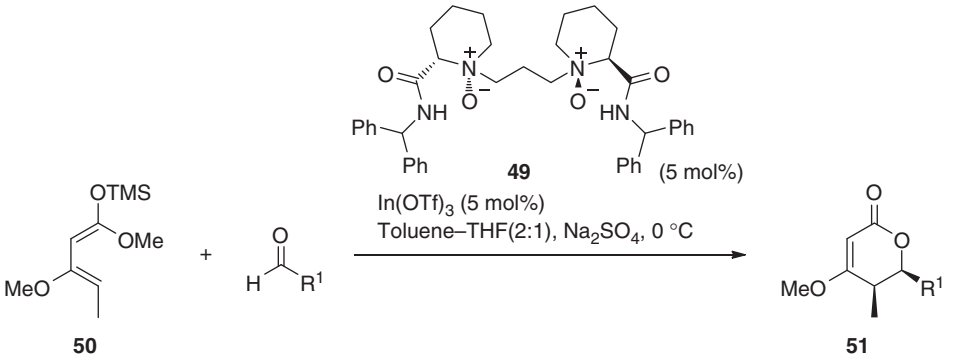

Scheme 12

For the hetero Diels–Alder reaction of the Brassard-type diene **50**, the use of the *N*,*N*-dioxide ligand **49** bearing *N*-diphenylmethyl groups gives better results than **45** (Scheme 13).[40] In the presence of a In(III) complex with **49**, the reaction of **50** with various aliphatic aldehydes gives δ-lactones **51** with high diastereo- and enantioselectivities. The addition of anhydrous Na_2SO_4 to the reaction mixture protects the system from instability caused by the absorption of moisture from air by $In(OTf)_3$.

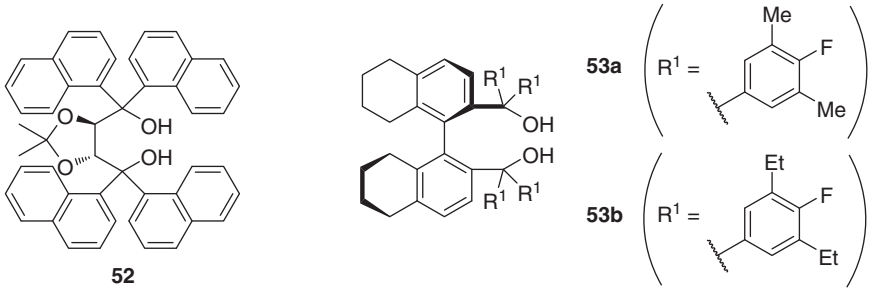
5.10.2.1.2 Chiral organocatalysts

Recent significant advances in organocatalysis have revealed that hydrogen-bonding catalysts can promote the hetero-Diels–Alder reaction of reactive substrates. For example, TADDOL **52** (Figure 4) catalyzed the enantioselective hetero-Diels–Alder reaction of 1-amino-3-siloxybutadiene **43** (Rawal's diene), which is a highly nucleophilic diene (equation 7, Table 8).[41] In the presence of **52** (20 mol%), the reaction with various unactivated aldehydes proceeds smoothly to yield (2*S*)-dihydropyrone **44** with high enantioselectivity after treatment with acetyl chloride. Axially chiral 1,1′-biaryl-2,2′-dimethanols (BAMOL) **53** (Figure 4) are also highly effective catalysts for the hetero-Diels–Alder reaction of **43**.[42] As shown in Table 8, **53** generally gives results superior to those with **52** under the same reaction conditions. Diols **52** and **53** catalyze the hetero-Diels–Alder reaction of both aromatic and



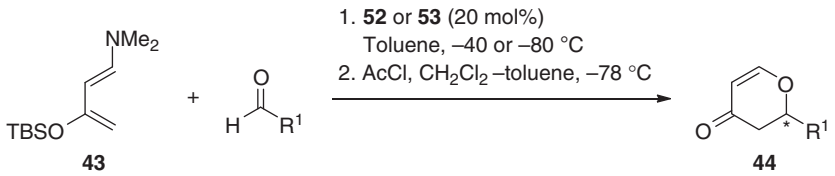


Figure 4 Axially chiral diols **53** and **54**.

aliphatic aldehydes. Aromatic aldehydes and straight-chain aliphatic aldehydes yield the corresponding adducts with excellent enantioselectivity, whereas aliphatic aldehydes with branched chains yield adducts with slightly lower enantioselectivity.

(7)

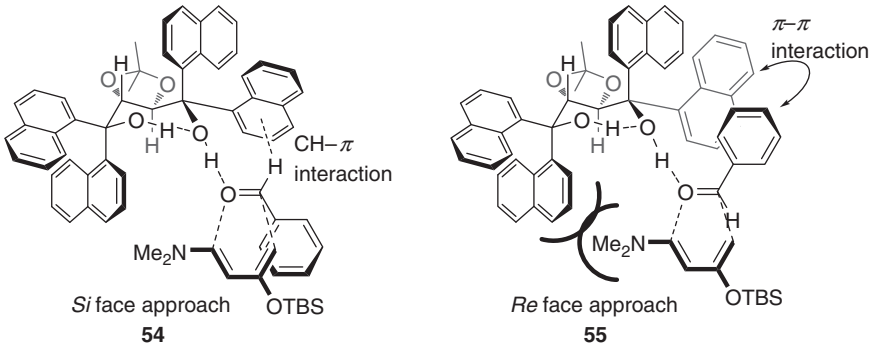
A theoretical study suggested that benzaldehyde is activated by TADDOL **52** through single-point hydrogen bonding.[43] Figure 5 shows the two lowest energy-transition structures **54** and **55** for *Si* face and *Re* face additions, respectively. Transition-state assembly **54** is stabilized by a CH–π interaction between the aldehyde CH and the pseudoequatorial naphthalene ring of **52**. However, transition-state assembly **55** lacks the CH–π interaction and instead possesses a π–π stacking interaction. The transition-state assembly **54** is more reactive than **55**, since the naphthyl moieties in **55** restrict the approach of the diene to the coordinated aldehyde, whereas transition-state assembly **54** has no steric repulsion of this type. The calculated difference between **54** and **55** ($\Delta E = 1.5$ kcal mol^{-1}) corresponds to an *S*:*R* product ratio of 97:3 at -40 °C, which is in reasonable agreement with the experimentally observed enantiomer ratio of 99:1.



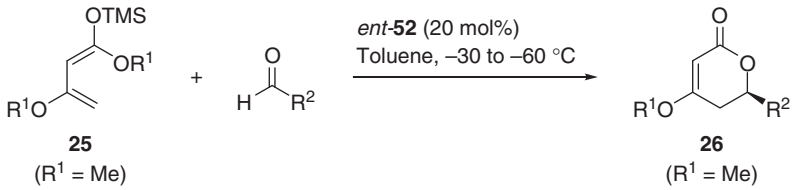


Figure 5 Proposed transition-state assemblies based on a theoretical study.

TADDOL **52** also catalyzes the hetero-Diels–Alder reaction of Bassard's diene **25** (R^1 = Me) with aromatic aldehydes to give the corresponding δ-lactone derivatives **26** in moderate to good yields with high enantioselectivities (Scheme 14).[44] Although the reaction can proceed under solvent-free conditions, a small amount of toluene is used to reduce the viscosity of the reaction mixture at a low reaction temperature.

3,3′-Diphenyl-1,1′-binaphthyl-2,2′-diyl hydrogenphosphate (**56a**, Figure 6) catalyzed the hetero-Diels–Alder reaction of less nucleophilic dienes, which have less than two oxygen substituents, with the activated aldehyde ethyl glyoxylate.[45] In the presence of **56a** (5 mol%), the reaction of 2-siloxydienes or 1-methoxydienes with ethyl glyoxylate yields the corresponding (2*S*)-*anti*-adducts with high diastereo- and enantioselectivity (Table 9). In contrast, conventional chiral Lewis catalysts yield adducts with high *syn*-diastereoselectivity, probably due to the dominant secondary π-orbital interactions and the steric demand of the chiral LA catalysts. Chiral phosphoric acid catalyst **56b**, which possesses bulkier aryl groups at the 3- and 3′-positions, also yields a *syn*-adduct with low enantioselectivity. For the **56b**-catalyzed reaction, it has been proposed that the *endo*-orientation (*endo*-**57b**) of

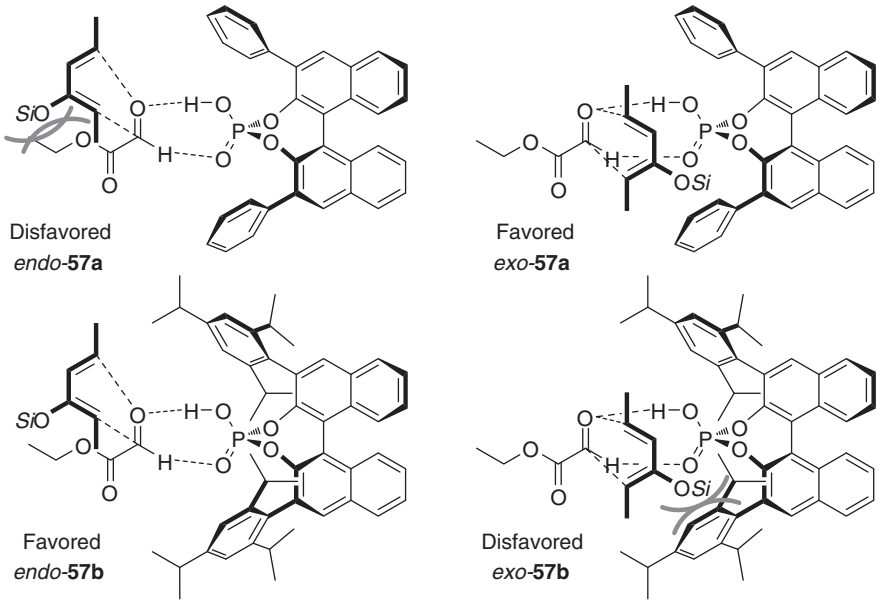
the diene to aldehyde is preferred over the *exo*-orientation (*exo*-**57b**) because of the steric hindrance between the diene substituents and the bulky aryl groups of **56b** around the activation site (Figure 7). For the **56a**-catalyzed reaction, the much smaller phenyl groups at the 3- and 3′-positions of **56a** allow the diene to occupy an *exo*-orientation (*exo*-**57a**). The *endo*-selectivity (*endo*-**57a**) is not favorable because of the steric repulsion between the diene substituents and ethyl glyoxylate.



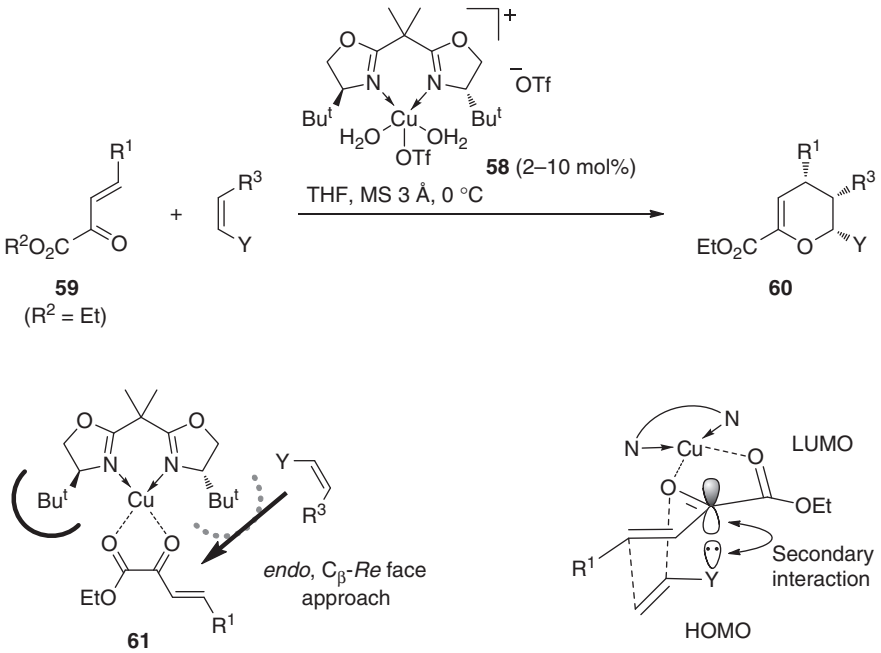


Figure 7 Plausible transition-state assemblies **57** (*Si*=TBDMS).

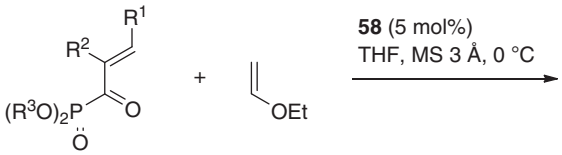
5.10.2.2 Inverse Reactions of α,β-Unsaturated Aldehydes and α,β-Unsaturated Ketones

5.10.2.2.1 Chiral LA catalysts

Chiral bis(oxazoline)–copper(II) complexes **58** are the catalysts that are most frequently used for inverse electron-demand hetero-Diels–Alder reactions, such as those of β,γ-unsaturated α-keto esters and α,β-unsaturated acyl phosphonates.[46–51] The ester and phosphonate groups activate the heterodienes as the substrate for a hetero-Diels–Alder reaction by lowering the LUMO. In addition, they provide a second 'docking point' for coordination to the chiral copper(II) LA. In the presence of aquo complex **58** (2–10 mol%) and MS 3 Å, β,γ-unsaturated α-keto esters **59** (R^2=Et) react with various vinyl ethers or vinyl thioethers to give the corresponding *endo*-adducts **60** (R^2=Et) with high diastereo- and enantioselectivity (Scheme 15, Table 10).[46,47] Although aquo complex **58** shows poor catalytic activity, MS 3 Å activate **58** *in situ* to give a catalyst which shows high activity and high selectivity. The reaction is presumed to proceed



Scheme 15

through a bidentate activated intermediate **61**, and the dienophile should approach the Cβ-*Re* face of the activated heterodiene via an *endo* transition state. The *endo* preference can be explained by a secondary orbital interaction between the oxadiene C-2 (LUMO) and dienophiles Y group (HOMO), which may stabilize the transition-state assembly.

Table 10 Inverse-electron-demand hetero-Diels–Alder reaction of **59** catalyzed by aquo complex **58** (**Scheme 15**)

The hetero-Diels–Alder reaction of α,β-unsaturated acyl phosphonates **62** (R^3=Me) is also catalyzed by the aquo complex **58** to give the corresponding cycloadducts **63** in high yields with high enantioselectivities (**Scheme 16**).[46,48] Cycloadducts **63** can be converted to various chiral compounds (**Scheme 17**). For example, treatment of **63** with dry HCl in methanol followed by hydrolysis under mild acidic conditions gives aldehydic esters **64** in yields of 73–86%. Rh/C-catalyzed hydrogenation of the enol

double bond in **63** gives **65** with high diastereoselectivity ($dr > 20{:}1$). Under the standard dihydroxylation conditions, α-hydroxy lactone **66** is obtained stereoselectively, presumably via the intermediacy of the α,β-dihydroxy phosphonate **67**. $RuCl_3$-catalyzed oxidation of **63** gives **67** with high diastereoselection. Subjection of **67** to the action of $NaHCO_3$ (MeOH, 25 °C, 5 min) results in the elimination of dimethyl phosphite to give **66**.

The γ-phthalimido-β,γ-unsaturated α-keto ester **69** is a useful heterodiene for the inverse electron-demand hetero-Diels–Alder reaction with vinyl ethers (Scheme 18).[51] The reaction of **69** is catalyzed by the chiral copper(II)–bis(oxazoline) complex **68** to give the corresponding *endo*-adducts **70** with high enantioselectivities. The present approach can be used for the synthesis of a series of different types of protected amino sugars.

Scheme 18 Hetero-Diels–Alder reaction of γ-phthalimido-β,γ-unsaturated α-keto ester **69**.

As described above, copper(II) complexes require EWGs, such as ester or phosphonate groups, in oxadienes to promote the hetero-Diels–Alder reaction. However, the chiral chromium(III) catalysts **8** (Figure 1) can promote the enantioselective inverse electron-demand hetero-Diels–Alder reaction of unactivated α,β-enals, which do not bear EWGs.[52] In the presence of **8** (X=Cl) (5–10 mol%), the reactions of α,β-enals **71** with ethyl vinyl ether take place under solvent-free conditions to give the corresponding dihydropyran derivatives **72** in high yields and excellent enantioselectivities (equation 8, Table 11). The reaction of 3-oxoprop-1-en-1-yl benzoate (**71**, R^1=H, R^2=OBz) provides the corresponding 4-benzoyloxy-substituted dihydropyran derivative, which is a versatile intermediate for an assortment of useful substitution reactions (Scheme 19).[53]

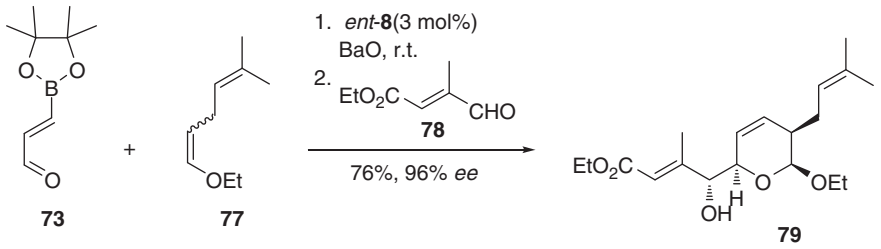
3-Boronoacrolein pinacolate (**73**) is a useful oxadienophile for the inverse-electron-demand hetero-Diels–Alder reaction. In the presence of *ent*-**8** (X=Cl) (0.3–1 mol%), the hetero-Diels–Alder reaction of enal **73** with ethyl vinyl ether affords the corresponding adduct **74**, subsequent oxidation/hydrolysis of which quantitatively gives the secondary alcohol **75** with 96% enantiomeric excess (Scheme 20).[54–56] The use of distilled **73** is crucial for obtaining high enantioselectivity. The adduct **74** also undergoes a subsequent allylboration reaction with various aldehydes to give the corresponding dihydropyrans **76** in high yields (61–92%) and excellent diastereoselectivities (Scheme 20).[54–56] This methodology has been successfully applied to the synthesis of various natural compounds. For example, the hetero-Diels–Alder/allylboration sequence between enal **73**, enol ether **77**, and



Scheme 19 Substitution reaction of the dihydropyran derivative **72** (R^1 = H, R^2 = OBz).

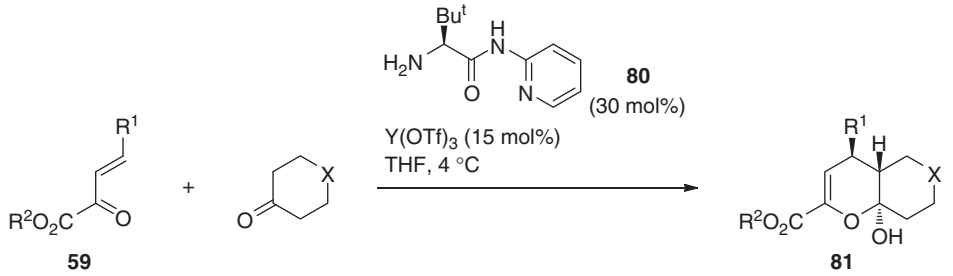
Scheme 20 Hetero-Diels–Alder of 3-boronoacrolein pinacolate **73**.



aldehyde **78** gives the dihydropyran **79** in 76% yield and 96% enantiomeric excess (Scheme 21). Although the 2-substituted enol ether **77** is an isomeric mixture, the *Z*-form is more reactive than the *E*-form, and this provides dihydropyran **79** as a single diastereomer. The cycloadduct **79** is a key intermediate for the total synthesis of a potent thiomarinol antibiotic.[57]

Scheme 21 Hetero-Diels–Alder/allyboration sequence as part of the synthesis of a potent thiomarinol antibiotic.

As described above, in most of the inverse-electron-demand hetero-Diels–Alder reactions, enol ethers derived from aldehydes act as electron-rich alkenes (dienophiles). However, a Y(III) complex with chiral ligand **80** bearing a primary amino group can catalyze the enantioselective reaction of β,γ-unsaturated α-keto esters **59** with cyclohexanone derivatives to give the *endo*-adducts

81 in high yields with high enantioselectivity (equation 9, Table 12).[58] Only two *endo*-diastereomers are detected, even though three to four stereogenic centers are generated in the present hetero-Diels–Alder reaction. The reaction of **59** (R^1 = Ph, R^2 = Bn) with 4-methylcyclohexanone gives the corresponding adduct in which four stereogenic centers are stereoselectively created.

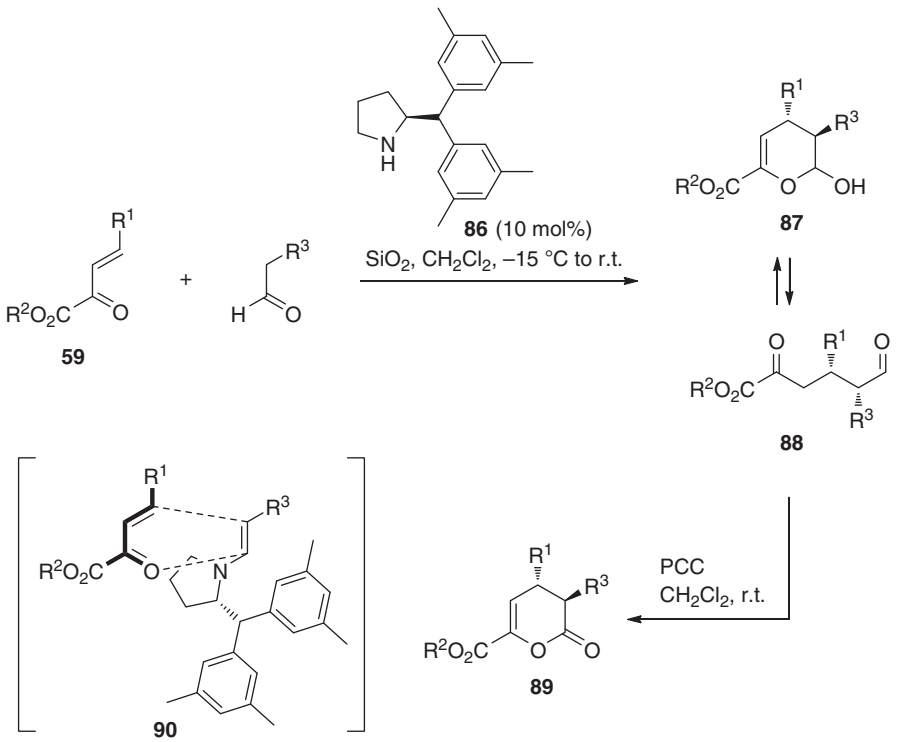
The following reaction mechanism is proposed for the inverse-electron-demand hetero-Diels–Alder reaction catalyzed by the Y(III) complex with **80** (Scheme 22).[58] The 1:1 complex **82** is a bifunctional catalyst, the primary amino group of which activates the cyclohexanone derivative via the formation of an enamine intermediate **83** by raising the HOMO energy. In addition, the Y(III) LA moiety of **82** simultaneously activates **59** through chelation. The proposed transition-state assembly **84**, which features an *endo*-selective mode of the reaction, matches well with the relative stereochemistry at C4 and C4a. The sterically hindered *tert*-butyl group shields the *Re* face of the enamine, and thus the activated enone approaches the *Si* face, which accounts for the



Scheme 22 Proposed catalytic cycle.

absolute configuration of **81**. The water generated *in situ* plays a critical role in the hydrolysis of the aminal intermediate **85**. When MS are included in the reaction, the hetero-Diels–Alder reaction is noticeably slower and the yield decreases significantly.

5.10.2.2.2 Chiral organocatalysts

Chiral secondary amines have emerged as effective catalysts for the enantioselective reactions of aldehydes, which proceed via chiral enamine intermediates. Thus, the inverse electron-demand hetero-Diels–Alder reaction of aldehydes with reactive α,β-unsaturated carbonyl compounds is catalyzed by a chiral secondary amine.[59,60] The *in situ* generation of a chiral *trans*-enamine from the secondary amine catalyst **86** and an unactivated aldehyde, followed by a hetero-Diels–Alder reaction with the β,γ-unsaturated α-keto esters **59**, yields a mixture of two isomers of hemiacetals **87** and aldehydes **88** (Scheme 23, Table 13).[59] Oxidation of this mixture gives lactones **89** as single diastereomers with high enantioselectivity. The presence of silica (50 mg on a 0.5 mmol scale) facilitates the hydrolysis of an aminal intermediate to the acetal **87**. The absolute and relative stereochemistries of the hetero-Diels–Alder adduct are consistent with the proposed transition-state assembly **90**. The 2,2-diarylmethyl substituent on the pyrrolidine ring shields the *Si* face of the enamine to control the addition of the enone to the *Re* face of the alkene moiety.

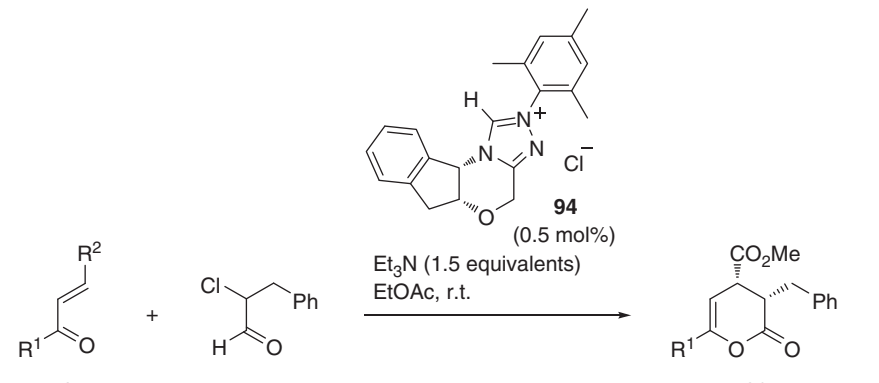
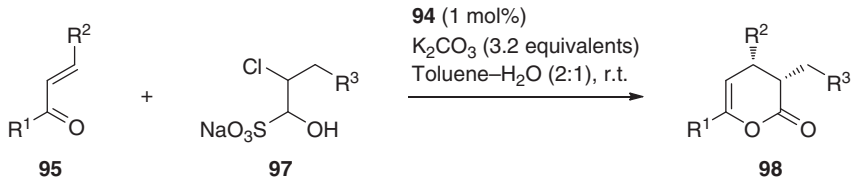
Prolinal dithioacetal **91** is an effective catalyst for the inverse-electron-demand hetero-Diels–Alder reaction with α,β-unsaturated acyl phosphonates **62** (R^2 = H, R^3 = Et) (Scheme 24).[60] Pyridinium chlorochromate (PCC) oxidation of the adducts **92** gives the corresponding lactones **93** with high enantioselectivity (up to 94% *ee*).



A chiral *N*-heterocyclic carbene prepared from triazolium salt **94** with triethylamine can catalyze the enantioselective hetero-Diels–Alder reaction of α-chloroaldehydes with α,β-unsaturated carbonyl compounds.[61–63] For example, the *N*-heterocyclic carbene-catalyzed hetero-Diels–Alder reaction of 2-chloro-3-phenylpropionaldehyde with α,β-unsaturated ketones **95** (R^2 = CO_2Me)

R^1	R^4	Yield of **92**	*ee* of **93**
Me	Me	79%	87%
Me	Bn	69%	94%
Et	Et	71%	89%



Scheme 24 Inverse electron-demand hetero-Diels–Alder reaction with α,β-unsaturated acyl phosphonates **62** catalyzed by chiral secondary amine **91**.

gives corresponding adducts **96** with high enantioselectivity, albeit the diastereoselectivity is moderate in some cases (Scheme 25).[61] The lower diastereoselectivity appears to result from epimerization of the initially formed *cis*-annulated products. In addition, α-chloroaldehydes are sensitive to moisture and oxygen, and their preparation and storage require precautions. In contrast, α-chloroaldehyde bisulfite adducts **97**, which are bench-stable solids that are readily prepared by the addition of aqueous sodium bisulfite to a solution of the appropriate aldehydes, can be used as precursors of α-chloroaldehydes under aqueous conditions (equation 10, Table 14).[62] The use of an inorganic base, K_2CO_3 (1.0 M aqueous solution), and a less polar solvent, toluene, successfully suppresses the epimerization of the *cis*-annulated products and gives the adduct **98** as single diastereomers with high enantioselectivity.

The *N*-heterocyclic carbene prepared from **94** can also activate α,β-unsaturated aldehydes and promote the inverse-electron-demand hetero-Diels–Alder reaction with various α,β-unsaturated ketones **95** to give **99** with high enantioselectivity (equation 11, Table 15).[63] For the selective promotion of the desired hetero-Diels–Alder reaction, following three factors are beneficial: (1) the use of a catalytic amount of weak amine bases such as 4-(dimethylamino)pyridine (DMAP) and *N*-methylmorpholine (NMM) gives the best results; (2) toluene and CH_2Cl_2 are the preferred solvents; and (3) a slightly elevated temperature (40 °C) gives cleaner reactions. Otherwise, the competing formation of cyclopentenes **100** is predominant.[64,65]

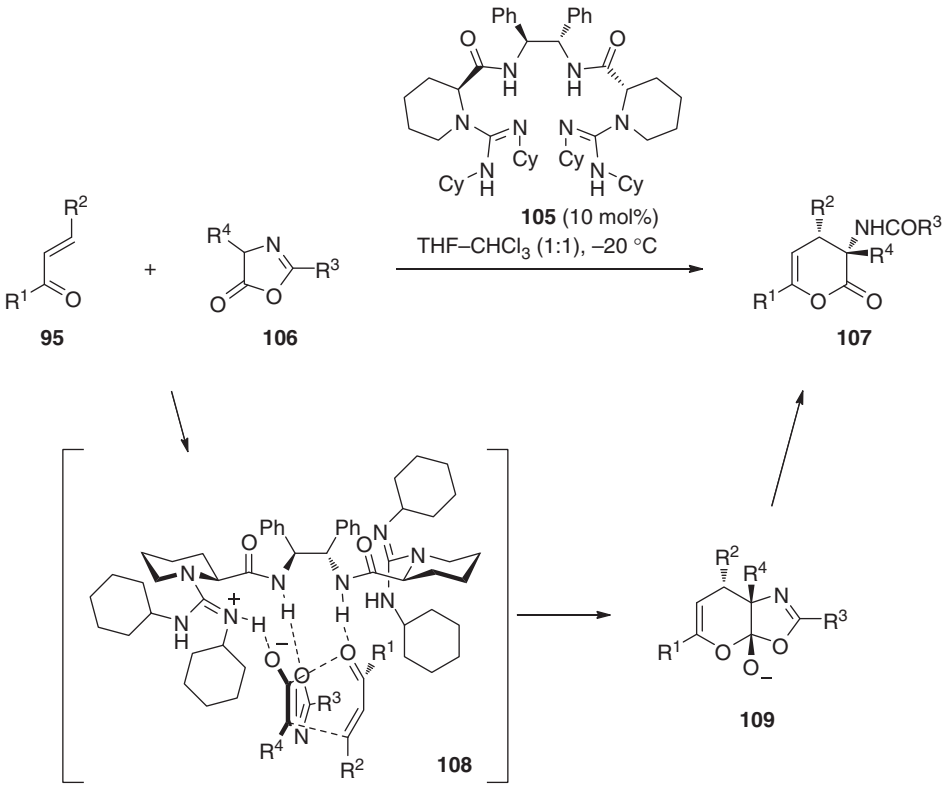
A plausible mechanism for the *N*-heterocyclic carbene-catalyzed hetero-Diels–Alder reaction is shown in Scheme 26.[63] *N*-Heterocyclic carbene **101**, prepared from azolium salt *ent*-**94** with a base NR^4_3, activates α,β-unsaturated aldehydes to form the homoenolate equivalents **102** and **103**. The reaction of the homoenolates **102** and **103** with α,β-unsaturated carbonyl compounds **95** gives cyclopentenes **100**.[64,65] If the conjugate acid of the catalytic base NR^4_3, generated by the deprotonation of *ent*-**94**, is acidic enough to protonate the homoenolate **103** at the β-position, the enolate equivalent **104** is formed. If the α,β-unsaturated carbonyl compound **95** is sufficiently electrophilic, annulation occurs to give the hetero-Diels–Alder adduct **99**. In the transition-state assembly, the mesityl group shields the *Re* face of the enolate to control the addition of the enone **95** to the *Si* face of the alkene moiety.

Scheme 26 Plausible catalytic cycle of the *N*-heterocyclic carbene-catalyzed hetero-Diels–Alder reaction.



Chiral bisguanidine **105** catalyzes the inverse-electron-demand hetero-Diels–Alder reaction of racemic azlactones **106** with chalcones **95** (R^1, R^2 = aromatic group) to give δ-lactones **107** with high enantioselectivity (Scheme 27, Table 16).[66] Both electron-deficient and electron-rich chalcones show high enantioselectivities. In this reaction, chiral bisguanidine **105** activates azlactones **106** through deprotonation by raising the HOMO energy. Based on the absolute configuration of the product **107**, it is conceivable that the reaction proceeds via the *endo*-transition-state assembly **108**, in which the enolized azlactone approaches the C*β*-*Re* face of **95** to give adduct **109**. The subsequent ring-opening of **109** gives δ-lactones **107**.

5.10.3 Aza-Diels–Alder Reactions

5.10.3.1 Reactions of Imine Dienophiles

5.10.3.1.1 Chiral LA catalysts

As in the case of the hetero-Diels–Alder reactions of carbonyl compounds, in the normal electron-demand reaction, an imine is activated by an acid catalyst through lowering of the LUMO energy to react with an electron-rich diene. Chiral boron compounds **110** and **111** (Figure 8) can promote the aza-Diels–Alder reaction of aldimines **112** with Danishefsky's diene **1** (equation 12, Table 17).[67–69] Although the reaction requires a stoichiometric amount of **110** or **111**, the cycloadducts **113** are obtained with high enantioselectivity. The use of chiral aldimines bearing an *N*-(α-methylbenzyl) group improves the enantioselectivity.

Attempts to catalytically promote the enantioselective aza-Diels–Alder reaction of imines faces the problem that the product is more basic than the starting imine, which leads to a difficulty in turnover. Indeed, when the reaction of **1** and **112** is conducted in the presence of 10 mol% of **110**, **113** is obtained in less than 5% yield. However, both turnover and asymmetric induction can be achieved, when two catalysts are used, one chiral (catalytic) and one nonchiral (excess), and the excess nonchiral additive frees up the chiral catalyst for turnover. For example, the chiral (*S*)-VAPOL–B catalyst **115**, prepared from (*S*)-VAPOL **114** (5–10 mol%) and $B(OPh)_3$ (100 mol%), can promote the enantioselective aza-Diels–Alder reaction of *N*-diphenylmethylaldimine **116** with Danishefsky's diene **1** to give the corresponding adducts **117** with high enantioselectivity (Scheme 28, Table 18).[70] The use of a bulky *N*-diphenylmethyl group is crucial for obtaining high enantioselectivity. The reaction of various aromatic aldimines and α-branched aliphatic aldimines gives adducts with high enantioselectivities, whereas sterically less-hindered aldimines give racemic adducts. These results indicate that the (*S*)-VAPOL–B(OPh) catalyst selectively interacts with aldimines **116** to promote the enantioselective aza-Diels–Alder reaction. A study of the binding constants showed that the (*S*)-VAPOL–B(OPh) catalyst binds to **116** (R^1 = Ph) seven times stronger than $B(OPh)_3$, whereas it binds to **117** (R^1 = Ph) only about twice as strongly.

The chiral zirconium(IV) complex **118** (Figure 9) prepared from $Zr(OBu^t)_4$, (*R*)-6,6′-dibromo-1,1′-binaphthol, and *N*-methylimidazole catalyzes the aza-Diels–Alder reaction of aldimine **122** with Danishefsky-type diene **121** to give cycloadducts **123** in high yields with high enantioselectivities (equation 13, Table 19).[71] The use of *N*-methylimidazole as an additional ligand gives the best results. Although various aromatic aldimines are converted to the corresponding adducts with high enantioselectivities, the reaction of cyclohexyl (Cy)-substituted aldimine ($R^2 = {}^cC_6H_{11}$, $R^3 = H$) shows low enantioselectivity. This may be caused by isomerization of the *cis* and *trans* forms of the imine. The introduction of a methyl group to the *N*-phenyl group ($R^3 = Me$) prevents this isomerization to improve the enantioselectivity (86% *ee*).

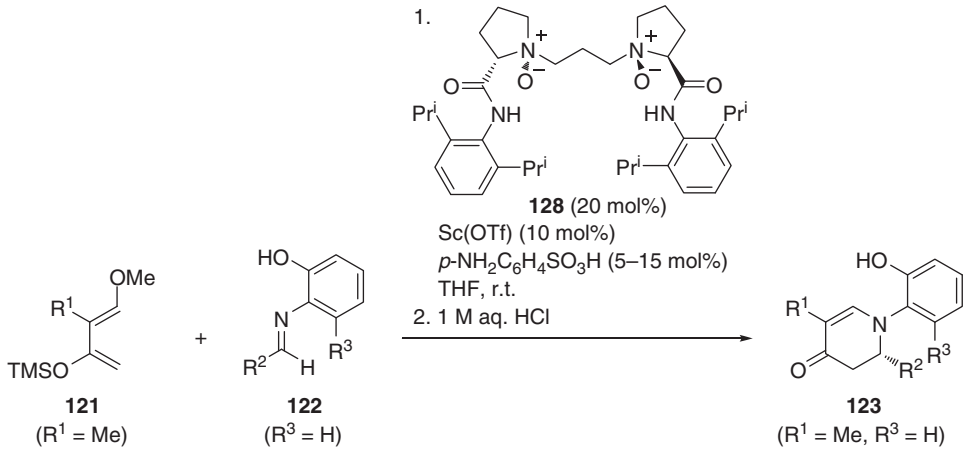
[a]Condition A: in toluene at −45 °C. Condition B: in the presence of MS 3 Å in benzene at r.t.

The chiral zirconium(IV)-3,3′-substituted BINOL complex **119** (Figure 9) prepared from $Zr(OBu^t)_4$ (20 mol%), (*R*)-6,6′-dibromo-3,3′-diphenyl-1,1′-binaphthol (40 mol%), and *N*-methylimidazole (60 mol%) also catalyzes the aza-Diels–Alder reaction of aldimine **122** (R^3 = H) (equation 13, Table 19).[72] The use of MS 3 Å improves the enantioselectivity. Very interestingly, the introduction of phenyl groups at the 3,3′-positions of BINOL reverses the absolute stereochemistry of the adducts: the **118**-catalyzed reaction gives (*S*)-**123**, whereas (*R*)-**123** is obtained by the use of **119** as a catalyst. In the reaction of not only various aromatic aldimines but also aliphatic aldimines, **119** shows high enantioselectivity. Another chiral zirconium(IV)-3,3′-substituted BINOL complex **120** (Figure 9) shows higher catalytic activity than **118** and **119** in the aza-Diels–Alder reaction of aldimines **122** (equation 13, Table 19).[73] Only 1–5 mol% of **120** can catalyze the reaction to give cycloadducts **123** in high yields with high enantioselectivities, whereas catalyst loadings of 10–20 mol% are required in the reactions catalyzed by **118** and **119**.

In a related study, a zirconium(IV) complex derived from 3,3′,6,6′-tetraiodo–BINOL **124** and $Zr(OPr)_4$•PrOH was shown to catalyze the aza-Diels–Alder reaction of *N*-benzoylhydrazones **126** with Danishefsky-type diene **125** to give the corresponding 2,3-dihydro-4-pyridones **127** with high enantioselectivities (Scheme 29).[74] Since the N–N bond of **127** can be easily cleaved by reduction with SmI_2, adducts **127** are highly useful as chiral building blocks for the synthesis of several nitrogen-containing natural products.



R^1	Yield	*ee*

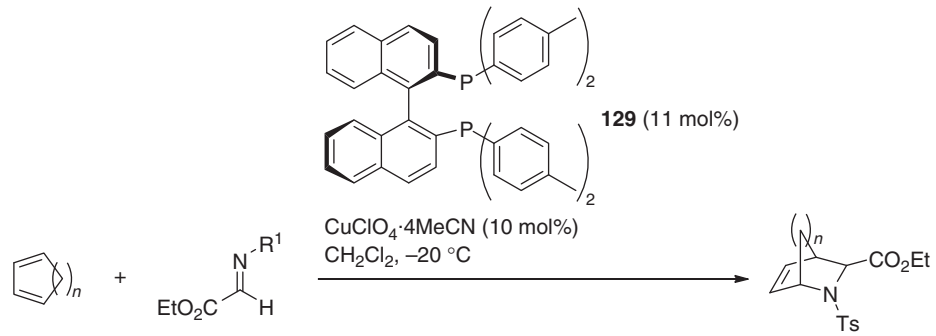
Pr	70%	93%
Bu^i	31%	92%
$^cC_6H_{11}$	44%	89%

Scheme 29 Enantioselective aza-Diels–Alder reactions of *N*-benzoylhydrazones **127**.

A chiral scandium(III) complex with the L-proline-derived *N*,*N*′-dioxide ligand **128** also catalyzes the aza-Diels–Alder reaction of aldimine **122** (R^2 = H) with Danishefsky-type diene **121** (R^1 = Me) (Scheme 30).[75] The addition of 5–15 mol% of sulfanilic acid (4-$NH_2C_6H_4SO_3H$) improves the enantioselectivity. Under the optimized conditions, aromatic, heteroaromatic, conjugated, and aliphatic aldimines are converted into the corresponding 2,5-disubstituted dihydropyridinones **123** (R^1 = Me, R^3 = H) with moderate to good yields and up to 90% *ee*. Based on the NMR study, it is conceivable that a C_2 symmetric scandium-**128** (1:2) complex may be generated as an active catalyst species. Since the reaction shows a strong positive nonlinear effect, the homochiral complex seems to be more active than the heterochiral complex.

A chiral Cu(I) complex with (*R*)-(+)-2,2′-bis(di-*p*-tolylphosphino)-1,1′-binaphthyl ((*R*)-Tol-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP), **129**) is an efficient catalyst for the aza-Diels–Alder reaction of α-imino esters **130** (Scheme 31).[76,77] In the presence of 10 mol% of the Cu(I) complex, the reaction of **130** (R^1 = Ts) with cyclopentadiene and cyclohexadiene gives the corresponding *endo*-adducts **131** with high enantioselectivities. In the reaction with Danishefsky's diene **1**, *N*-*o*-methoxyphenyl glyoxylate imine **130** (R^1 = C_6H_4–2-OMe) and *N*-*p*-methoxyphenyl glyoxylate imine **130** (R^1 = C_6H_4–4-OMe) are converted to the corresponding cycloadducts **132** with high enantioselectivities. Although the reaction of *N*-tosyl glyoxylate imine **130** (R^1 = Ts) shows poor enantioselectivity in dichloromethane, the use of THF as a solvent improves the results.



N-Sulfonyl imines are very appealing heterodienophiles because of their low LUMO energy and the high crystallinity of their adducts. The dimeric Cu(I) complex **133** prepared from CuBr and a chiral phosphino sulfenyl ferrocene ligand catalyzes the aza-Diels–Alder reaction of *N*-sulfonyl imines **134** with Danishefsky-type diene **121** (equation 14, Table 20).[78] In the presence of $AgClO_4$ (10 mol%), the reaction successfully proceeds to give the cycloadducts **135** in high yields with high enantioselectivities. An active cationic form of the copper(I) catalyst may be generated *in situ* as a result of the presence of $AgClO_4$, which acts as a halogen scavenger. The presence of an additional substituent at the diene or a change in the nature of the arylsulfonyl group of the heterodienophile provides similar results in terms of both chemical yield and enantioselectivity. Importantly, α,β-unsaturated imines (R^3 = CH = CHPh) act as heterodienophiles in the **133**-catalyzed aza-Diels–Alder reaction.

A chiral silver(I) complex prepared from AgOAc and the phosphine ligand **136a** catalyzes the aza-Diels–Alder reaction of relatively inactive imines **137** with Danishefsky diene **1** (equation 15, Table 21).[79] A catalyst loading of only 0.1–1 mol% is required to complete the reaction and give the cycloadducts **138** in high yields with high enantioselectivities. The presence of an *ortho*-methoxy group in the imine substrates is required for high enantioselectivity, but not for reactivity. In addition, the presence of isopropyl alcohol significantly increased both the reactivity and enantioselectivity. Importantly, the present reaction can be carried out in the presence of air with undistilled commercial solvents, or under solvent-free conditions with little change in yield or enantioselectivity. The stereoselective reduction of the adduct **138** (R^2=Ph) with $LiAlH_4$ gives cyclic amine **139** with 9:1 diastereoselectivity (Scheme 32). The treatment of **138** (R^2=Ph) with diisobutylcuprate followed by stereoselective reduction with $Zn(BH_4)_2$ gives the linear 1,3-amino alcohol **140** with 10:1 diastereoselectivity (93% *ee*).

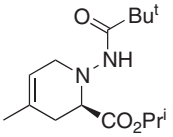
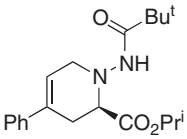
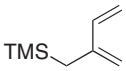
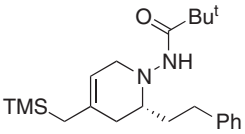
Scheme 33 Direct three-component enantioselective aza-Diels–Alder reaction catalyzed by a silver(I) complex with phosphine ligand **136b**.

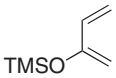
The enantioselective aza-Diels–Alder reactions described above are limited to the use of highly reactive Danishefsky-type dienes, and reactions with non-Danishefsky-type dienes are rare. A stoichiometric amount of chiral silane **142** can promote the aza-Diels–Alder reaction of acyl hydrazones **143** with non-Danishefsky-type dienes (Scheme 34, Table 22).[81,82] The reaction proceeds in a stepwise fashion via allyl cation intermediate **145**. The use of sterically hindered pivaloyl hydrazones **143** selectively gives the aza-Diels–Alder adducts **144**, whereas the [3 + 2] cycloadduct is obtained along with **144** when *o*-methoxybenzoyl hydrazone is used. Both electron-poor hydrazones ($R^3 = CO_2Pr^i$) and less reactive aliphatic aldehyde-derived hydrazones ($R^3 = (CH_2)_2Ph$) are converted to the corresponding adducts **144** with high enantioselectivities. The **142**-promoted reaction with diene **146** gives the corresponding *endo*-adduct **147** with complete regio- and diastereoselectivity and 86% *ee* (Table 22). However, the reaction with diene **148** gives **149** with reversed regioselectivity. The reaction appears to be governed by the minimization of steric interaction during the initial C–C bond formation.

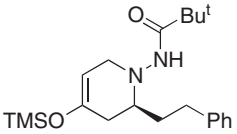


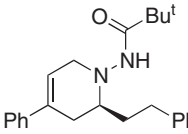


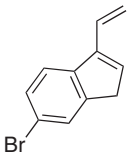


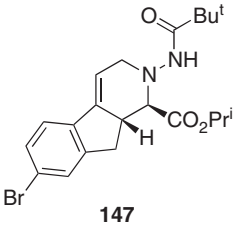


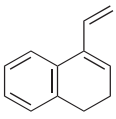


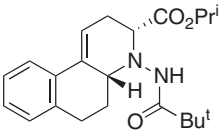






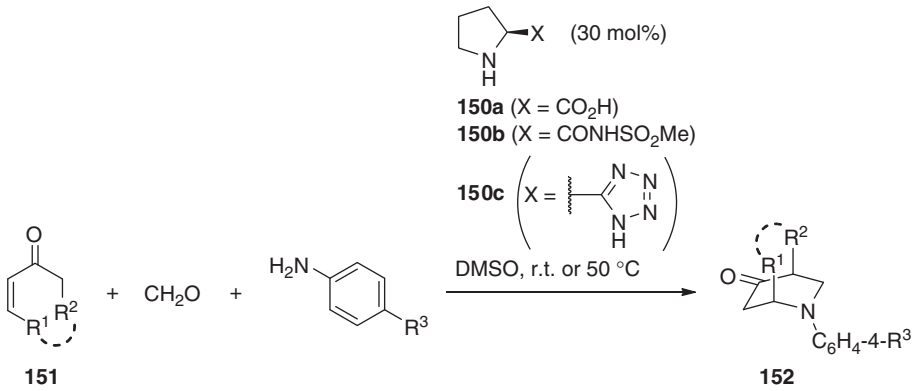






5.10.3.1.2 Chiral organocatalysts

(*S*)-Proline **150a** and its derivatives **150b** and **150c** can catalyze the three-component direct aza-Diels–Alder reaction between aromatic amines, formaldehyde, and α,β-unsaturated ketones **151** in dimethylsulfoxide (DMSO) (equation 16, Table 23).[83]



Scheme 34

α,β-Unsaturated cyclohexenones and cyclopentenones are excellent substrates, and the corresponding bicyclic adducts **152** are obtained with high enantioselectivities. For the reaction of α,β-unsaturated cyclopentenones, (*S*)-proline **150a** is the most effective catalyst. However, the reaction of 3-methylcyclohex-2-enone only generates the α,β-unsaturated Mannich adduct in 40% yield with 94% *ee*, and not the aza-Diels–Alder product.

(16)

[a]Yield of the corresponding alcohol (a 1:1 *cis*/*trans* mixture) obtained by *in situ* reduction of **152** with $NaBH_4$ after column chromatography on silica gel.

Based on the absolute stereochemistry of the adducts and the generation of the Mannich product, the following reaction mechanism is proposed (Scheme 35). In the first step, the (*S*)-proline derivative **150b** activates an α,β-unsaturated ketone **151**

through the formation of chiral dienamine **153**. Next, the *in situ*-generated imine reacts with **153** via transition state **154**, followed by a selective 6-*endo-trig* cyclization to give the bicyclic compound **155**. In the transition state **154**, the Brønsted acidic site may act as a directing group for the imine to approach the *Si* face of **153**. The final hydrolysis of **155** affords the aza-Diels–Alder adduct **152**, and the (*S*)-proline derivative is regenerated.

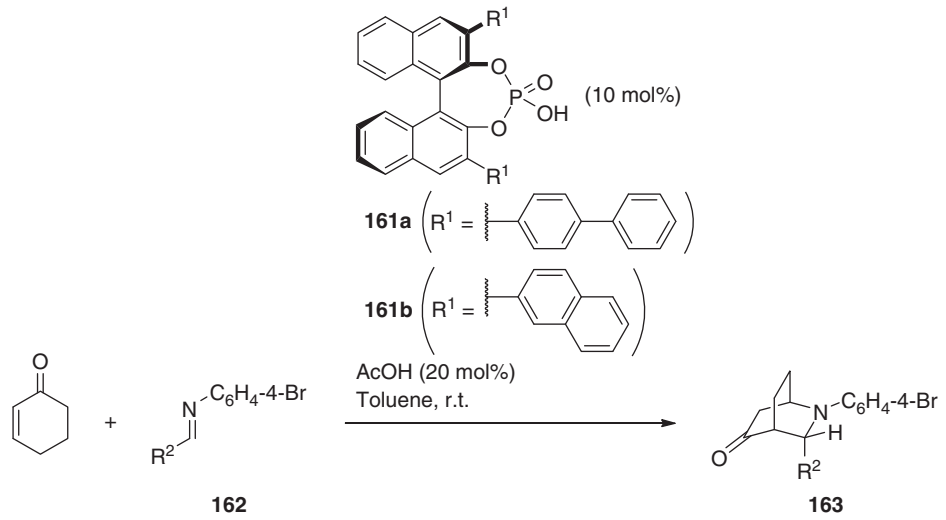
Scheme 36 Chiral Brønsted acid-catalyzed aza-Diels–Alder reaction with Danishefsky's diene **1**.

Chiral phosphoric acids **156** and **159** derived from (*R*)-BINOL are efficient catalysts for the enantioselective aza-Diels–Alder reaction of aldimines **157** with Danishefsky's diene **1** and Brassard's diene **25**. For the reaction with Danishefsky's diene **1**, the chiral Brønsted acid **156** is highly effective for giving the corresponding cycloadducts **158** with high enantioselectivities (Scheme 36).[84] The addition of a protic additive such as acetic acid (1.2 equivalents) improves the enantioselectivity, although its role is not clear.

Brassard's diene **25** (R^1 = Me) is also a useful diene for the aza-Diels–Alder reaction of aldimines, which affords piperidinone derivatives. In the presence of the pyridinium salt of chiral phosphoric acid **159** (3 mol%), the reaction of aldimine **157** with Brassard's diene **25** is conducted in mesitylene at $-40\ ^\circ C$, and subsequent treatment of the reaction mixture with $PhCO_2H$ (1 equivalent) gives dihydropyridone derivatives **160** with high enantioselectivity (Scheme 37, Table 24).[85] Interestingly, the less acidic pyridinium salt **159** shows greater catalytic activity than the corresponding phosphoric acid. This result may be attributed to the instability of Brassard's diene **25** toward strong Brønsted acids. Indeed, a ^1H NMR study showed that, in the presence of **159**, 75% of **25** was detected after 1 h, whereas only 12% of **25** was detected in the presence of the corresponding phosphoric acid. The presence of the hydroxyl moiety on the *N*-aryl group is essential for attaining high enantioselectivity. These results suggest that the present aza-Diels–Alder reaction proceeds via a nine-membered cyclic transition state, wherein the phosphoryl oxygen atom participates in hydrogen bonding with the hydrogen atom of the imine hydroxyl moiety, with the nucleophile preferentially attacking the *Re* face of the aldimine **157** (Scheme 37). The methoxy group of the product can be transformed into other functionalities via acid hydrolysis, followed by an addition–elimination reaction.



Scheme 37

The simultaneous use of a chiral strong Brønsted acid catalyst and an achiral weak Brønsted acid catalyst can promote the direct aza-Diels–Alder reaction of aldimines **162** with cyclohexenone (equation 17, Table 25).[86] In this reaction, the chiral strong Brønsted acid activates the aldimine **162** through protonation, and the achiral weak Brønsted acid activates cyclohexenone through the formation of cyclohexadienol. Thus, the fundamental requirement for successful promotion of the reaction is that the achiral Brønsted acid is not able to activate the aldimine **162**. Under the optimized conditions, chiral BINOL-phosphoric acids **161** are suitable as a strong chiral Brønsted acid catalyst, and acetic acid works best as an achiral weak Brønsted acid. In the presence of **161** (10 mol%) and acetic acid (20 mol%), the reaction of aldimines **162** with cyclohexenone gives the corresponding isoquinuclidines **163** in good yields with high enantioselectivities.

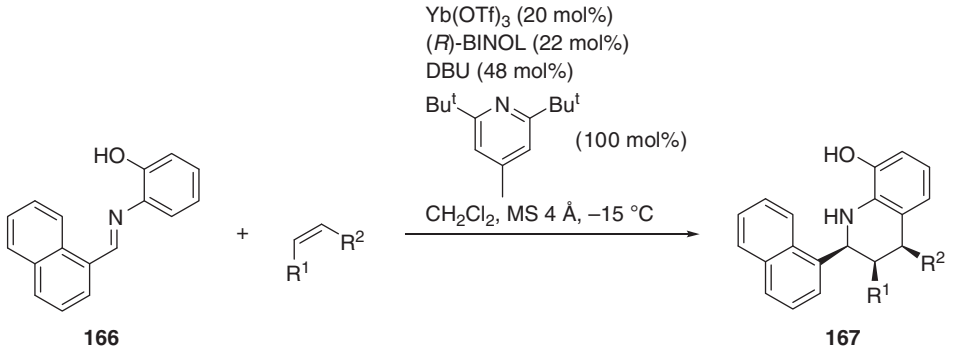
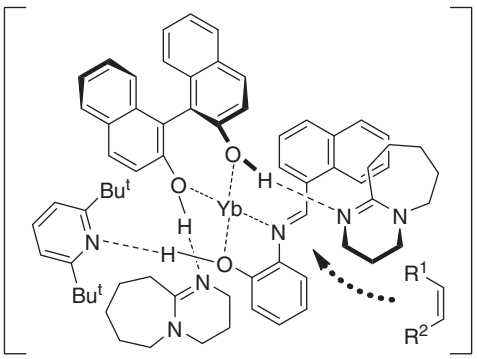
It is conceivable that the reaction proceeds in a stepwise fashion as shown in **Scheme 38**. In the first step, the chiral Brønsted acid **161** activates an aldimine **162** to form a chiral ion pair **164**, whereas cyclohexadienol is formed with the aid of achiral weak Brønsted acid (acetic acid) through a shift of the keto–enol equilibrium. The subsequent intermolecular Mannich reaction provides the adduct **165**, which leads directly to the corresponding chiral isoquinoline **163**. The rate-determining step of the reaction may be the formation of cyclohexadienol, since no significant conversion is observed in the absence of acetic acid.

5.10.3.2 Inverse Reactions of Azabutadienes

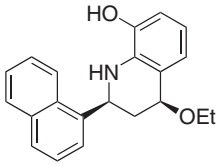


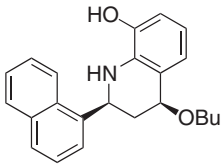
Aza-1,3-butadienes are versatile building blocks for the construction of various nitrogen-containing heterocyclic compounds.[9,12] Due to their electron-deficient nature, aza-1,3-butadienes tend to undergo an inverse electron-demand Diels–Alder reaction with electron-rich dienophiles such as vinyl ethers and enamines.

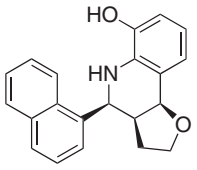


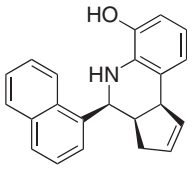
LA catalysts activate an aza-1,3-butadiene by lowering its LUMO energy to promote the inverse electron-demand aza-Diels–Alder reaction with alkenes. For example, aldimine **166** acts as a 2-aza-1,3-butadiene and is activated by a chiral Yb(III) complex prepared from $Yb(OTf)_3$, (*R*)-BINOL, and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (**Scheme 39**, **Table 26**).[87] In the presence of

Scheme 38 Plausible catalytic cycle.

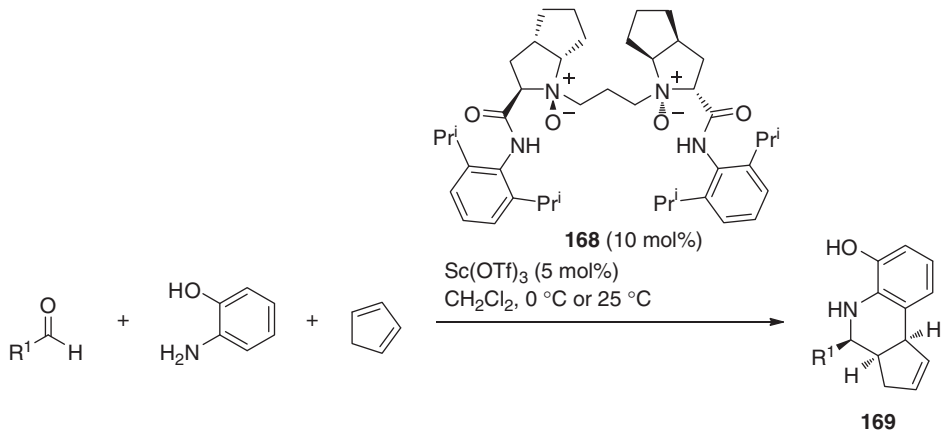








the chiral Yb(III) complex, aldimine **166** reacts with electron-rich alkenes to give the tetrahydroquinolines **167** with good enantioselectivities. The use of 2,6-di-*tert*-butyl-4-methylpyridine as the additive is crucial for preventing the interaction of DBU with the phenolic hydrogen on the aldimine **166** and for improving the selectivity. A proposed transition-state assembly is shown in Scheme 39. $Yb(OTf)_3$, (*R*)-BINOL, and DBU form a complex with two hydrogen bondings, and 2,6-di-*tert*-butyl-4-methylpyridine may interact with the phenolic hydrogen of **166**. Since the top face of the coordinated imine is shielded by DBU, the dienophile approaches the bottom face.

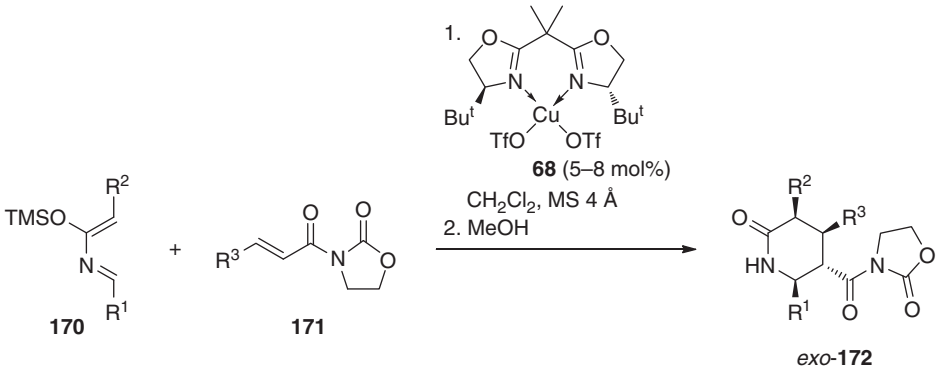


Scheme 39

Table 26 Inverse electron-demand aza-Diels–Alder reaction of aldimine **166** catalyzed by the Yb(III) complex (**Scheme 39**)

Dienophile	*Adduct*	*Yield (%)*	Cis/trans	ee *(%)*	*References*
		74	>99:1	91	87
		80	66:34	70	87
		90	91:9	78	87
		69	>99:1	68	87

As in the case of normal electron-demand aza-Diels–Alder reactions, the three-component direct inverse electron-demand aza-Diels–Alder reaction can be catalyzed by a chiral scandium(III) complex with *N*,*N*′-dioxide ligand **168** (equation 18, **Table 27**).[88] In the presence of the Sc(III) complex (5 mol%), the reaction of aldehydes, 2-aminophenol and cyclopentadiene proceeds to give ring-fused tetrahydroquinolines **169** with three contiguous stereocenters. In this reaction, *in situ*-generated aldimines act as 2-azadienes and cyclopentadiene acts as a dienophile. The present reaction can be applied to a variety of aldehydes to give adducts **169** in high yields with excellent enantioselectivities.



(18)

2-Azadienes **170** are electron-rich dienes and react with *N*-alkenoyloxazolidinones **171**, which are electron-deficient dienophiles, in the presence of an LA catalyst (equation 19, **Table 28**).[89] The copper(II)–bis(oxazoline) complex **110** is an efficient catalyst for the present reaction and subsequent methanolysis gives piperidones **172** in high yields with high diastereo- and enantioselectivities. As in the case of the enantioselective carbo-Diels–Alder reaction with 1,3-dienes, *N*-alkenoyloxazolidinones **171** are activated by the Cu(II) catalyst **110** in a bidentate fashion by lowering of its LUMO energy. Thus, mechanistically, the aza-Diels–Alder reaction of **170** is categorized as a 'normal electron-demand' reaction. The absolute configuration of **172** is consistent with the proposed transition-state assembly for the **68**-catalyzed carbo-Diels–Alder reaction of **171** (*see* Chapter 5.09).[90]

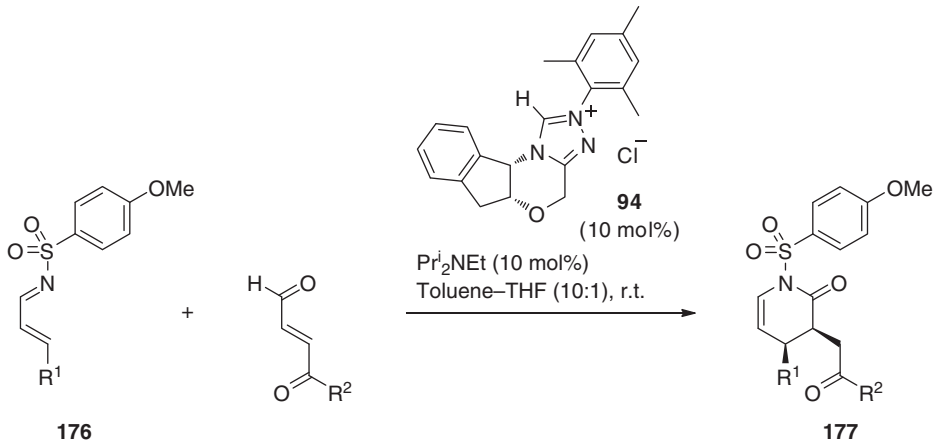
Section 5.10.3.1.1 states that *N*-sulfonylimines **134** including α,β-unsaturated derivatives act as azadienophiles and react with Danishefsky-type dienes **121** with the aid of the chiral Cu(I) complex **133** (equation 14). In contrast, a chiral Ni(II) complex with DBFOX-Ph ligand **173** promotes the inverse electron-demand aza-Diels–Alder reaction of α,β-unsaturated *N*-[(8-quinolyl)sulfonyl]imines **174** with propyl vinyl ether to give the corresponding adducts **175** (equation 20, Table 29).[91] In this reaction, α,β-unsaturated imines **174** act as 1-aza-1,3-butadienes, and the *N*-(8-quinolyl) group is crucial for obtaining high yield and high enantioselectivity. The enantioselectivity strongly depends on the R^2 group of **174**, whereas *para*-substituted aryl groups are compatible, sterically demanding 2-naphthyl group and sterically less-hindered vinyl group significantly reduce the enantioselectivities.



(20)

As described in Section 5.10.2.2.2, the chiral *N*-heterocyclic carbene prepared from triazolium salt **94** catalyzes the *oxo*-Diels–Alder reaction of α,β-unsaturated carbonyl compounds **95** with α,β-enals (equation 11). The chiral *N*-heterocyclic carbene can also

catalyze the aza-Diels–Alder reaction of α,β-unsaturated *N*-(*p*-methoxybenzenesulfonyl)aldimine **176** (equation 21, **Table 30**).[92] In the presence of **94** (10 mol%) and *N*,*N*-(diisopropyl)ethylamine (10 mol%), the reaction of **176** with α,β-unsaturated aldehydes gives the corresponding dihydropyridinones **177** with excellent diastereo- and enantioselectivities. This process tolerates a full range of unsaturated aldimine substrates including both electron-rich and electron-deficient cinnamaldehyde derivatives as well as heterocyclic and aliphatic examples. As in the *oxo*-Diels–Alder variant, the (*Z*)-enolate **104** is believed to be generated as the active species and react with **176** via an *endo*-transition state (see **Scheme 26**).

The chiral secondary amine **178** (10 mol%) and benzoic acid (10 mol%) can activate α,β-unsaturated aldehydes to promote the aza-Diels–Alder reaction with *N*-tosylaldimines **179** (equation 22, **Table 31**).[93] In contrast to the *N*-heterocyclic carbene-catalyzed reaction, this reaction gives the corresponding hemiaminals **180** bearing a dimethylvinyl group in high yields with excellent diastereo- and enantioselectivities. As in the case of the oxo-Diels–Alder reaction of α,β-unsaturated carbonyl compounds **59** (**Scheme 23**), the reaction proceeds via a chiral enamine as the active species, which is an electron-rich dienophile. The addition of water leads to a dramatic acceleration of the reaction due to facile hydrolysis of the aminal intermediate. The reaction of **179** (R^1=Ph, R^2=CO_2Et) with unbranched α,β-enals **181** followed by PCC oxidation selectively gives the corresponding lactam **182** bearing an (*E*)-alkenyl group with high enantioselectivities (**Scheme 40**). Saturated aldehydes are also activated by the combined use of **178** and acetic acid (10 mol% each), and the reaction with **179** (R^1=Ph) gives the corresponding hemiaminals **183** with high diastereo- and enantioselectivities (**Scheme 41**).[94] The use of acetic acid instead of benzoic acid slightly improves the enantioselectivity. For the reaction with butyraldehyde, a wide range of substituents can be presented at the β-position of **179**.

As described in Section 5.10.2.2.2, azlactones **106** are versatile dienophiles for the hetero-Diels–Alder reaction with α,β-unsaturated ketones (Scheme 27). When the reaction of **106** (R^3 = Ph) with α,β-unsaturated aldehydes is conducted in the presence of an electron-rich aniline, δ-lactams **189** are obtained with high enantioselectivities (Scheme 43, Table 33).[96] The use of chiral phosphoric acid **188** gives the best results in terms of yield and stereochemical outcome. It is conceivable that the three-component reaction proceeds through the formation of α,β-unsaturated aldimines. The chiral phosphoric acid simultaneously activates the aldimines and azlactones **188** to promote the aza-Diels–Alder reaction.

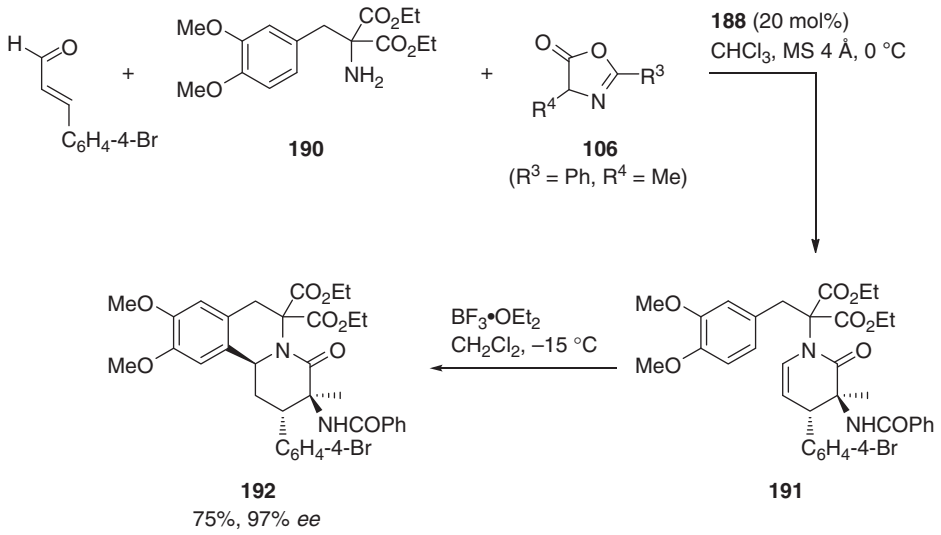
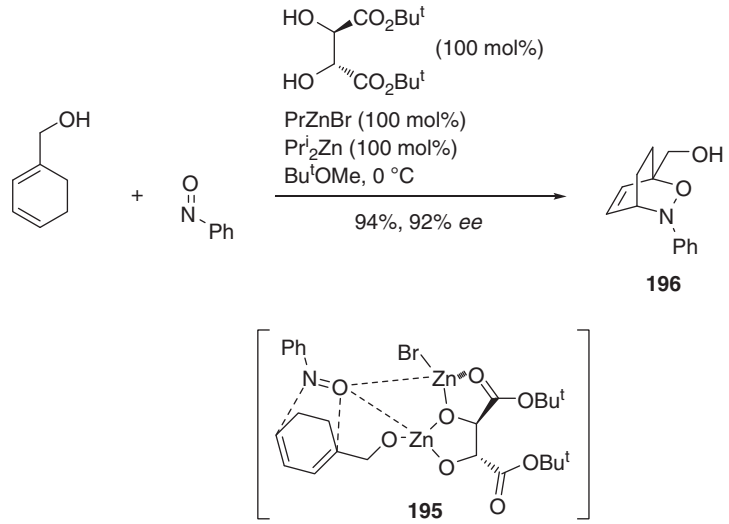
Importantly, substituted 2-arylethylamines are good reaction partners for the **188**-catalyzed three-component reaction. When the reaction of *p*-bromocinnamaldehyde, 2-arylethylamine **190**, and azlactone **106** (R^3 = Ph, R^4 = Me) is conducted under the optimized conditions, the corresponding δ-lactam **191** is obtained (Scheme 44). Treatment of **191** with $BF_3 \cdot OEt_2$ in dichloromethane promotes the Pictet–Spengler-type reaction to give the benzo[*a*]quinolizidine derivative **192** in 75% overall yield with 97% *ee*.



5.10.4 Diels–Alder Reactions of Nitroso Compounds

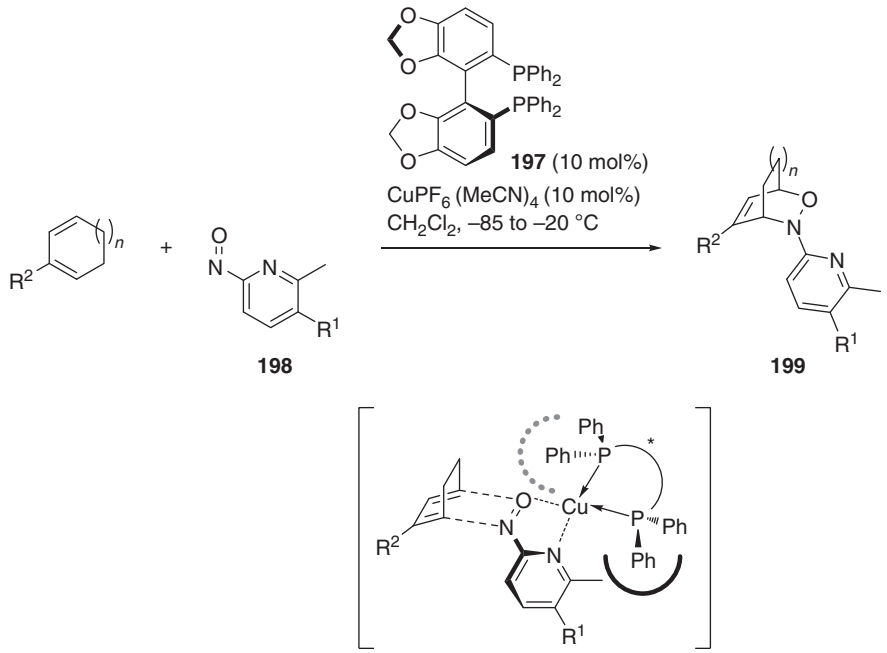
Nitroso compounds are highly reactive and useful dienophiles for the Diels–Alder reaction.[97–100] The nitroso Diels–Alder reaction between compounds **193** and unactivated dienes gives 3,6-dihydro-1,2-oxazines **194**, which could serve as 1-amino-4-hydroxy-2-ene derivatives, in a single step (equation 23). This section summarizes recent advancements in diastereo- and enantioselective nitroso Diels–Alder reactions.



(23)

The first enantioselective nitroso Diels–Alder reaction, which was reported in 2003, uses a stoichiometric amount of a zinc(II)–tartaric acid ester complex (Scheme 45).[101] The dinuclear zinc complex and (cyclohex-1,3-dienyl)methanol forms zinc alkoxide **195**, which reacts with nitrosobenzene to give the corresponding adduct **196** with complete diastereoselectivity in 94% yield with 92% *ee*.

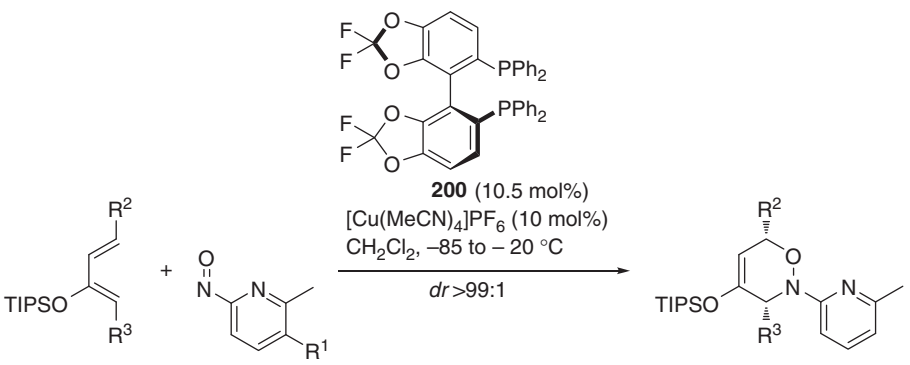
Scheme 44 Synthesis of benzo[*a*]quinolizidine derivative **192**.



Scheme 45 Enantioselective nitroso Diels–Alder reaction promoted by a zinc(II)–tartaric acid ester complex.

Since nitroso compounds exist in organic solvents as a monomer-azetoxy dimer equilibrium, the generation of chelated monomeric nitroso derivatives with a suitable LA is important for catalytic promotion of the enantioselective nitroso-Diels–Alder reaction. When the reaction of 6-methyl-2-nitrosopyridines **198** with cyclic 1,3-dienes is conducted in the presence of the Cu(I) complex of (*S*)-SEGPHOS (**197**) (10 mol%), the corresponding adducts **199** are obtained in high yields with high enantioselectivities (Scheme 46, Table 34).[102] It is conceivable that the chelation of pyridine and the nitroso oxygen would generate the monomeric nitrosopyridine–catalyst complex (Scheme 46), which would immediately react with dienes.

6-Methyl-2-nitrosopyridine **198** ($R^1 = H$) also reacts with acyclic 2-triisopropylsilyloxy (OTIPS)-1,3-butadienes **201** to give the corresponding adducts **202** with excellent regio- and enantioselectivities (Scheme 47).[103] In this reaction, the use of (*S*)-DIFLUORPHOS (**200**) as the ligand gives better results than (*S*)-SEGPHOS (**197**). The OTIPS dienes **201** show higher reactivity and enantioselectivity than the corresponding trimethylsilyloxy (OTMS) or *tert*-butyldimethylsilyloxy (OTBDMS) dienes. The high reactivity of **201** arises from the bulk of the triisopropylsilyl (TIPS) group, which forces the diene to adopt an *s-cis* conformation in favor of the concerted [4 + 2] cycloaddition reaction.



When the Diels–Alder reaction of 2-nitrosopyridine with racemic diene **204** is conducted using the chiral Cu(I) complex of Walphos-CF_3 (**203**), only two of eight possible isomers are generated through kinetic resolution (equation 24, Table 35).[104] The two products, **205** and **206**, are isolated by column chromatography in high combined yields with high enantioselectivity. In particular, the use of a sterically hindered R^1 substituent, such as CMe_2OTMS or aryl groups, completely suppresses the generation of other isomers. The present method has been successfully applied to a total synthesis of (+)-*trans*-dihydronarciclasine (**209**), a potent antitumor and

(25)

A completely regioselective and efficient enantioselective nitroso Diels–Alder-type bicycloketone synthesis can be achieved using preformed or *in situ*-generated dienamine. As in the case of the addition reaction of carbon nucleophiles to nitroso compounds (nitroso aldol reaction),[99,106,107] the appropriate amine framework of the enamine and a proper adjusted acidity of the Brønsted acid catalyst contribute to the regioselectivity of the nitroso Diels–Alder-type bicycloketone synthesis.

In the presence of the chiral binaphthol **210** bearing tri(*m*-xylyl)silyl groups at the 3,3′-positions, the reaction of 2-morpholino-4,4-dimethylcyclohexadiene **211** (R^2 = Me) with nitroso compounds yields single-regioisomer 2-oxa-3-aza-bicycloketones **212** (R^2 = Me) with high enantioselectivity (equation 26, Table 36).[108] Importantly, the steric bulkiness of the triarylsilyl group in the catalyst plays an important role in constructing the chiral environment. As the triarylsilyl group becomes sterically bulky, the enantioselectivity increases, and chiral binaphthol **210** bearing tri(*m*-xylyl)silyl groups gives the highest enantioselectivity.

However, the more sterically bulky substituent tri(*o*-tolyl)silyl causes a significant decrease in enantioselectivity. In contrast to the reaction of **211** (R^2 = Me), the reaction of 2-morpholino-4,4-diphenylcyclohexadiene **212** (R^2 = Ph) exclusively produces the corresponding *N*-nitroso aldol adduct **213** (R^2 = Ph) in 37% yield with 61% *ee* (Table 36).

Scheme 48 Proposed transition-state assemblies in the **210**-catalyzed nitroso Diels–Alder reaction.

The present reaction may proceed through a sequential *N*-nitroso aldol/Michael reaction. To account for the observed diastereo- and enantioselectivities, the overall hydrogen-bonding network between the two hydroxyls of **210** via the Brønsted acid-assisted Brønsted acid system and the nitroso oxygen may be the dominant factor (Scheme 48).[108] Nucleophilic attack of the dienamine is postulated to occur from the *Re* face (transition state **214**), which gives the *N*-nitroso aldol adduct. A subsequent Michael addition occurs in the case of a dimethyl group via a conformational change that involves a 60° counterclockwise rotation as transition state **215**. In contrast, the sterically more demanding diphenyl group does not allow such a counterclockwise rotation to receive the subsequent Michael attack. Thus, the *N*-nitroso aldol iminium intermediate is hydrolyzed during workup to yield the *N*-nitroso aldol product **213**.

In contrast to the chiral binaphthol **210**, the pyrrolidine-derived tetrazole **216** catalyzes the reaction of α,β-unsaturated ketone **217** to yield 3-oxa-2-aza-bicycloketones **218** with excellent enantioselectivity (Scheme 49, Table 37).[108,109] Pyrrolidinyl tetrazole **216** exhibits higher reactivity than proline and gives the cycloaddition with complete enantioselectivity. These bicycloketone products shown in Tables 36 and 37 are useful precursors of various optically active cyclic amino alcohols.

5.10.5 Other Heterodienes and Heterodienophiles

In addition to carbonyl, imine, and nitroso compounds, various heterodienes and heterodienophiles undergo diastereo- and enantioselective Diels–Alder reactions. Such heterodienes and heterodienophiles include azo compounds, benzoquinones, benzoquinone imides, and benzoquinone diimides. This section describes the diastereo- and enantioselective Diels–Alder reactions of these heterodienes and heterodienophiles.

The hetero-Diels–Alder reaction of azo compounds (azo hetero-Diels–Alder reaction) produces 1,4-diamines, which are important structural motifs as building blocks for the synthesis of pharmaceutically important compounds such as human immunodeficiency virus (HIV) protease inhibitors. The 2-azopyridine **220** undergoes an enantioselective hetero-Diels–Alder reaction with 1,4-disubstituted siloxydienes **219** in the presence of a silver(I) complex of (*R*)-BINAP (5 mol%) to give the corresponding cycloadducts **221** in good yields and high enantioselectivities (equation 27, Table 38).[110] The use of a 2:1 complex of Ag(OTf) and (*R*)-BINAP in propionitrile gives the best results. The cycloadducts **221** can be readily converted into the corresponding acyclic 1,4-diamino alcohols by reductive cleavage of the N–N bond with samarium(II)

iodide. This catalytic process is an effective synthetic route to chiral 1,4-diamines, which are pharmaceutically important compounds.

Several *ortho*-quinones undergo hetero-Diels–Alder reactions with ketene enolates generated *in situ* from the corresponding acyl chlorides.[111] In the presence of benzoylquinidine (**222**) (10 mol%) and *N,N*-diisopropylethylamine (1 equivalent), 3,4,5,6-tetrachlorobenzo-1,2-quinone (**223**) reacts with various acyl chlorides to afford the corresponding adducts **224** with high enantioselectivity (Scheme 50). The cycloadducts **224** can be readily converted into chiral α-hydroxy carboxylic acid derivatives

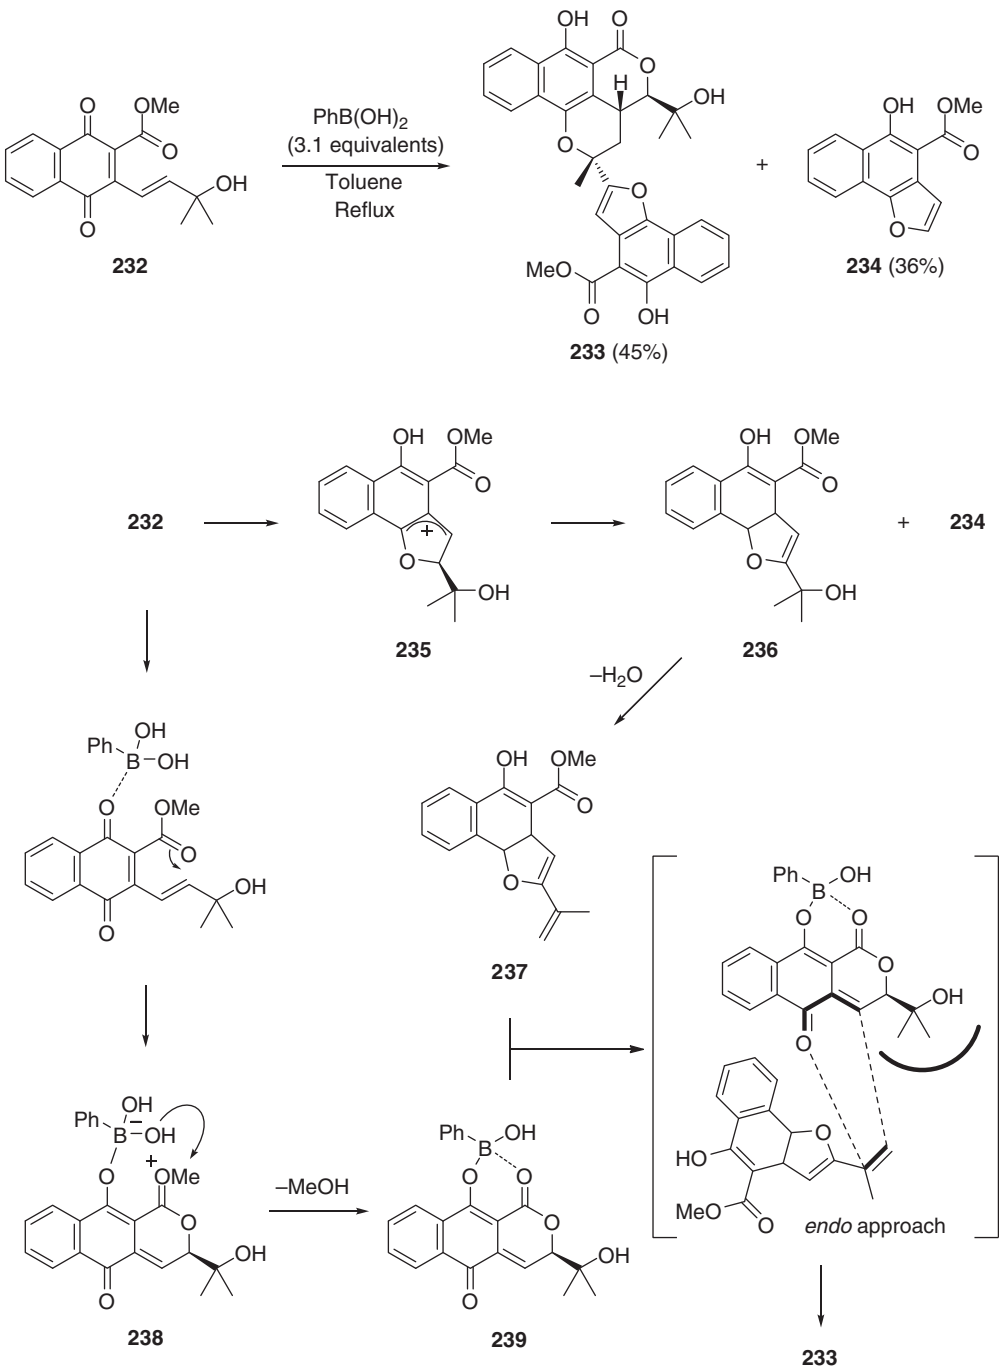
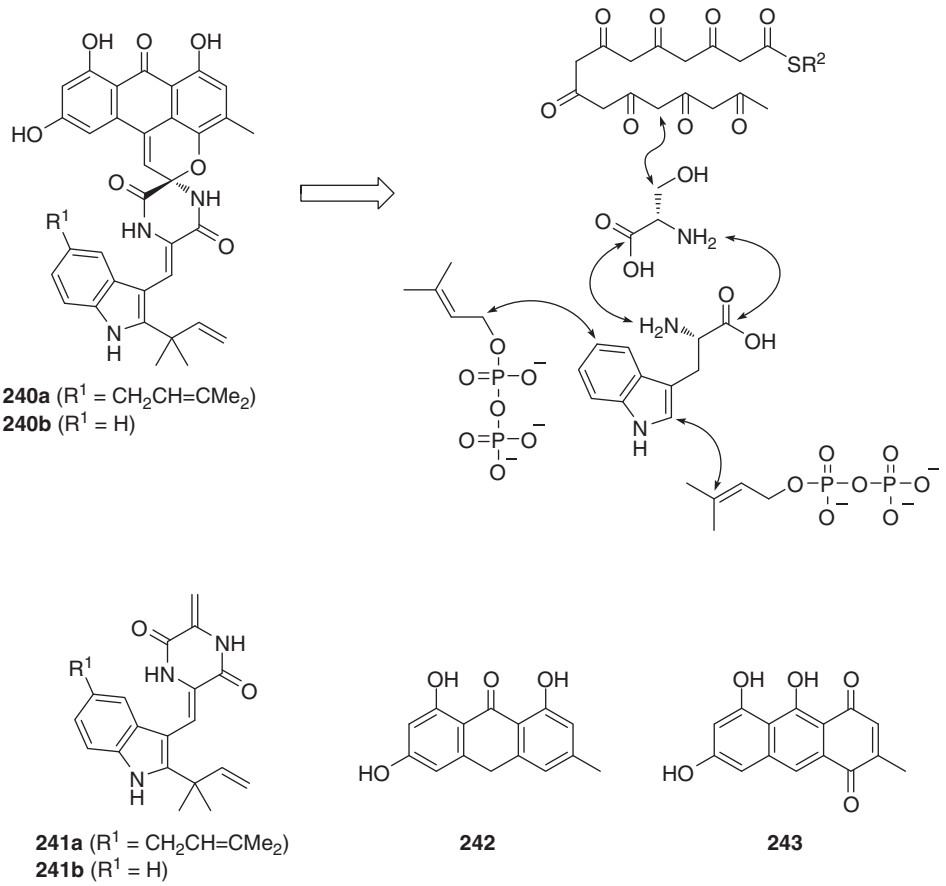


Scheme 51 Proposed bifunctional mechanism for the palladium(II)-cocatalyzed reaction.

Scheme 52 Enantioselective Diels–Alder reaction of *o*-benzoquinone imides **228** and *o*-benzoquinone diimides **230**.

225 via methanolysis followed by oxidation with cerium(IV) ammonium nitrate (CAN). For less reactive acyl chlorides, the reactivity is improved by the addition of a phosphine complex of a transition metal as a cocatalyst without any loss of enantioselectivity.[112] For example, in the presence of *trans*-dichlorobis(triphenylphosphine)palladium(II) (10 mol%), the reaction of quinone **223** with 3-methylbutanoyl chloride ($R^1 = Pr^i$) gives the corresponding adduct in 88% overall yield and 93% *ee* (Table 39). A proposed mechanism for the *trans*-$(Ph_3P)_2PdCl_2$ cocatalyzed reaction is shown in Scheme 51. The acid chloride and benzoylquinidine (**222**), with the aid of Pr^i_2NEt, form a chiral ketene enolate **226**, which is in equilibrium with free ketene. The enolate **226** then binds to the palladium cocatalyst, thus increasing its relative concentration and providing enhanced chemoselectivity toward the quinone **223**. Once this cocatalyst-bound enolate **227** and quinone **223** react, they release both catalysts while forming the [4 + 2] cycloaddition product **224**.

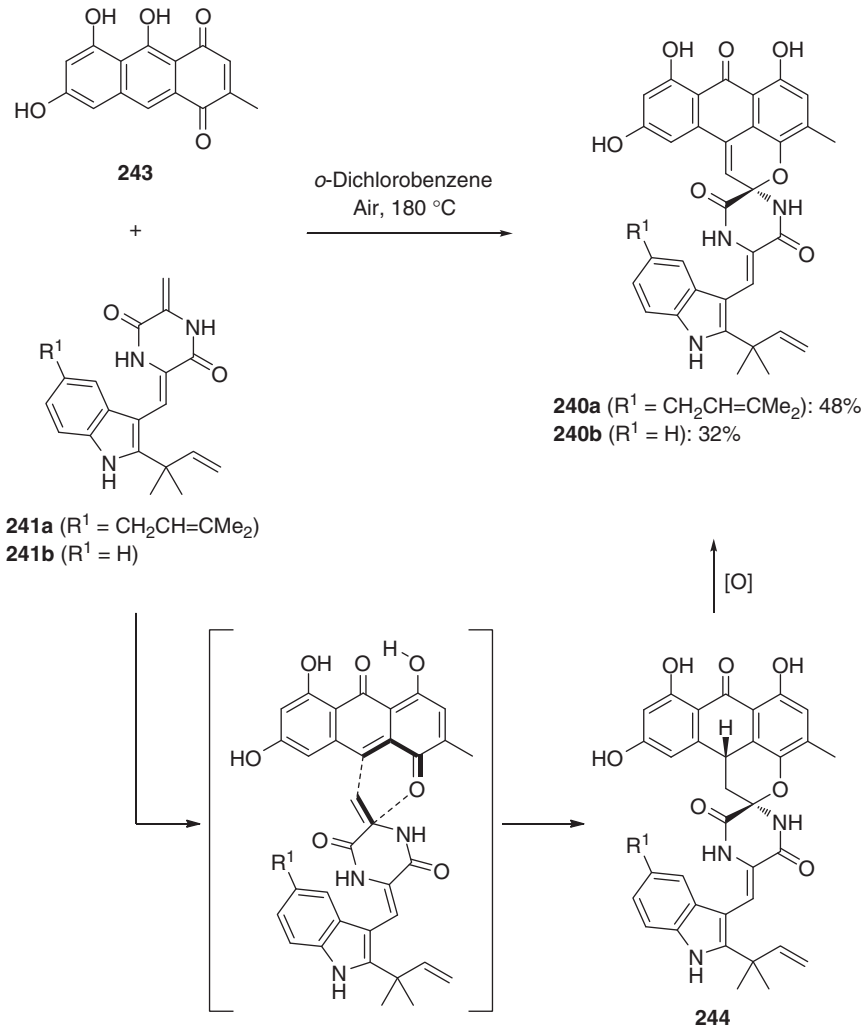


Scheme 53 Biomimetic synthesis of rubicordifolin (**233**).

The same catalytic system can be used in the hetero-Diels–Alder reactions of ketene enolates with *o*-benzoquinone diimides[113,114] or *o*-benzoquinone imides.[113,115,116] In the presence of $Zn(OTf)_2$ (10 mol%) as an LA cocatalyst, the reaction of *ortho*-benzoquinone imide **228** with acyl chlorides gives the corresponding adducts **229** with >99% *ee* (Scheme 52).[114] In contrast to the reaction of quinone **223**, activation of the potentially chelating *ortho*-benzoquinone diimides by an LA cocatalyst may increase the rate of the desired reaction. The observed regioselectivity is explained by the stepwise mechanism shown in Scheme 52, where the reaction is initiated by the nucleophilic attack on the more electrophilic nitrogen. The reaction of *ortho*-benzoquinone imides **230** is also promoted by the combined use of benzoylquinidine (**222**) and an LA cocatalyst, $Sc(OTf)_3$.[116] Subsequent methanolysis of the adducts gives α-amino carboxylic acid derivatives **231** with excellent enantioselectivity. The aryl group of **231** can be removed by oxidative cleavage with CAN.

5.10.6 Biomimetic Synthesis of Natural Compounds Using Hetero-Diels–Alder Reactions

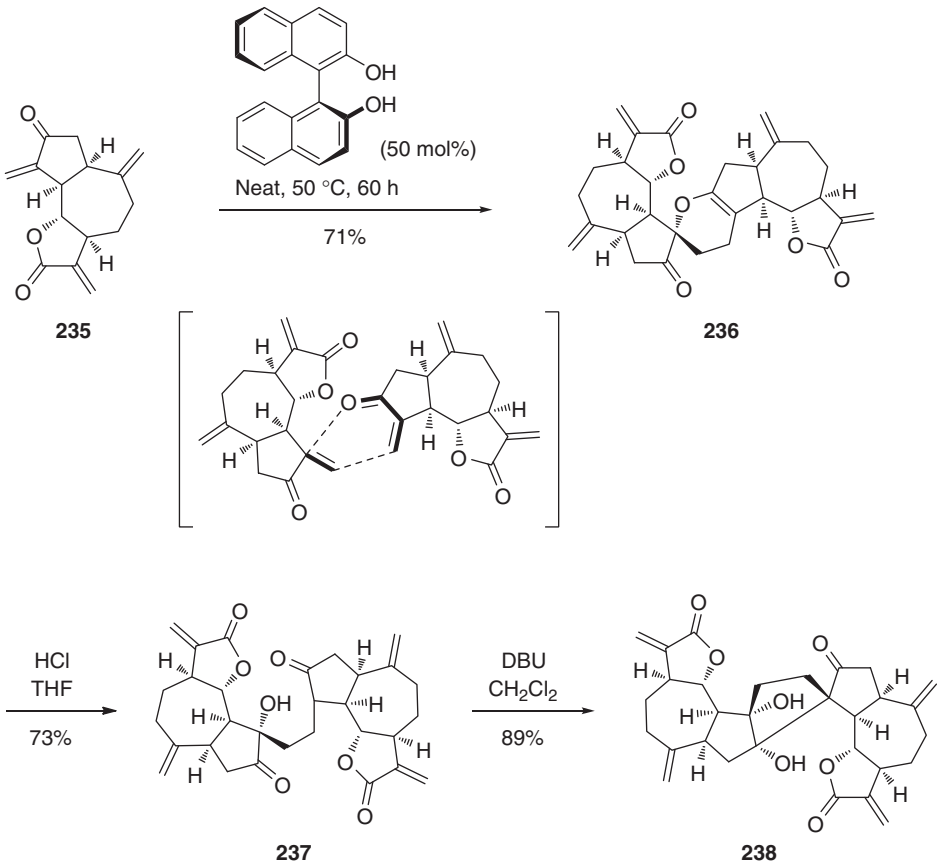
An intriguing aspect of the biosynthetic proposals regarding various secondary metabolites involves the possible enzymatic catalysis of Diels–Alder reactions, which would accommodate the stereochemistry extant in the respective natural products.[117] 'Biomimetic synthesis' is an attempt to assemble natural products using a specific reaction or sequence that mimics a proposed biosynthetic pathway. Biomimetic synthesis has become a powerful tool for the efficient, stereoselective construction of highly complex skeletons of natural products from rather simple precursors.[118,119] This section focuses on the biomimetic synthesis of bioactive natural compounds using hetero-Diels–Alder reactions.



Rubicordifolin (**233**), isolated from the methanolic extract of the dried roots of *Rubia cordifolia*, shows significant cytotoxicity and inhibits the growth of sarcoma ascites in mice at low concentration.[120] It has been proposed that this natural product may be biosynthesized via the Diels–Alder dimerization of vinyl quinone **232**. Thus, in the presence of phenylboronic acid (3.1 equivalents), the biomimetic Diels–Alder dimerization of **232** proceeds in toluene at reflux conditions to give rubicordifolin (**233**) in 45% yield along with furomollugin (**234**) in 36% yield (Scheme 53).[121] The mechanism of this dimerization can be explained as follows. Under thermal conditions, the unstable vinyl quinone **232** is converted into naphthofuran **236** and furomollugin (**234**). For example, 23% yield of **236** and 24% yield of **234** are obtained when **232** is allowed to stand in THF at

Scheme 54 Proposed biosynthesis of variecolortides A (**240a**) and B (**240b**).

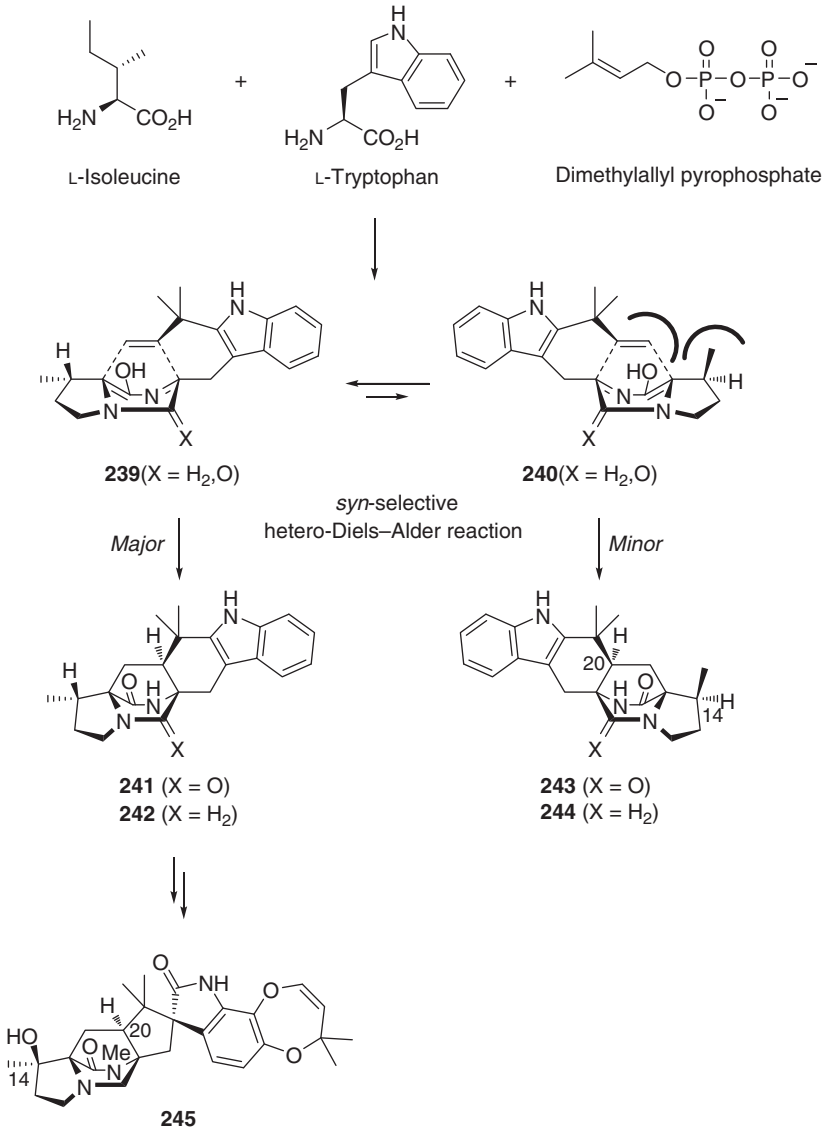
ambient temperature for 5 days. This reaction presumably proceeds through cation **235**, which undergoes either deprotonation to give **236** or retro-Friedel–Crafts hydroxyalkylation to give **234**. Dehydration of naphthofuran **236** gives **237**. Simultaneously, the phenylboronic acid-mediated cyclization of **232** gives **238**, intramolecular demethylation of which affords *ortho*-quinone methide **239**. The hetero-Diels–Alder reaction of the electron-deficient α,β-enone **239** with the electron-rich alkene **237**, followed by hydrolysis, gives rubicordifolin (**233**). The stereochemical outcome of this Diels–Alder reaction is compatible with an *endo*-transition state, the diastereoselection of which is governed by the bulky hydroxyisopropyl group.



Variecolortides A (**240a**) and B (**240b**) are cytotoxic compounds isolated from a halotolerant strain of the fungus *Aspergillus variecolor* (Scheme 54).[122] The variecolortides **240** appear to be biosynthesized from a C_{16} polyketide, serine, tryptophan, and 1 or 2 equivalents of dimethylallyl pyrophosphate. Since emodin anthrone (**242**) and hydroxyviocristin (**243**) are isolated from *Aspergillus cristatus*[123] and unsaturated diketopiperazine isoechinulin B (**241a**) is isolated from *Aspergillus ruber*,[124] the variecolortides **240** might be biosynthesized through the assembly of these compounds, although compounds **241–243** have not been reported to occur in *Aspergillus variecolor*. In agreement with this consideration, variecolortide A (**240a**) is obtained in 48% yield when diketopiperazine isoechinulin B (**241a**) and hydroxyviocristin (**243**) are heated at 180 °C under aerobic conditions (Scheme 55).[125] Variecolortide B (**240b**) is also generated from **241b** and **243** in 32% yield under the same conditions. It is conceivable that the reactions proceed through the hetero-Diels–Alder reaction of *exo*-methylene diketopiperazines **241** with the quinone methide tautomer of **243**, followed by rapid oxidation of the labile benzylic C–H bond of adduct **244** in the presence of air. Theoretical calculations strongly support the notion that the reaction between **241** and **243** proceeds through a concerted cycloaddition pathway.

Scheme 55 Total synthesis of variecolortides A (**240a**) and B (**240b**).

A sesquiterpene lactone dimer (+)-ainsliadimer A (**238**), which was isolated from *Ainsliaea macrocephala*, has potent inhibitory activity against the production of nitric oxide in RAW264.7 cells stimulated by lipopolysaccharide (Scheme 56).[126] The biosynthesis of **238** appears to involve the hetero-Diels–Alder dimerization of monomeric sesquiterpene lactone dehydrozaluzanin C

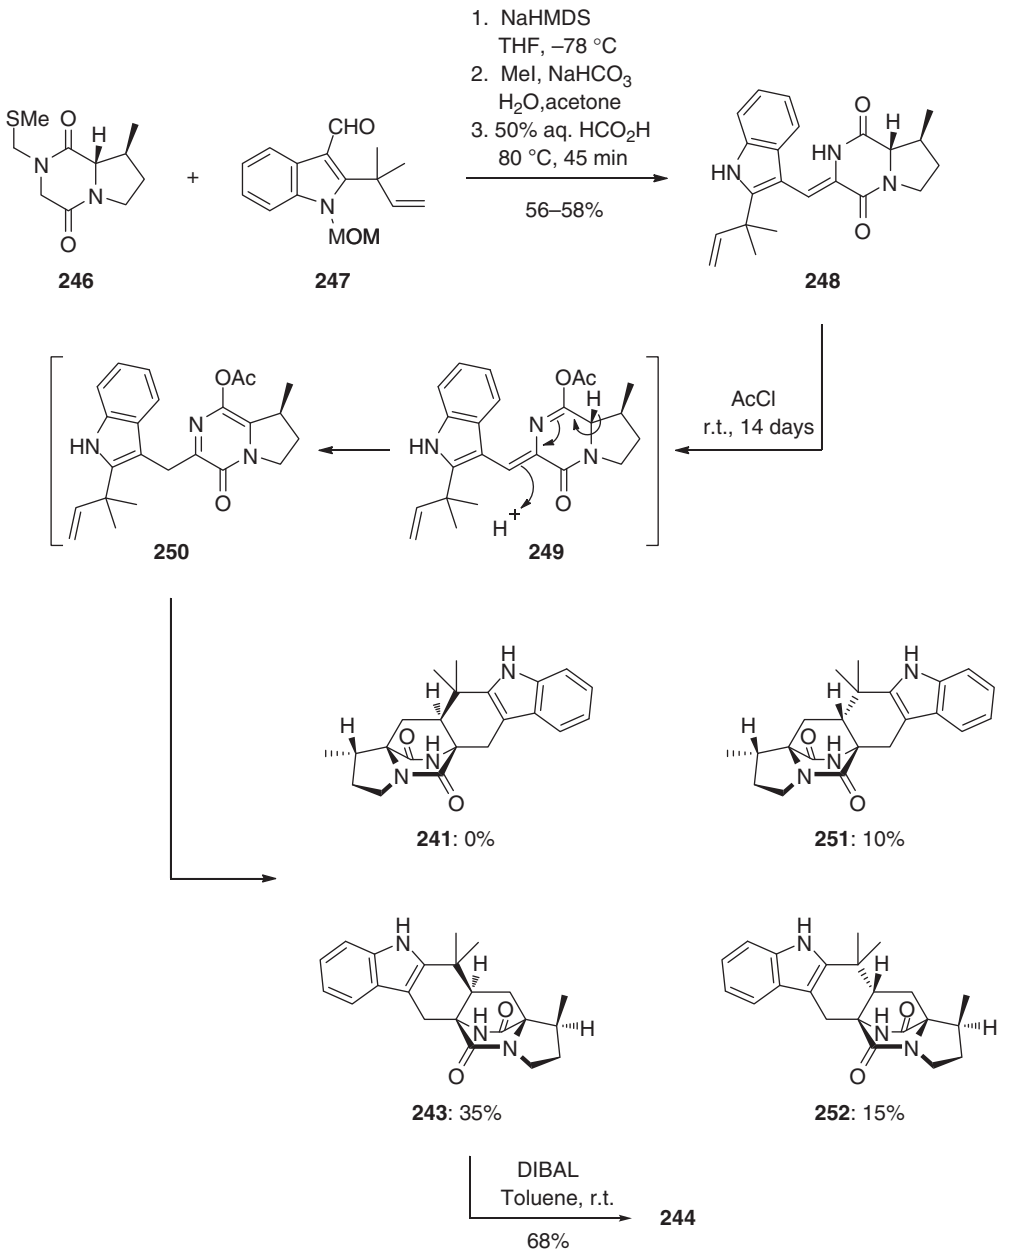


(**235**) as a key reaction. Based on this biosynthetic hypothesis, (+)-ainsliadimer A (**238**) was synthesized from **235**. Although the exposure of **235** to several LA catalysts led to either no reaction or decomposition, the use of (+)-BINOL as a hydrogen bonding catalyst showed good catalytic activity to give the desired dimer **236** in 71% yield (Scheme 56).[127] Interestingly, chiral BINOL showed a slightly higher activating effect than racemic BINOL (64% yield). This result might be explained by the fact that, on the solid state, racemic BINOL could be composed of a centrosymmetric structure characterized by intermolecular hydrogen bonding between a pair of (+)- and (−)-enantiomers, which reduces the hydrogen bonding effect on the substrate **235**. The high facial selectivity can be explained by the fact that the bulky seven-membered ring of dienophile blocks the *β*-face, and as a result, the diene approaches the dienophile from the less-hindered α-face. Acidic hydrolysis of dimer **236** gives compound **237** in 73% yield. The subsequent intramolecular aldol reaction is promoted by a large excess of DBU in dilute CH_2Cl_2 solution (0.0008 M) to give (+)-ainsliadimer A (**238**) in 89% yield.

Scheme 56 Biomimetic synthesis of (+)-ainsliadimer A (**238**).

Paraherquamide A (**245**), which was isolated from *Penicillium paraherquei*, is a potent anthelmintic alkaloid that bears a spirooxindole core (Scheme 57).[128] Other members of this class include VM55599 (**244**), which contains an indole ring instead of an oxindole ring.[129] Interestingly, the relative stereochemistry of C14 and C20 in **244** is opposite that in **245**. These compounds are proposed to be biosynthesized from L-isoleucine, L-tryptophan, and dimethylallyl pyrophosphate via the intramolecular hetero-Diels–Alder reaction between the azadiene and the terminal alkene in **239** or **240** (Scheme 57).[130] When the hetero-Diels–Alder reaction occurs from the more hindered face of the azadiene system (**240**), the corresponding adduct **243** is obtained. The reduction of **243** gives VM55599 (**244**). However, the hetero-Diels–Alder reaction from the other face of the azadiene system (**239**) gives the adduct **241**, which is a biosynthetic precursor of paraherquamide A (**245**).

Based on the proposed biosynthesis, VM55599 (**244**) is synthesized from diketopiperazine **246** and the indole derivative **247**. The base-promoted addition of **246** to aldehyde **247** followed by removal of the methylthiomethyl (MTM) group and acid treatment gives **248** as a precursor of the hetero-Diels–Alder reaction (Scheme 58).[131] The treatment of **248** with acetyl chloride gives a mixture of three diastereomeric cycloadducts: **243** (35%), **251** (10%), and **252** (15%). It has been proposed that the acetylation of **248** gives the *O*-acetyl lactim **249**, which tautomerizes to azadiene **250**, which in turn undergoes an intramolecular hetero-Diels–Alder reaction followed by loss of acetate. Very interestingly, cycloadduct **241**, which contains the relative and absolute stereochemistry of paraherquamide A (**245**), is not obtained from the hetero-Diels–Alder reaction. The cycloaddition reaction shows a proclivity for the formation of adduct **243**, which has the same relative stereochemistry as VM55599. In sharp



Scheme 57 Proposed biosynthesis of paraherquamide A (**245**) and VM55599 (**244**).

contrast, in the biological system, the diastereochemical distribution is expressed as >600:1 (corresponding to **241** or **242**:**243** or **244**) without the generation of anti-adducts (such as **251** and **252**). The reduction of adduct **243** with an excess of diisobutylaluminium hydride (DIBAL) in toluene gives VM55599 (**244**) in 68% yield.

5.10.7 Conclusion and Outlook

This chapter describes the recent advances in stereoselective hetero-Diels–Alder reactions. The most significant achievement in this field is the development of high-performance catalysts, including chiral LA catalysts and chiral organocatalysts. Based on these significant developments, the hetero-Diels–Alder reaction has become one of the most powerful tools for the efficient synthesis of bioactive natural products.

Catalytic enantioselective promotion of the normal electron-demand hetero-Diels–Alder reaction of unactivated ketones is still a challenge, since ketones are less reactive than aldehydes. The asymmetric inverse electron-demand hetero-Diels–Alder reaction with simple alkenes that do not have an electron-donating group is also an important issue to address for the synthesis of a variety of optically active heterocycles. As described in this chapter, diastereo- and enantioselective hetero-Diels–Alder reactions are currently limited to heterodienes and heterodienophiles, which contain oxygen and/or nitrogen as heteroatoms. The development of catalytic asymmetric hetero-Diels–Alder reactions that include other heteroatoms such as sulfur, phosphorus, and selenium is also a task for chemists in the coming years.

Scheme 58 Biomimetic synthesis of VM55599 (**244**).

5.11.1 Introduction

The Diels–Alder (DA) [4 + 2] cycloaddition, first disclosed[1] in 1928, quickly gained respect as an unusually powerful synthetic method because of its stereospecificity, its diastereo- and regioselectivity, and its ability to form up to four contiguous stereocenters in a single step.[2] The intramolecular DA (IMDA) cycloaddition[3] (Figure 1) took longer to become established,[4] but now enjoys a well-deserved reputation as a particularly potent and rapid technique for building up molecular complexity, especially in the field of total synthesis.[5] As depicted in Figure 1, the IMDA cycloaddition can be subdivided into two types, depending on the position of the tether linking the diene and dienophile components. The IMDA process has been the subject of a number of extensive reviews,[3a,5] and it is the purpose of this chapter to highlight some of the major advances in the field since the first edition[6] of *Comprehensive Organic Synthesis*. Transannular DA (TADA) cycloadditions (Figure 1) will also be discussed. For both the IMDA and TADA reactions, emphasis will be placed on the use of such cycloadditions as key transformations in multistep target oriented synthesis, in particular the total synthesis of structurally complex and biologically active natural products and analogs thereof.

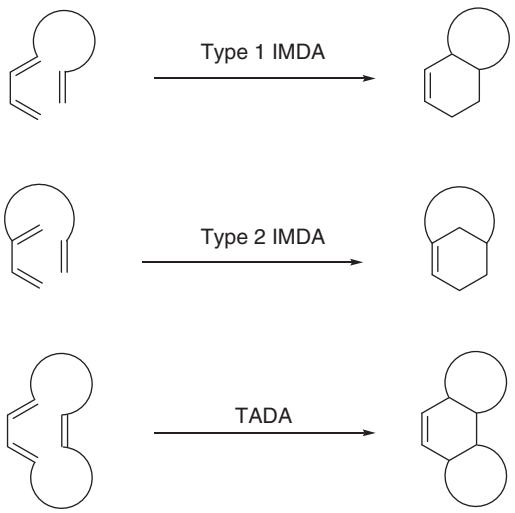

Figure 1 Three different modes of IMDA cycloadditions: Type 1, Type 2, and TADA.

5.11.2 Type 1 IMDA: Effects of the Tether

In its archetypical form, the type 1 IMDA cycloaddition involves a 'permanent' all-carbon tether of an appropriate length that allows access to relatively unstrained transition states, which usually means that the reaction is possible only if the tether contains at least three atoms (Figure 2, top). The IMDA process can be a stereochemically intricate one, the observed stereochemical outcome being dependent on the length and nature of the tether, along with the number, position, and nature of substituents attached to the reacting partners (Figure 2). This can be illustrated by the results of extensive recent studies[7] combining experiment and density functional theory (DFT) calculations; in all cases, good to excellent agreement between experiment and calculation was obtained, highlighting the importance of high-level computational methods as an explanatory/predictive tool which allows detailed analysis of subtle steric and electronic effects in competing transition states. For example, the DFT calculations provided a convincing explanation[7a] for the observed diastereoselectivity and the cooperative effect of the allylic methyl

group and the bromine atom in the IMDA reaction of **3** (X = Br). From a synthetic viewpoint, the vinylic bromine substituent in **3** serves not only as a useful stereocontrol element but can also be regarded as a surrogate C–H bond or used as a convenient 'handle' for introduction of further functionality via cross-coupling or other techniques. The topic of substrate-controlled IMDA cycloaddition in asymmetric synthesis will be discussed further in Section 5.11.7.

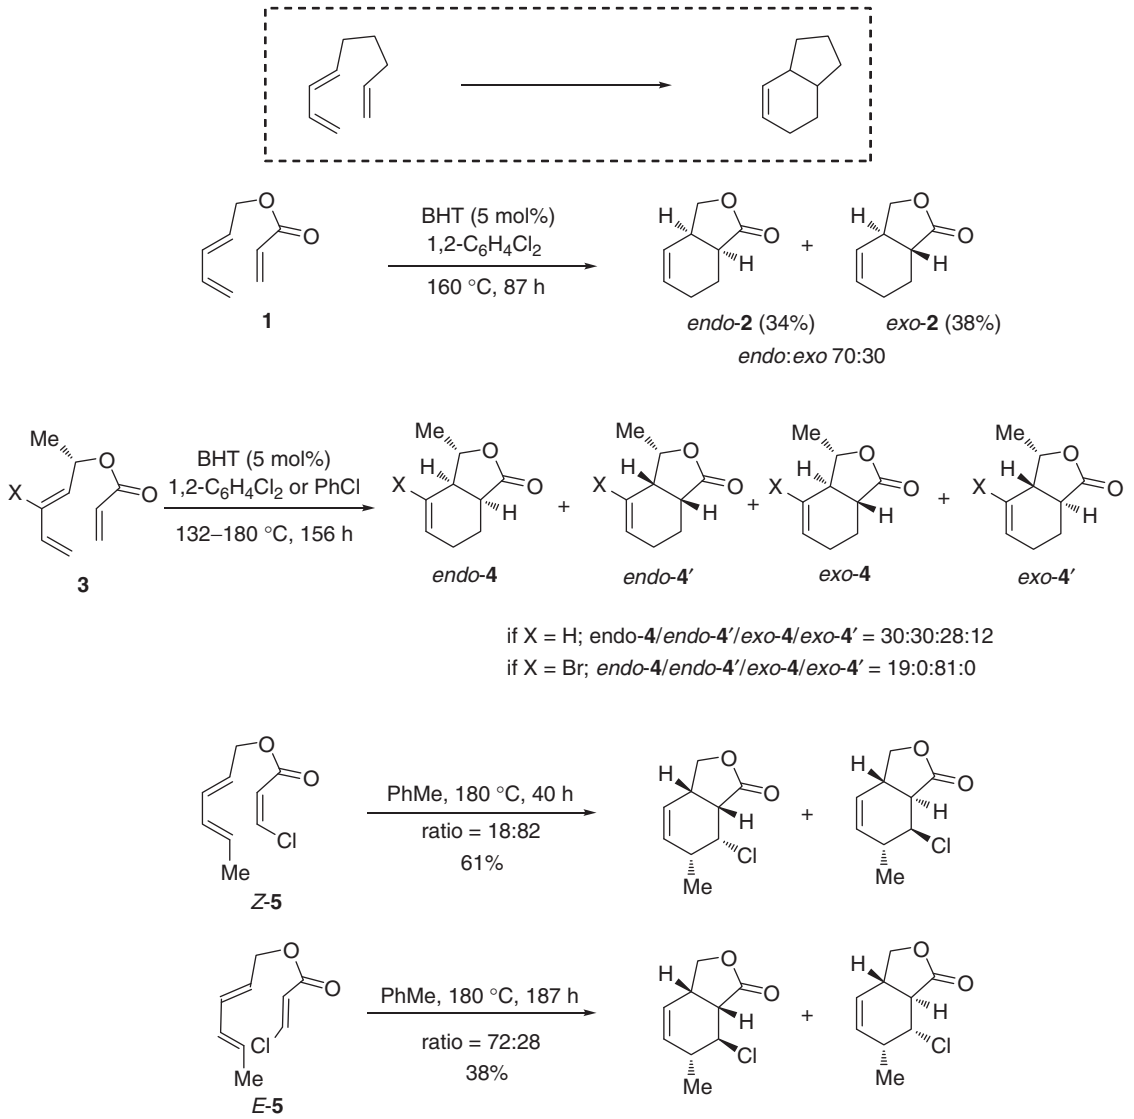

Figure 2 Type 1 IMDA cycloaddition influenced by functional groups and substituents.

The ester tethers shown in Figure 2 illustrate a very useful synthetic tactic, i.e., the use of a 'temporary' (disposable) tether to provide the advantages[8] of an intramolecular process (enhanced regio- and/or stereoselectivity and lower negative entropy of activation), followed by cleavage of the tether, which overall affords the products of a highly regio- and stereoselective intermolecular process (Figure 3, top). Of the linking groups that have been developed, tethers based on silicon[8] have proved to be versatile, and some examples are shown in Figure 3. From the IMDA reaction of **6**, a single (racemic) diastereomer was formed, arising from an *exo* transition state. This remarkable result underscores that, at the high temperature required for the cycloaddition process, the normal preference for the *endo* transition state (because of secondary orbital overlap between the diene and dienophile π-systems), has been overridden by other factors (both steric and stereoelectronic). As well as minimizing nonbonded steric interactions, a key feature of reactive conformer **6** is suggested[9] to be the alignment of the allylic C–O bonds: in the diene component, the acceptor 1,2-σ^* orbital is aligned *syn* to the 3,4 bond (minimum overlap with π-system, maximum nucleophilicity of diene), whereas the acceptor 1′,2′-σ^* has maximum overlap with the dienophile π-system (maximum electrophilicity of dienophile). A more recent variation on the silicon-tether theme is provided by the reaction of siloxacyclopentenes[10] such as **9**, which are expected to react via transition state **10** to yield *trans*-fused cycloadducts such as **11**. The pseudoaxial alignment of the alkoxyl group in **11** is dictated by the constrained nature of the dienophile, and Fleming–Tamao oxidation of the cycloadducts

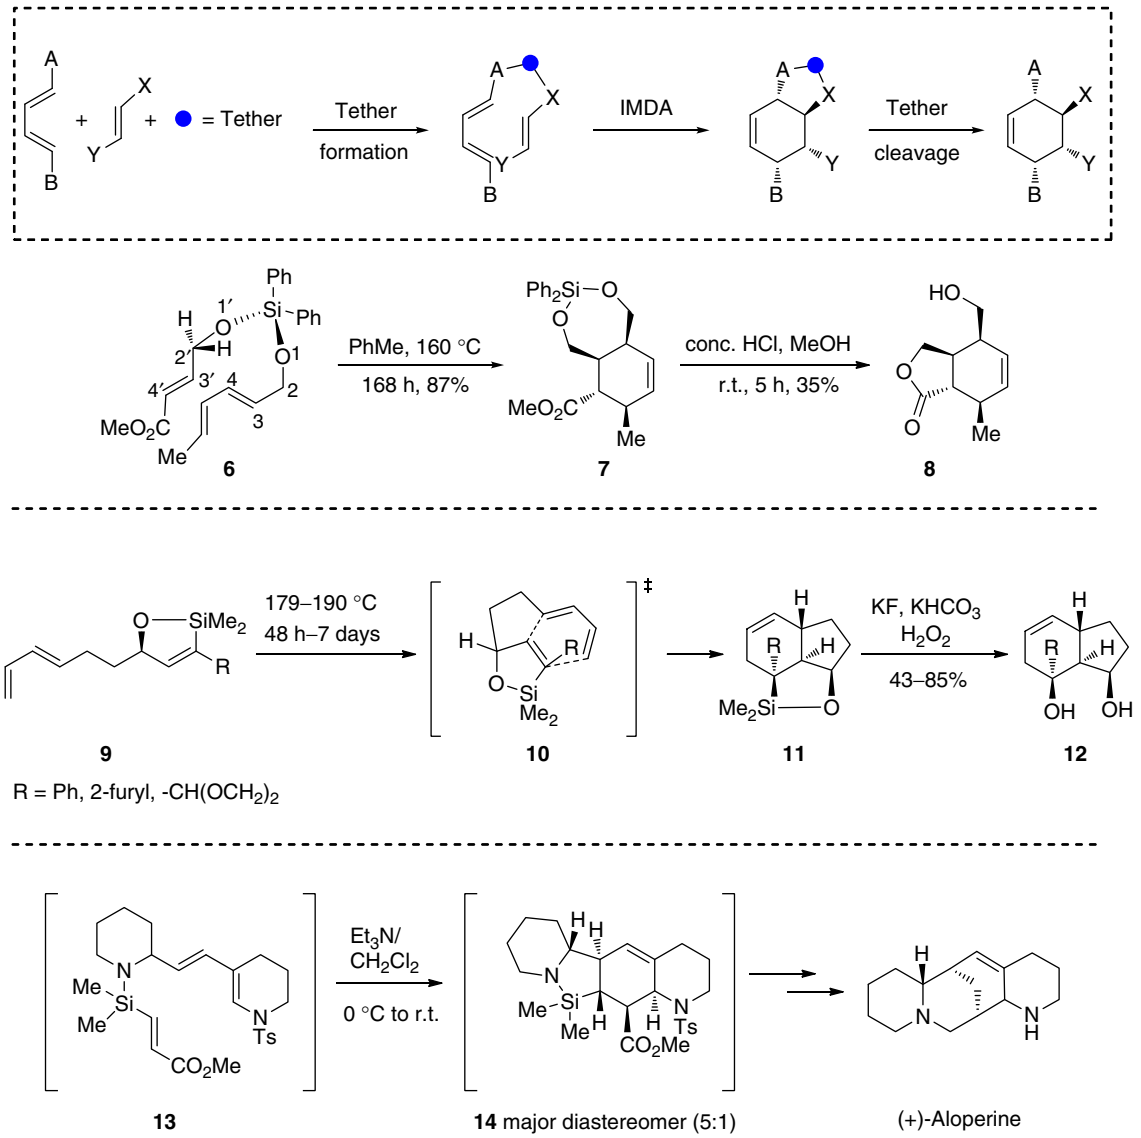

Figure 3 Type 1 IMDA involving silicon tethers.

yields diols **12** containing four stereogenic centers. This IMDA strategy proved to be highly diastereoselective for the expected *trans*-fused products (>20:1 selectivity) and provides convenient access to fused bicyclic motifs found in a wide range of biologically active natural products.[10] The use of an *N*-silyl linkage for IMDA cycloaddition is highlighted[11] in the impressive conversion of **13** to tetracycle **14**, as a key step in a total synthesis of the alkaloid (+)-aloperine. For further examples of the use of IMDA cycloaddition in the complex settings characteristic of natural product target molecules, the reader is referred to Section 5.11.11.

Intramolecular [4 + 2] cycloaddition by means of temporary connection through metal centers[12a] is also possible, and it is instructive to compare the relative rates of reaction for **15** and **16** (Figure 4). In **16**, the 'dienophile' is formally a vinyl carbanion, which indicates that the mechanism of the cycloaddition is a stepwise process[12b] rather than a concerted IMDA reaction, but the intermediacy of species **16′** was inferred from quenching experiments using D_2O. Aluminum and zinc species[12c] can also be used to tether and mediate the intramolecular cycloaddition of otherwise recalcitrant reaction partners. The oxophilicity of boron[13] makes it also a useful tether component for IMDA, and two examples[14,15] are shown in Figure 4. Bicyclic compound **22**, obtained as a single regio- and diastereomer, contains four contiguous stereocenters, attesting to the power of the IMDA process to rapidly build up molecular complexity in a stereocontrolled fashion; this particular example was an important stage in the total synthesis of taxol. The IMDA cycloaddition of intermediate alkenylboronate **25** yields the *endo* adduct **26** with high diastereoselectivity and complete regiocontrol. The method could be extended to give IMDA cycloadducts containing four contiguous stereocenters, with complete diastereoselectivity.

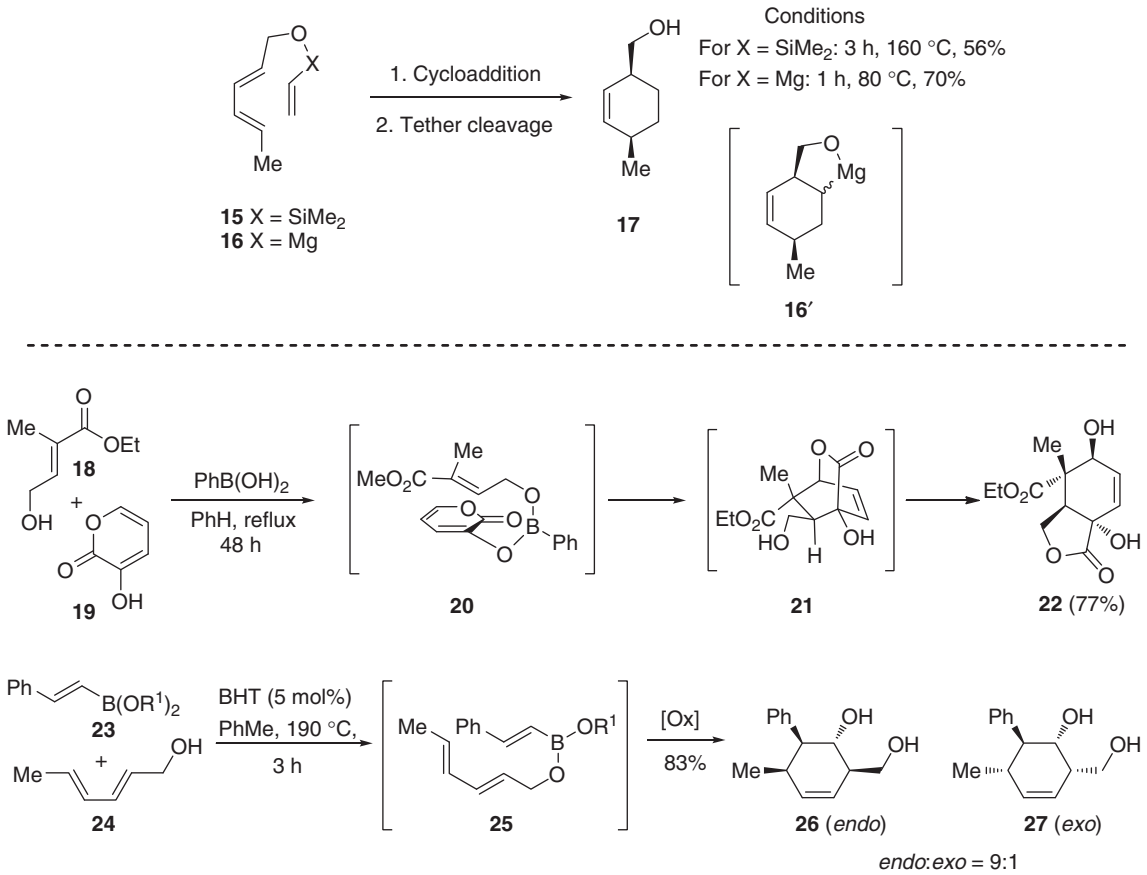

Figure 4 Type 1 IMDA cycloaddition by means of temporary connection through metal centers.

5.11.3 Acceleration of IMDA Cycloadditions

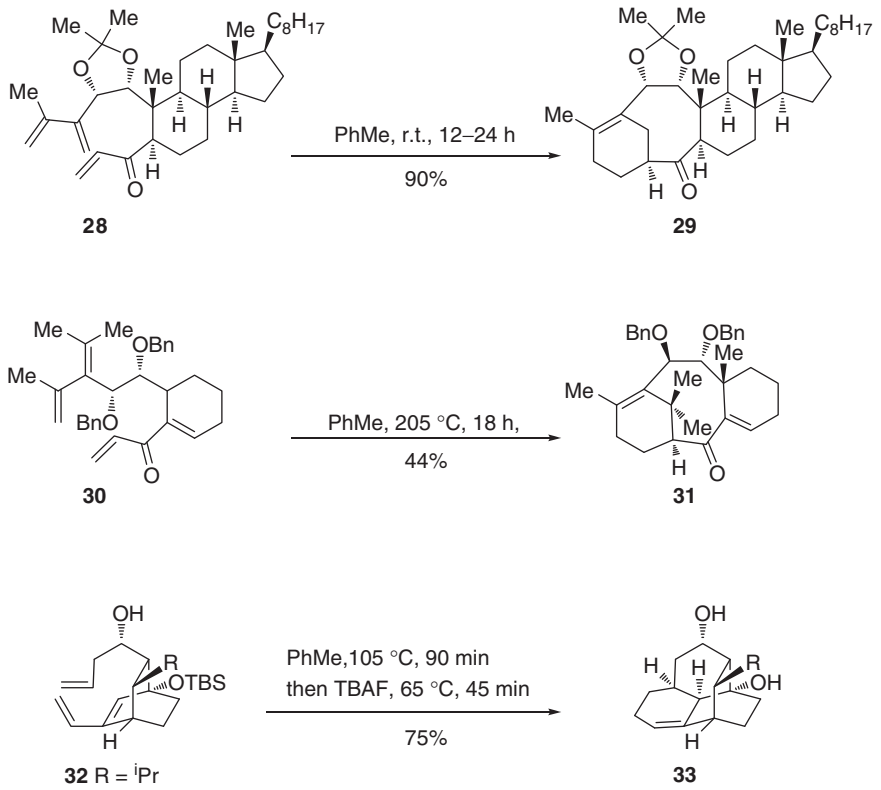
5.11.3.1 Proximity Effects

R. B. Woodward once famously remarked[16] that "enforced propinquity often leads on to greater intimacy" and two examples of this precept in the form of remarkably rapid IMDA reactions, both involving proximity effects highly conducive to bond formation, are presented in Figure 5. IMDA cycloaddition[17] of **28** to **29** occurs under unusually mild conditions, being complete at room temperature within 24 h. This can be compared and contrasted with the corresponding reaction[18] of **30**, which requires a similar reaction time, but at 205 °C (both **29** and **31** were important intermediates for the construction of taxol analogs). In **28**, the acetonide moiety serves as a conformational constraint, providing a low-energy pathway (via an entropic effect) to the required pericyclic transition state; the absence of the geminal dimethyl grouping on the diene (as compared to **30**) is obviously also an important factor (the reactions of **28** and **30** are excellent examples of Type 2 IMDA, further discussion of which is deferred to Section 5.11.5). Both **28** and **30** have the electronically matched DA combination of electron-rich diene (high-energy highest occupied molecular orbital (HOMO)) and electron-deficient dienophile (low-energy lowest unoccupied molecular orbital (LUMO)). In this respect, the ease of the (quantitative) IMDA reaction[19] of **32** is even more remarkable than that of **28**, because in **32** neither diene nor dienophile is electronically activated. This striking observation was made in the course of a total synthesis of the natural product vinigrol.

5.11.3.2 Use of 5 M Lithium Perchlorate in Diethyl Ether

In the early 1990s, the intriguing observation[20] was made that both the rate and diastereofacial selectivity of intermolecular DA reactions can be enhanced when the cycloaddition process is carried out in 5 M lithium perchlorate–diethyl ether. An instructive example, involving the often-troublesome furan as the diene component, is shown in Scheme 1. The conditions are remarkably mild, and the major product (the *exo*-anhydride) possesses the correct stereochemical array for the total synthesis of the natural product cantharidin (which will be discussed in Section 5.11.3.3).

The accelerative effect has been attributed to either high 'internal pressure'[20] (i.e., cycloaddition in this medium is suggested to be akin to cycloaddition in 'normal' solvents under high external pressure – see Section 5.11.3.3) and/or Lewis acid catalysis[21] by



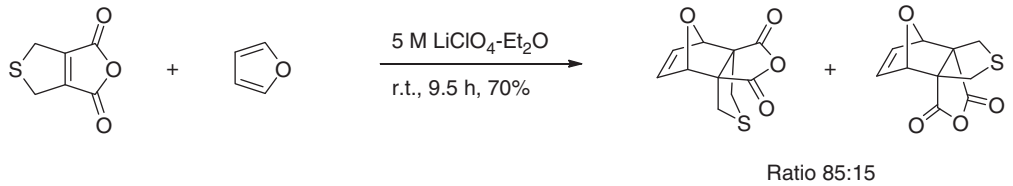


Figure 5 Proximity effects in IMDA cycloadditions.

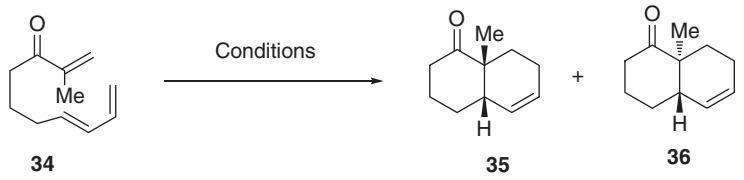
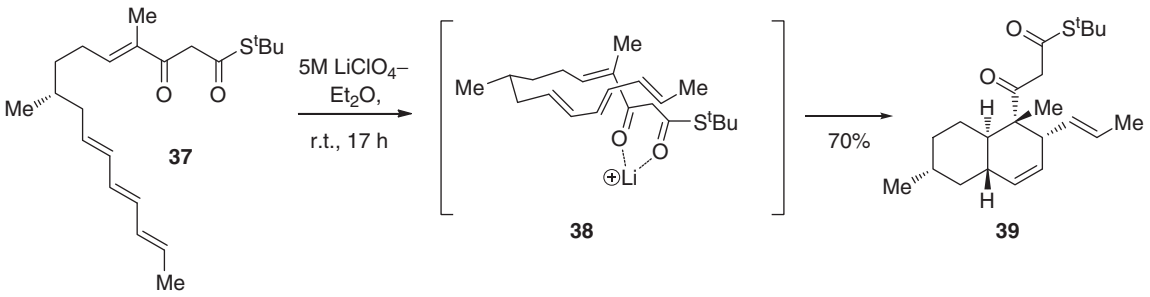


Scheme 1

the lithium ion. The enhancement of both rate and *endo*/*exo* selectivity was also observed[22] for the IMDA process, as shown in Figure 6 (conversion of **34** to **35** and **36**). Furthermore, addition of catalytic amounts of camphorsulfonic acid (CSA) to the lithium perchlorate–diethyl ether medium further increased reaction rate and diastereofacial selectivity. A prime example of the use of this technique as a key step in the total synthesis of the natural product equisitin is also shown; it was suggested[23] that the type 1 IMDA of **37** proceeds via the highly ordered reactive conformation **38** which has a chair-like arrangement with a pseudoequatorial methyl group and an *endo* arrangement of the dienophile, which is further organized by the lithium cation. The diastereomeric ratio of the cycloadducts was >95:5. In this way, the stereochemical bias associated with the single (and remote) stereocenter in **37** is parlayed into four new contiguous centers in **39**, one of which is quaternary. The use of aqueous media for IMDA cycloadditions is discussed further in Sections 5.11.6.2 and 5.11.12.



5.11.3.3 Use of High Pressure

It has long been recognized that since the DA cycloaddition has a negative volume of activation (i.e., the transition state is more compact than the reactants), it is a prime candidate for the application of high pressure[24] to promote the reaction. A classical example[24] is the high-pressure intermolecular DA cycloaddition of furan shown in Scheme 2. This formed the basis of a short and efficient synthesis of the natural product cantharidin **40**, a target molecule which had been unsuccessfully pursued, by means of a thermal cycloaddition, by Diels and Alder themselves[25] as early as 1929. The synthesis can also be compared to that shown in Scheme 1, for which 5 M lithium perchlorate–diethyl ether was used to promote the cycloaddition at ambient temperature.

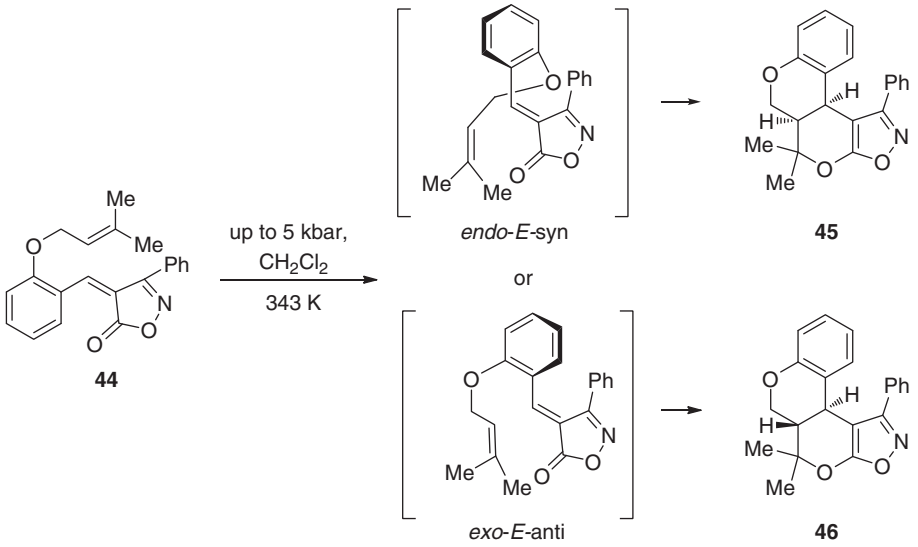
40

Scheme 2

The advantages of these two complementary techniques become apparent as alternatives to the purely thermal DA reaction for cycloadditions with unreactive dienes such as furan derivatives, in cases where thermal cycloreversion is a problem, and for reactions in which the cycloadducts decompose readily at high temperature.

The use of high pressure for IMDA cycloadditions using furan as the diene component (Intramolecular Diels–Alder with furan as diene (IMDAF), see also Section 5.11.6.1) was thoroughly and systematically investigated[26] towards the end of the 1990s (Scheme 3). This kinetics study employed unconventional dienophile components such as **41** which are activated exclusively by



41 42 43

Scheme 3

their strain energy, and give rise to some rather unusual cycloadduct topology, as in **42**. An important conclusion from this work was that IMDA processes do not necessarily have less negative activation volumes than their intermolecular counterparts.

A similarly rigorous physical-organic investigation[27] of an intramolecular hetero-DA (IMHDA) cycloaddition (see also Section 5.11.6.2) was performed to study not only kinetics but also the aspect of pressure-induced diastereoselectivity. The substrate chosen was the benzylidene–isoxazolone **44** (Scheme 4). Before cyclization, **44** isomerizes at the benzylidene moiety, and the two competing transition states for formation of **45** and **46**, respectively, are as shown. This study revealed the first example of an intramolecular transformation for which a pressure-induced shift in diastereoselectivity could be observed, the proportion of **45** increasing steadily with pressure. It can be concluded that the *endo* transition state, leading to **45**, has the more negative activation volume.

Entry	*P* [bar]	Ratio **45**:**46**
1	500	5.48:1
2	1200	5.53:1
3	2000	5.63:1
4	5000	6.75:1

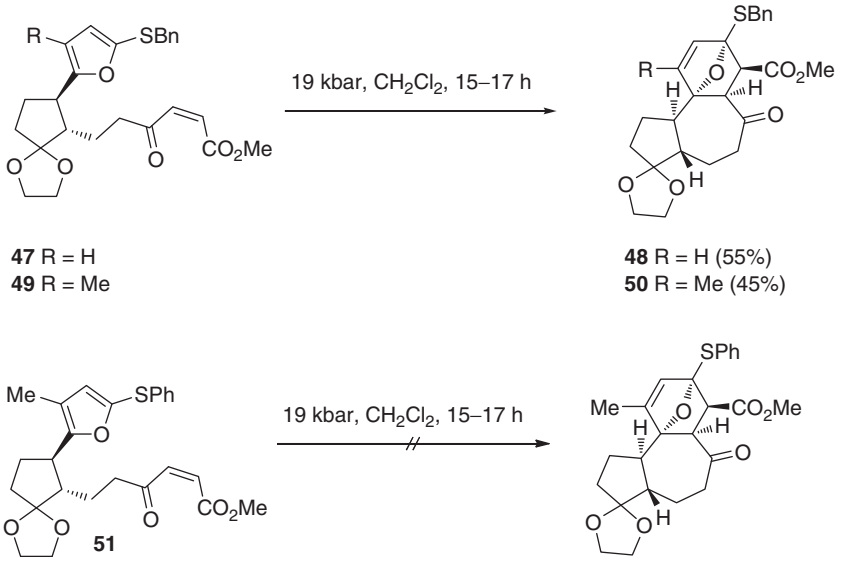
Scheme 4

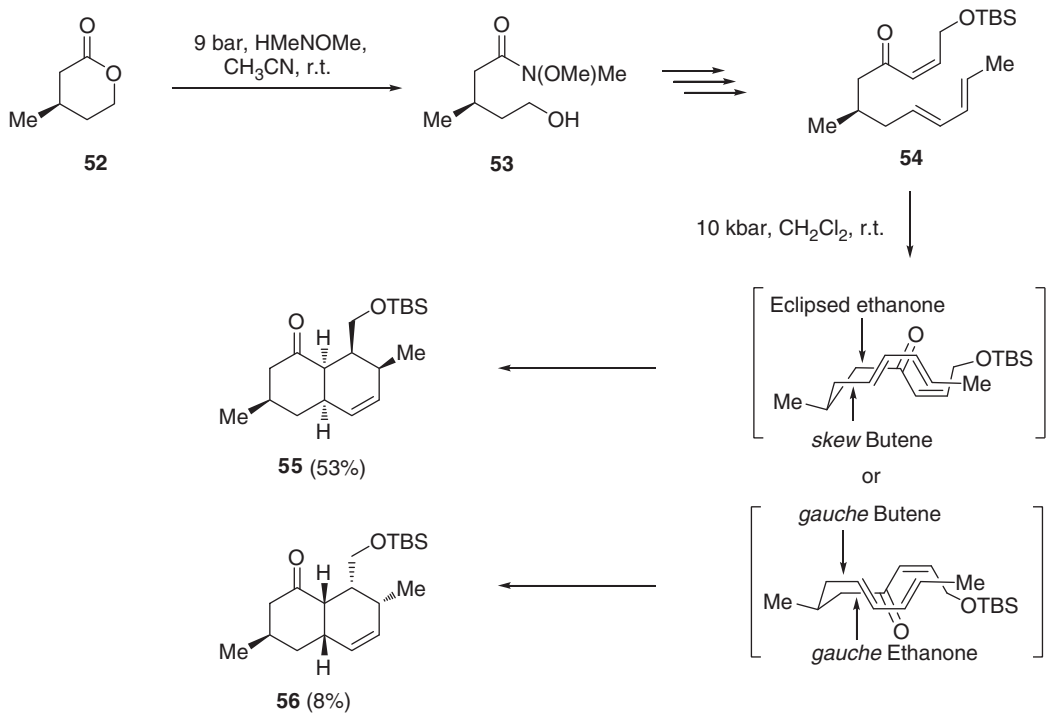
Returning to the IMDAF cycloaddition, this reaction has been used in 'ultra-high pressure' mode[28] as part of a synthetic study aimed at the phorbol class of natural products (Figure 7). Reaction of **47** under 19 kbar pressure gave a single cycloadduct, the 2-thioether substituent on the diene being crucial for both the cycloaddition and the later cleavage of the oxygen bridge. Unexpectedly, the nature of the thioether moiety was also all-important (compare the performance of **49** and **51**, the latter giving either no reaction or decomposition under a range of high-pressure conditions). A plausible explanation is that the benzylthioether enhances the HOMO energy of the furan unit, whereas the phenylthioether does not.

A high-pressure type 1 IMDA cycloaddition was used in an enantioselective route[29] to chiral hexahydronaphthalene units characteristic of the mevinolin family of natural products (Scheme 5). Interestingly, high pressure was also used in the synthesis of IMDA precursor **54** from **52**, via Weinreb amide **53**. For the IMDA process, the predominant formation of **55** was explained on the basis of steric effects: the 'eclipsed ethanone – *skew* butene' conformational combination being the one of lower energy.

5.11.3.4 Use of Microwave Heating or Ionic Liquids

To test a proposition regarding the biosynthesis of the alkaloid symbioimine,[30] the innocuous-looking *trans*-enone **57** (Figure 8) was heated under conventional IMDA conditions and was also subjected to the action of well-established Lewis acid catalysts, but no cycloadduct formation was observed. Success was finally achieved by the use of microwave heating,[31a] a technique[31b] that has proved to be very useful also for many other reaction types. The role of IMDA cycloaddition in the symbioimine biosynthetic proposal will be further discussed in Sections 5.11.4.1 and 5.11.11.1.2.





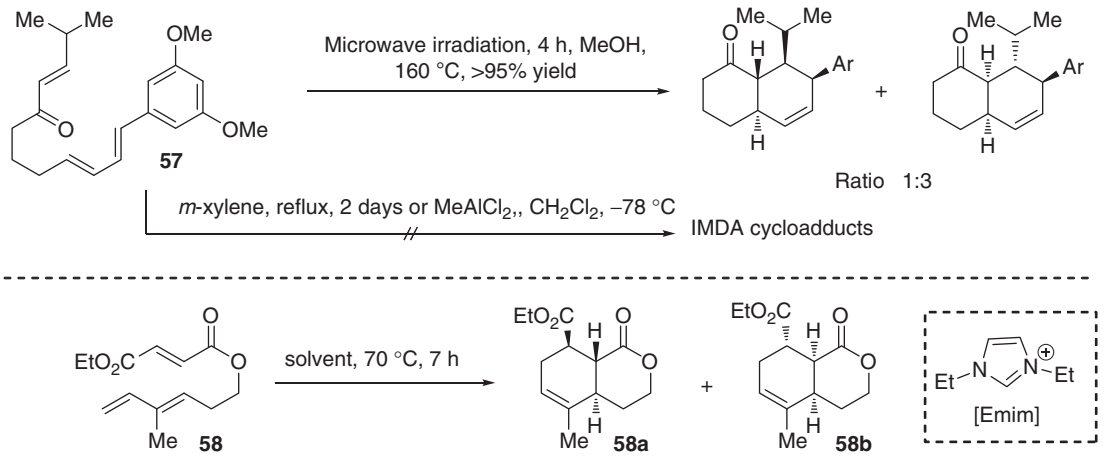


Figure 7 Pressure induced IMDA cycloaddition.

Scheme 5

For the promotion of organic reactions by use of 'green' media, ionic liquids[32] offer the advantages of high thermal stability, negligible vapor pressure, and recyclability. A recent example[33] involving an IMDA cycloaddition in ionic liquid media is shown in Figure 8, and the results can be compared to those obtained when precursor **58** was heated in 'normal' solvents, of either low (xylene) or high (water) polarity. It was suggested that the ionic liquid medium, by virtue of its polarity, helps to negate the repulsive dipole interaction between the two oxygens of the ester in the *cisoid* conformation shown for **58**, thus facilitating the IMDA process. It was also speculated that the microviscosity of the ionic liquid medium assisted the diene component in folding into the correct orientation for the cycloaddition.

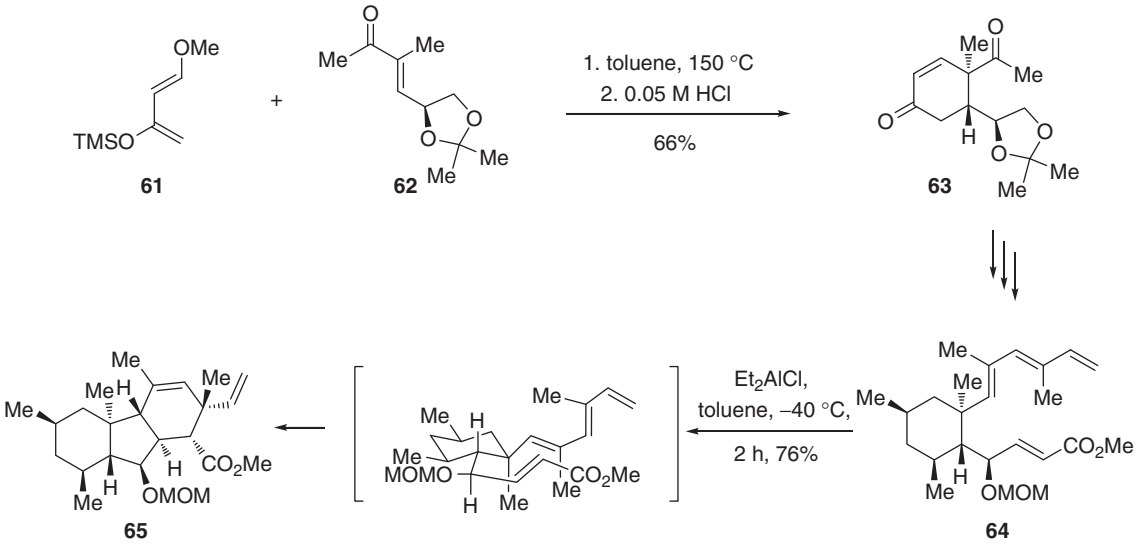
5.11.4 Catalysis of IMDA Cycloaddition

The most cursory of literature searches suffices to ascertain that the literature on the general subject of catalysis of DA cycloadditions is indeed vast. Because the present writing is not intended to provide an encyclopedic collection of data, only a small selection of recent methods (from the period 2000–11) for the catalysis of IMDA reactions is presented in the following subsections.

5.11.4.1 Oxophilic Lewis Acid Catalysis

The use of Lewis acids to facilitate the DA cycloaddition has been known for over 50 years[34] and a plethora of such mediators/catalysts (including chiral species suitable for asymmetric synthesis, see Section 5.11.6) is now available.[35] The role of the Lewis acid is to activate the dienophile component (typically by complexation to a carbonyl or carboxyl oxygen) thus lowering the LUMO energy, and such catalysts/promoters are capable of enhancing not only reaction rate but also regio- and stereoselectivity. The earliest examples[34] of Lewis acid-mediated DA cycloaddition employed stoichiometric amounts of aluminum trichloride in conjunction with robust cycloaddition partners, but it did not take long before catalytic procedures came into use, involving delicate applications to the total synthesis of complex natural products such as the prostaglandins.[36] It should be emphasized, however, that many DA and IMDA reactions described as being 'Lewis acid catalyzed' actually involve stoichiometric or even superstoichiometric amounts of the promoter; nevertheless, for the purpose of comparison with other approaches, it is appropriate to include such processes at this point, because many Lewis acid-mediated DA/IMDA cycloadditions take place under remarkably mild conditions.



In Section 5.11.3.4 (Figure 8, top) was documented the failure of a Lewis acid ($MeAlCl_2$) to mediate the cycloaddition of precursor **57** in an attempted synthesis of the alkaloid symbioimine, a project that was inspired by a proposal for the biosynthetic generation of the natural product, involving an unusual *exo*-selective IMDA process. A more recent study[37] (Scheme 6) employed the stereochemically more elaborate IMDA precursor **59** that proved amenable to Lewis acid 'catalysis' (by Me_2AlCl) and delivered

Scheme 6

a single diastereomer of the cycloadduct under very mild conditions. The product was apparently formed via the *endo* transition state, which cast doubt on the original biosynthetic proposal (which had duly been modified[38] to include an alternative pathway via the more traditional *endo* mode). This result is also noteworthy in that the single stereogenic center at the allylic position of the dienophile unit of **59** which, in the IMDA transition state, is out with the pericyclic array leading to the product, is capable of exerting a very high level of stereocontrol over the π-facial selectivity of the cycloaddition. A related example of such 'exocyclic' stereocontrol by an allylic substituent in the diene component – in a thermal IMDA cycloaddition – is presented in Section 5.11.7.1.

A total synthesis[39] of the antitumor antibiotic GKK1032 agents (Scheme 7) began with an intermolecular DA using the classical Danishefsky diene **61** that was elaborated to IMDA precursor **64**. After some screening of Lewis acids, Et_2AlCl was found to mediate the IMDA cycloaddition under mild conditions to give **65** as a single diastereomer in 76% yield. The corresponding thermal IMDA reaction (toluene, 120 °C) gave the desired product in only 46% yield, along with 20% of a compound formed via an intramolecular ene reaction (a process which is also subject to Lewis acid catalysis). The preferred *endo* transition state for the IMDA, which minimizes steric repulsion between the cyclohexane ring and the proximal methyl group on the triene side-chain, is indicated in Scheme 7.

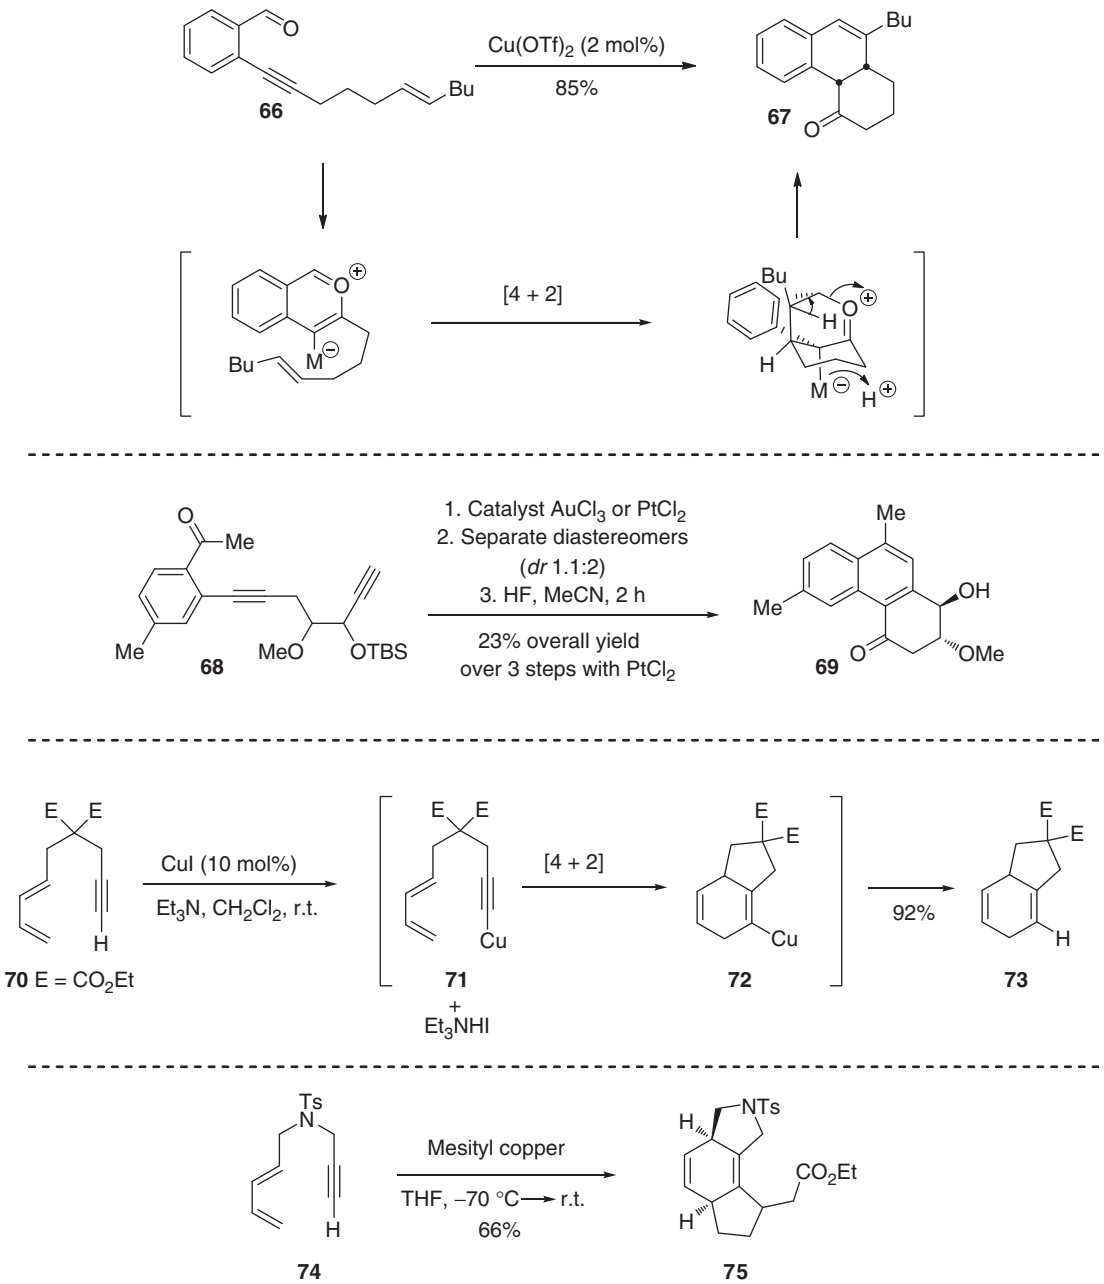
Scheme 7

5.11.4.2 Carbophilic Lewis Acid Catalysis

Soft, carbophilic Lewis acids (e.g., salts of Cu, Au, and Pt) can be used to activate alkynes and catalyze a variety of their reactions, including intramolecular [4 + 2] cycloadditions, as outlined in Figure 9. Stereoselective formation[40] of tricycle **67** can be explained by initial coordination of copper to the alkyne, followed by formation of an isobenzopyrylium intermediate that undergoes an intramolecular [4 + 2] cycloaddition and bond rearrangement to give the product, with regeneration of the catalytic species. Au(III) complexes can also catalyze this type of reaction. A total synthesis[41] of the natural product heliophenanthrone **69** relied on either Au(III) or Pt(II) catalysts to form the tricyclic system via cycloaddition and aromatization. The gold catalyst gave only 35% total yield in the key cyclization step, whereas the Pt(II) species gave 71% (mixture of diastereomers). Copper (I) catalysts[42] have been used to promote the IMDA of unactivated dieneynes such as **70** via copper acetylide and vinylcopper intermediates (**71** and **72**, respectively). Evidence for **72** was obtained by quenching the reaction with D_2O, and computational studies indicated that formation of **71** significantly lowers the alkyne LUMO energy, thus facilitating the IMDA cycloaddition. An elegant cascade sequence (see Sections 5.11.5.2 and 5.11.8), initiated by mesitylcopper, was also developed (IMDA followed by intramolecular Michael addition of the vinylcopper intermediate).

5.11.4.3 Brønsted Acid Catalysis

Although Lewis acids can efficiently promote or catalyze DA cycloadditions with carbonyl/carboxyl-substituted dienophiles, often with enhanced stereo- and regioselectivity, attempts at Lewis acid catalysis of the corresponding nitroalkene cycloadditions have met with little success.[43] Recently, however, the Brønsted acid **77** has been reported[44] to catalyze a nitroalkene type 1 IMDA cycloaddition with enhanced stereoselectivity as compared to the thermal process (Scheme 8). For pyridinium catalyst **77**, the



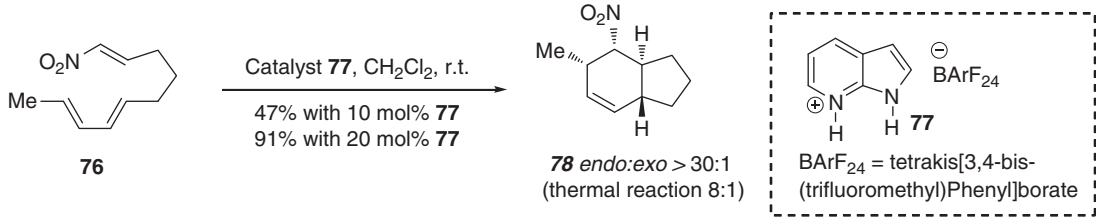


Figure 9 Carbophilic Lewis acid-assisted IMDA cycloadditions.

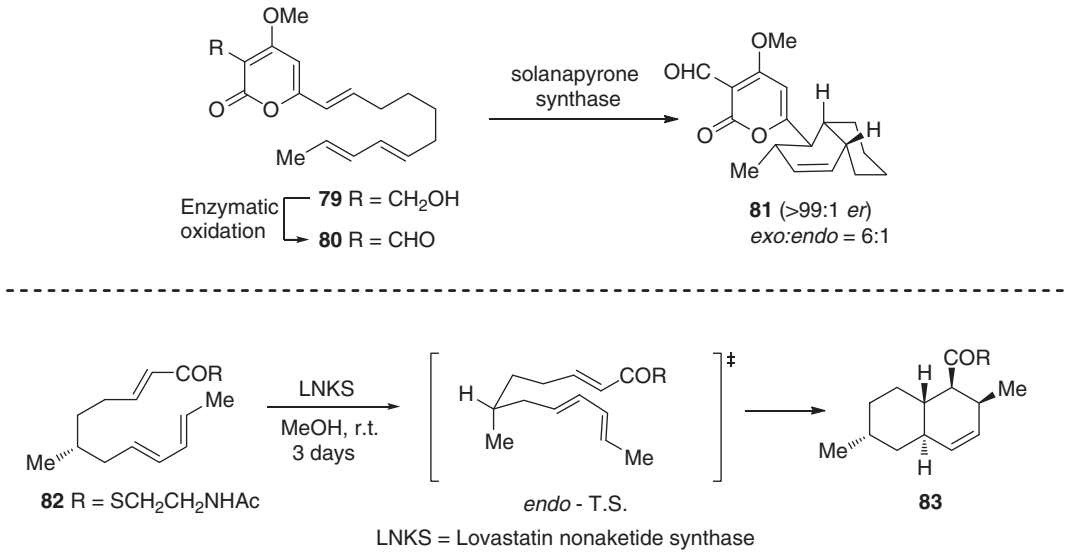
Scheme 8

yield of the cycloaddition increased with catalyst loading, which was not the case when the corresponding Na salt was used. This is a useful addition to the IMDA armory in view of the versatile chemistry of the nitro group in subsequent transformations.

5.11.4.4 Enzymatic Catalysis – 'Diels–Alderases'?

The fascinating topic of 'Diels–Alderases' has piqued the interest of organic chemists for considerable time.[45] In 1998, the first claimed Diels–Alderase, solanapyrone synthase, was used[46] to catalyze the *exo*-selective IMDA cycloaddition of **79** (the enzyme first oxidizes the alcohol group to the aldehyde **80**, which is the actual IMDA precursor). The natural product (–)-solanapyrone A **81** was obtained in essentially enantiomerically pure form, and the *exo*-selectivity of the IMDA reaction was 6:1 (Figure 10, top). This is in contrast to the nonenzymatic IMDA process, which in a variety of organic solvents and especially in water, gave *endo*-selectivity (up to 20:1). An alternative mode of catalysis for the synthesis of the solanapyrone family is presented in Section 5.11.7.3.3.



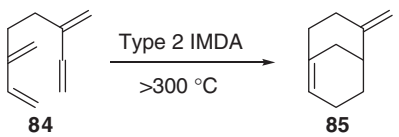


Figure 10 Enzymatic IMDA cycloadditions.

Although the solanapyrone synthesis utilized a crude cell-free preparation of the enzyme, a later study[47] of Diels–Alderases employed the purified enzyme lovastatin nonaketide synthase (LNKS) to catalyze the *endo* IMDA cyclization of **82** to **83** (Figure 10). Again, the course of the enzyme-catalyzed cyclization was markedly different from the nonenzymatic IMDA: cycloadduct **83** (which has the same stereochemistry as intermediates on the biosynthetic pathway to the lovastatin natural products) was observed only in the LNKS reaction, and is formed via a transition state in which the Me group is pseudoaxial. It was proposed that the hydrophobic active site of the protein determines the folding of the substrate as it approaches the transition state, and hydrogen bonding to the carbonyl oxygen is also likely to aid the cyclization by lowering the LUMO energy of the dienophile.

A very interesting recent paper[48] describes the computational design of an enzyme catalyst for a stereoselective bimolecular (i.e., intermolecular) DA cycloaddition, for which naturally occurring enzymes have yet to be found. The topic of biosynthetic IMDA cycloadditions is discussed in Section 5.11.12.

5.11.5 Type 2 IMDA

Fifty years after the original Diels and Alder paper, the first example[49] of a type 2 IMDA cycloaddition was discovered serendipitously (Scheme 9). Tetraene **84** (generated at temperatures >300 °C) yielded the highly strained and reactive *anti*-Bredt alkene **85** which nevertheless could be isolated and characterized. This unexpected result opened up a new area of DA cycloaddition, rich

Scheme 9

in opportunities for physical-organic and synthetic organic chemists alike. The type 2 IMDA was the subject of an excellent and extensive review[50] in 2001 and only selected examples taken from the literature in the period since 2000 will be described in Section 5.11.5.2 below (two examples[17,18] have already been presented in Section 5.11.3.1).

5.11.5.1 Type 2 and Type 1 IMDA Compared

Because the Type 2 IMDA process yields a strained bridgehead alkene and because the transition state is characterized by repulsive nonbonding interactions, the free energy of activation is usually considerably higher than that for the type 1 IMDA counterpart. Experimentally derived activation energies[50] lie in the range 155–172 kJ mol^{-1}, a barrier that originally was overcome by extended heating at elevated temperatures. However, the advantages of Lewis acid catalysis (as described earlier for the type 1 IMDA reaction) soon became apparent[51] (compare the thermal and Lewis acid-promoted reactions of **86** shown in Figure 11). More recently,[52] microwave heating has proved to be a useful activation method, for example, the conventional thermal reaction of **88** (Figure 11) gave yields between 40% and 60%. As for type 1 IMDA (Section 5.11.3.4), the microwave technique is particularly useful for cases when the cycloaddition substrates and/or products are unstable at high temperatures or contain functionality incompatible with Lewis acids. In line with the Type 1 IMDA, the stereospecificity of the type 2 IMDA reaction is consistent with a concerted pericyclic process.

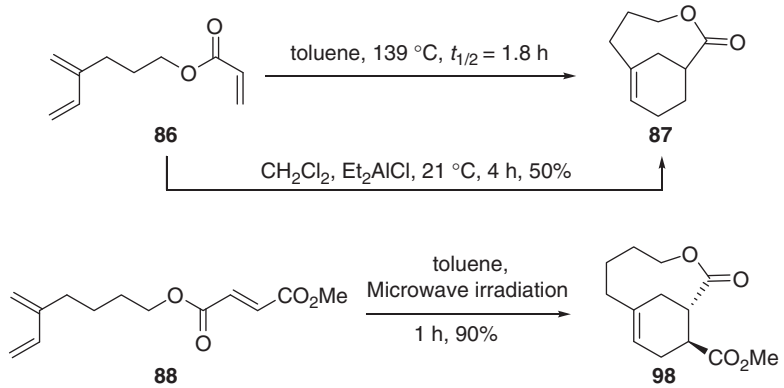

Figure 11 Type 2 IMDA cycloadditions influenced by conventional and microwave heating.

5.11.5.2 Some Recent Examples of Type 2 IMDA

The type 2 IMDA reaction provides a very convenient one-step entry to bridgehead alkenes and constitutes a powerful methodology for the total synthesis of complex molecules, including natural products. Some recent examples are shown in Figure 12. The remarkably smooth conversion of **90** to bridgehead alkene **91** was a key early step in the asymmetric total synthesis of the CP molecules.[53] A dramatic example[54] is provided by the intramolecular [4 + 2] cycloaddition of **92,** which after loss of CO_2, and deacetylation, provided the very unusual natural product haouamine A (**94**), which contains a nonplanar aromatic ring (for further examples of aromatization via IMDA reactions, see Sections 5.11.6.2 and 5.11.6.3). An approach to the welwitindolinone alkaloids[55] utilized a type 2 IMDAF (cf. Sections 5.11.3.3 and 5.11.6.1) with substrate **95** as part of an attractive cascade sequence (see also Sections 5.11.6.2 and 5.11.8). The cycloaddition was completely diastereoselective.

5.11.6 IMDAF, IMHDA and Inverse Electron Demand IMDA Cycloaddition

The following sections will deal with the topics of IMDAF[56] (see also Section 5.11.3.3), IMHDA (see also Section 5.11.3.3), and IMDA reactions with inverse electron demand. Emphasis will be placed on recent applications in complex molecule synthesis.

5.11.6.1 IMDAF Cycloaddition

A large-scale enantioselective synthesis of the tetracycline antibiotics[57] involved an IMDAF reaction with the diastereomeric mixture of alcohols **97** (Figure 13). The reaction was carried out on a 98 g scale, and the chiral allylic amine efficiently directed the diene to a single π-face of the dienophile. Another interesting aspect was that the major cycloadducts from the stereoisomeric alcohols were both *endo* diastereomers; furan-DA cycloadditions tend otherwise to be *exo*-selective, because of reversibility, and in the present case, the 3-methoxy substituent on the furan is the key factor.[58] The IMDAF reaction of **98** proceeded efficiently under

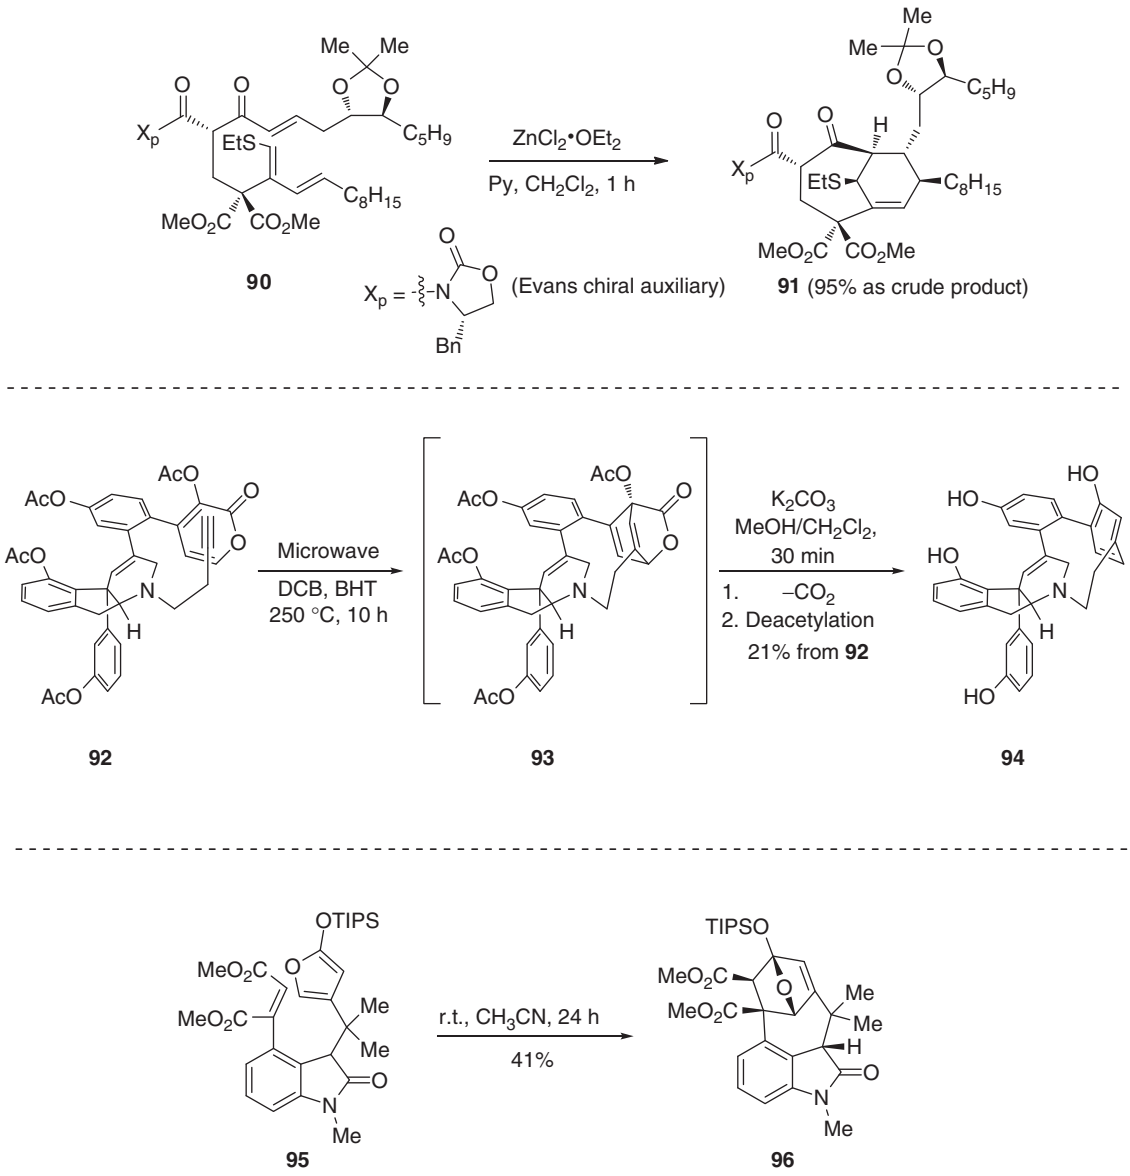

Figure 12 Examples of type 2 IMDA cycloadditions.

thermolytic conditions, the initially formed cycloadduct being subject to a nitrogen-assisted ring opening to yield **100**, an intermediate for the projected total synthesis of the lycopodium alkaloid fawcettidine.[59] In Section 5.11.3.3, the use of high pressure to enable IMDAF reactions is described. The cycloaddition of furans **101** with unactivated alkynes employed a very different form of acceleration, in the form of a Grignard addition reaction.[60] The formation of a chelated magnesium species was suggested to be important for the rate acceleration, by raising the HOMO energy of the furan diene component. The Grignard-accelerated reactions were also more stereoselective than the corresponding purely thermal processes. Oxanorbornadienes such as **102** are versatile building blocks for further synthesis.

5.11.6.2 IMHDA Cycloaddition

Incorporation of heteroatoms (in particular, N, O, and S) into the pericyclic array of a DA cycloaddition allows for the synthesis of heterocycles, and an impressive array of examples can be found.[61] Not surprisingly, much effort has been concentrated on *N*-heterocyclic systems, and some recent examples of type 1 IMHDA reactions are shown in **Figure 14**. In pursuit of the total synthesis of the marine natural products fasicularin and lepadiformine, an IMHDA cycloaddition using an acylnitroso grouping as the dienophile was developed.[62] Periodate oxidation of **103** generated the substrate **104** for the cycloaddition, which gave best yield and stereoselectivity when carried out in aqueous media (taking advantage of the 'hydrophobic effect').[63] The major cycloadduct **105** was suggested to be formed via the then-unprecedented *anti*-facial transition state **107**, with the tether equatorially disposed.

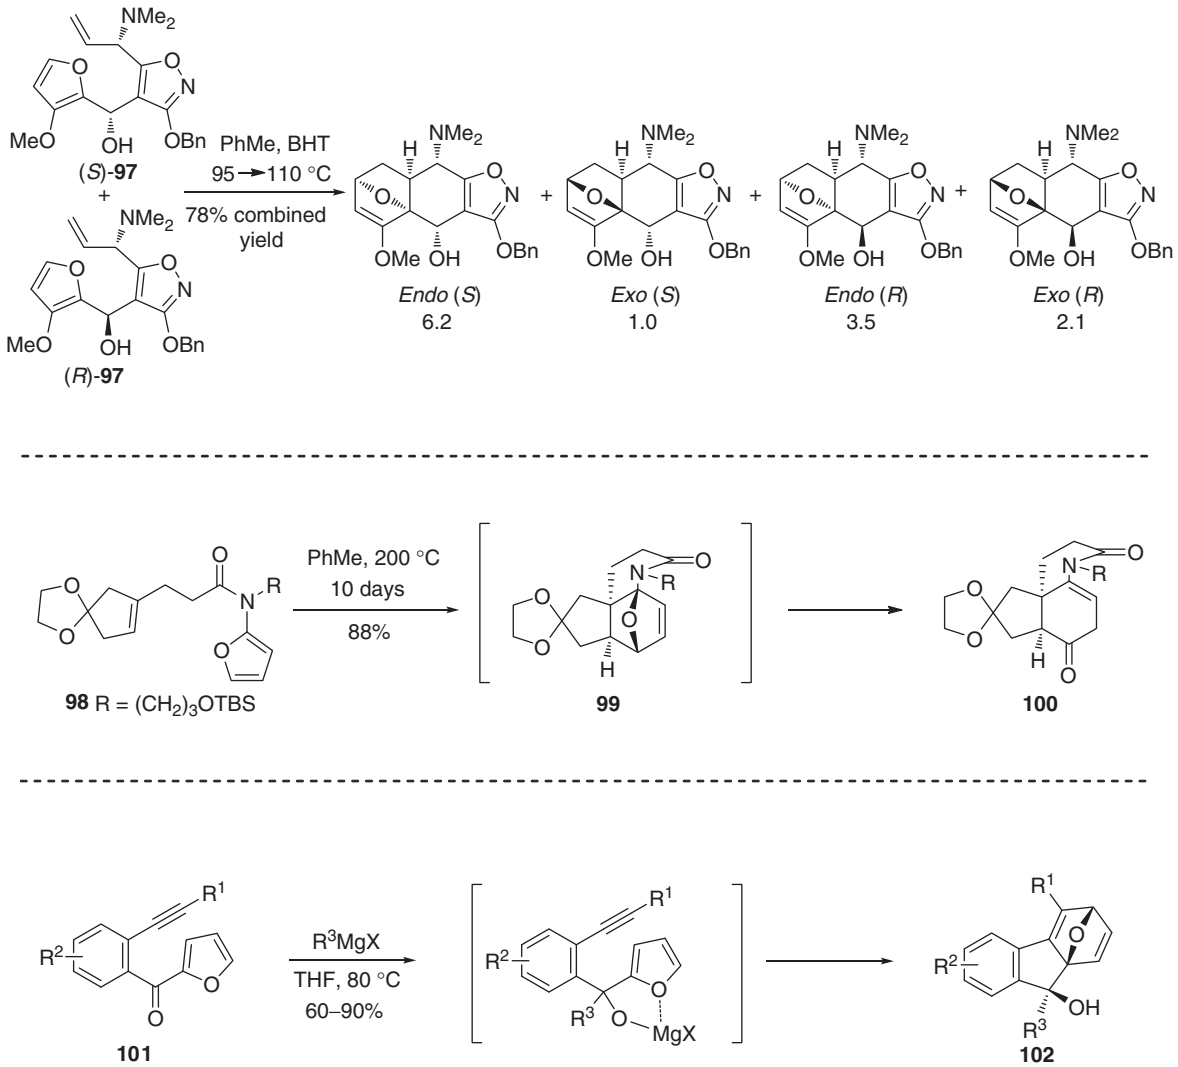

Figure 13 Examples of IMDAF cycloadditions.

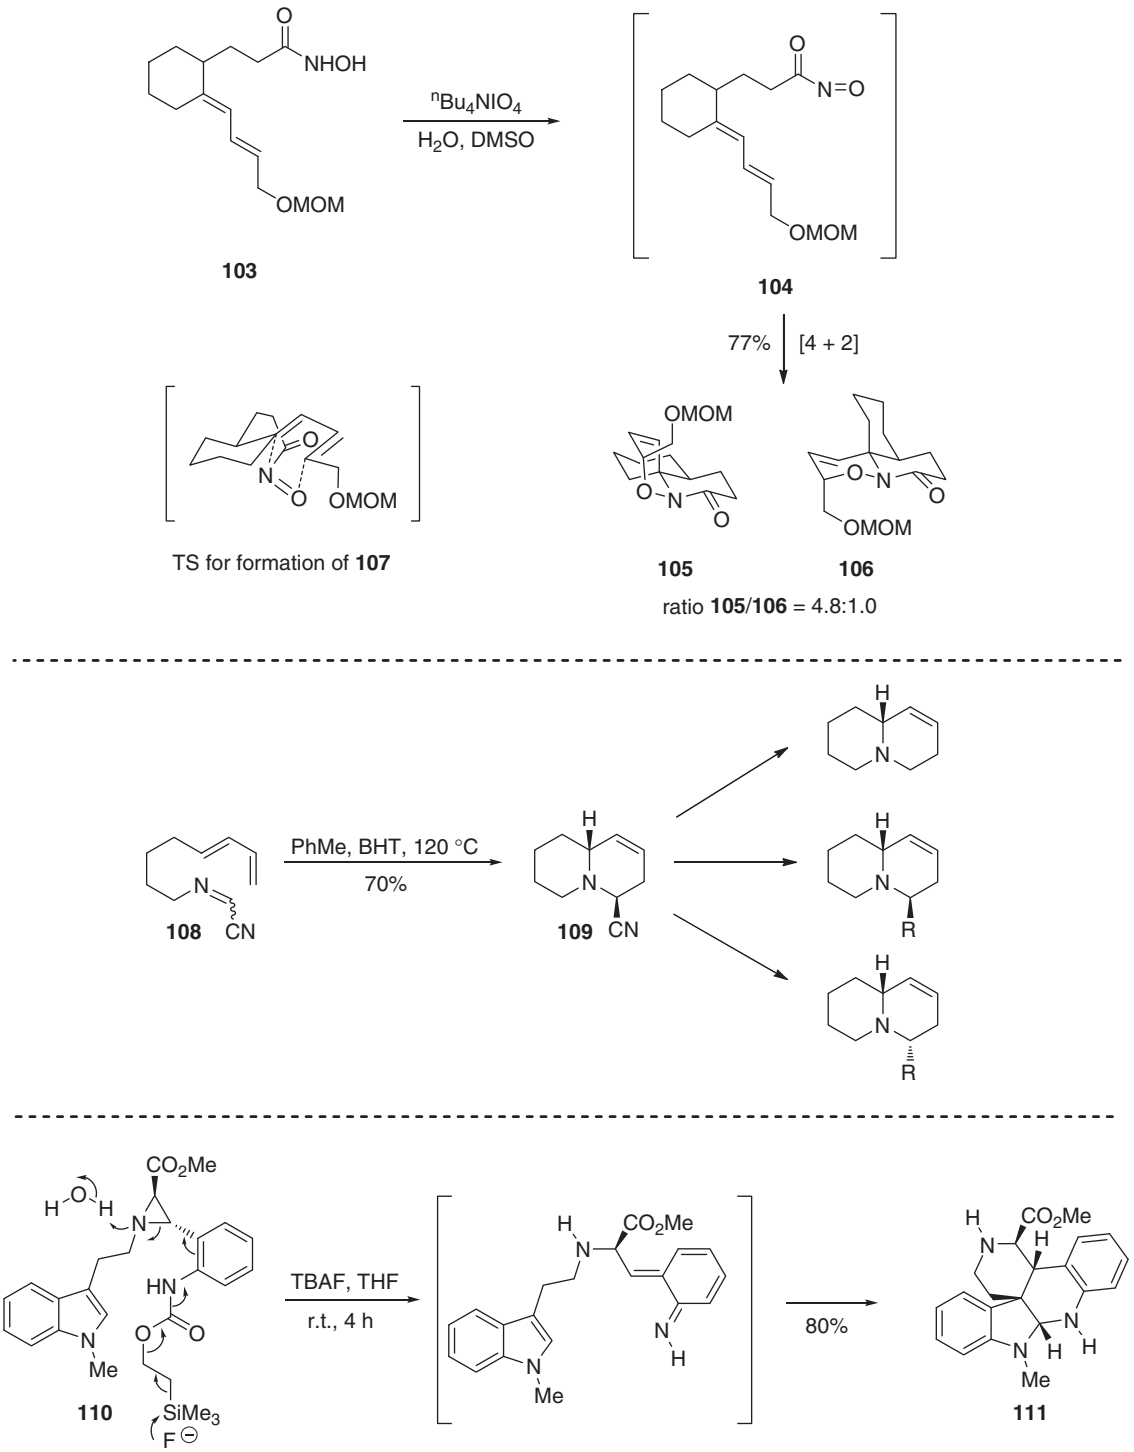
This meant that the least hindered approach of the dienophile was to the face of the diene opposite to the anchor position of the tether. Interestingly, the facial selectivity of this IMHDA process could be reversed by the simple expedient of placing a bromine atom in the 2-position of the diene, to take advantage of 1,3-allylic strain effects[64] (this is similar to one of the IMDA substrates shown in Figure 2). Iminoacetonitriles such as **108** were introduced[65] as azadienophiles in 2003 and provide simple access to bicyclic α-amino nitriles **109** via a stereoconvergent process (both isomers of the iminoacetonitriles give the product with the axial cyano group, via equilibration). It is important to note that the α-amino nitrile grouping present in **109** is a latent iminium ion, ripe for unmasking by the action of mild protic or Lewis acids, thereby providing a convenient handle for further stereoselective introduction of functionality. An intriguing IMHDA involving an indole as dienophile and an aza-*ortho*-xylene (see **110**) was developed[66] for the total synthesis of a pentacyclic substructure of communesin B. The highly reactive azadiene component was generated *in situ* from an aziridine under mild conditions, and the desired cycloaddct **111** was obtained in excellent yield.

A convenient route to substituted pyridines[67] is provided by a high-pressure IMHDA reaction of oximino malonate dienophiles such as **112**, followed by aromatization under mild conditions to give **114** (Scheme 10). Further examples of IMDA followed by aromatization are presented in Section 5.11.6.3.

Figure 15 summarizes progress[68] in the use of type 2 IMHDA cycloadditions that allow convenient access to a range of *N*-heterocycles suitable for further synthetic manipulation. In particular, the studies of the *N*-acylazo substrates **116** revealed improved protocols for oxidation of the hydrazide precursors **115**, and allowed an evaluation of Lewis acid catalysis for the IMHDA process. It was found that oxidation of **115** with *N*-bromosuccinimide[69] allowed for the isolation of **116**, which in the presence of 10 mol% $ZnCl_2$ smoothly provided the cycloadduct **117** under mild conditions. This is a rare example[70] of Lewis acid-catalyzed DA reactions of azo compounds. The bridgehead alkene, the lactam grouping, and the N–N bond of **117** provide excellent opportunities for subsequent synthetic elaboration.



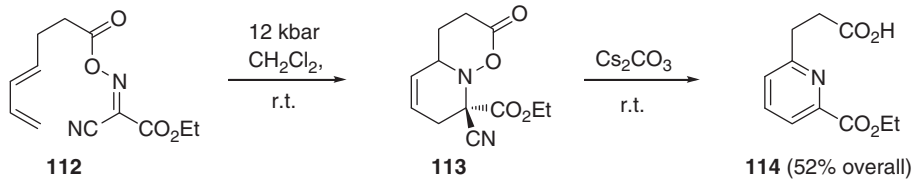


Figure 14 Examples of IMHDA cycloadditions.

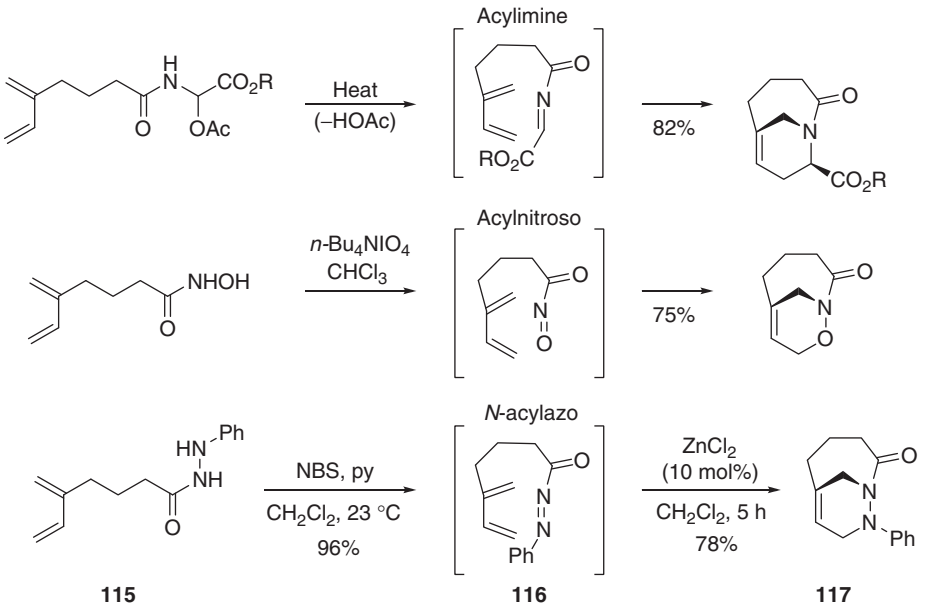

5.11.6.3 IMDA and IMHDA Cycloadditions with Inverse Electron Demand

'Normal' DA, IMDA, and IMHDA cycloadditions are controlled by the ($HOMO_{diene}$–$LUMO_{dienophile}$) combination of frontier molecular orbitals.[71] However, with the correct choice of substituents on the pericyclic array, the electronic situation can be inverted to allow smooth cycloaddition between an electron-deficient diene and an electron-rich dienophile. Figure 16 exemplifies some applications of inverse electron demand IMDA/IMHDA reactions to the synthesis of biologically significant natural products. Vinyl quinone **119** underwent[72] a slow and relatively inefficient thermal IMDA, and addition of Lewis acids (to further lower the diene LUMO) did little to improve the yield. Success was realized by application of high pressure (Section 5.11.3.3)

112 **113** **114** (52% overall)

Scheme 10

115 **116** **117**

Figure 15 Type 2 IMHDA cycloadditions.

which provided the aromatized product **121** in excellent yield, via cycloadduct **120**. Because **120** could not be isolated, the simple diastereoselectivity of the IMDA reaction (*exo*/*endo*) could not be estimated directly, but DFT calculations provided insight on this matter. Sequential IMHDA reactions were used[73] for the total synthesis of pentacyclic *Amaryllidaceae* alkaloids, the first cycloaddition with subsequent loss of N_2 taking place at ambient temperature to give **125** in near-quantitative yield. The second cycloaddition required elevated temperature, but was also very high-yielding, and provided access to advanced intermediate **127** (after loss of N_2 and aromatization by elimination of methanol).

5.11.7 Asymmetric Synthesis via IMDA Cycloaddition

As noted in section 5.11.1, the stereospecificity and regio- and diastereoselectivity of the DA cycloaddition allows – in a single operation – control over up to four contiguous stereocenters, which can be augmented to six by manipulation of the newly formed endocyclic double bond. These features make the DA reaction (in both inter- and intramolecular modes) a uniquely powerful method for stereochemical control in either a relative or absolute sense. The IMDA cycloaddition of **119** (Figure 16) is an excellent example of substrate-controlled asymmetric synthesis, in which a 'permanently resident' stereocenter efficiently steers formation of one or more new stereocenters via a diastereoselective reaction with a highly-ordered transition state. Numerous other examples of substrate control in the IMDA reaction can be found throughout the preceding discussion (starting with the cycloaddition of **3** depicted in Figure 2), and this section will focus on some of the important strategic and tactical developments within the field of asymmetric IMDA cycloadditions. Strategically, the general arena of asymmetric synthesis offers four possibilities: (1) substrate control, (2) the use of chiral auxiliaries, (3) reagent control, and (4) the use of chiral catalysts. This quartet can certainly be regarded as a hierarchy of increasing difficulty, sophistication, and efficiency – with enantioselective catalysis at the pinnacle – but, given the present state of the art, it is still appropriate to consider these approaches as complementary solutions to the very challenging problem of absolute stereocontrol.[74a]

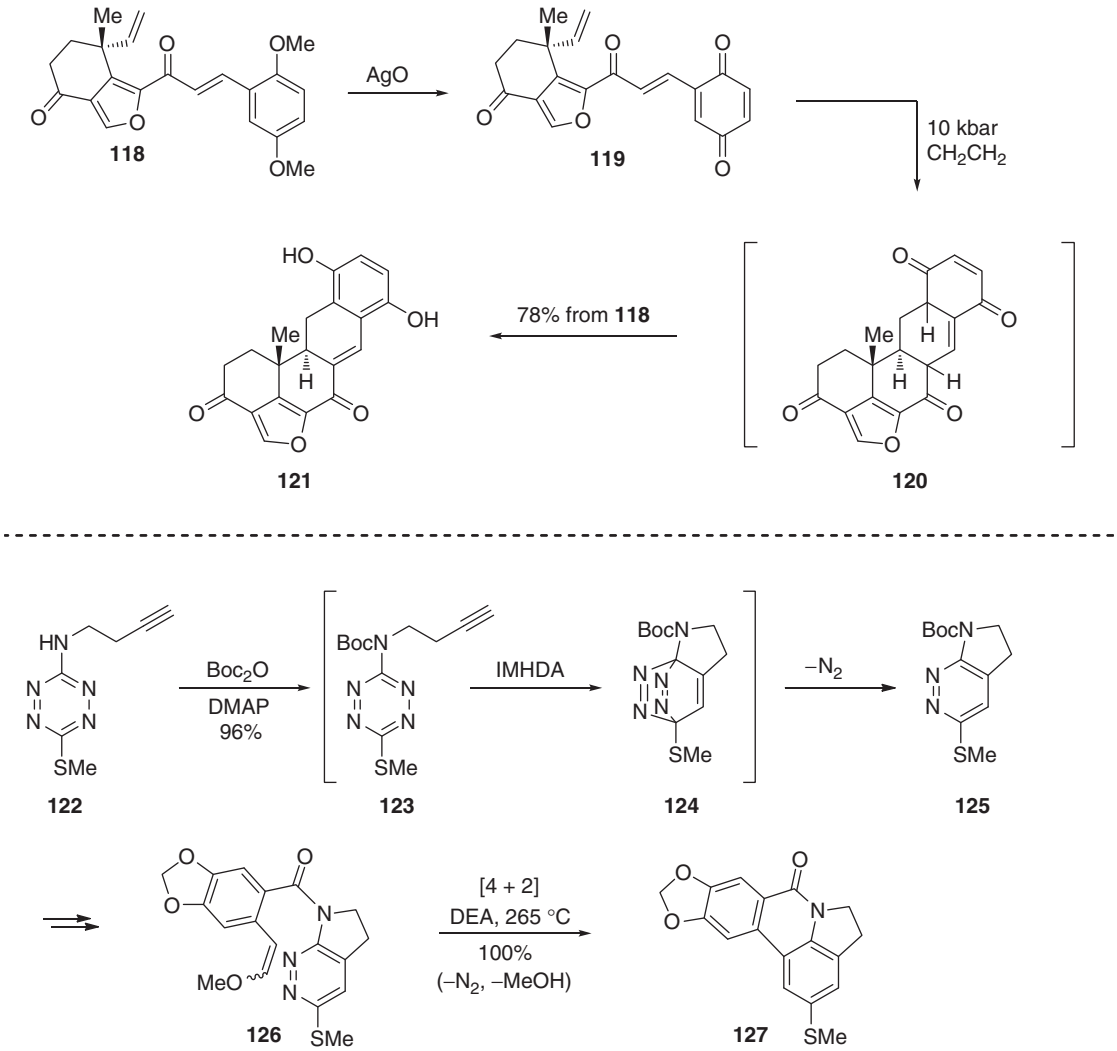

Figure 16 IMDA and IMHDA with inverse electron demand.

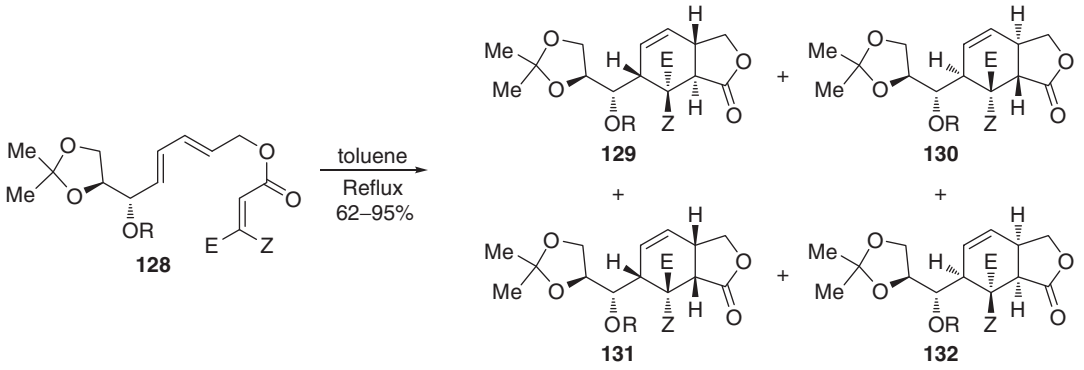
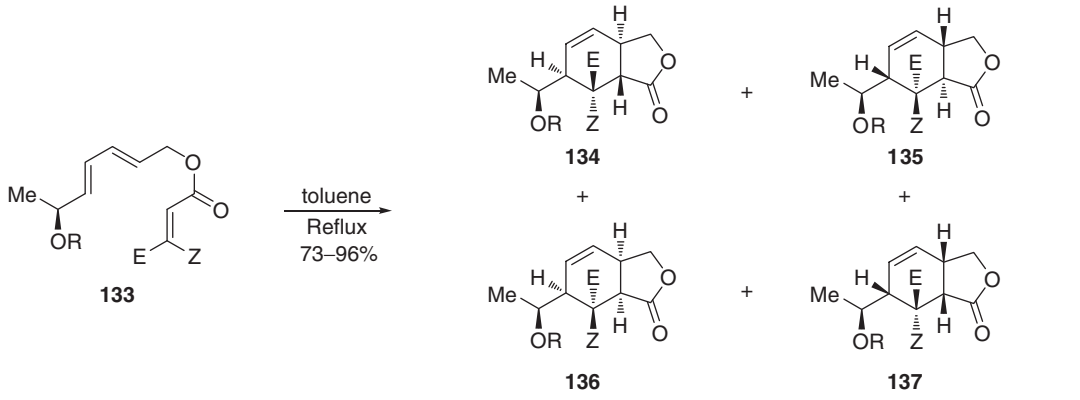


5.11.7.1 Substrate Control of IMDA Cycloaddition

In Section 5.11.2 (Figure 2) the (limited) ability of an allylic stereocenter in the tether of the Type 1 IMDA substrate **3** (X=H) to exert a bias on both the *endo*/*exo* and the π-facial selectivity of the cycloaddition was described.[7] A later study,[74b] also involving a combination of experimental and computational methods, explored the scope and limitations of stereocontrol by a stereogenic center at the terminus of an acyclic diene (Figure 17). Enantiomerically pure substrates were used in all cases. The nature and steric bulk of the group R was found to have a major impact on the diastereoselectivity of the cycloaddition, with bulky silyl groups (triisopropylsilyl (TIPS)) providing the highest levels of stereocontrol. The influence of the homoallylic stereocenter was probed using substrates **133**, which gave considerably lower π-facial selectivities.



As in the previous investigation[7] DFT calculations were used to probe the stereochemical intricacies of the transition states, in particular how the allylic conformational preferences influenced the π-facial selectivity. For substrates such as **133** the reactive conformer was suggested to be that shown in Figure 18, in which the C–OSi bond eclipses the double bond, with a stabilizing electrostatic interaction between the C–OSi and the C2–H bonds. This array is similar to that suggested earlier for silylacetal-tethered IMDA reactions[9] (cf. the reaction of **6** shown in Figure 3). In **133**, it is thus a combination of the stereoelectronic preference of the silyloxy group and the steric properties of the allylic Me group which determines the π-facial selectivity.

5.11.7.2 Use of Chiral Auxiliaries

Of the multitude of chiral auxiliaries that have been developed,[75] the readily available Evans oxazolidinones[76a] and Oppolzer camphorsultams[76b] probably take pride of place, due to their versatility. The use of the former in a type 2 IMDA has actually

R / *E* / *Z*	Yield (%)	**129** : **130** : **131** : **132**
H / H / CO_2Me	86	56 : 32 : 8 : 4
TIPS / H / CO_2Me	68	92 : 7 : 1 : 0

R / *E* / *Z*	Yield (%)	**134** : **135** : **136** : **137**
H / H / CO_2Me	88	41 : 36 : 5 : 18
TIPS / H / CO_2Me	85	63 : 26 : 5 : 6

Figure 17 Substrated controlled IMDA cycloaddition.

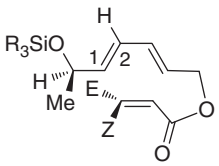


Figure 18 Reactive conformer for the substrate 133.

already been alluded to in Figure 12 (cycloaddition[53] of **90**) but a more detailed discussion is presented below, for the type 2 IMDA[77] of **138** and **140** (Figure 19). These reactions are mediated by a Lewis acid, Me_2AlCl, which forms a chelate with the 1,3-dicarbonyl unit of the dienophile, locking the enone substrate into the s-*cis* conformation that avoids repulsive nonbonded interactions with the oxazolidinone substituent. The molecule then folds into an *endo* transition state with the diene approaching the less hindered face of the dienophile. The diphenylmethyl substituent R provided the highest levels of diastereoselectivity, and a single crystallization gave the pure compound (minor diastereomer not detectable by proton nuclear magnetic resonance (^{1}H NMR) spectroscopy). The Evans oxazolidinones possess all the qualities desirable in a chiral auxiliary: ease of availability, introduction and removal, high levels of diastereoselection, and ease of diastereomer separation.

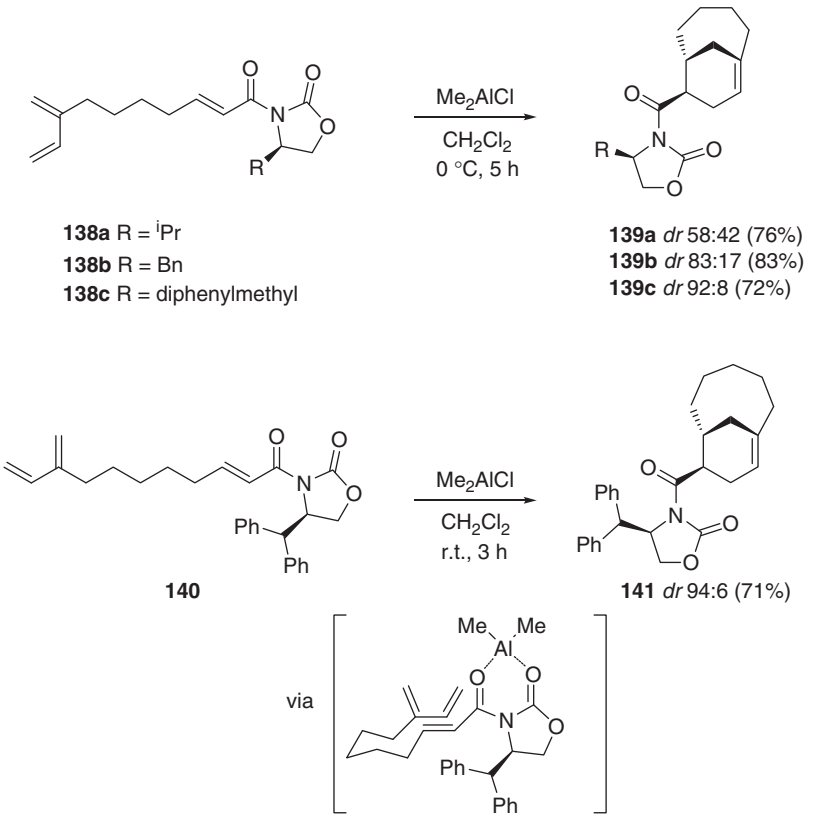

Figure 19 Diastereoselective type 2 IMDA mediated by a chiral auxiliary and a Lewis acid.

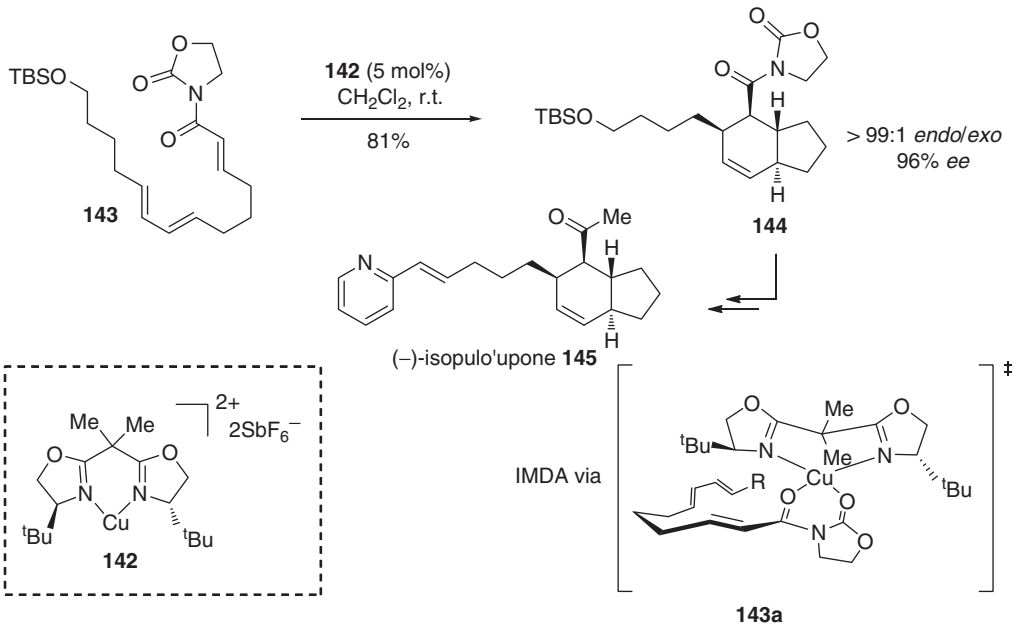
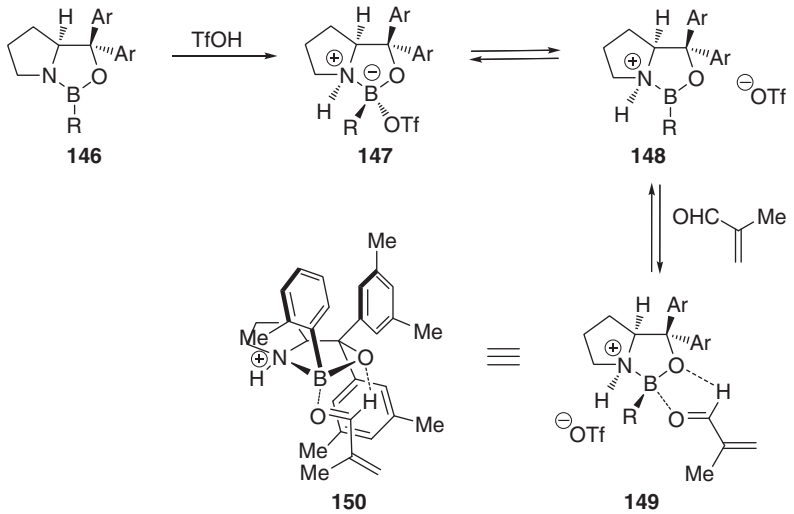
5.11.7.3 Use of Chiral Catalysts



The following sections highlight the use of enantioselective catalysis[78] in IMDA cycloadditions, with emphasis on applications to total synthesis.

5.11.7.3.1 Chiral metal complexes for enantioselective catalysis

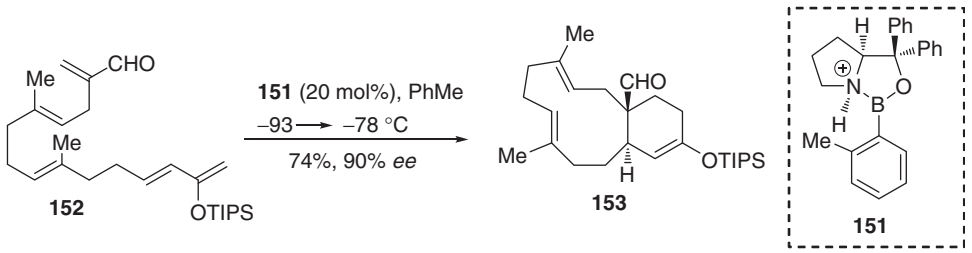
In the 1990s, a major breakthrough in catalytic enantioselective IMDA cycloadditions was provided by chiral C_2-symmetric Cu(II) complexes[79] such as **142** (Scheme 11). The example shown was part of an asymmetric synthesis[80] of the marine natural product (–)-isopulo'upone **145**. The (achiral) oxazolidinone moiety in IMDA precursor **143** is proposed to form a four-coordinate square planar Cu(II)–chiral ligand complex that mediates reaction via essentially a single *endo*-transition state (>99:1 *endo*/*exo*, 98:2 *er*), involving approach of the diene to the Si-face of the dienophile (see assembly **143a** in Scheme 11). The C_2 symmetry of the ligand reduces the number of possible diastereomeric transition states. This IMDA reaction required only 5 mol% of the catalyst and provided **144** in 81% yield under mild conditions. Other noteworthy features are that the reaction could be run at high concentration (1 M in substrate) and that both reactivity and enantioselectivity are dependent on the nature of the counterion, with SbF_6^- being superior to triflate. The chelating ability of the oxazolidinone is reminiscent of its role in the auxiliary-mediated asymmetric synthesis shown in Figure 19.



5.11.7.3.2 Use of chiral oxazaborolidine catalysts

Chiral oxazaborolidine complexes were originally developed[81] to catalyze the enantioselective reduction of ketones, a process which inspired their application to intermolecular DA cycloaddition[2b,82] followed by catalysis of the IMDA reaction.[83] Before discussing the IMDA reaction, the rationale[82] behind the use of chiral oxazaborolidine complexes for enantioselective catalysis will be presented. Precatalyst **146** (Scheme 12) is easily derived from proline, and when subjected to reaction with a strong protic acid such as TfOH forms **147**, which is in equilibrium with **148** (a process which can be monitored by NMR spectroscopy at low temperature). The cationic character of **148** makes it a powerful Lewis acid, well-suited to coordination with carbonyl groups, with the added bonuses of a hydrogen bond to the formyl hydrogen of an aldehyde, as shown for the methacrolein complex **149**, and an attractive π–π interaction between the enal and the proximal aryl group on the oxazaborolidine ring. This exquisite pre-organization should be ideal for enantioselective DA cycloaddition, via assembly **150**. For the intermolecular DA cycloaddition, the optimal R substituent was found to be *o*-tolyl, whereas the best geminal Ar moiety was 3,5-dimethylphenyl: this combination

Scheme 11



catalyzed the DA cycloaddition between methacrolein and cyclopentadiene with 96% *ee* (89:11 *exo/endo* selectivity). One of the 3,5-dimethylphenyl groups effectively blocks one of the π-faces of the dienophile, which controls the approach of the diene.

Scheme 12

This methodology was applied, in stunning fashion,[83] to the IMDA cycloaddition shown in Scheme 13, which formed part of a program aimed at the enantioselective total synthesis of the dolabellane-type marine natural products. The catalyst used in this case was **151**, which proved to be unique in promoting the IMDA cyclization (standard Lewis acids such as Me_2AlCl or application of heat did not lead to the desired product). The transition state for the IMDA cycloaddition is presumed to resemble that proposed for the bimolecular DA reaction shown in Scheme 12, and involves the Si-face of the dienophile. The impressive transformation of **152** to **153** is both a catalytic enantioselective IMDA reaction and a macrobicyclization, and provides a common key intermediate for the asymmetric total synthesis of a variety of natural products.

More recently, computational investigations[84] of similar DA reactions have revealed an alternative transition state assembly that does not involve CH–O hydrogen bonding, and which is probably involved in the [4 + 2] cycloaddition of certain ester-activated dienophiles. The topic of enantioselective catalysis will be returned to in Section 5.11.13, which deals with TADA cycloadditions.

Scheme 13

5.11.7.3.3 Organocatalysis

In recent years, few areas of organic synthesis have burgeoned like organocatalysis, i.e., the use of small organic molecules to catalyze organic transformations.[85] The role of the organocatalyst is to activate one or more of the reactant partners and thereby facilitate the reaction by lowering the energy barrier. Several modes of activation are now available,[85] including transient formation of an iminium species (to lower the LUMO of a carbonyl or α,β-unsaturated carbonyl species) or via enamine formation (to raise the HOMO of an alkene or diene). Both these approaches have recently been applied to catalysis of the IMDA process, and are presented in Figure 20. The imidazolidinone[86a] organocatalyst **155** (as its triflic acid salt) enables the highly diastereo- and enantioselective type 1 IMDA cycloaddition[86b] of **154** via iminium species **156**. In this pretransition state array, the *E*-iminium ion is favored in the orientation shown for steric reasons (minimize clash with ^{t}Bu) whereas the benzyl group effectively shields one of the faces of the dienophile. The diene then folds into the reactive conformation for a π-facial selective *endo*-IMDA reaction. This transformation sets four contiguous centers in a single operation, and provided a short route to the natural product solanapyrone D. This chemistry can be compared with the enzyme-catalyzed IMDA route[46] to the related molecule solanapyrone A shown in Scheme 10. Organocatalyst **155** was also used for the first example of a catalytic enantioselective type 2 IMDA cycloaddition[86b] involving conversion of **159** to **160** with superb levels of diastereo- and enantioselectivity. Proline derivatives **161** can be used as organocatalysts[87] for intramolecular [4 + 2] cycloadditions by electronically activating the diene HOMO via formation of enamines **163** (formed via the corresponding iminium species). The substituent on the stereogenic center of **163** dictates the orientation and π-facial selectivity of the diene in what is formally an *endo*-selective IMDA cycloaddition (formation of **164** can also be described in terms of a stereoselective Michael–Mannich sequence.) Elimination from **164** yields the bicyclic product **165** and regenerates the organocatalyst. An example of the use of organocatalysis in connection with a tandem sequence involving an IMDA cycloaddition is given in Section 5.11.8.1.

5.11.8 Tandem Reaction Sequences involving IMDA Cycloaddition

Tandem reaction sequences are those in which the product of one reaction is the substrate for a subsequent one, allowing two or more transformations to be carried out in a one-pot operation (the terms 'domino reactions'[88a,b] and 'cascade reactions'[88c] are also used). Examples have been mentioned briefly in Sections 5.11.4.2 and 5.11.5.2 (see Figures 9 and 12, respectively) and this section will seek to further illustrate the variety of reaction types that can be harnessed to the IMDA cycloaddition reaction.

5.11.8.1 Tandem Sequences for Polycyclic Carbon Frameworks

Section 5.11.7.3.3 was a showpiece for the area of organocatalysis, and this section will start by continuing on that theme, with an excellent example of the use of organocatalysis for an efficient asymmetric domino sequence,[89] in tandem with a Lewis acid-catalyzed IMDA as the final step.[90] As shown by the retrosynthetic analysis in Figure 21, this elegant Michael/Michael/aldol/IMDA strategy should allow for the one-pot construction of three rings, five carbon–carbon bonds and eight stereocenters. The proline-derived organocatalyst **161** (20 mol%) mediated the first three steps of the cascade involving **166**, **167**, and **168** to yield IMDA precursor **169**, which in the same pot was treated with the Lewis acid Me_2AlCl to promote the cycloaddition. The tricyclic cycloadduct **170** was obtained in 49% yield, 10:1 *dr*, and >99% *ee*, and the sterically most favored *endo* transition state is indicated in Figure 21. These functionalized carbocycles are excellent starting points for the total synthesis of natural products.[90]

Tandem sequences based on a combination of enzyme-catalyzed kinetic resolution (KR) of a racemate, metal-catalyzed racemization of the slow-reaction enantiomer, and IMDA have also been applied[91] to the asymmetric synthesis of tricyclic carbon frameworks (Scheme 14). The combination of the enzyme and the ruthenium catalyst provides an efficient dynamic KR (DKR) of the racemic allylic alcohol **171** in a transesterification reaction yielding the IMDA precursor **172** that reacts via an *exo* transition state to **173**. Compounds such as **173** are useful for the synthesis of important natural products such as forskolin.[91]

Ruthenium catalysts are also well known in alkene/alkyne metathesis chemistry,[92] and this too can be combined with an IMDA cycloaddition, as shown in Figure 22. Baylis–Hillman product **174** was subjected to a one-pot Ru-catalyzed enyne cross-metathesis and Dess–Martin oxidation to give **175**, which spontaneously underwent the IMDA cycloaddition to give **176** in good overall yield. Both *E*- and *Z*-**175** converged to the *cis*-fused cycloadduct via *exo* and *endo* transition states, respectively.[93] A tandem

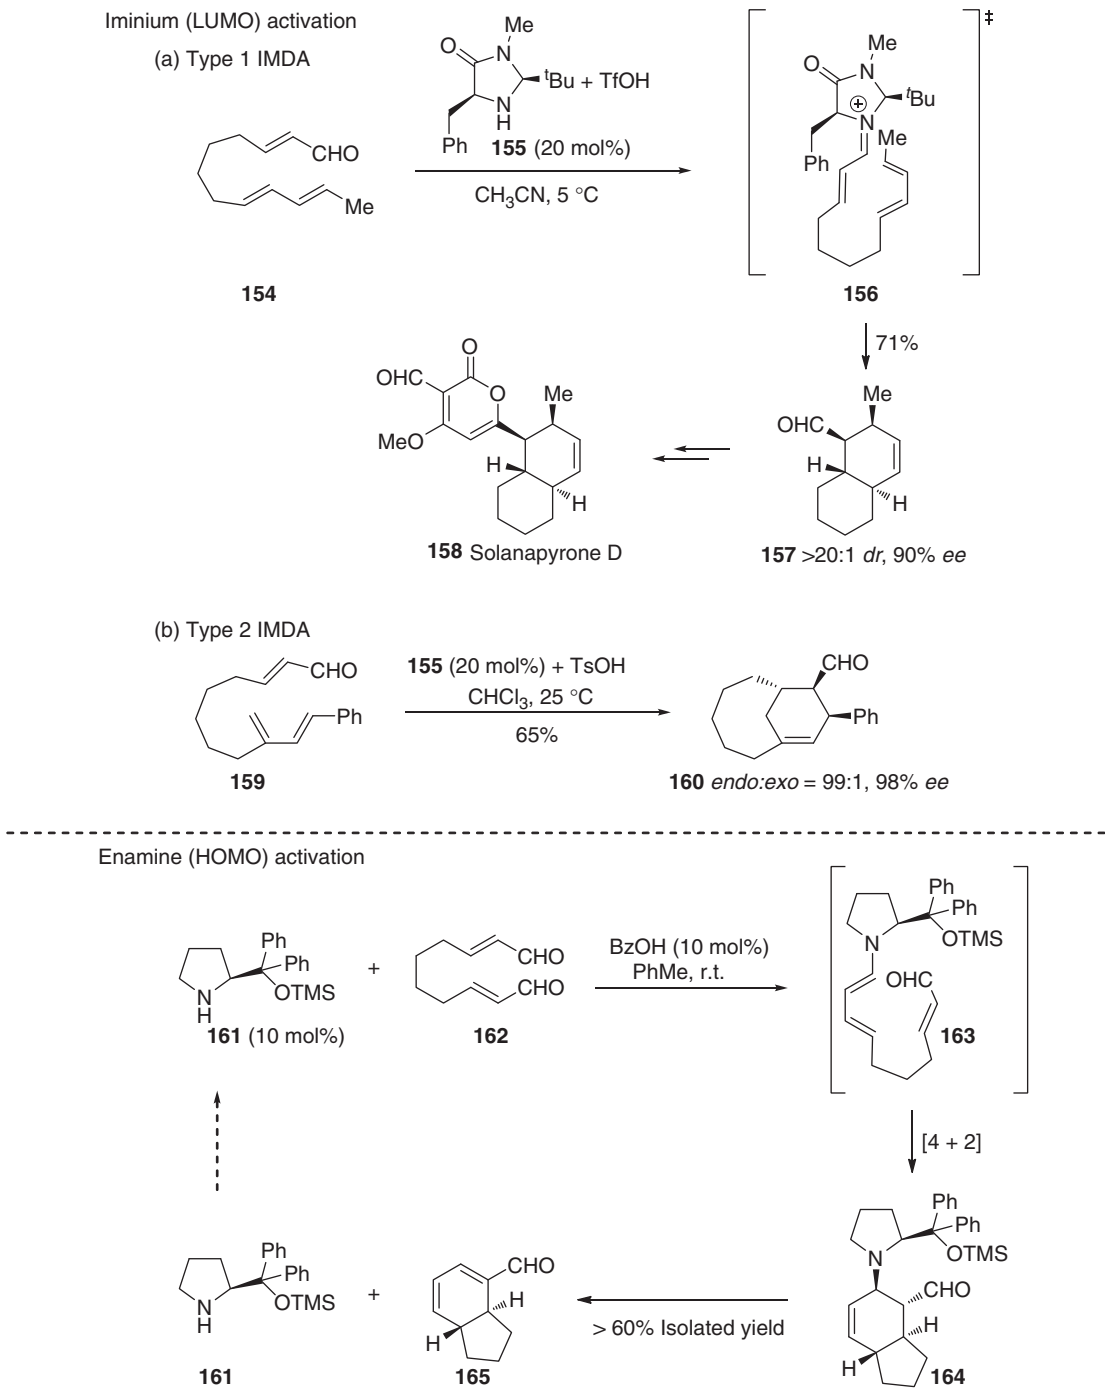


Figure 20 Organocatalyzed IMDA cycloadditions.

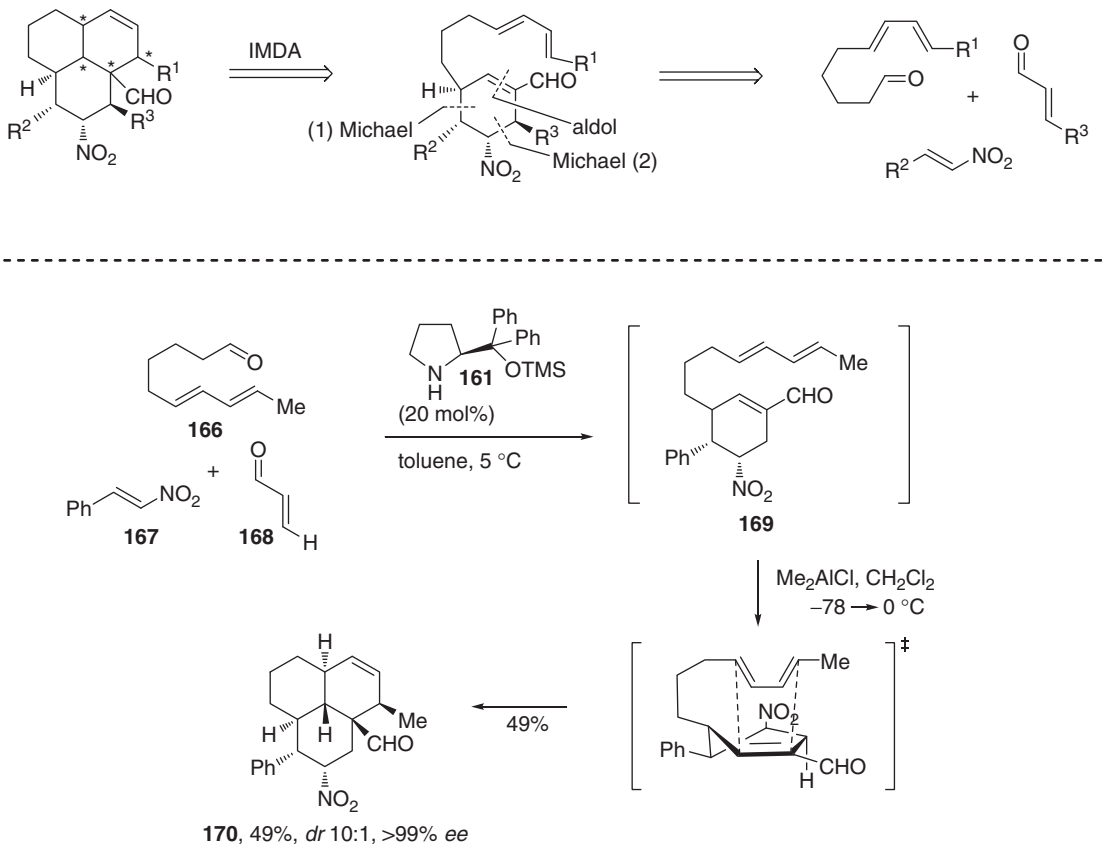
sequence[94] to linear triquinanes characteristic of sesquiterpene natural products is also described in Figure 22. In this sequence, the IMDA cycloaddition of **177** was the first step, and was carried out under conditions of microwave heating[31a] (see also Section 5.11.3.4). The Grubbs II ruthenium catalyst was then added to the solution containing **178**, to mediate a fascinating sequence of ring-closing–ring-opening–cross-metathesis (RCM–ROM–CM) which yielded the linear triquinane **179**.

A projected asymmetric total synthesis of the natural product salvinorin A employed an IMDA cycloaddition in harness with a substrate-controlled Tsuji–Trost allylation (Scheme 15) to set up a *trans* decalin system **182** with control over three contiguous stereocenters, two of which are quaternary.[95] Although this is not strictly a tandem, i.e., one-pot, sequence (the IMDA was unfortunately nonstereoselective, and the diastereomeric cycloadducts had to be separated by recrystallization before the Tsuji–Trost reaction), it is nevertheless a very good example of the strategic use of the IMDA process: the cycloaddition of



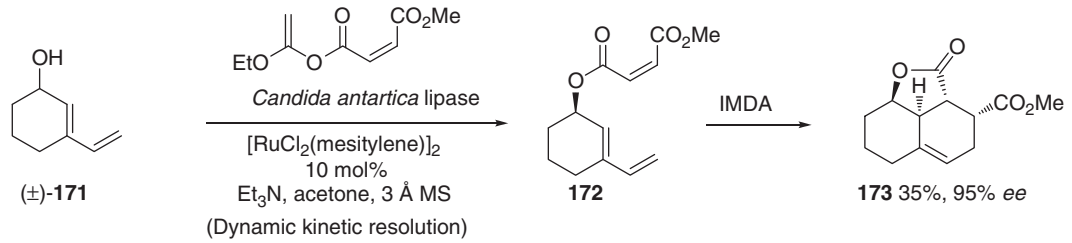


Figure 21 Organocatalysis in tandem with a Lewis acid-catalyzed IMDA cycloaddition.

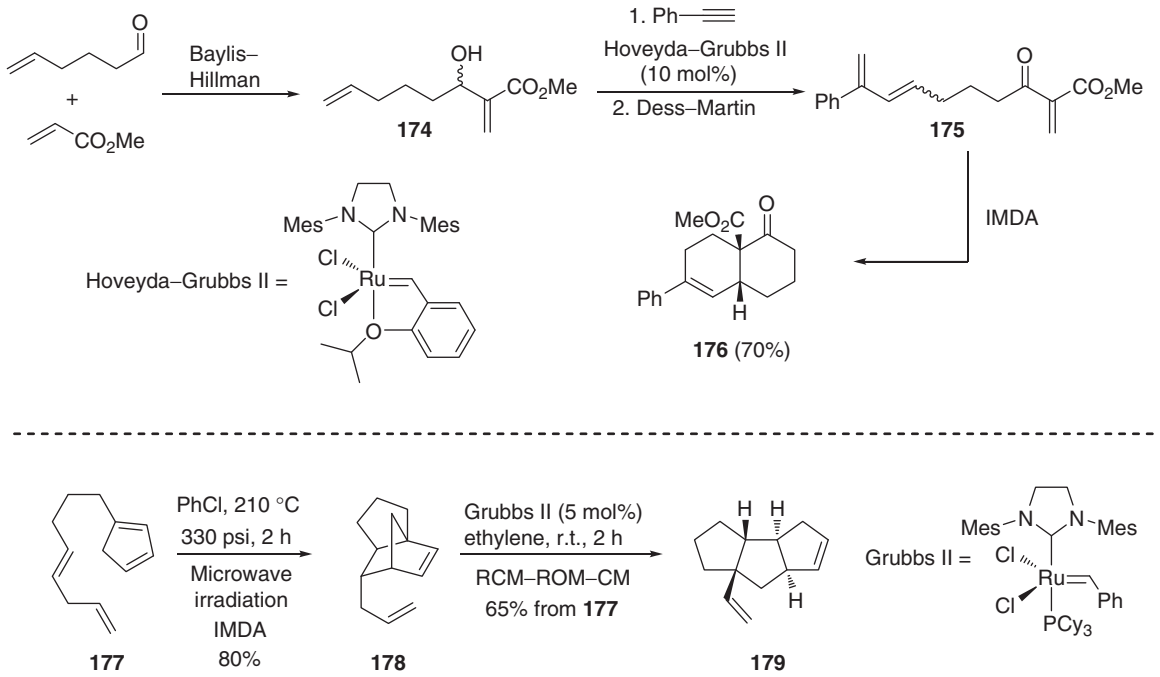
Scheme 14

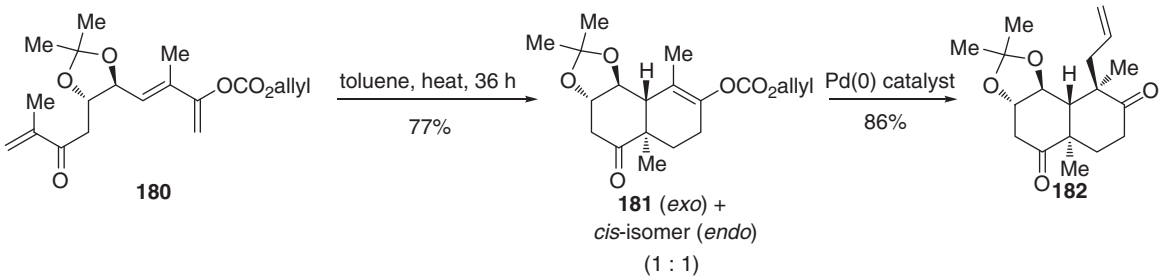
enantiopure **180** (derived from tartaric acid) regioselectively provides an enolate equivalent in **181**, with the allyl group required for the Tsuji–Trost reaction cleverly incorporated. The stereochemical course of the allylation is controlled by the angular methyl group in **181**, leading to **182** via net equatorial addition to the enolate species.

A tandem sequence consisting of two pericyclic reactions (Ireland–Claisen and IMDA) was used as a key step in a very short total synthesis[96] of the structurally intriguing basiliolide/transtaganolide natural products (Scheme 16). Ester **183** was sigmatropically rearranged to **184** via the Ireland–Claisen technique, followed directly by a thermal IMDA cycloaddition with the pyrone diene component. The ratio of diastereomers in the (racemic) product was 2:1 with respect to C8 in **185**, both being formed via *endo* transition states. In this case, there is obviously no low-energy pathway for loss of CO_2 from the cycloadduct (cf. Section 5.11.5.2).

5.11.8.2 Tandem Sequences for *N*-Heterocyclic Frameworks

This section will concentrate on some recent applications of IMDA cycloaddition to tandem sequences for the total synthesis of *N*-heterocyclic systems, particularly biologically significant alkaloids. The discussion of a particularly elegant and efficient cascade sequence for the total synthesis of certain pentacyclic alkaloids is deferred until Section 5.11.12.





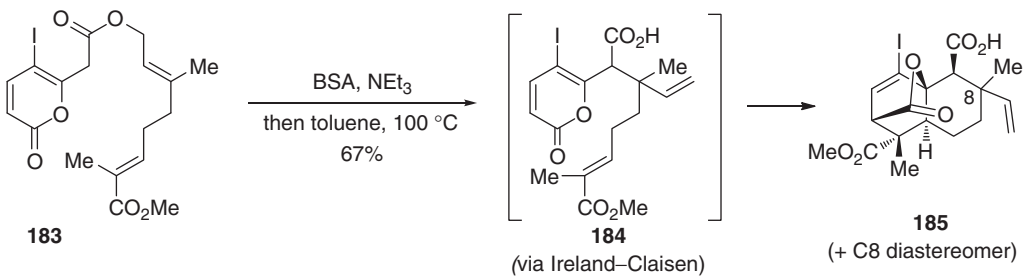


Figure 22 Tandem Ru-catalyzed metathesis/IMDA cycloaddition sequence.

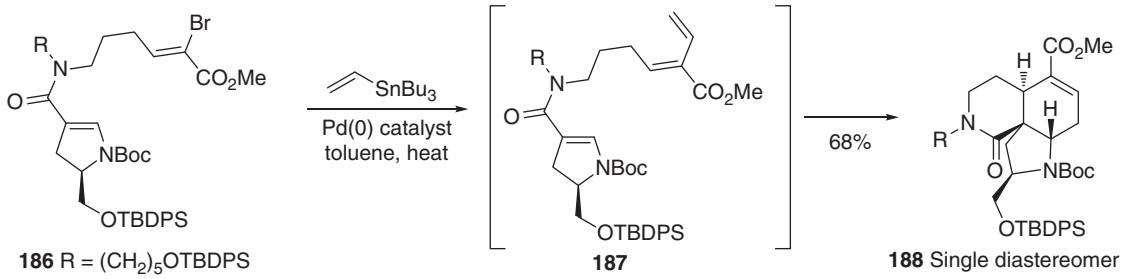
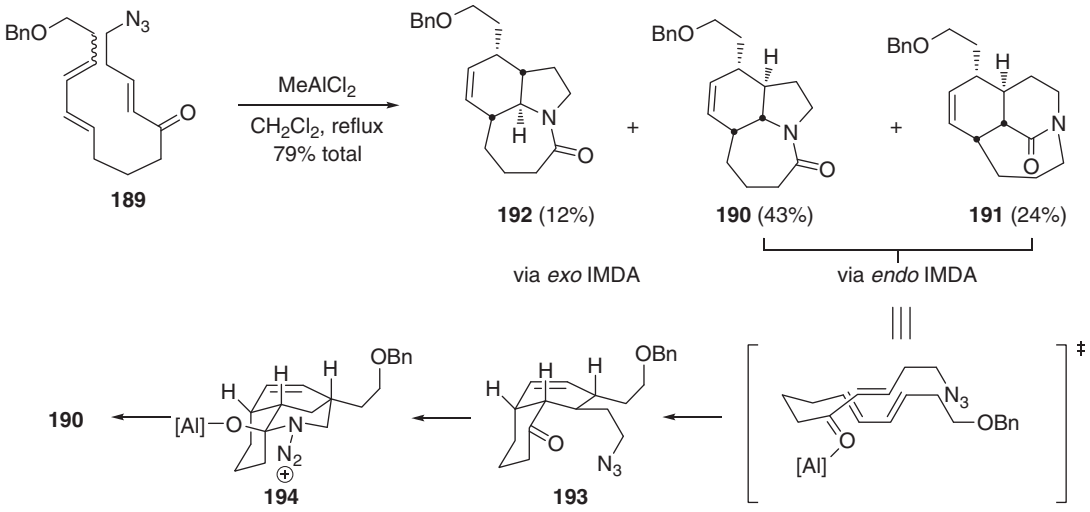


Scheme 15



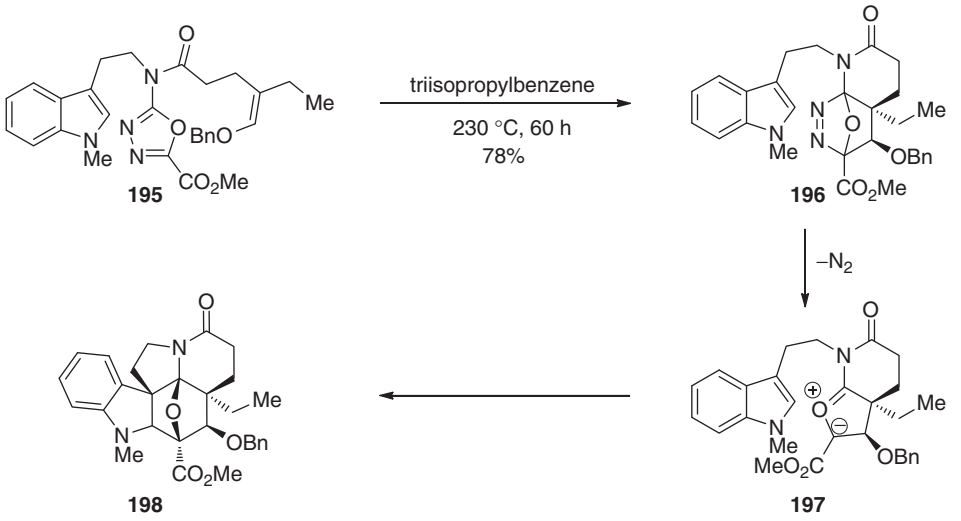
Scheme 16

An enantioselective total synthesis[97] of the marine alkaloid manzamine A took advantage of a tandem Stille cross-coupling–IMDA cycloaddition for preparation of advanced tricyclic intermediate **188**. The Stille reaction was used to fashion the diene component of **187** via stereospecific cross coupling of vinyl bromide **186**. Continued heating of the solution containing **187** smoothly furnished **188** as a single diastereomer in 68% yield. The IMDA cycloaddition is substrate-controlled, the diene approaching the less hindered face of the dienophile (Scheme 17). The biosynthetic origin of the manzamine family of natural products is further discussed in Section 5.11.12.

Scheme 17

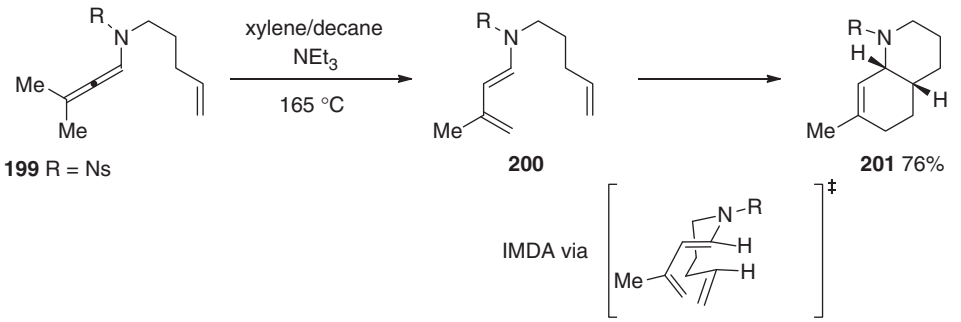
Scheme 18 shows a tandem sequence with azidotriene **189** in which both steps were Lewis acid-catalyzed: a type 1 IMDA was immediately followed by an intramolecular Schmidt reaction.[98] Of the three diastereomers formed, the major one **190** had the correct stereochemistry for use in a total synthesis of the racemic form of the alkaloid stenine. Diastereomers **190** and **191** both emanated from the *endo* IMDA cycloadduct **193** (boat-like arrangement of the forming cyclohexanone ring),[99] which then followed two regioisomeric pathways in the Schmidt reaction; the Schmidt intermediate leading to the major product is **194**, with an equatorially disposed N_2^+ group, (C–to–N) migration occurring in the stereoelectronically favorable antiperiplanar fashion. Compound **192** was produced via the *exo* IMDA–Schmidt tandem route.

Scheme 18



An admirably concise route to the pentacyclic alkaloid vindorosine employed a tandem sequence of IMDA cycloaddition and 1,3-dipolar cycloaddition to set up the pentacyclic system with formation of four new C–C bonds, three rings, and six stereocenters in a single operation (Scheme 19).[100] Prolonged heating of **195** promoted the IMDA reaction with inverse electron demand (Section 5.11.6.3) followed by loss of N_2 from **196** to give 1,3-dipole **197** that completed the intramolecular sequence by reaction with the indole. Product **198** was obtained as a single diastereomer in yields up to 78%, provided the reaction was carried out in dilute solution to disfavor competing bimolecular reactions.

N-tethered allenamides such as **199** were subjected to a stereoselective isomerization to give 1-amidodienes **200** that underwent *endo* selective IMDA cyclization to **201** on heating.[101] A range of bi-, tri- and tetracyclic heterocycles, including quinoline derivatives, could be accessed by this elegant method in good to moderate yields and with diastereoselectivities up to 10:1 (Scheme 20).



5.11.9 Photochemically Generated Reactive Intermediates for IMDA Cycloaddition

5.11.9.1 Photochemical Generation of Reactive Dienophiles

In the 1960s it was reported[102] that ultraviolet irradiation (>300 nm) of *Z*-cycloheptenone and *Z*-cyclooctenone caused isomerization to the corresponding highly strained *E*-isomers that were excellent dienophiles for the intermolecular DA reaction.

Scheme 19

Scheme 20

Surprisingly, more than 30 years were to pass before this technique was applied[103] to the IMDA cycloaddition, some examples being shown in Figure 23. The photoisomerization of 4-substituted cycloheptenones **202** complicates the stereochemical analysis, in that the 4-substituted *E*-enones are planar chiral in addition to having a stereogenic center. Two diastereomers are thus possible, each of which can react via an *endo* or *exo* transition state, for a total of four possible diastereomeric cycloadducts. In the event, irradiation of **203** using a uranium glass filter gave an 88% yield of three cycloadducts **204–206**, the major product being derived from the transition state with three chair-like conformations. The stereospecificity of the DA reaction ensures that the *trans* ring junction is formed exclusively in all cases. The diastereoselectivity of the reaction of **203** could be enhanced significantly (10:1) by running the reaction at low temperature (ca. -75 °C). This also attests to the high reactivity of the *E*-enone: refluxing in xylene is required[103] to promote the thermal IMDA reaction of *Z*-**203**. The effect of the length of the tether was also examined, and an interesting difference was found between the 'regular' IMDA and the IMDAF (Section 5.11.6.1) substrates with a two-carbon tether (compare the reactions of **207** and **209**). For **207**, the IMDA reaction is completely out-competed by the photochemically allowed [2 + 2] cycloaddition.

5.11.9.2 Photochemical Generation of Reactive Dienes

Hydroxy-*o*-quinodimethanes such as **213** are excellent candidates for both bimolecular DA reactions and IMDA cycloadditions, and can be generated[104a] by photochemical enolization of benzaldehyde derivatives **212** (Figure 24). Cycloadducts **214** are densely functionalized polycycles adorned with stereogenic centers (including quaternary) and are useful building blocks for total synthesis. An application to the total synthesis of the hamigeran family of natural products[104b] made use of cycloadduct **216** that was formed very rapidly at ambient temperature via the transient hydroxy-*o*-quinodimethane. The single stereocenter in **215** efficiently controls the way the IMDA substrate folds into the transition state, setting up the crucial *trans* relationship between the angular Me and the ^{i}Pr groups in **216**. Use of a related, enantiomerically pure substrate gave the cycloadduct in >99% enantiomeric purity on a multigram scale.[104b]

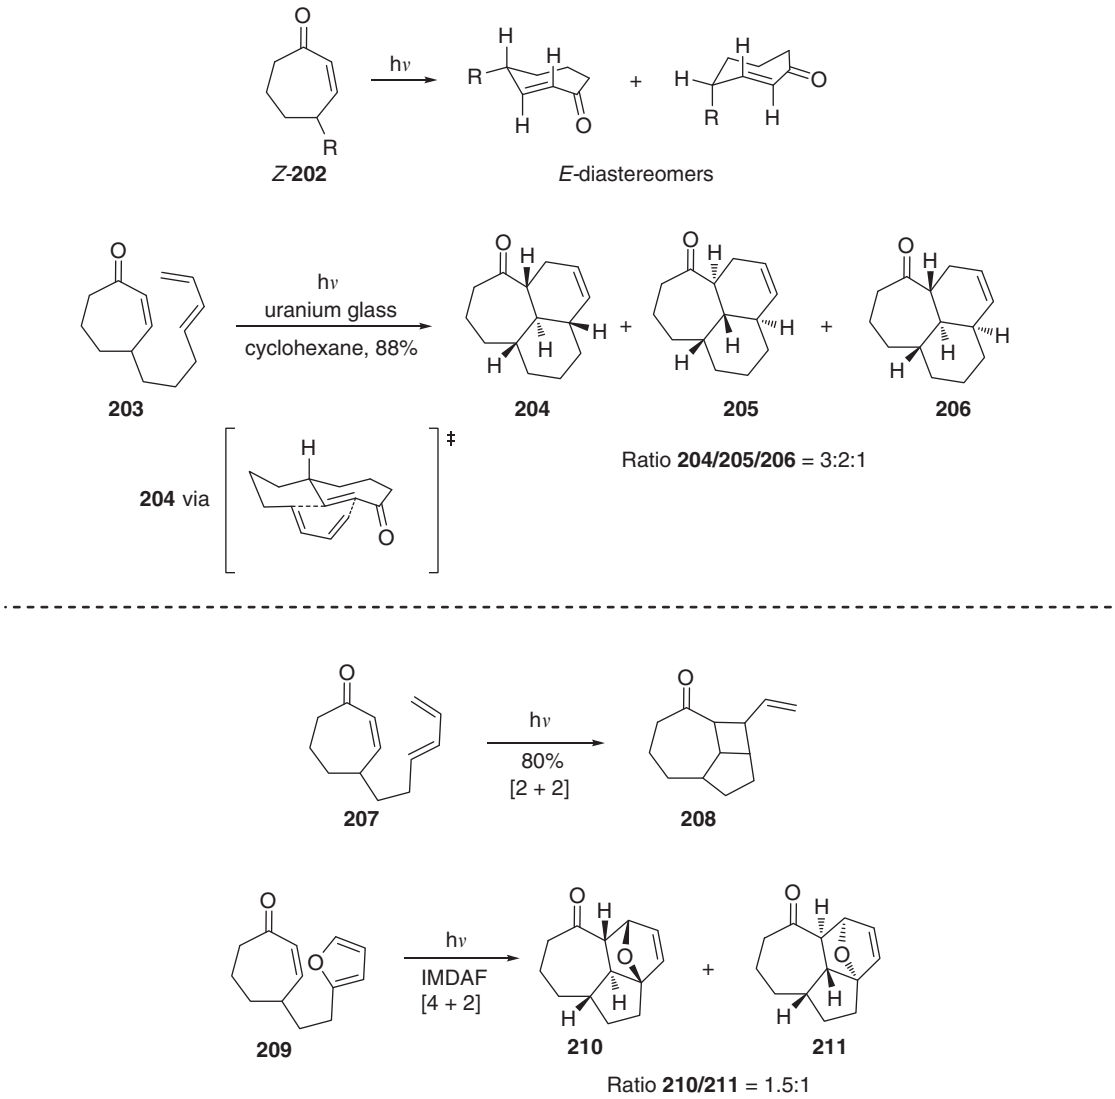


Figure 23 Photochemically induced IMDA cycloadditions.

5.11.10 *Exo* Selectivity Regardless: IMDA Reactions of Cyclopropenone Ketals

Cyclopropenone ketals are chemically surprisingly robust moieties[105] that are nevertheless characterized by high ring strain energy (ca. 100 kJ mol^{-1}). A [4 + 2] cycloaddition with the cyclopropenone acetal as the dienophile would considerably relieve the ring strain, making these species attractive substrates for both DA and IMDA reactions. Reactivity and stereoselectivity in the IMDA mode were studied[105] using the substrates **217** shown in Scheme 21. The substituents R in **217** were chosen to ring the changes in the electronic properties of the diene (from electron-deficient, through aryl-conjugated and unactivated, to electron-rich). In all cases, the *exo* products were the only detectable ones, the fastest reacting dienes being **217a** and **217d**, for which the cycloaddition was complete at 25 °C. The ease of reaction of the unactivated diene **217c** (12 h at 45 °C) is remarkable, and under these mild conditions the IMDA reaction is considerably more facile than potential competitors such as [1 + 2], [3 + 2], and [3 + 4] cycloadditions[105] via singlet vinylcarbenes.

5.11.11 Recent Applications of IMDA Cycloadditions to Total Synthesis

Given the extraordinary power and versatility of the IMDA cycloaddition, it is hardly surprising that this methodology has been utilized time and again in impressive multistep total syntheses, some of which have been referred to in the previous sections. An excellent far-reaching review of applications of IMDA reactions to the stereoselective total synthesis of complex and biologically active natural products appeared[3a] in 2005, followed by a shorter version[3b] in 2009, so in this section only a selection of examples

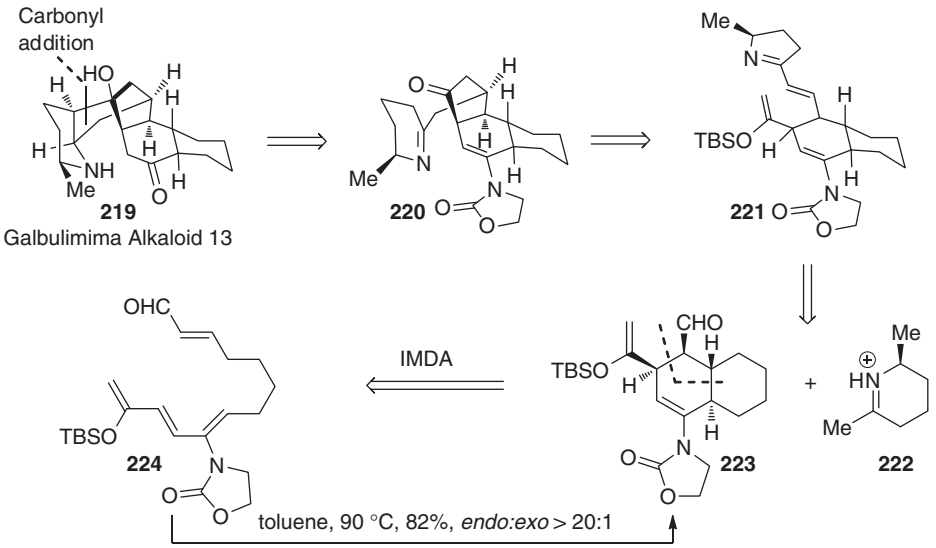
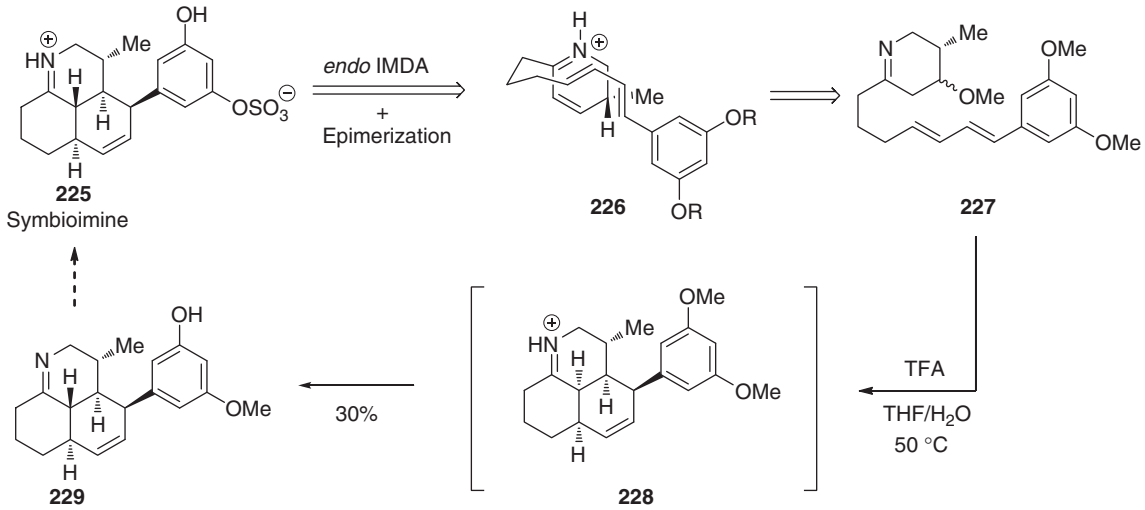
will be presented. A variety of natural product types (following the convention of reference[3a]) is considered, and only completed total syntheses are discussed. Each synthesis is laid forth in retrosynthetic form, to highlight the strategic importance of the IMDA transformation, without much detailed discussion of the steps before, or following, the cycloaddition event.



5.11.11.1 Alkaloids

5.11.11.1.1 Total synthesis of (–)-galbulimima alkaloid 13



The galbulimima alkaloids such as galbulimima alkaloid 13 (**219**, Scheme 22) present a major challenge to synthetic planning and execution.[106] Careful consideration of possible biosynthetic pathways led to the strategic bond disconnection shown for **219**, which simplified the target to tetracyclic intermediate **220**. Further retrosynthetic simplification revealed **221**, which in turn was traced back to two relatively simple building blocks **222** and **223**, the latter containing the IMDA retron (the oxazolidinone moiety serves as a masked ketone). It was decided to prepare **223** in racemic form and couple it with the enantiomerically pure reagent derived from regioselective lithiation of **222**, followed by separation of the diastereomeric products. The IMDA precursor **224**, prepared via a short convergent route, was heated in toluene to give key intermediate **223** in 82% yield and with excellent diastereoselectivity (>20:1, *endo*:*exo*). The successful completion of the total synthesis allowed a revision of the absolute stereochemistry of the natural product, highlighting the important role which synthesis still has to play in structural elucidation and assignment.[107]

5.11.11.1.2 Total synthesis of (+)-symbioimine

The marine natural product symbioimine (**225**, Scheme 23) has been alluded to in Sections 5.11.3.4 and 5.11.4.1, and was of interest for both its biological properties (possible treatment of osteoporosis) and its mode of biosynthesis (originally proposed[30] to occur via an unusual *exo*-selective IMDA reaction). As shown in Scheme 23, an alternative route[108] is available via the more common *endo*-selective IMDA cycloaddition of **226** followed by epimerization to the thermodynamically more stable product containing all-*trans* ring junctions. The IMDA precursor **226** is a chiral cyclic iminium ion, expected to induce high levels of

Scheme 22

Scheme 23

diastereoselectivity in the cycloaddition reaction, and was generated by acid treatment of readily available **227**. Under the conditions for the cycloaddition, the initially formed **228** epimerized to **229** that was isolated as a single diastereomer, albeit in modest yield (ca. 30%). The poor yield notwithstanding, this brief route provided evidence to support the modified biosynthetic pathway.

5.11.11.1.3 Total synthesis of (+)-yohimbine

The indole alkaloid yohimbine **230** is a classical target for total synthesis, and an interesting recent approach[109] is shown in Figure 25. The synthesis was projected to rely on two key features: enantioselective synthesis of **233** and *endo*-selective IMDA cycloaddition of **232** or **231**. The first problem was readily solved via a highly enantioselective (94% ee) catalytic asymmetric acyl-Pictet–Spengler reaction of **234**. Based on literature precedent, the IMDA *endo* selectivity of **231** and/or **232** was a greater cause for concern, and DFT calculations on model substrates were used to guide the synthetic efforts. The calculations actually predicted poor *endo* diastereoselectivity for **231**, but this option was nevertheless pursued. It was reasoned that a chiral catalyst for the IMDA reaction could be brought into play should the substrate-controlled route fail. The substrate for the crucial IMDA reaction was **235** that under mild conditions of (achiral) Lewis acid catalysis delivered the desired cycloadduct **236** in high yield and as a single diastereomer. The very high *endo* diastereoselectivity was not predicted by the original calculations (which involved an unprotected indole nitrogen), and was found to be dependent on the indole protecting group. Further modeling of the transition states

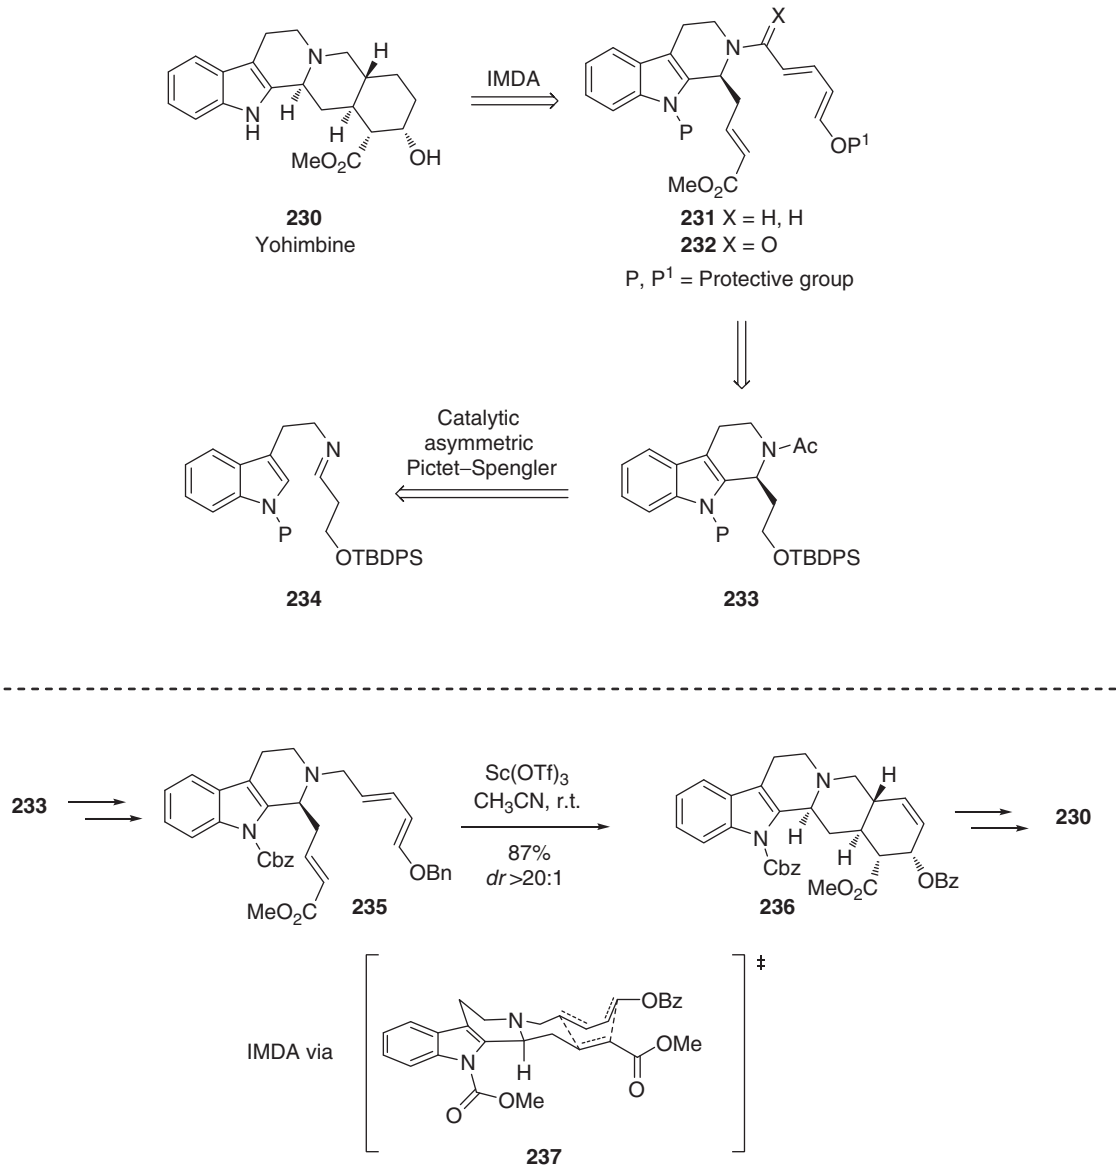


Figure 25 IMDA cycloaddition as a key step in the total synthesis of Yohimbine.

revealed the *endo* array **237** to be the one of lowest energy, dictated in part by the strong preference of the carbamate group to be coplanar with the indole ring.

5.11.11.1.4 Total synthesis of the zoanthamine alkaloids

The zoanthamine alkaloids[110] (e.g. norzoanthamine, **238**, Figure 26) are truly daunting synthetic targets, but the IMDA cycloaddition has on two occasions risen admirably to this task. In the first approach,[111] the bis-*N*,*O*-acetal was disconnected first followed by retrosynthetic manipulation of **239** to reveal the IMDA retron in **240**. IMDA substrate **241** was projected to be available via photosensitized oxidation of the trisubstituted furan moiety in **242**. This demanding IMDA, if successful, would set up two quaternary all-carbon stereocenters in a single operation. Not surprisingly, high temperature was required for the cycloaddition, which proceeded in near-quantitative total yield with a 72:28 ratio in favor of the desired *exo* adduct. Key intermediate **244** was isolated as a crystalline solid in 51% overall yield. The pretransition state conformation for the *exo*-selective cyloaddition is shown in Figure 26, and is the arrangement that minimizes steric interactions between the two methyl groups on the perimeter of the pericyclic array. This crucial transformation that enabled completion of a benchmark total synthesis required 43 steps, with an overall yield of 2.2% (an average of 92% per step).

A complementary route[112] to norzoanthamine, relying on a similar endgame involving the heterocyclic moieties, was devised on the basis of an alternative IMDA cycloaddition (Figure 27). Tetracycle **245** was envisioned to arise from **246** via an IMDA reaction and a Saegusa oxidation. Retrosynthetically, **246** could in turn be traced back to the enantiomerically pure Hajos–Parrish

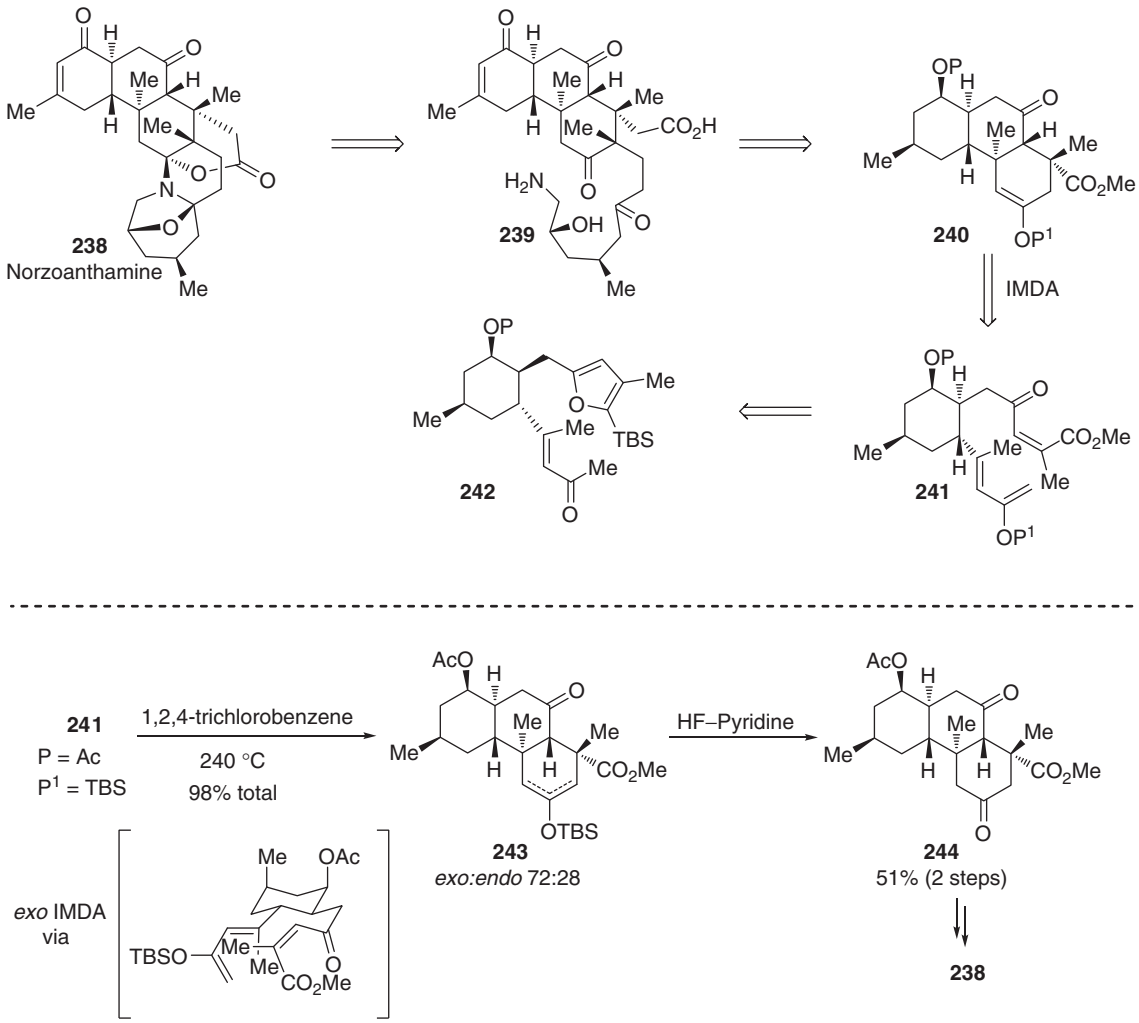

Figure 26 IMDA cycloaddition as a key step in the total synthesis of Norzoanthamine.

ketone **247**. In practice, it proved impossible to obtain **246** (R=Me) in useful yields, so the key IMDA was carried out on the simpler diene with R=H. After Saegusa oxidation of cycloadduct **248**, tetracycle **249** was obtained as a single diastereomer. The 'missing' methyl group could then be introduced via a Saegusa oxidation–Michael addition sequence. The conformation of **246** which leads to the IMDA transition state is proposed to have a chair-like array with the *O-tert*-butyldimethylsilyl (OTBS) pseudoequatorial, a key feature in determining the excellent diastereoselectivity observed.

5.11.11.1.5 Total synthesis of strychnine

For the organic chemist, few natural products have captured the imagination like strychnine[113] (**250**, Figure 28) and the IMDA cycloaddition has played a prominent role in the total synthesis of this intriguing target molecule.[114a,114b] To date, the shortest synthesis[114c] of strychnine (in racemic form) proceeds via a longest linear sequence of only six steps. The key transformation was a formal IMDA cycloaddition involving a Zincke aldehyde and an indole as the diene and dienophile components, respectively (see structure **254**). Intermediate **254** was itself to be assembled easily from three very simple starting materials. In practice, **254** was replaced by **255** which underwent base-promoted cycloaddition and conjugation to yield **256** in 64% yield. Conversion to **253** (M=$SiMe_3$ and R=H) was also efficient, but the otherwise impressive progression toward the target almost foundered completely on the transformation of **253** to the Wieland–Gumlich aldehyde **252** (an operation requiring a Brook rearrangement and a conjugate addition that proceeded in a meager 5–10% yield, despite very extensive experimentation).

5.11.11.2 Polyketides

5.11.11.2.1 Total synthesis of dynemicin A

Dynemicin A **257** (Scheme 24) is a member of one of the most unusual class of natural products, the enediyne antibiotics. After insightful retrosynthetic analysis, a total synthesis[115] of racemic dynemicin A was devised that relied on an early-stage Lewis

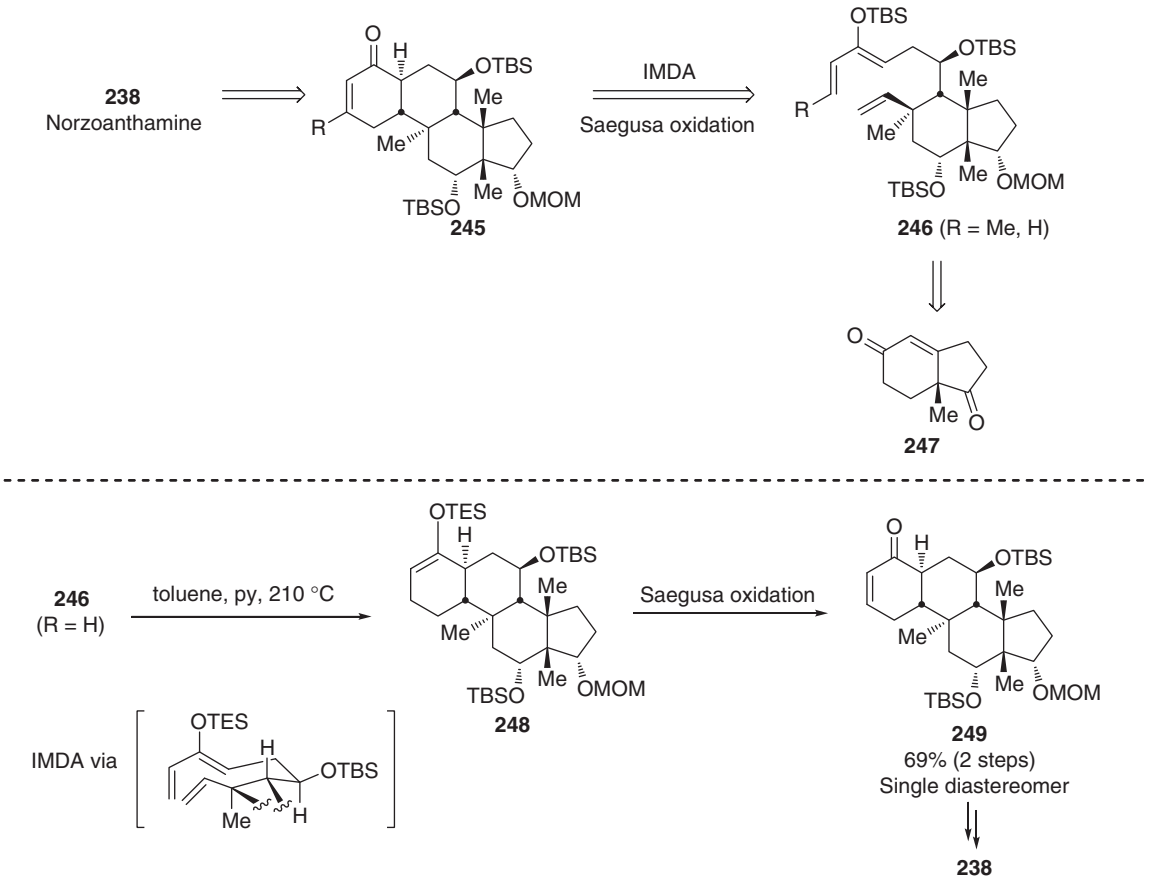

Figure 27 An alternative IMDA route to Norzoanthamine.

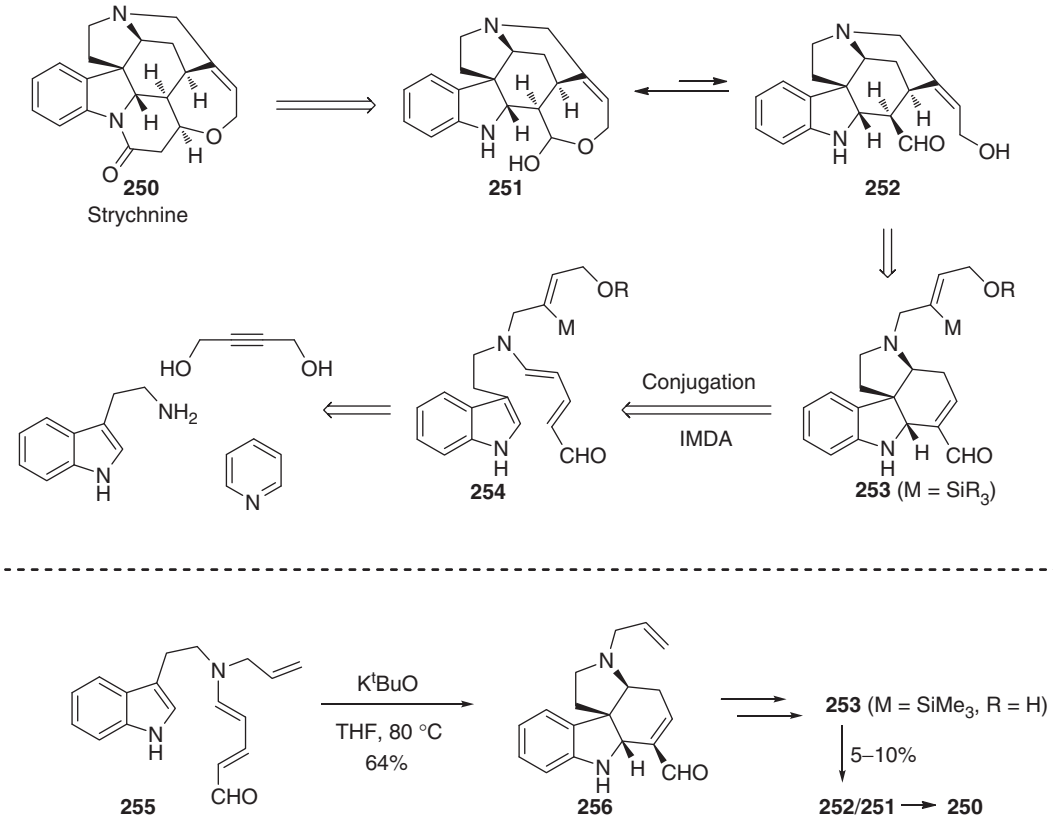
acid-catalyzed IMDA to cleverly set up two stereocenters of key intermediate **259** via **260** and **261** (compare the asterisked carbons in the latter two structures). The IMDA cycloaddition of **262** was completely *endo*-selective provided a Lewis acid was used (the diastereoselectivity of the purely thermal process was only 3: 1). As can be imagined from the extraordinary (and sensitive) structure of the target molecule, the rest of the dynemicin A adventure involved the solution of many challenging synthetic problems at both the strategic and tactical levels, a discussion of which is beyond the scope of this writing. Suffice it to say that one of the late-stage key steps involved a (formal) intermolecular DA cycloaddition with **259** as dienophile and the anion of **258** as diene.

5.11.11.2.2 Total synthesis of (–)-chlorothricolide

Chlorothricolide (**263**, Figure 29), the aglycon of the antibiotic chlorothricin, is a target molecule that virtually impels the application[116] of cycloaddition methodology, given the presence of two DA retrons. As shown in Figure 29, the synthesis was planned to proceed via a tandem (Section 5.11.8) inter- and intramolecular DA sequence, defining **264** and **265** as the key building blocks. Consideration of all the feasible DA/IMDA stereo- and regiochemical combinations reveals 96 possible products from the proposed tandem sequence. Fortunately, the desired mode of reaction is expected to be one of the lowest energy: for example, for the IMDA process the C2–C3 bond is the most reactive dienophile (lowest LUMO) and will react fastest with the C8–C11 diene. For the bimolecular process, previous studies[116] had indicated that the C18–C21 portion of the conjugated triene subunit would react fastest with **265**. The synthesis was thus approached with confidence, and the results of the tandem cycloaddition are summarized in Figure 29. Heating **264** and **265** in toluene yielded initially a mixture of **266** (ca. 40%) and **267** (ca. 30%) as the major components, the latter being resubjected to the action of **265** to provide the desired **266** in 55–59% yield overall (the C20–C21 double bond isomerizes under the conditions of the cycloaddition, and only the *Z* isomer undergoes the DA reaction). The key elements of stereocontrol are the high diastereofacial and *exo* selectivity of **265** for the bimolecular DA, and the steric directing effect of the bulky C9-trimethylsilyl group for the IMDA (see Figure 29, bottom). The preferred IMDA transition state is the one in which destabilizing nonbonded interactions are minimized, and the trimethylsilyl group is a surrogate for the C9–H bond of the target molecule.

5.11.11.2.3 Total synthesis of (+)-cochleamycin A

A biosynthetic proposal for (+)-cochleamycin (**268**, Scheme 25) involves an IMDA reaction of a polyketide-derived intermediate. A total synthesis[117] of **268** via key intermediate **269** employed a Lewis acid-catalyzed IMDA reaction to set up the tetrasubstituted



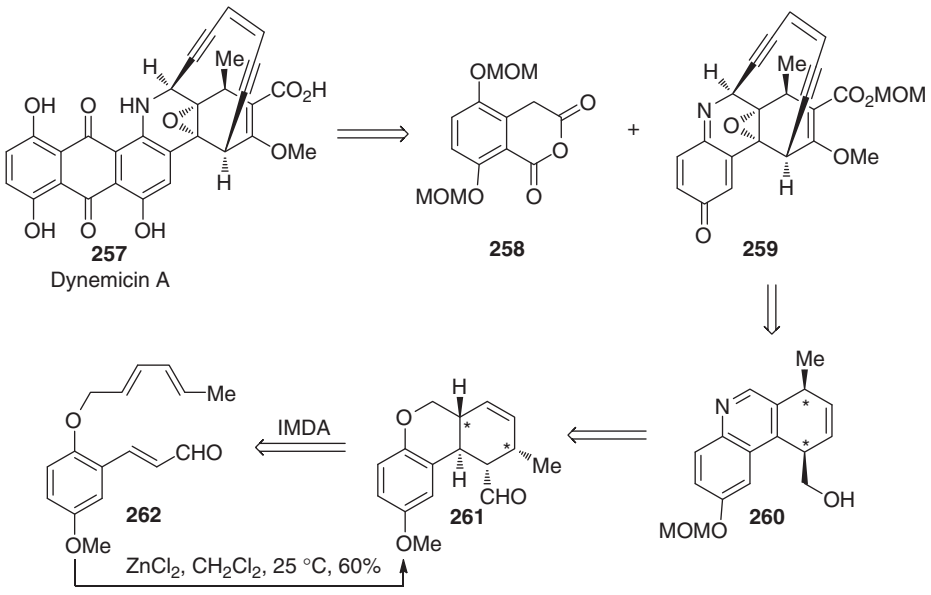


Figure 28 IMDA cycloaddition as a key step in the total synthesis of Strychnine.

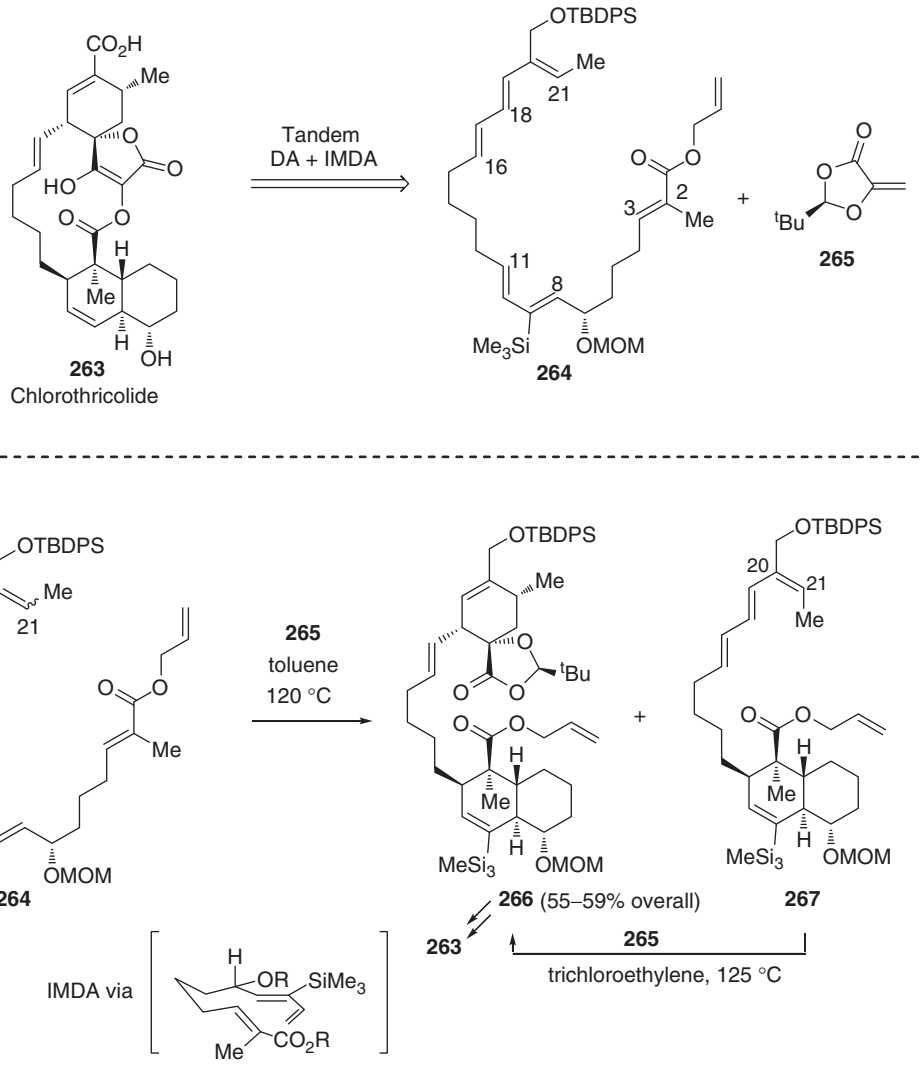
Scheme 24

tetrahydroindan unit of **270** from the (*E,Z,E*)-triene **271**. The required *Z* configuration at the C6–C7 bond (which controls the *cis* fusion geometry in the cycloadduct) was secured by controlled reduction of the corresponding alkyne, formed by a Sonogashira cross-coupling reaction (C7–C8). A possible *endo* transition state leading to **270** is depicted as a Newman projection about the C4–C5 bond of **271** (Scheme 25). These studies provide yet another example of the use of total synthesis for the determination of absolute configuration.



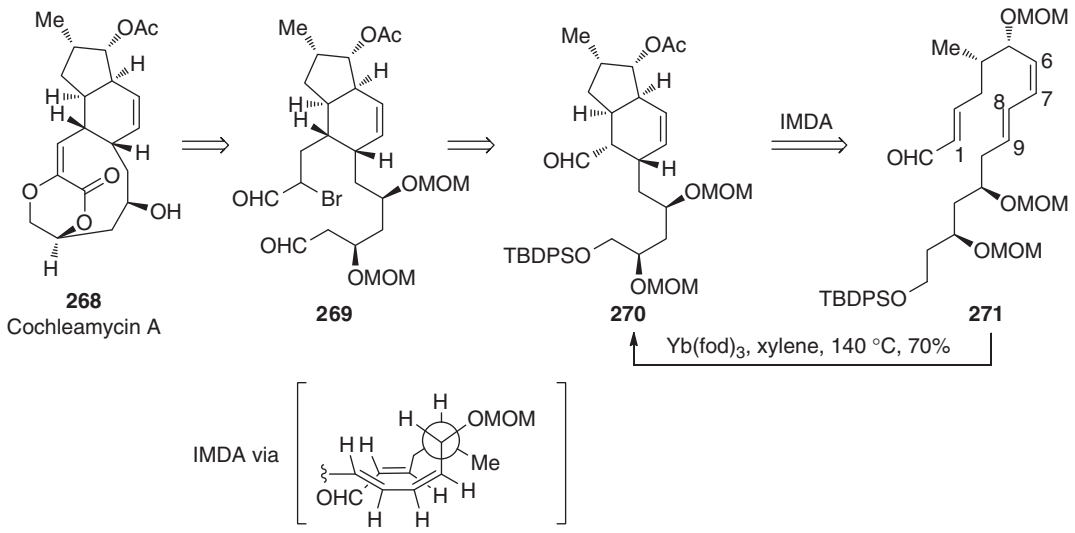


Figure 29 IMDA cycloaddition as a key step in the total synthesis of Chlorothricolide.

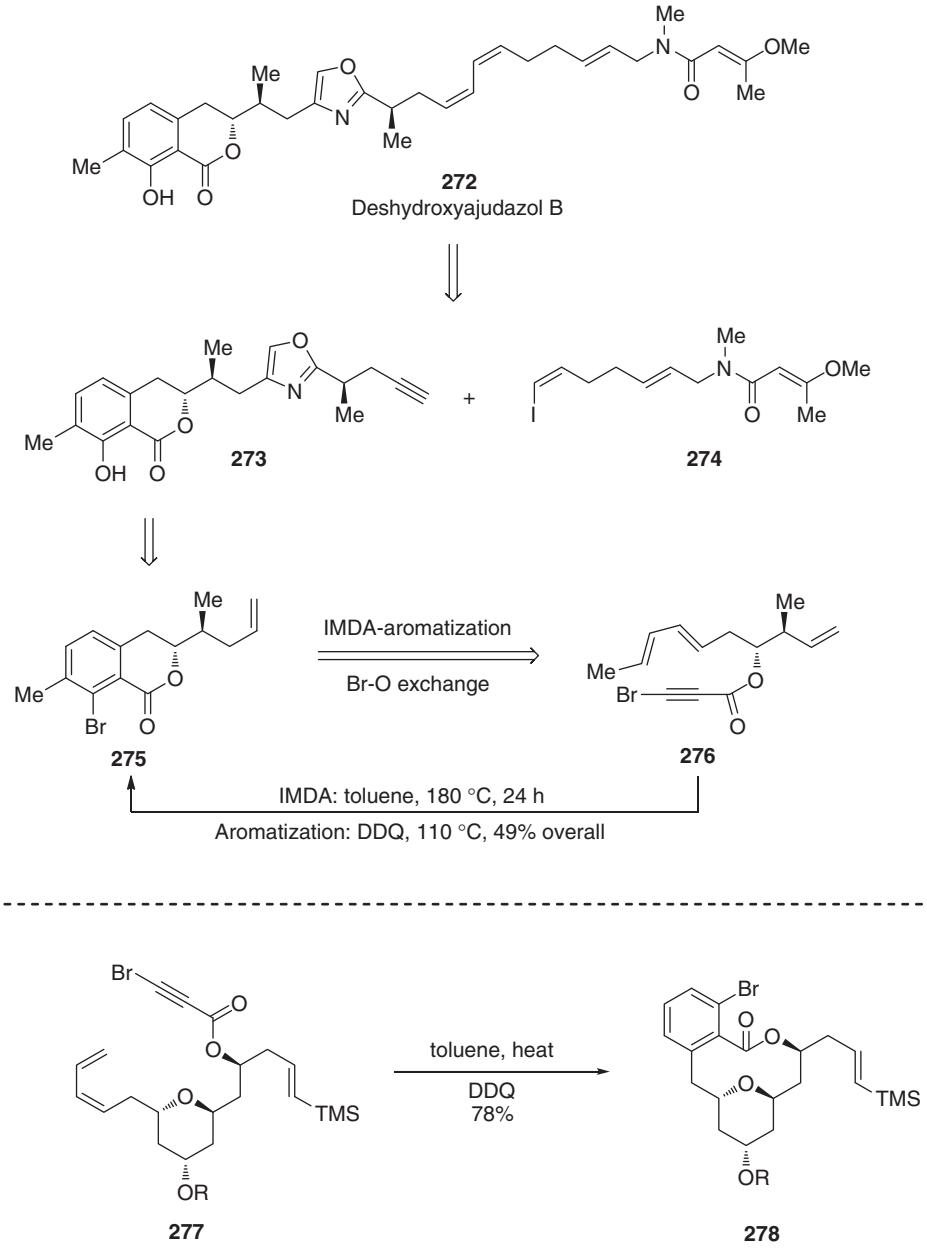
Scheme 25

5.11.11.2.4 Total synthesis of 8-deshydroxyajudazol B

At first sight, 8-deshydroxyajudazol B (**272**, Figure 30, top) is not a prime candidate for an IMDA disconnection, but closer analysis does in fact reveal an IMDA strategy[118] for construction of the isochromanone unit. This is based on retrosynthetic Br→O exchange and an aromatization process, defining **276** as the precursor for the synthesis of **275**. The IMDA-aromatization sequence was performed in tandem, with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone being used to oxidize the cyclic 1,4-diene produced by the cycloaddition. This technique was based on an earlier formal total synthesis[119] of the natural product (–)-apicularen A in which an elegant IMDA-aromatization sequence with **277** was used to simultaneously create a 10-membered ring (Figure 30, bottom).



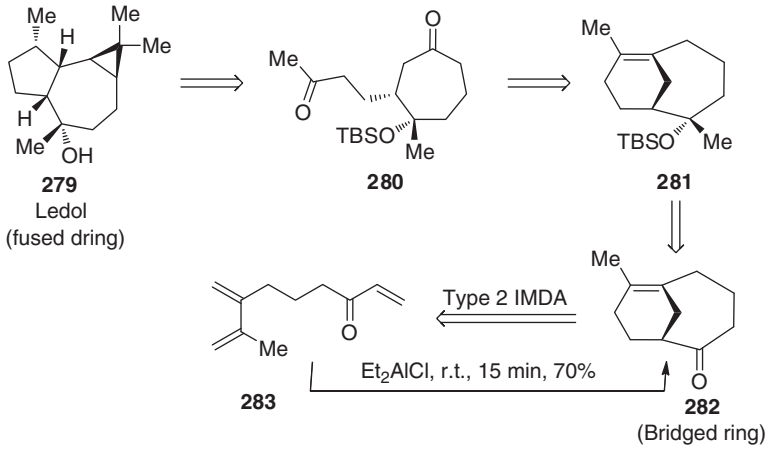


Figure 30 IMDA cycloaddition as a key step in the total synthesis of Deshydroxyajudazol B.

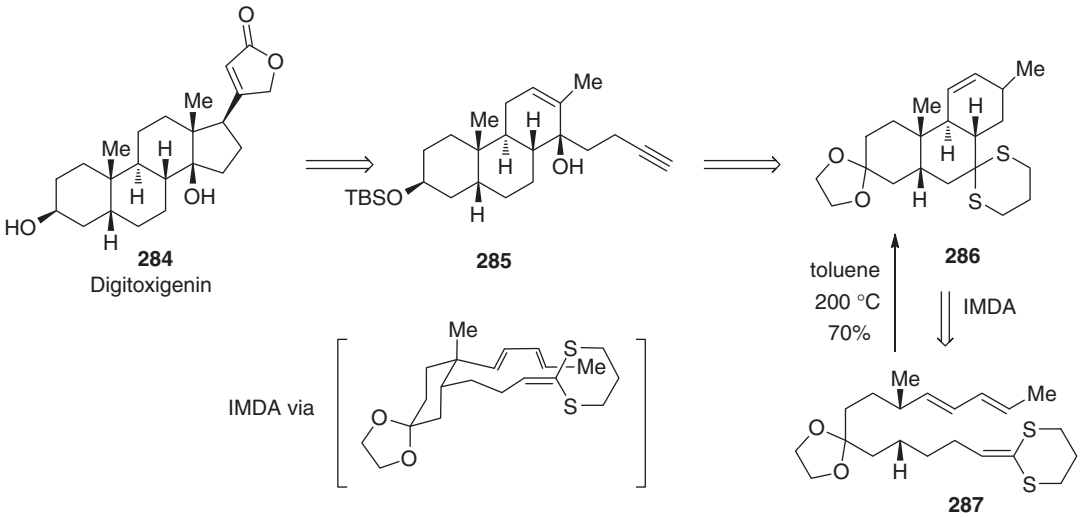
5.11.11.3 Terpenoids

5.11.11.3.1 Total synthesis of ledol

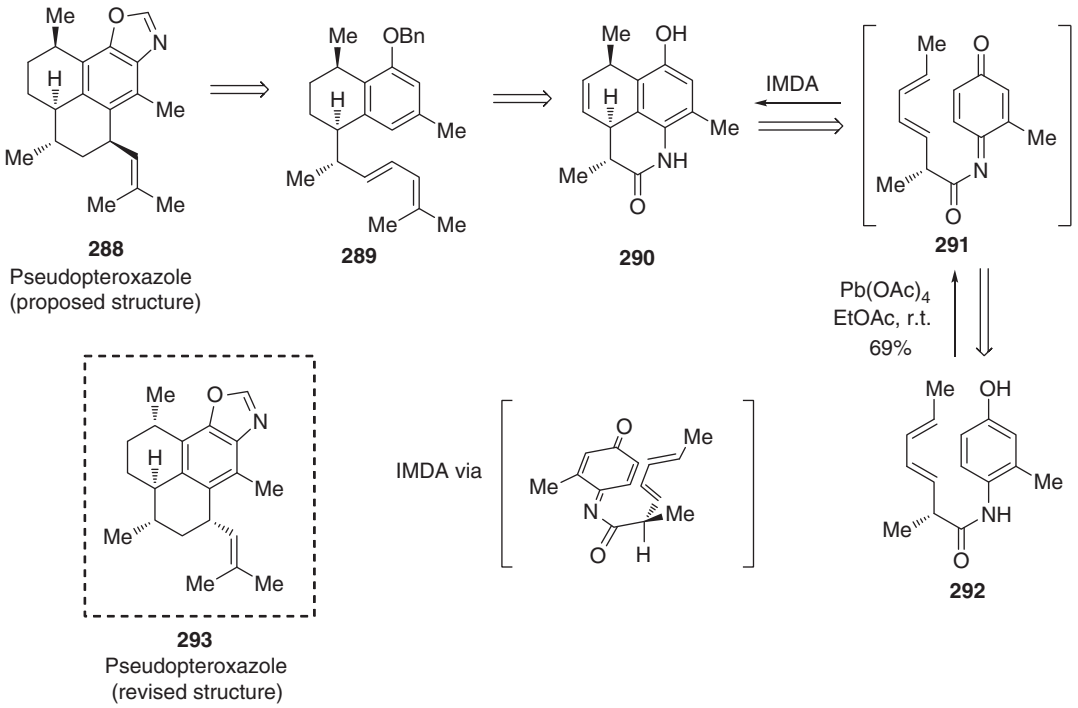
The total synthesis of ledol (**279**, Scheme 26) illustrates a 'bridged-to-fused ring interchange' strategy[120a] and also highlights the use of a type 2 IMDA cycloaddition for formation of medium rings[120b] in target molecules that themselves bear little resemblance



Scheme 26

to DA cycloadducts. Disconnective simplification of the target molecule to **280**, followed by retrosynthetic reconnection of the carbonyl groups reveals **281** and thus type 2 IMDA cycloadduct **282**. The cycloaddition of **283**, which proceeded under exceptionally mild conditions, not only formed the seven-membered ring of the target molecule but also provided a conformationally strongly biased system for diastereoselective nucleophilic attack on the carbonyl. The bridged ring system could then be dismantled and eventually transformed into the fused ring system of **279**.

5.11.11.3.2 Total synthesis of (+)-digitoxigenin



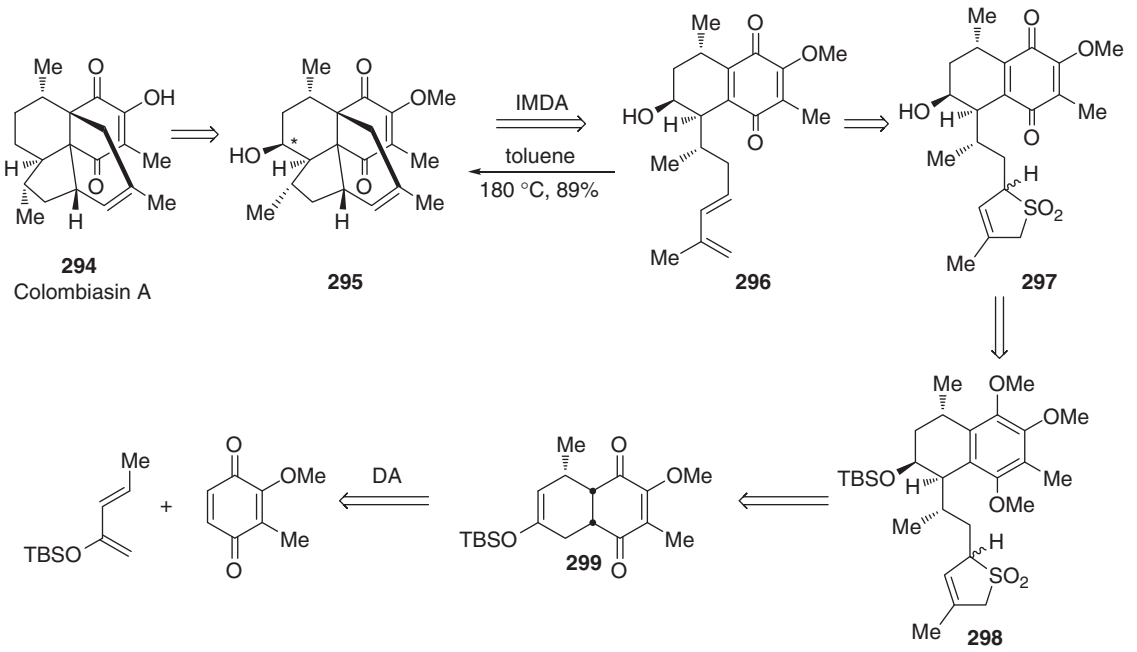
The cardenolide steroid (+)-digitoxigenin (**284**, Scheme 27) was assembled[121] via intermediate **285** that derived in turn from IMDA cycloadduct **286**. Thermal cycloaddition of **287** was completely diastereoselective, proceeding presumably via the *endo*-type conformation shown in Scheme 27. The use of the dithiane moiety as a masked carbonyl was important, because none of the other usual *endo*-selective substituents on the dienophile (e.g., CN or NO_2) could later be transformed into the carbonyl group which was necessary for stereoselective introduction of the butynyl side-chain in **285**.

Scheme 27

5.11.11.3.3 Total synthesis of 'pseudopteroxazole' (proposed structure)

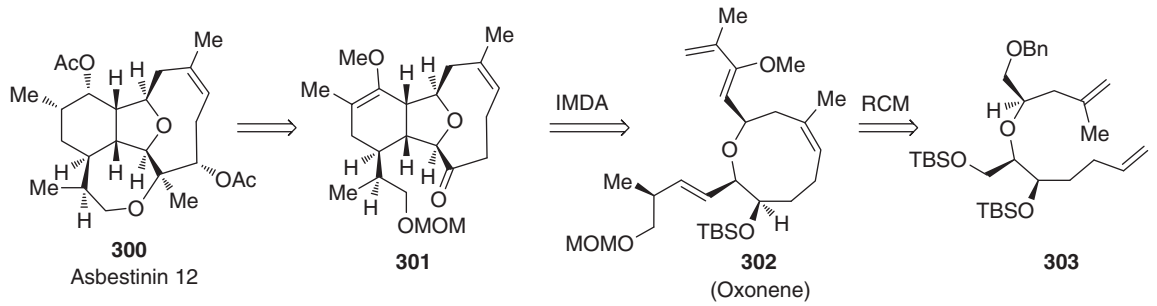
As pointed out in Sections 5.11.11.1.1 and 5.11.11.2.3, total synthesis is still an important tool (in some cases the only available one) for the correct assignment of structure and/or configuration. Another example[122] is given in Scheme 28, in the form of an asymmetric synthesis of the proposed structure of the biologically active marine natural product pseudopteroxazole **288**. As shown by the retrosynthetic analysis, the nitrogen tether in **292** ensures a regio- and diastereoselective substrate-controlled IMDA cycloaddition via transient formation of **291** by mild oxidation. The nitrogen also serves as a removable group to allow formation

Scheme 28



of key intermediate **289** from cycloadduct **290**. The final product was not identical with the natural isolate, necessitating a stereochemical revision; the probable structure[122] of pseudopteroxazole is **293**.

5.11.11.3.4 Total synthesis of colombiasin A

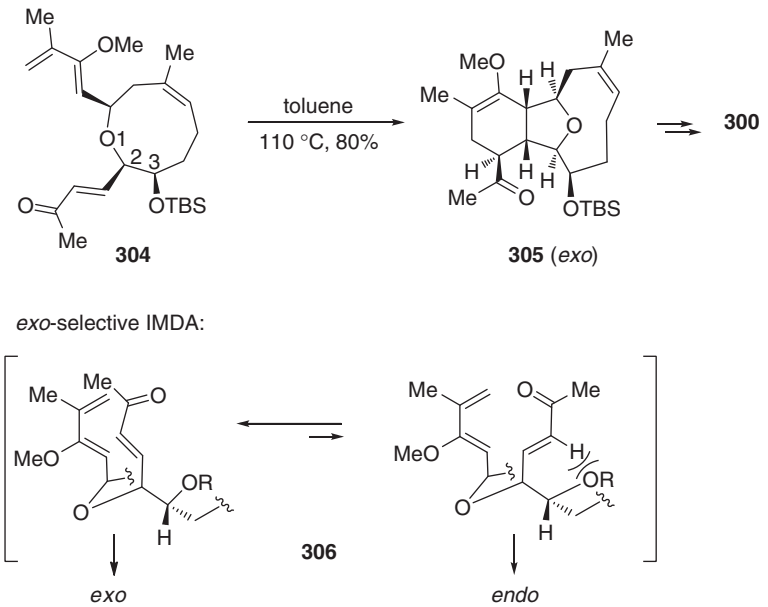


The diterpene colombiasin (**294**, Scheme 29) has a compact cage-like structure featuring six stereogenic centers, including two adjacent quarternary carbons. A total synthesis[123] of colombiasin was based on two key DA cycloadditions, one intermolecular, and one IMDA (the latter being used to install the two adjacent quaternary centers in one step). The synthesis proceeded via late-stage key intermediate **295** (Scheme 29), the extraneous oxygen at the asterisked carbon being necessary for correct introduction of the tethered diene in **296**. IMDA substrate **296** was generated transiently by cheletropic removal of SO_2 from **297**, a tactic made necessary by the incompatibility of the diene itself with reagents used for the oxidation of **298**. To complete the retrosynthetic analysis, **298** was traced back to **299**, which is the product of a regio- and stereoselective bimolecular DA cycloaddition. The IMDA reaction involving **296** was carried out in the dark to suppress competing photochemical [2 + 2] cycloadditions between the less-substituted portion of the diene and the quinone, and under these conditions an excellent 89% yield of **295** was obtained. Finally, use of a chiral Lewis acid catalyst (cf. Section 5.11.7.3.1) for the initial bimolecular DA cycloaddition provided enantiomerically enriched **299** that was used to assign the absolute configuration of the natural product.[123]

5.11.11.3.5 Total synthesis of asbestinins

An intriguing general strategy[124] for the total synthesis of the asbestinins (e.g., asbestinin 12, **300**, Figure 31) was based on the use of an oxonene template **302** to induce high stereoselectivity in an IMDA reaction, forming a tricyclic precursor **301** to the tetracyclic target molecule. Oxonene **302** was projected to be formed by RCM[92] of **303**. It was found that the exocyclic alkene in IMDA substrates such as **302** was not sufficiently dienophilic to participate in the desired IMDA cycloaddition, so the synthetic plan was modified to incorporate an electron-withdrawing group, as in **304**. This proved to be highly successful, the IMDA cycloadduct **305** being produced as a single diastereomer in 80% yield. The selectivity of the IMDA reaction rests on the conformational bias of the oxonene ring, as well as the steric bulk of the ether substituent and the configuration at C3 in **304**, which is responsible for the desired *exo*-selective cycloaddition (see partial structures **306**, Figure 31). For the IMDA to occur, both side-chains must adopt pseudoaxial positions and this means that in the *endo* conformation there is a steric clash between the OR group on C3 and one of the vinyl protons of the dienophile. This destabilizing nonbonded interaction is relieved in the *exo* conformation and, in line with this model, use of a sterically less demanding OR group (OPMB) at C3 gave lower diastereoselectivity (4:1 in favor of *exo*).

Scheme 29



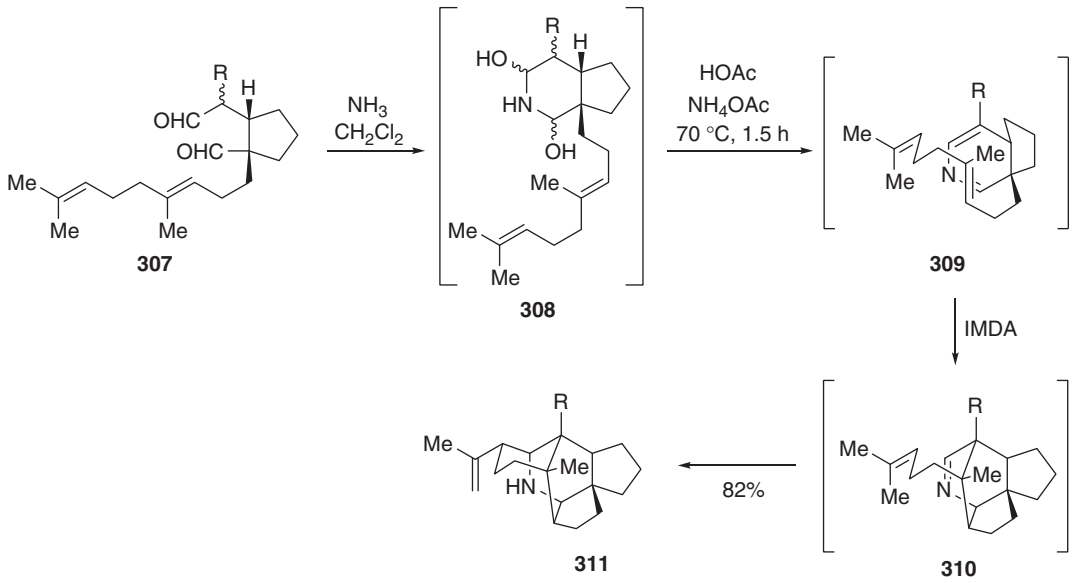


Figure 31 IMDA cycloaddition as a key step in the total synthesis of Asbestinin 12.

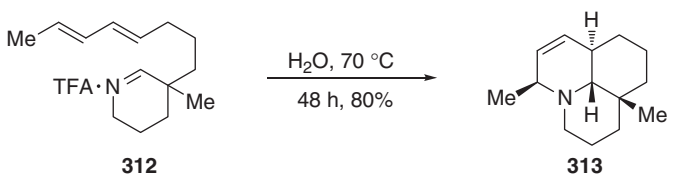
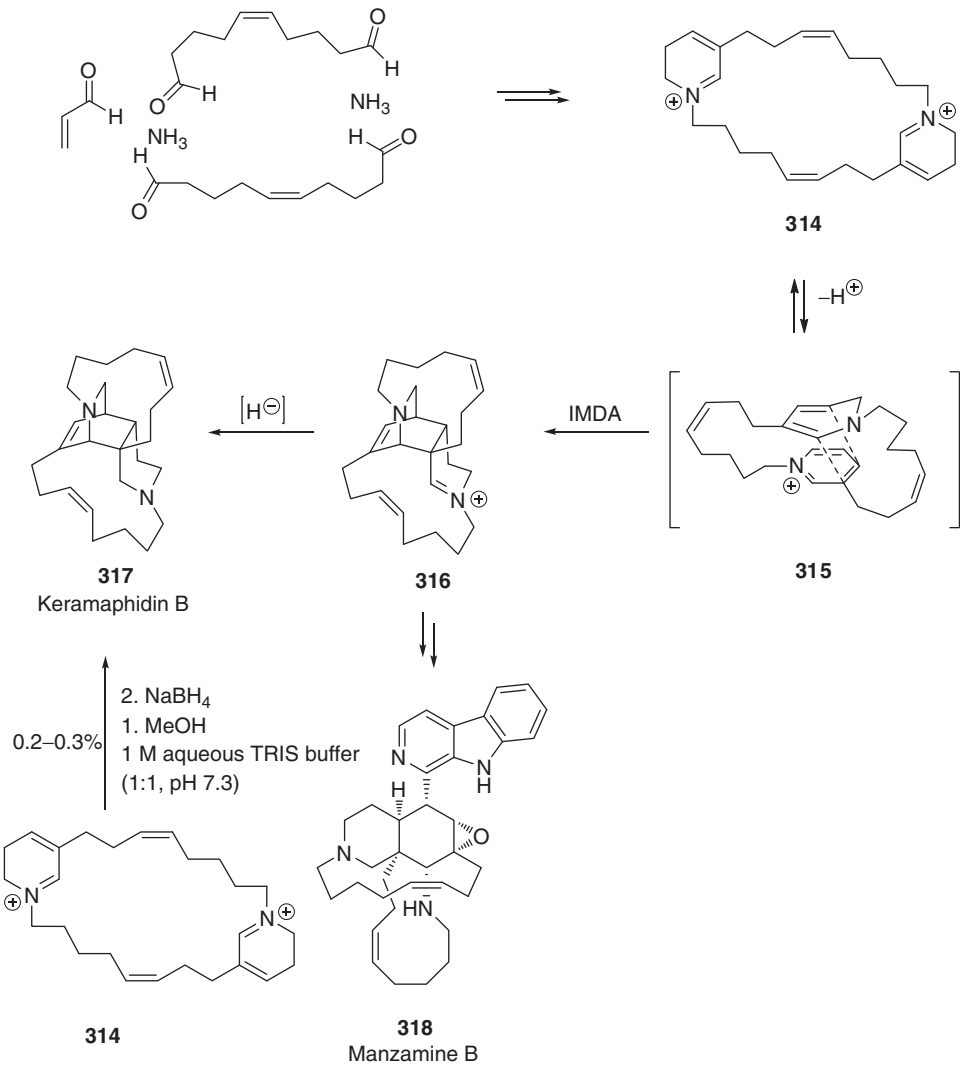
5.11.12 Biomimetic versus Bio-inspired IMDA Cycloadditions



In Section 5.11.4.4 the intriguing but contentious topic of Diels–Alderases was mentioned, and there is now a multitude of natural products[125] for which DA and/or IMDA reactions have been proposed as key steps on the biosynthetic pathway. Indeed, many of the total synthesis efforts described or referred to in previous sections have been motivated by consideration of possible biosynthetic [4 + 2] cycloadditions and, understandably, interest in this topic continues unabated.[126] At this point, it seems reasonable to make a distinction between the terms 'biomimetic' (which is meant here as reactions occurring in aqueous media at, or close to, ambient temperature) and 'bio-inspired' (which refers here to reactions designed on the basis of an established or putative biosynthetic step, but carried out under abiotic conditions vastly different from those pertaining to enzymatic processes).[127] Thus, to paraphrase (without denigrating) some of the extant experimental protocols, an IMDA cycloaddition which proceeds only on prolonged heating in a sealed vessel at temperatures well above the boiling point of the aromatic hydrocarbon solvent of choice, in the presence of (super-)stoichiometric amounts of a powerful 'man-made' Lewis acid, may well be bio-inspired but is not biomimetic.

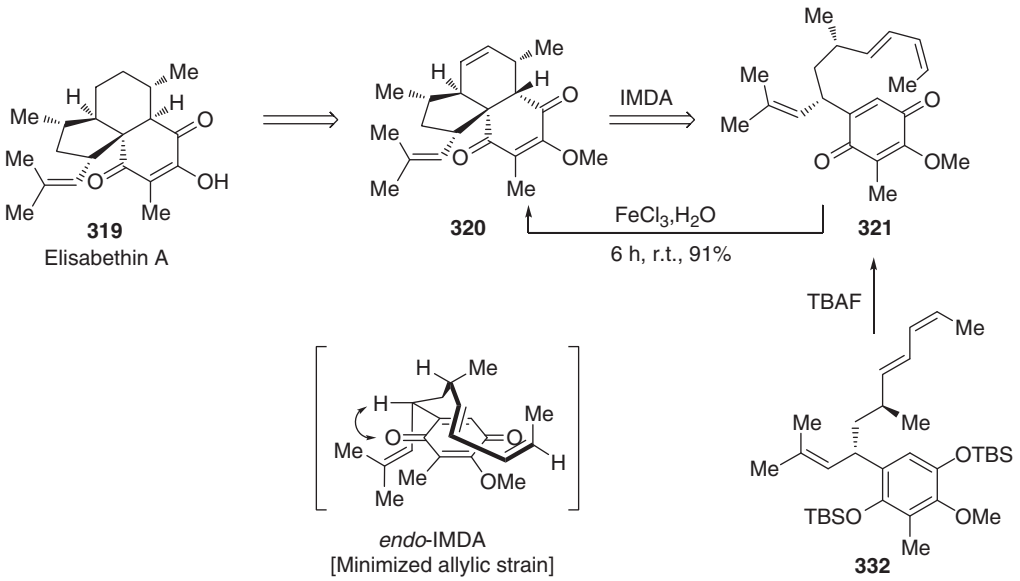
A classic example of a bio-inspired IMDA cycloaddition (as part of a cascade sequence, cf. Section 5.11.8.2) is the general approach[128] to the *Daphniphyllum* alkaloids summarized in Scheme 30. In a consummate combination of aesthetics and efficiency, a readily accessible dialdehyde such as **307** is treated sequentially with ammonia, acetic acid, and ammonium acetate to form IMDA precursor **309**. The acetic acid solution of the cycloadduct **310** is then heated to induce an aza-Prins cyclization which delivers pentacyclic amine **311**. At one fell swoop, this superbly designed and executed sequence elegantly forms three carbon–carbon and two carbon–nitrogen bonds, forges five rings, and establishes six stereocenters.



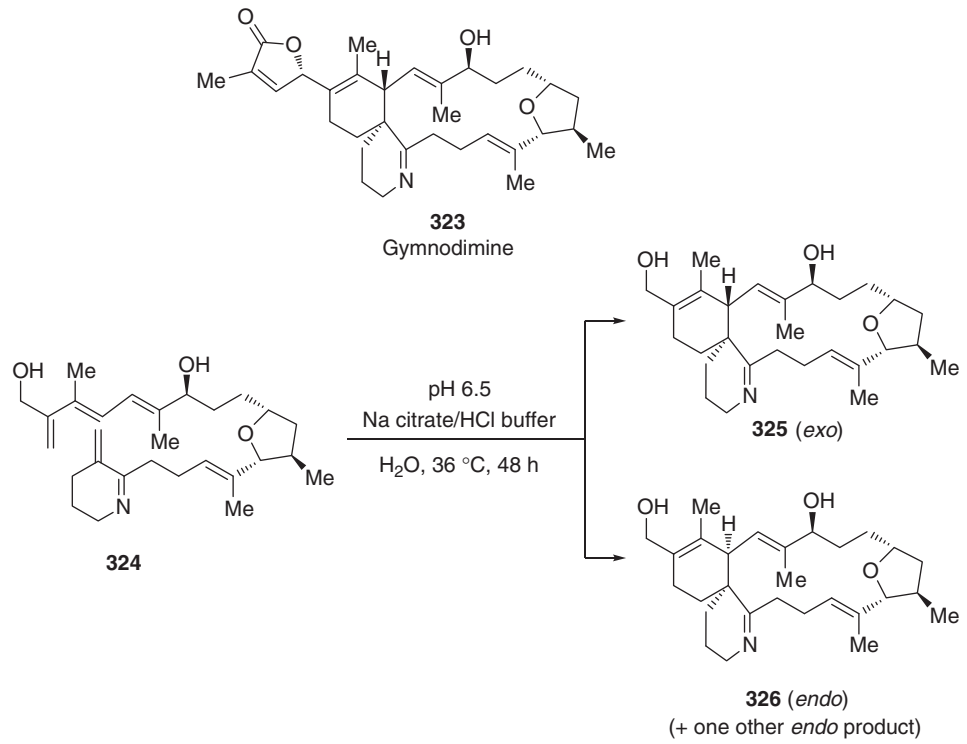
Scheme 30

As far as biomimetic reaction conditions are concerned, the use of aqueous media for the DA cycloaddition has been known since the work[129] of Diels and Alder themselves in 1931, but it was not until the 1980s that interest in this technique was rekindled in earnest.[130, 131] On occasion, water proved to be the medium of choice as shown for the IMHDA reaction[132] in Scheme 31. Cycloadduct **313** was obtained as a single diastereomer and, in this case, water easily outperformed other polar media such as 5.0 M lithium perchlorate–diethyl ether (Section 5.11.3.2) in which the reaction gave only 13% yield. Another fine example of the use of aqueous media to promote an IMHDA reaction[62] can be found in Section 5.11.6.2.

Scheme 31



In the early 1990s, an appealing biogenetic hypothesis was presented[133] to explain the unprecedented structure of the manzamine alkaloids (Scheme 32). An alkaloid related to the manzamines, keramaphidin B **317**, was later isolated[134] and it was proposed that the biosynthetic pathway from simple precursors to the intricate natural products involved an *endo*-selective IMDA cycloaddition[135] of bisdihydropyridine **315**, the product of which, **316**, would diverge to keramaphidin B and the manzamines (e.g. manzamine B **318**, the aromatic moiety of which comes from tryptamine). In practice, trace amounts of **317** could indeed be isolated from the reaction of **314** in aqueous medium, the major pathway being disproportionation of intermediate **315**. It was suggested that a putative Diels–Alderase could decrease or even exclude the disproportionation reaction and also have a favorable entropic effect on the IMDA cycloaddition by limiting the conformational freedom of the substrate.



Scheme 32

A plausible biosynthetic precursor to the natural product colombiasin **294** (Scheme 29) is elisabethin A (**319**, Scheme 33). Retrosynthetically,[136] **319** can be derived from **320** (requiring epimerization, demethylation, and reduction) that in turn leads back to IMDA precursor **321**, generated by oxidation of the corresponding hydroquinoid derivative **322**. The choice of the TBS protective groups was crucial to allow deprotection under mild conditions, and the IMDA reaction is noteworthy for the 'virtually biomimetic'[136] conditions, the very high yield and essentially complete diastereoselectivity, and the fact that this was apparently the first successful IMDA involving a terminal *Z*-alkene in the diene unit. The *endo* transition state shown in Scheme 33 is the one which minimizes allylic strain involving the quinoid carbonyl moiety. This admirable total synthesis also served to assign the absolute configuration of the natural product.

In Scheme 13, the use of an IMDA reaction for a macrobicyclization was presented, and this type of process also characterizes the synthesis of the core unit **325** of the natural product gymnodimine[137] **323** shown in Scheme 34. The α,β-unsaturated imine

Scheme 33

Scheme 34

324 (and also simpler congeners) was found to be remarkably stable in water at acidic and neutral pH, and underwent an IMDA cycloaddition at moderate temperatures and pH 6.5 to yield **325** (*exo*) and **326** (*endo*) as the major products. The *exo* cycloadduct remained unchanged in aqueous solution, whereas the *endo* species were prone to hydrolysis to keto-amines. These experimental results were taken as an indication that a biosynthetic IMDA leading to **323** could well occur without recourse to enzymatic catalysis.

Another intriguing set of experiments[138] is related to the question of possible enzymatic catalysis of an IMDA cycloaddition in the biosynthesis of UCS1025A (**327**, Figure 32), the putative IMDA precursor being triene **328**. The racemic form of **330** was dissolved in a phosphate buffer (pH 7.2, D_2O) at RT and was observed to immediately ring-open to **331** followed by rapid IMDA cycloaddition (with a $t_{1/2}$ of only 10 min) to give a 1:1 mixture of **332** and tetra-*epi*-**332** which on acidification yielded **327** and

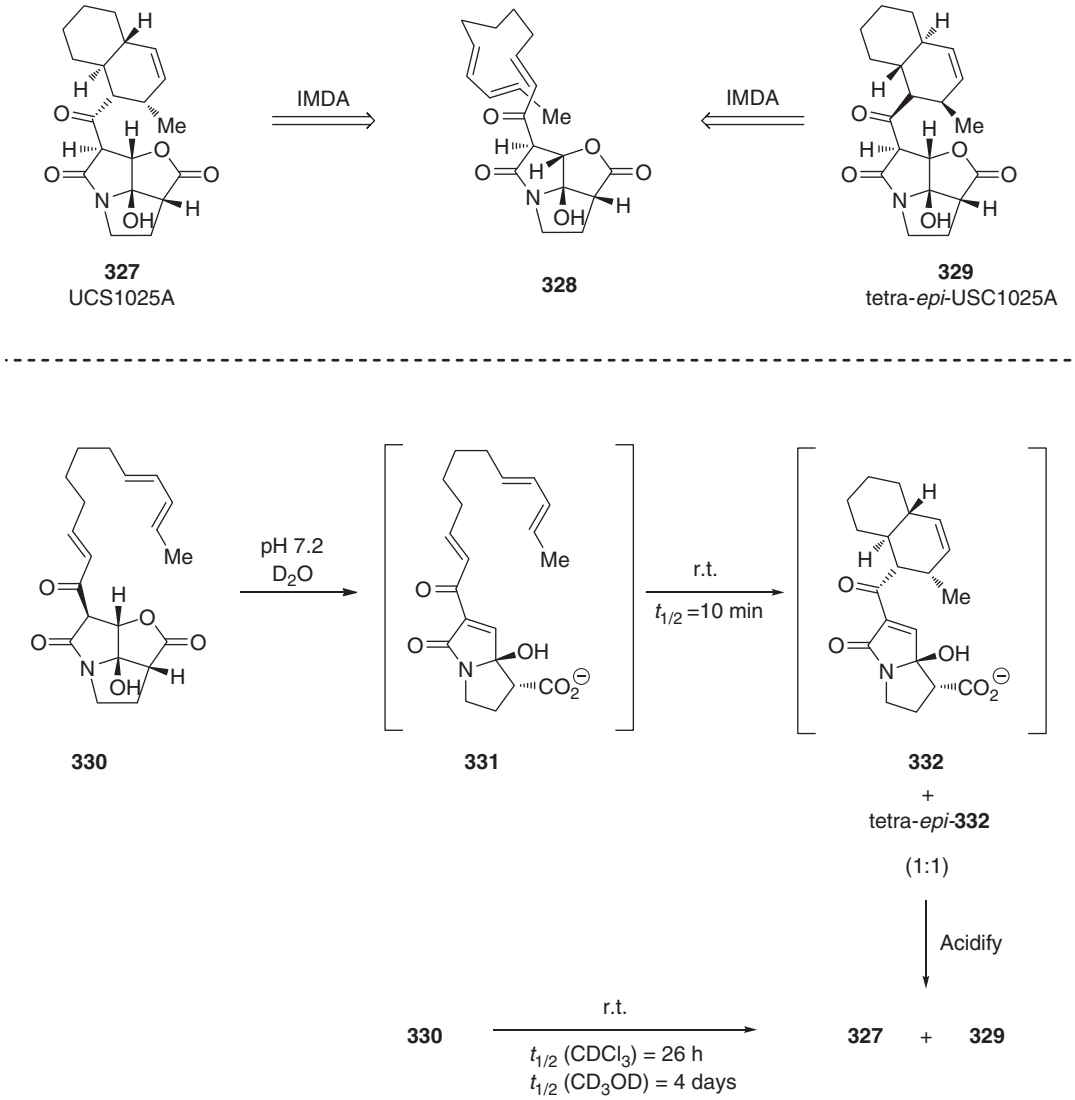


Figure 32 Experiments related to possible enzymatic catalysis of an IMDA cycloaddition.

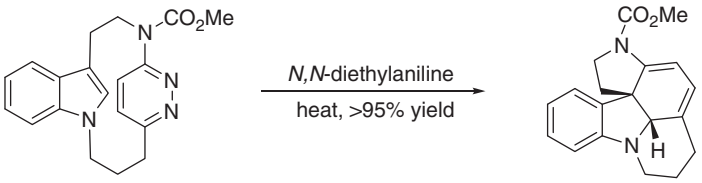
329, respectively. The aqueous medium obviously plays a major role in determining the rate of the cycloaddition (cf. the results obtained for $CDCl_3$ and CD_3OD solutions). The IMDA process is highly *endo*-selective, but essentially no diastereoselectivity was observed. Thus, although the rate of cycloaddition of **331** is fast enough to be the natural event, the lack of substrate-controlled diastereoselectivity means that some external stereocontrol element must be operative in the biosynthetic pathway leading to the natural diastereomer of **327**. Whether or not such control is provided by enzymatic catalysis is still a moot point.



5.11.13 TADA Cycloadditions

Transannulation reactions[139] can provide an appealing and efficient strategy for the synthesis of polycyclic molecular frameworks. The general approach requires initial construction of a medium or large ring appropriately functionalized to provide for the formation of one (or more) bond(s) across the perimeter, with the simultaneous formation of two or more smaller rings. If the smaller rings in the products are 'normal-sized' (5-, 6- or 7-membered) an obvious potential stumbling block is the generation of the 'awkward' ring sizes required in the substrates. Provided that the precursor can be accessed without too much difficulty, the overall success of the transannular strategy will then rest on the conformational and electronic preferences of the medium-sized or macrocyclic ring as the molecule approaches the transition state; it seems reasonable to assume that such steric and/or stereoelectronic bias can be induced by careful choice of the substituents on the ring perimeter. Since DA and IMDA reactions represent

extraordinarily efficient stereospecific methods for the rapid generation of molecular complexity, with often exquisite levels of regio- and stereoselectivity, dictated by a highly-ordered transition state, the TADA mode of cycloaddition would appear be a very powerful synthetic tool. It is of course not surprising that the evolution of the TADA reaction has gone hand in hand with methodological advances in the synthesis of medium and large rings. The historical development and deployment of the TADA cycloaddition strategy have been reviewed at length and in depth,[140] and this section will concentrate on a selection of recent examples, with the emphasis on applications to the total synthesis of natural products.

5.11.13.1 Cyclophanes as TADA Precursors

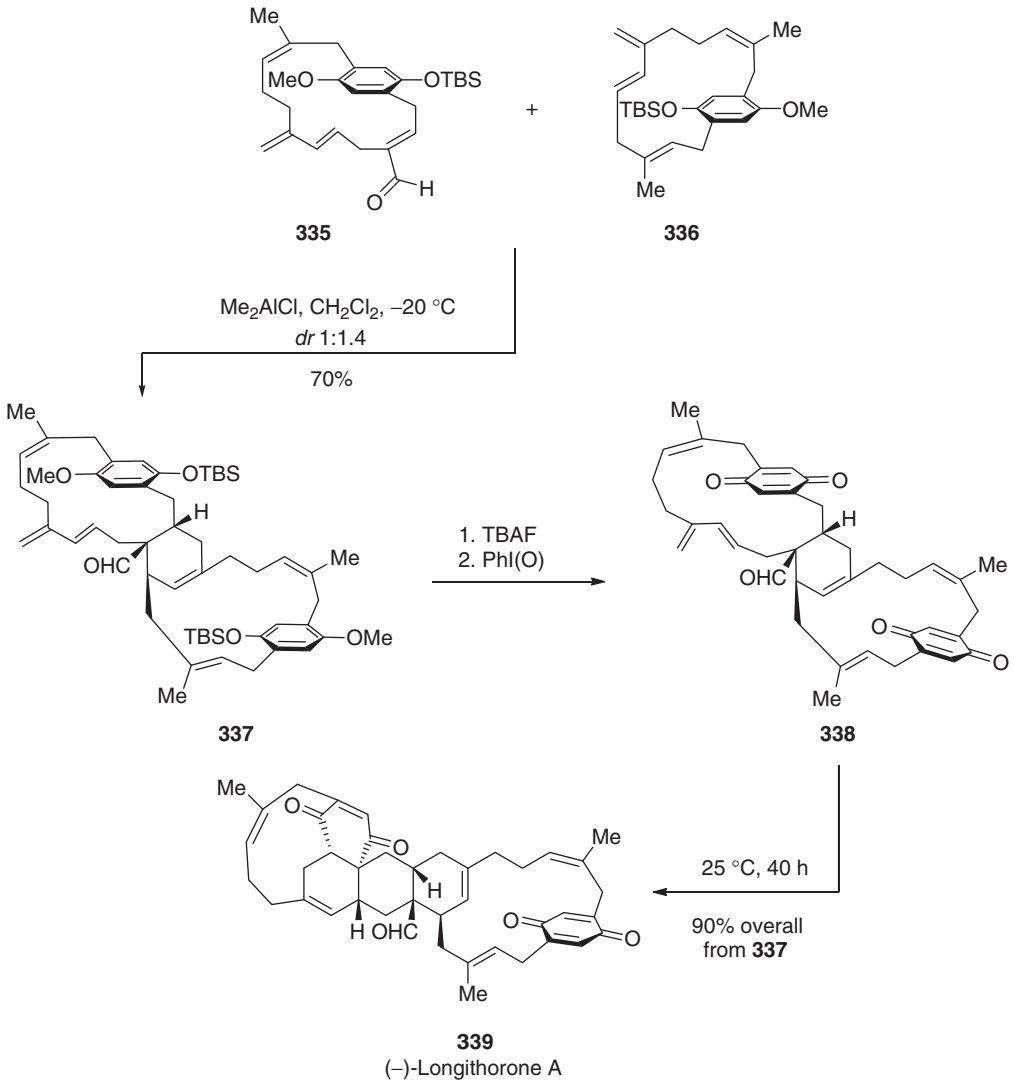
Scheme 35 shows an approach[141] to the total synthesis of strychnine which involves a highly efficient inverse electron demand TADA reaction of cyclophane **333**. It was claimed that **334**, formed via the TADA reaction and subsequent loss of N_2, could be transformed into a known key intermediate for the total synthesis, but this was later shown to be in error.[142]

333 **334**

Scheme 35

The enantioselective total synthesis[143] of (–)-longithorone A (**339**, Scheme 36) utilized first an intermolecular DA cycloaddition of the atropisomerically pure cyclophanes **335** and **336** followed by oxidation and a TADA reaction of transient bisquinone intermediate **338**. This total synthesis was inspired by a biosynthetic proposal, and is noteworthy for a very clever use of chirality transfer to dictate enantioselectivity via an elegant interplay of stereogenic centers and atropisomerism. The lack of stereocontrol in the bimolecular DA reaction (the desired product was the minor diastereomer) could be taken as evidence for the intervention of a Diels–Alderase in the biosynthetic pathway.

5.11.13.2 Tandem TADA Cycloadditions



An impressive tandem sequence involving a pair of TADA cycloadditions formed the basis of two very similar, independent and concomitant total syntheses[144] of the hexacyclic natural product FR182877 (**344**, Scheme 37). The second TADA reaction is of the hetero-Diels–Alder type, and the TADA precursors **340** differ only in the nature of the protective groups and the R^4 substituent. Both sequences delivered the pentacyclic intermediates **343** in respectable yields, in a truly spectacular demonstration of the power of the DA reaction to rapidly build up molecular complexity: five rings, three C–C bonds, one C–O bond and seven stereocenters are formed in a single operation. Interestingly, the same target molecule was later accessed[145] from key intermediate **345** by a tandem sequence of IMDA–IMHDA cycloadditions which provided the advanced building block **346**, albeit in modest yield (Scheme 38). A further comparison of IMDA and TADA approaches to a common target molecule is provided in Section 5.11.13.5.

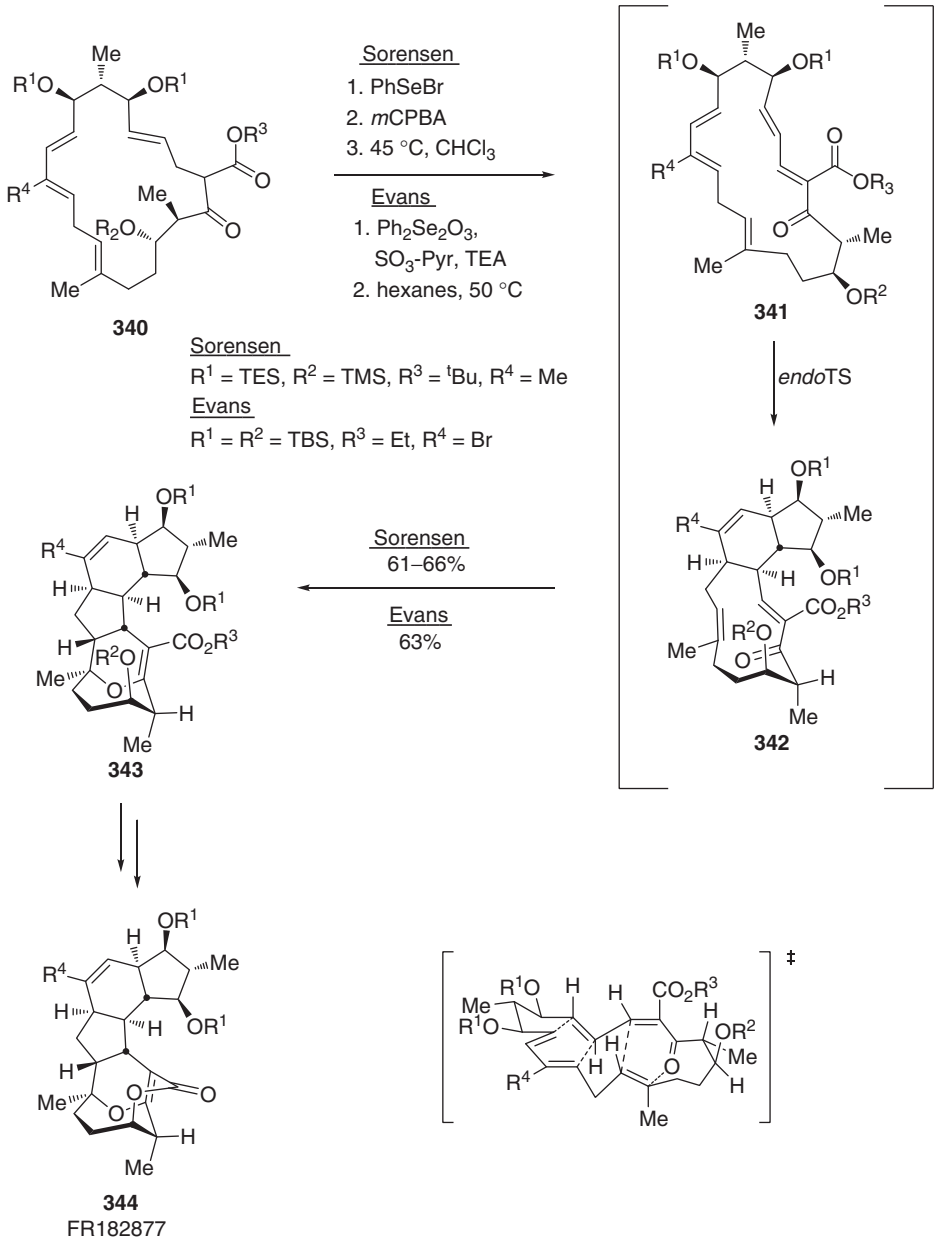
5.11.13.3 Total Synthesis of (+)-Macquarimicin A

Related to FR182877 is the tetracyclic compound macquarimicin A (**350**, Scheme 39) which was synthesized enantioselectively[146] via **349** by means of a TADA reaction of **348**. As indicated in Scheme 39, it is the (*Z*,*E*) geometry of the diene unit that determines the *endo* selectivity, whereas diastereofacial selectivity is controlled by the lactone moiety. This total synthesis also allowed for a structural reassignment of the natural isolate (the alkene exocyclic to the lactone ring in **350** is *Z*, rather than the *E* configuration which was originally proposed).

5.11.13.4 A TADA Approach to the Mangicols

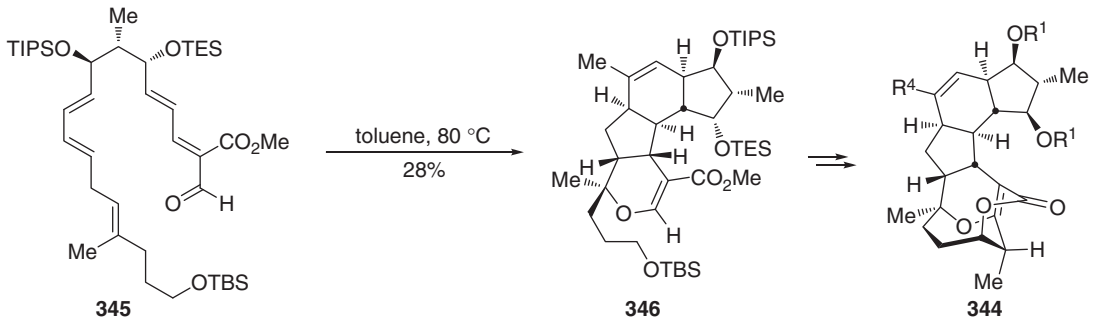
Scheme 40 shows a TADA-based approach[147] to the total synthesis of the mangicol family of natural products (e.g., mangicol A, **353**). The 12-membered macrocycle **351** gave a quantitative yield of TADA cycloadduct **352** as a single diastereomer. Unexpectedly, the outcome of the TADA reaction was found to be dependent on the configuration at the C3 allylic alcohol: the C3-epimer of **351**

Scheme 36



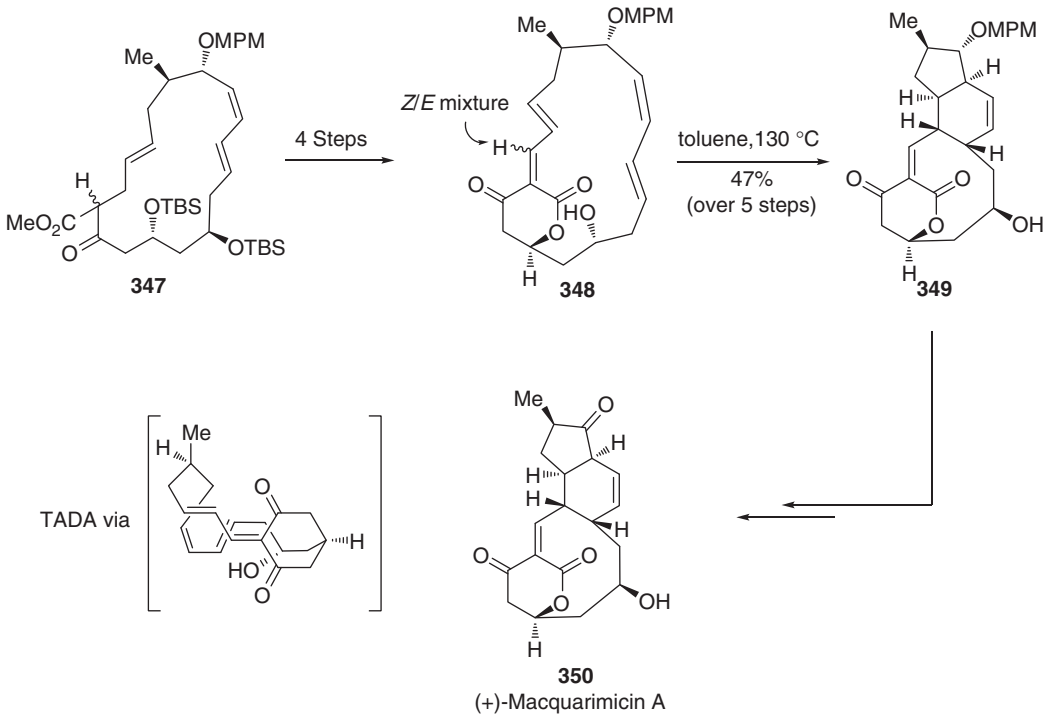
gave a 1:1 mixture of diastereomers under the same conditions as for **351** itself. It was suggested that the lower-energy transition state for the TADA reaction of **351** was that in which destabilizing transannular nonbonded interactions are minimized.

5.11.13.5 *Endo*-IMDA versus *Exo*-TADA



A projected synthesis[148] of the antibiotic branimycin (**354**, Figure 33) was envisioned to proceed either via an IMDA cycloaddition of **356** (*endo* transition state) or a TADA reaction of **358** (*exo* transition state). In the event, all attempts (heating, Lewis acid-catalysis, and high pressure) to access **355** by the IMDA reaction failed, whereas TADA precursor **358** smoothly delivered **357** in excellent yield and as a single diastereomer.

5.11.13.6 Catalytic Asymmetric TADA Cycloaddition



The enantioselective total synthesis[149] of the sesquiterpene 11,12-diacetoxydrimane **362** shown in Scheme 41 illustrates the powerful and elegant combination of a temporary silicon tether (cf. Section 5.11.2) and enantioselective catalysis via chiral oxazaborolidines (Section 5.11.7.3.2) for TADA cycloadditions. It was found that when the silicon-tethered macrocyclic TADA precursor **359** was subjected to the Corey catalyst **360**,[83] complete conversion of the *E,E*-isomer occurred to give **361** with >20:1 diastereoselectivity and 83% *ee*. Importantly, it was also found that the oxazaborolidine catalyst was capable of overriding any inherent diastereofacial bias in TADA substrates containing stereogenic centers, thus opening up a general synthetic route to many polycyclic terpene natural products.

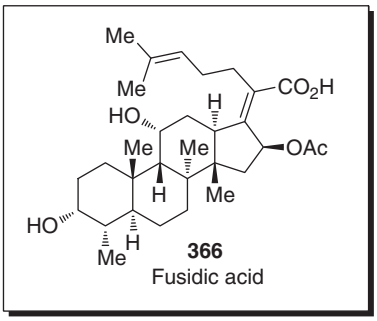
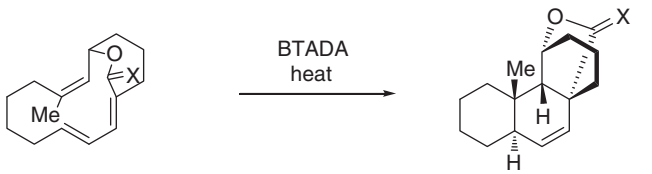
Scheme 41

5.11.13.7 Total Synthesis of (+)-Cassaine



An efficient substrate-controlled TADA reaction was used[150] as a key step in the asymmetric total synthesis of (+)-cassaine (**365**, Scheme 42). The diastereoselective TADA cycloaddition of **363** (see the pretransition state conformation in Scheme 42) efficiently set up the tricyclic system of **364**, with control over four new contiguous stereocenters (one of which was later epimerized). The TADA strategy also allowed for the use of an electronically unactivated dienophile.



Scheme 42

5.11.13.8 Bicyclic Transannular Diels–Alder (BTADA) Cycloaddition

The BTADA approach was considered[151] for the total synthesis of natural products such as fusidic acid **366**, and model studies revealed some very interesting patterns of reactivity (Scheme 43). Lactone **367** failed completely to undergo the desired cycloaddition, whereas ether **369** smoothly delivered tetracycle **370** in quantitative yield. DFT calculations revealed the reason for the lack of reactivity of **367**: there is a prohibitively high barrier (ca. 215 kJ mol^{-1}) for conversion of the lactone from its lowest energy conformation to the one in which the diene and dienophile components are correctly aligned to undergo the BTADA cycloaddition. The high barrier to interconversion is because of increased trannsannular strain and to loss of conjugation in the diene as the molecule changes conformation. Calculations also guided the choice of the ether **369**, for which the corresponding energy barrier is only 63 kJ mol^{-1} (the energy barriers for the BTADA reaction itself were calculated to be 100 and 110 kJ mol^{-1} for **367** and **369**, respectively).

5.11.14 Conclusions and Outlook

Since 1928, the DA cycloaddition has been one of the most powerful tools available for the rapid generation of molecular complexity, particularly in the field of total synthesis. The extension of this peerless reaction to the IMDA and TADA modes described above now allows impressively brief and highly stereoselective routes to target molecules of daunting complexity. It is expected that these already powerful synthetic transformations (perhaps in harness with new modes of catalysis) will continue to thrive and to provide uniquely efficient and elegant solutions to challenging problems in synthesis.

Glossary

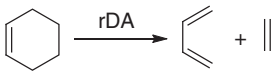
[4 + 2] Cycloaddition Reaction of a conjugated diene with a dienophile to give an adduct.

***Exo–endo* isomerization** The *endo* adduct is thermodynamically less stable than the *exo* adduct and isomerizations can occur by a sequence of DA/rDA reactions.

Retro Diels–Alder (rDA) fragmentation Decomposition of an adduct, which requires high temperature or sometimes flash vacuum pyrolysis; promoted rDA fragmentation: dienes and dienophiles formed are stable, volatile or easily removable.

Retro Diels–Alder (rDA) reaction A reverse process of a Diels–Alder reaction.

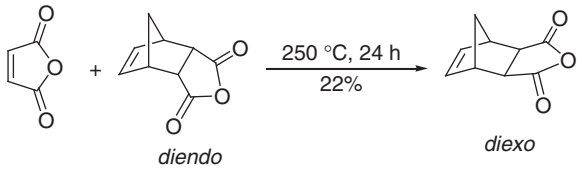
Retrodiene methods Retrodiene methods provide new approach for preparation of heterocycles synthetic application can be used in the chemistry of oligomers and polymers. New strategy involves synthetic application to fullerens and graphenes and suitable to build up natural products with complicated structures.



5.12.1 Introduction

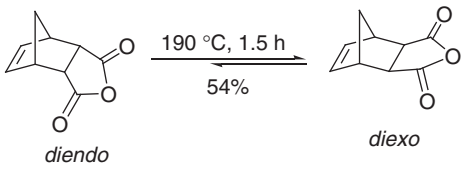
The Diels–Alder (DA) reaction comprises a reversible [4 + 2] cycloaddition between a conjugated diene and a substituted alkene, commonly termed dienophile. The reverse process is generally named as a retro DA (rDA) reaction. The thermally allowed cycloreversion [$_{\pi}4 + _{\pi}2_{s}$] of an organic compound containing a double bond in a six-membered ring leads to the formation of a diene and a dienophile. Even though the DA cycloaddition is thermodynamically reversible, the DA products are fairly stable, and their spontaneous cleavage generally does not occur. Besides the normal thermolysis of DA adducts, a wide range of conditions and other methods to facilitate the rDA process have been reported.

The rDA fragmentation usually requires high temperatures (simple heating of neat compounds or of solutions of the compounds in an inert solvent) in order to surmount the high activation barrier of the cycloreversion, but in some cases extreme conditions such as flash vacuum pyrolysis (FVP, at 600–900 °C) are required. It should be mentioned that the thermal rDA reaction of anthracene cycloadducts can be accelerated by electron-donating groups. Photochemical irradiation, sonication, and the application of high pressure or acid- and base-mediated processes also promote cycloreversion. The incorporation of an oxide into an anionic substituent strongly accelerates the rDA process too.[1,2]



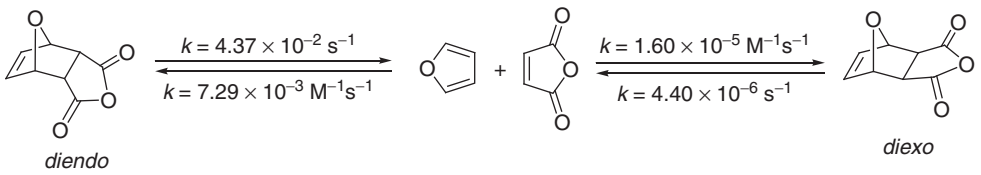
Promoted rDA fragmentation readily occurs when the dienes and/or dienophiles formed are particularly stable (e.g., an aromatic ring) or when volatile or easily removable molecules (e.g., nitrogen, carbon dioxide, acetylene, or ethylene) are formed. The rDA fragmentations, which often take place on analysis of organic compounds by mass spectrometry, are not of preparative importance and therefore not covered herein.

A fundamental and simple example of a thermal rDA process is the reaction of cyclohexene to 1,3-butadiene and ethylene (equation 1). With an appropriate driving force, the DA reaction may proceed in the reverse direction, providing the separable diene and dienophile from the starting cyclohexene.



(1)

In 1929, this process was described for the first time and applied to the detection of 1,4-bridged cyclohexadiene derivatives, from which ethylene and aromatic compounds were released through an rDA process.[3] Since then, a large number of substrates have been subjected to rDA reactions and a variety of dienes and dienophiles have been formed. When the rDA process is conducted in the presence of a scavenging diene or dienophile, numerous transient reactive species can be captured.[4] Likewise, the observation of *endo–exo* isomerization of DA adducts serves as evidence for an intervening rDA reaction.[5,6] It has been postulated that at high temperatures the kinetic *endo* adducts undergo isomerization to the thermodynamically more stable *exo* products via an rDA/DA sequence (equation 2).

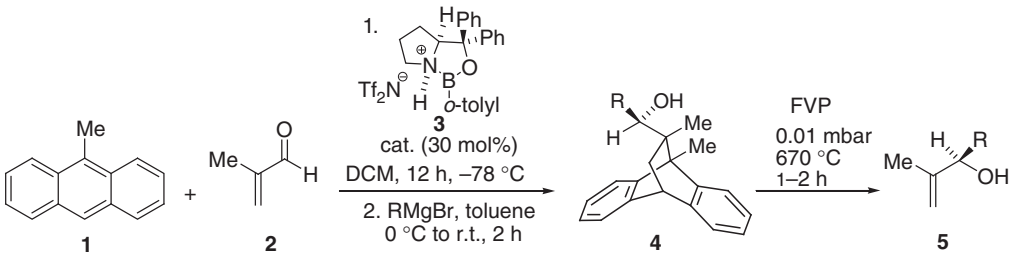


(2)

The DA reaction of cyclopentadiene with maleic anhydride (MA) occurs at room temperature, with kinetically favored formation of the *diendo* isomer. The cycloaddition is exothermic by ~25 kcal mol^{-1}.[6] The reaction of many substrates that undergo dissociative rDA processes proceed through similar cycloadducts that are not always easily detected. Interconversion to the *diexo* isomer at reasonable rates requires temperatures of approximately 150 °C, but best yields of the *diexo* isomer were isolated by heating of the *diendo* isomer at a higher temperature (equation 3).[7]

(3)

Another system that has been fully characterized and kinetically studied is the DA formation of *diexo*-7-oxabicyclo[2.2.1]-heptene-2,3-dicarboxylic anhydride (equation 4). Rate constants for both the DA and the rDA reaction were measured in MeCN at 40 °C.[8] The *diendo* isomer was formed much faster than the *diexo* adduct but was less stable especially in a diluted solution.



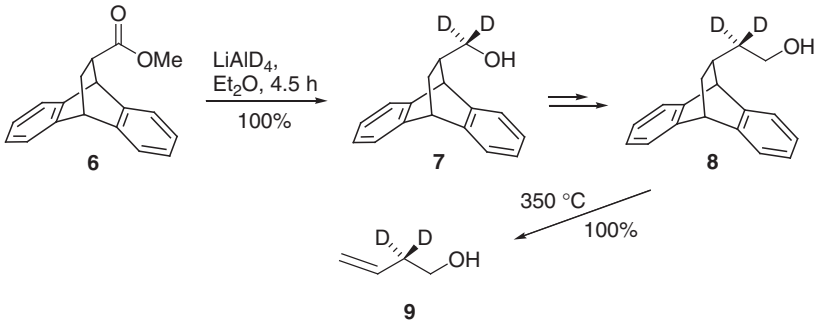
(4)

A number of comprehensive valuable review articles and books have been written related to rDA processes earlier, which surveyed this important reaction theoretically and/or practically.[9–18] The rDA reactions have become an important field of organic chemistry with regard to the mechanistic features and the wide-ranging preparative applications.

5.12.2 Preparation of Substituted Alkenes

5.12.2.1 α,β-Unsaturated Alcohols

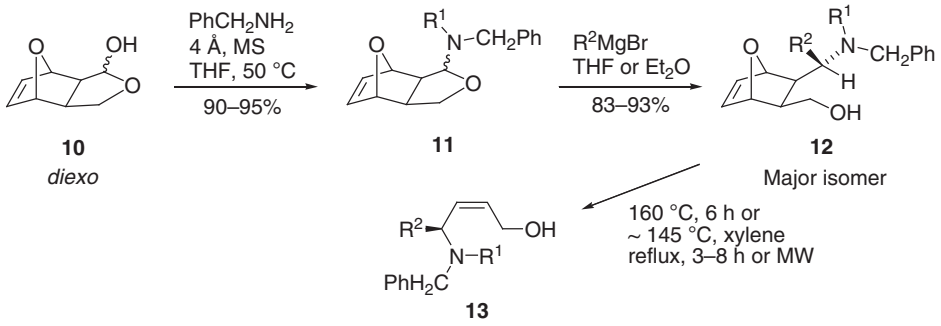
Allylic alcohols have been prepared enantioselectively by oxazaborolidinium ion-catalyzed DA/rDA reactions. The procedure is based on anthracene templates with chiral substituents for the generation of small-molecule building blocks with high enantioselectivity. The catalytic DA cycloaddition of 9-methylanthracene **1** to methacrolein **2** using Corey's cationic oxazaborolidine **3** resulted in the regioselective formation of the aldehyde–adduct intermediate (ratio 92:8). Reaction of the major cycloadduct with various Grignard reagents (Scheme 1) led to alcohols **4** in yields of 59–87%. As the diastereoselectivity of this reaction could not be fully controlled, compounds **4** needed purification by column chromatography or recrystallization. The final diastereomeric ratio (*dr*) was high (from 84:16 to 98:2). FVP of the cycloadducts furnished the secondary allylic alcohols **5** in excellent yields and high *ee* (Table 1).[19]



Scheme 1

Table 1 Cycloreversion of adduct **4** by FVP (Scheme 1)

No.	*R*	*Yield (%)*	ee
1	Me	93	82
2	Et	94	76
3	Ph	99	86
4	CH_2=CH	94	63
5	CH≡C	94	82

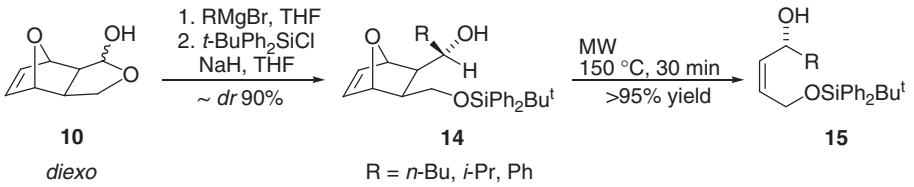


By application of the anthracene template, labeled 3,3-dideuterobut-1-en-4-ol **9** was prepared from the anthracene–methylacrylate DA adduct **6**. Lithium aluminum deuteride reduction of **6** yielded the hydroxymethyl derivative **7**, which was converted to the bromide and then to the Grignard reagent, which was reacted with methyl chloroformate. Reduction of the ester

gave the hydroxymethyl derivative **8** quantitatively, which was cleaved by FVP to yield the labeled unsaturated primary alcohol **9** Scheme 2.[20]

Scheme 2

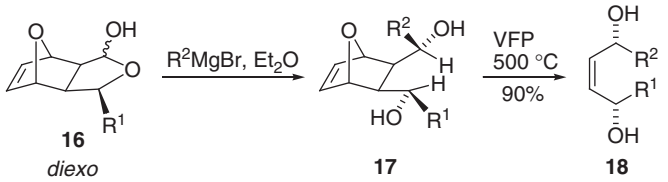
The additions of organomagnesium bromides to the C=N bond of masked chiral imines were found to be highly diastereoselective, and this allowed the preparation of unsaturated amino alcohols. The reactions of lactols **10** with an excess of benzyl- or dibenzylamine afforded hemiaminals **11**, which reacted with the Grignard reagents to give oxabicyclic amino alcohols **12** after hydrolysis with excellent stereoselectivity (Scheme 3). Simple rDA reactions of **12** afforded substituted unsaturated amino alcohols **13** on heating of the neat compound or refluxing of a solution in xylene.[21] The microwave (MW)-assisted thermolysis of 7-oxabicyclo[2.2.1]hept-2-en-1,4-amino alcohols **12** resulted quantitatively in the desired unsaturated derivatives **13** within a very short time (10–15 min) and at relatively low temperature s (120–140 °C) (Table 2). Conventional heating at similar temperatures required longer reaction times (3–10 h). Thus, MW activation at 300 W under solvent-free conditions proved best for the rDA reaction. For monobenzylated amino alcohols, this was the only method that proceeded fast and cleanly. All products exhibited similarities in their hydrogen-1 nuclear magnetic resonance spectroscopy (^{1}H-NMR) spectra; the values of the coupling constants between the vicinal ethylenic protons were characteristic of *Z*-olefins.[22]



Scheme 3

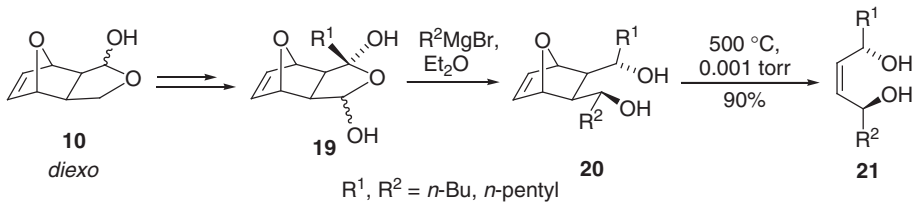
Table 2 Preparation of unsaturated amino alcohols **13** by cycloreversion (Scheme 3)

No.	R^1	R^2	*rDA conditions*	*Yield of* ***13*** *(%)*
1	H	*n*-Bu	Neat, 160 °C, 6 h	74
2	H	CH_2=CH	Neat, 160 °C, 6 h	80
3	$PhCH_2$	*n*-Bu	Xylene, 145 °C, 8 h	85
4	$PhCH_2$	CH_2=CH	Xylene, 145 °C, 2.5 h	95
5	$PhCH_2$	Me	Xylene, 145 °C, 4 h	85
6	H	*n*-Bu	MW, 120 °C, 15 min	≥98
7	$PhCH_2$	*n*-Bu	MW, 140 °C, 10 min	≥98



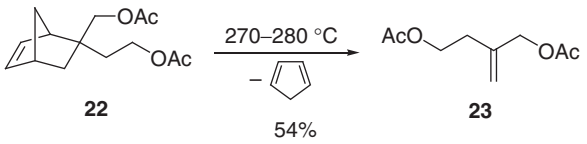
Starting from racemic lactol **10**, the efficient syntheses and rearrangements of (*Z*)-allylic trichloroacetimidates have been reported. Treatment of *diexo* **10** with different Grignard reagents and protection of the resulting primary hydroxy group with *t*-butyldiphenylchlorosilane, followed by MW-assisted rDA, led to the monoprotected allylic diols **15** (Scheme 4).[23]

Scheme 4



5.12.2.2 Unsaturated 1,4-Diols

Nucleophilic Grignard addition to the tricyclic lactol **16** or its diastereoisomer led to allylic diols **18** with very high selectivity via reductive ring opening and then pyrolysis (Scheme 5). From scalemic lactol **16**, three of the four possible diastereoisomeric *syn* or *anti* 1,4-diols were obtained. This example of remote asymmetric induction is evident from the synthesis of optically pure (2*R*,5*R*)-2,5-hexanediol and (3*S*,6*R*)-4-decene-3,6-diol **18** (R^1, R^2 = Et, *n*-Bu).[24]

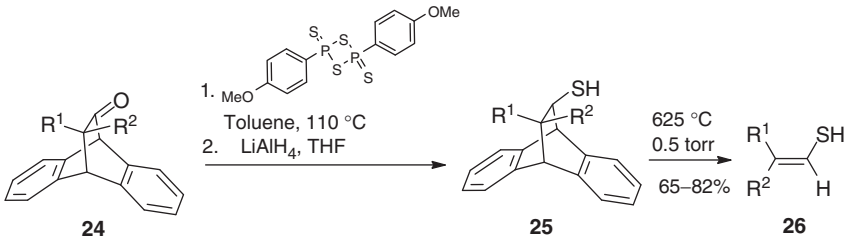


Scheme 5

Bicyclic 1,4-diols **20** were prepared from lactol **10** through Grignard reactions followed by oxidation, recyclization to the lactols and repeated Grignard processes (Scheme 6). Addition of alkylmagnesium bromides to lactol **10** led to bicyclic monoalkylated diols; oxidation of the primary alcohol with tetrapropylammonium perruthenate as selective and mild oxidizing agent in the presence of 4-methylmorpholine *N*-oxide gave lactols **19**, which reacted with another Grignard reagent to afford dihydroxyalkyl-7-oxabicyclo[2.2.1]hept-5-enes **20** with good diastereoselectivity. Under FVP conditions, chiral (*Z*)-alkene-1,4-diols **21** were obtained from these substrates.[25]

Scheme 6

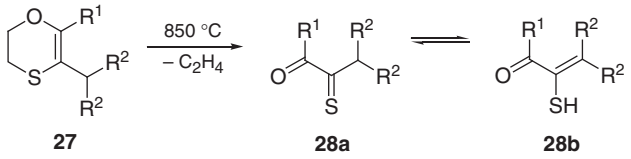
One of the key reactions of a recent synthesis of alternaric acid[26,27] was the Julia olefination of a tertiary aldehyde and a phenylsulfone containing an *exo*-methylene motif. The diester precursor **23** required for the preparation of the latter synthon was indirectly obtained by rDA reaction from 2-norbornenyl-1,4-butanediol-1,4-diacetate **22** (equation 5).



(5)

From suitable 9,10-dihydro-9,10-ethanoanthracene-*cis*-11,12-diols, a number of (*Z*)-1,2-disubstituted ethenes, including derivatives with two different substituents, have been prepared by rDA reactions. However, attempts to prepare 1,3,2-dioxasiloles bearing substituents only on the Si atom failed and resulted in dimers containing the ten-membered ring system (*Z*,*Z*)-2,2,7,7-tetraalkyl-1,3,6,8-tetraoxa-2,7-disilacyclodeca-4,9-diene. These compounds were formed diastereoselectively with regard to the double bonds.[28]

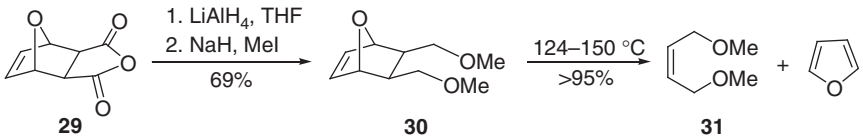
Five (*Z*)-2-alkoxyvinyl (isopropyl, butyl, hexyl, decyl, and 10-undecenyl) acetates were prepared by application of an rDA technique. Through the use of cyclopentadiene instead of anthracene in DA reactions, the synthesis of these typical detergents with long alkyl residues could be markedly improved. Amphiphilic polymers were obtained by cationic homopolymerization of these long-chain derivatives.[29]



5.12.2.3 α,β-Enethiols

On treatment with Lawesson's reagent [2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphethane-2,4-disulfide], 11-oxo-9,10-dihydro-9,10-ethanoanthracenes **24** resulted in thioxo derivatives, which were reduced to thiols **25** using $LiAlH_4$. Compounds **25** underwent cycloreversion to give enethiols **26** on application of an FVP technique (Scheme 7).[30]

Scheme 7

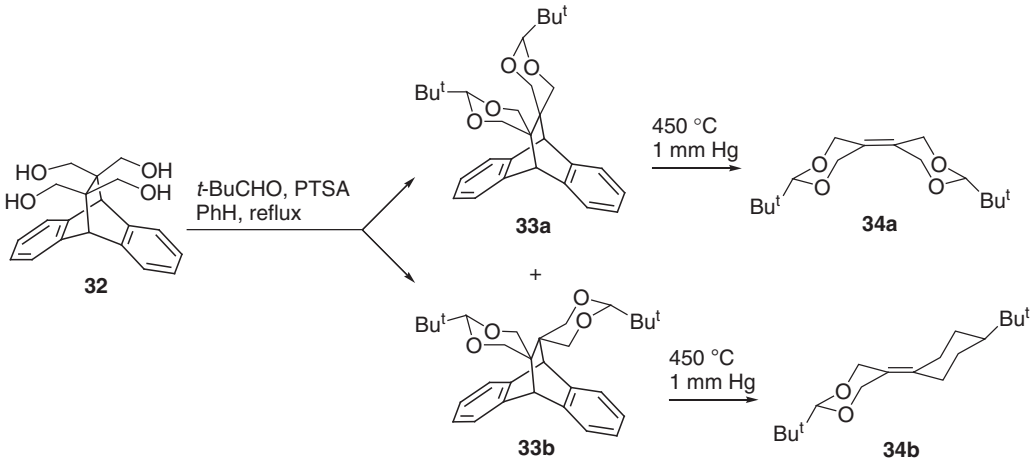


Retroene reactions of 2,3-dihydro-1,4-oxathiins **27** or FVP of α-allylthio-carbonyl compounds have been used to synthetize enethiolizable α-oxothiones at high temperatures (equation 6) by the extrusion of ethylene. In the course of the cleavage, α-thioxo-β-oxo alkanes **28a** are formed, which are in equilibrium with the enethiol forms **28b**.[31]

(6)

5.12.2.4 Unsaturated Mono- and Polyethers

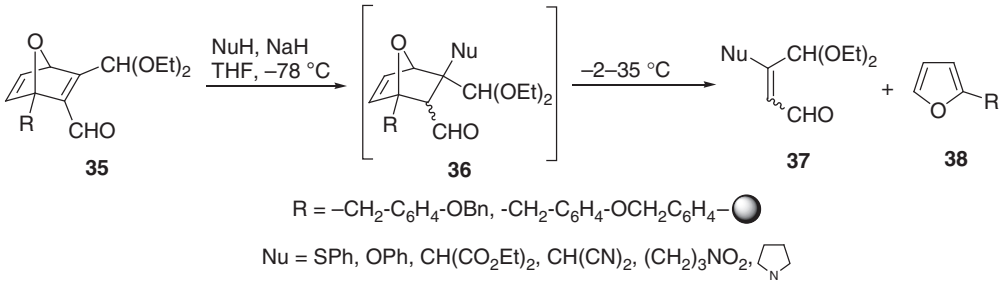
In experimental and theoretical studies of rDA reactions, 5,6-disubstituted-7-oxabicyclo[2.2.1]hept-2-ene derivatives have recently been applied.[32] The corresponding cyclic anhydride, methoxy ether or cyclic ether were submitted to thermal analysis to measure the kinetics of cycloreversion at different temperatures. The classical DA *diexo*-anhydride adduct **29** was methylated in two steps using an excess (2.5 equivalents) of MeI after reduction (Scheme 8). Thermogravimetric analysis (TGA) under a nitrogen atmosphere revealed rapid and complete decomposition, and thermolysis of **30** furnished the expected (*Z*)- *cis*-1,4-dimethoxy-2-butene **31**.



Scheme 8

5.12.2.5 Alkenediol Acetals

The stereofacial selectivity of addition reactions to the C=C bond of methylenecyclohexanes and methylenedioxanes is influenced by a substituent in a conformation fixed with respect to the double bond. Hence, 5-methylene-1,3-dioxanes containing a conformationally locked Ph or *t*-Bu group have been applied in theoretical and experimental studies.[33] One of these model compounds, anthracene-protected tetrole **32**, was condensed with pivalaldehyde by acid catalysis to give a mixture of two separable isomeric compounds. Sublimation of the bisacetals **33a,b** thus obtained afforded the stereoisomerically pure unsaturated *cis*- and *trans*-acetals **34a,b** (Scheme 9).



5.12.2.6 α,β-Unsaturated Aldehydes and Ketones

2- and 3-Benzylated soluble furans have been subjected to a sequence involving a DA reaction with an α,β-acetylenic carbonyl compound and a Michael addition, followed by an rDA process to yield a small library of α,β-unsaturated aldehydes.[34,35] Application of a resin with a dienic moiety immobilezed the unsaturated compounds by DA; after transformation of the

Scheme 9

cycloadduct, rDA cleavage released the modified unsaturated carbonyl products with regeneration of the starting resin under mild conditions. Functionalzation of α,β-ethylenic aldehydes **35** was attained through Michael additions with thiophenol, phenol, pyrrolidine, diethyl malonate, etc. An excess of the nucleophile and a catalytic amount (0.3 equivalent) of NaH were used (Scheme 10, Table 3). At room temperature, the reaction resulted in furans **38** and aldehydes **37** in variable ratios of the *E* and *Z* isomers. When a 2-furyl resin was used in a solid-supported procedure, only one regioisomer was obtained in the DA reaction, and a higher diastereoselectivity was observed both in the Michael addition and in the yields of the olefinic products.

Scheme 10

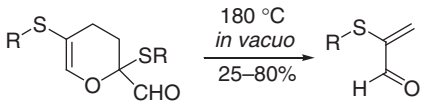


Table 3 Reactions of **35** with Michael donors and subsequent rDA conditions (Scheme 10)

No.	*Nucleophile (NuH) (3 equivalents)*	*Temperature of rDA*	*Product **37** Z/E ratio*	*Yield (%)*
1	PhSH	– 2–20 °C	75/25	88

5	$CH_2(CN)_2$	20 °C	–	–
6		35 °C	100/0	51[c]

[a]With polymer-bound DA adduct.
[b]On heating at 55 °C, the *Z*/*E* ratio was 41/59.
[c]Instead of NaH, benzyltrimethylammoniumhydroxide (Triton® B) was used.

Retrodiene decomposition of 2,5-dialkylthio-3,4-dihydro-2*H*-pyran-2-carbaldehydes **39** as cyclodimers resulted in α-alkylthioacrolein monomers **40** by thermal cleavage[36] (equation 7). On heating to 175–200 °C, the diethylacetal derivative of **39** underwent the rDA reaction and gave 2-butylsulfanylprop-2-enal (R=*n*-Bu) and the corresponding acetal. Similar partial

decomposition was observed during the gas chromatography–mass spectrometry analysis (injector temperature 250 °C and oven temperature 280 °C), when the diethylacetal of **39** was formed.[37]

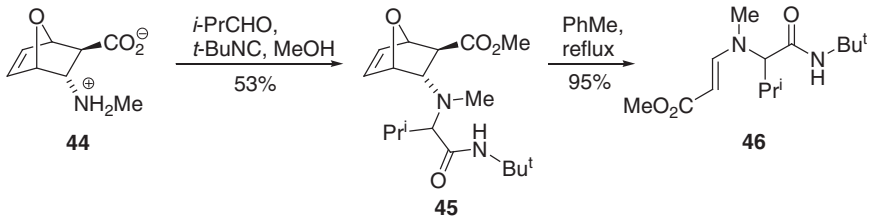
5.12.2.7 α,β-Unsaturated Esters and β-Aminoesters



β-Aminoacrolein itself is unstable, whereas its *N*-substituted derivatives and esters are stable. β-Aminoacrolein cannot be prepared directly from *diendo* or *diexo*-3-aminobicyclo[2.2.1]hept-5-ene-2-carboxylic acids in an rDA reaction. The thermolysis of *N*-protected oxa- or methylene-bridged bicyclic β-amino acids was developed by Akssira et al.[38] Starting from dicarboxylic monoesters **41,** through the protected aminoacid esters **42**, *N*-*t*-butyloxycarbonyl β-aminoacids **43** were prepared via the Curtius rearrangement followed by cycloreversion. Saponification of the aminoacid ester **43** (R=Me) and acidification gave the free unsaturated acid (R=H) (Scheme 11).

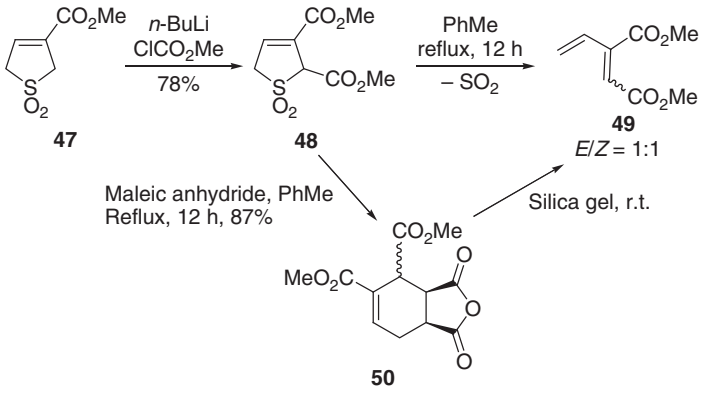
41 *diendo, diexo* **42** **43**

Scheme 11

By modification of a known procedure, a multicomponent reaction was devised that involved conversion of the unsaturated bicyclic *trans*-β-amino acid **44** to the sole diastereoisomer **45**, which was subjected to an rDA process to furnish compound **46** (Scheme 12). This method was successfully applied with chiral auxiliaries and the reverse DA reactions proceeded under very mild conditions.[39]

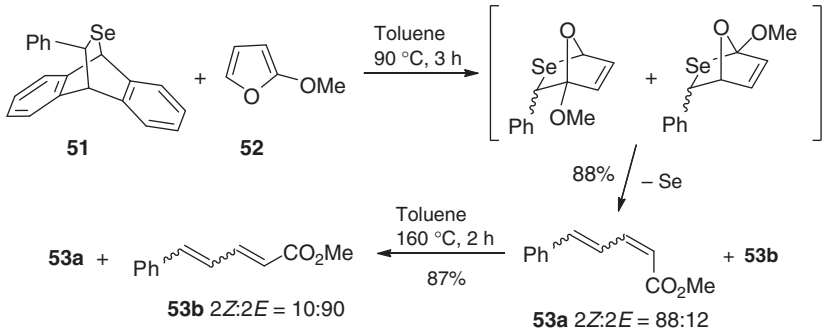
44 **45** **46**

Scheme 12



5.12.3 Preparation of Polysaturated Hydrocarbons and Arenes

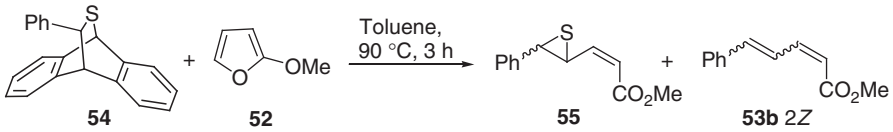
5.12.3.1 Acyclic 1,3-Dienes



Treatment of sulfolene monoester **47** with 2 equivalents of *n*-BuLi led to the dianion, which was acylated with methyl chloroformate to yield diester **48**. On heating, a sigmatropic elimination of SO_2 occurred to afford stable but volatile 1,3-dienes **49** as a mixture of *E* and *Z* isomers. When **48** was refluxed with MA, two isomeric cycloadducts **50** were formed in a ratio of approximately 1:1 (Scheme 13). By chromatographic purification on a silica gel column, anhydride **50** underwent rDA cleavage, which gave back the MA and resulted in dimethylpenta-2,4-dienoate **49**.[40]

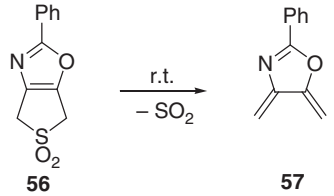
The selenoaldehydes regenerated in thermal rDA reactions of anthracene cycloadducts under neutral conditions reacted with 2-methoxyfuran **52** to give methyl penta-2,4-dienoates.[41] Thus, the reaction of compound **51** and 2-methoxyfuran **52** led to methyl 5-phenylpenta-2,4-dienoate **53a** (as a mixture of four geometrical isomers) and Se (Scheme 14).

An increase in the temperature influenced the ratio of the 2*Z* and 2*E* isomers of the resulting dienes, whereas the substituents on the aromatic ring did not affect the isomer ratio. A sulfur analog was subjected to a similar reaction: when the



Scheme 13

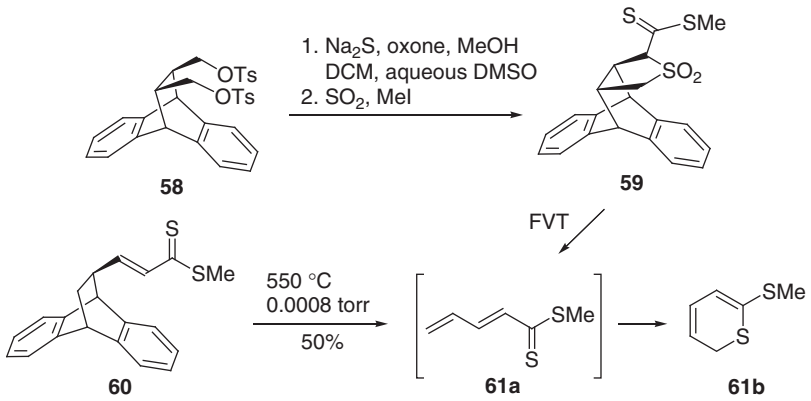
Scheme 14



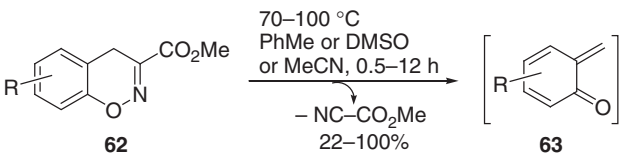
thioaldehyde–anthracene-[4 + 2] cycloadduct **54** was heated with 2-methoxyfuran, the thiirane derivative **55** was formed and isolated as a mixture of *cis* and *trans* isomers together with 2*Z*-penta-2,4-dienoate **53b** (equation 8).

(8)

5.12.3.2 Exo- and Endocyclic 1,3-Dienes



The thermal reactivity was studied and theoretical considerations were taken into account in the process by which 2-phenyloxazolo-3-sulfolene **56** afforded the exocyclic 1,3-diene 4,5-dimethylidene-2-phenyl-4,5-dihydro-1,3-oxazole **57** by extrusion of sulfur dioxide (equation 9).[42]

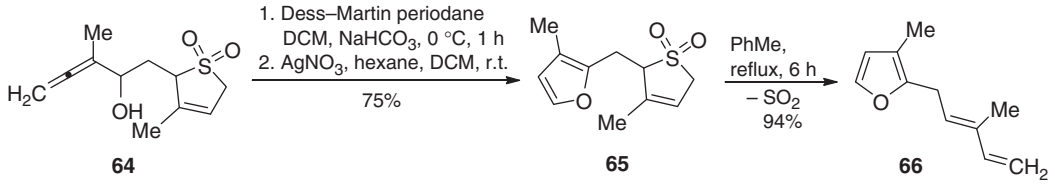


(9)

Methyl penta-2,4-dienedithioate **61a** was generated by flash vacuum thermolysis of the ethanoanthracene precursors **59** or **60** via different routes (Scheme 15). One of the key intermediates, sulfolene **59**, was obtained from the 1,4-diol ditosylate **58** in a multistep procedure. However, the acyclic 1,3-diene **61a** proved to be unstable and underwent spontaneous transformation to the much more stable endocyclic diene **61b**.[43]

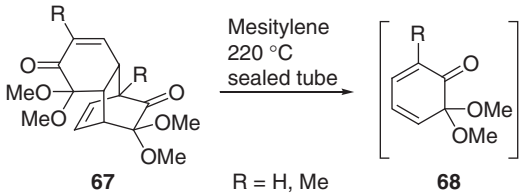
When heated at different temperatures, 4*H*-1,2-benzoxazines **62** with various substituents on the benzo-ring afforded *o*-quinone methides through an rDA process (equation 10). The *o*-quinone methides **63** formed are highly reactive short-lived intermediates and underwent immediate DA reactions with dienophiles *in situ* to yield phenol and chromane derivatives.[44]

Scheme 15



(10)

R = H, Me, F, Cl, Br, CF_3, CN, NO_2

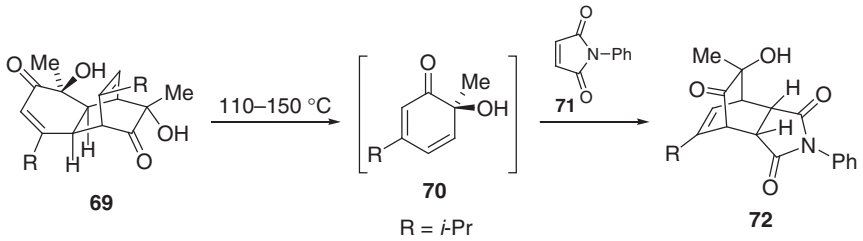


In an analogous process, 3-methyl 4*H*-1,2-benzoxazine **62** (R = H) underwent thermolysis when boiled in $CHCl_3$ and gave the tetracyclic 12a-methyl-7*H*,12a*H*,13*H*-[1,3]benzoxazino[3,2-*b*][1,2]benzoxazine. Rearrangement to the isomeric 5a-methyl-5a*H*,11*H*,13*H*-[1,3]benzoxazino[2,3-*b*][1,3]benzoxazine took place on prolonged heating (~17 h), and *o*-quinonemethide was also generated by thermolysis; the latter was trapped by ethyl vinyl ether to yield 2-ethoxy dihydrobenzopyran.[45]

A straightforward synthesis of an unusual bis(acyclic–cyclic) 1,3-diene from an allenic alcohol was achieved by Winkler et al.[46] The Dess–Martin oxidation of **64** to the corresponding ketone, followed by furan formation by Ag^+-promoted intramolecular cyclization led to 2-furanylsulfolene **65**. rDA fragmentation of this compound in the presence of $NaHCO_3$ (with the loss of SO_2) gave bisdiene **66** (Scheme 16).

Scheme 16

Dimers **67** were prepared by the self-dimerization of cyclohexa-2,4-dienones through *endo* [4 + 2] cycloaddition. However, this reaction was reversible at higher temperatures leading to the *in-situ* generation of dienes **68** (equation 11). These compounds, which proved to be unstable intermediates, could be masked very successfully with *o*-benzoquinones for further DA reactions with dienophiles.[47]



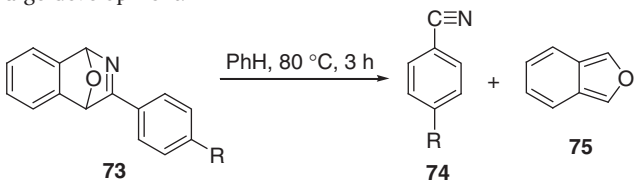
(11)

Tandem rDA/DA reactions of dimers derived from *o*-quinol or masked *o*-benzoquinone proceed well, for example, between the readily accessible dimer (–)-**69** and *N*-phenylmaleimide **71** as dienophile, in a thermolytic process (Table 4). Although the reactions in toluene and chlorobenzene generated the desired cycloadducts **72** in moderate to good conversions after 12 h, the

reactions in mesitylene at 150 °C gave both excellent conversions and yields of the isolated cycloadduct **72** after 1.5 h.[48] A concise total synthesis, which involves an rDA/DA cascade of dimer **69**, was achieved for both enantiomers of chamaecypanone C, a novel microtubule inhibitor.

Table 4 Tandem thermolytic rDA/DA reactions of dimer **69** (Scheme 17)

No.	*Solvent*	*T* (°C)	*Reaction time (h)*	*Conversion (%)*
1	Toluene	110	12	74
2	Chlorobenzene	130	12	92
3	Mesitylene	150	1.5	>99

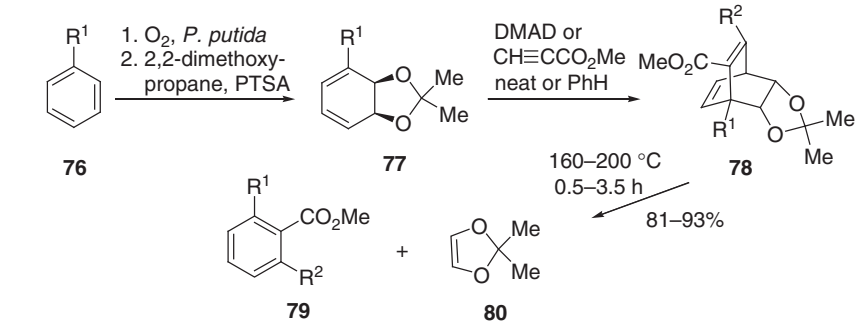


Scheme 17

Various examples have been detailed in the review articles which survey these domino rDA/DA reactions and report alternative preparations of masked *o*-benzoquinones as key synthons.[49–53]

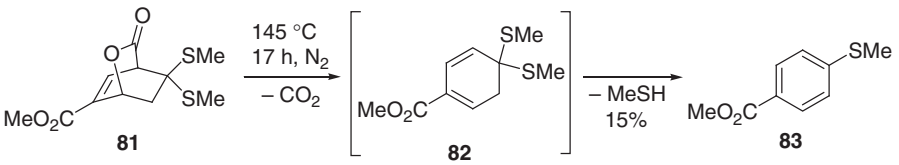
5.12.3.3 Benzene and Other Aromatic Ring Systems

The rDA expulsion of benzonitriles **74** from 1,4-dihydro-1,4-epoxy-3-phenylisoquinolines **73** led to the formation of isobenzofuran **75** when the adducts were heated (equation 12). The sequence proved suitable for the preparation of isobenzofuran, which could be utilized *in situ* or isolated as a solution for subsequent applications. Benzyne cycloadducts have also been prepared from 4-(4-nitrophenyl)- and 4-(4-methoxyphenyl)oxazoles, in order to assess the effects of the remote substituents in rDA reactions. The first-order rate constants were determined at three different temperatures in the range of 40–70 °C. The order of reactivity was found to be *p*-NO_2 > H > *p*-OMe; the substituent effects were small, with a factor of <4 separating the rate for *p*-NO_2 from that for *p*-OMe. All three substrates exhibited small ΔS values. The expulsion of the nitrile was presumed to occur in a concerted reaction with little charge development.[54]



(12)

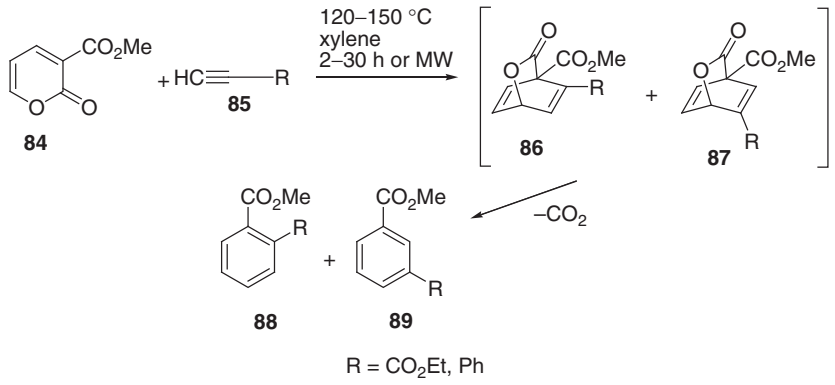
In a world patent, Williams reported an rDA method for the preparation of polysubstituted benzene derivatives. Starting from cycloadducts of type **78** endowed with either hydroxy or acetal groups, methyl benzoates or dimethyl phthalates were formed with the concomitant elimination of dioxolene species.[55] Adducts **78** can be obtained by DA cycloaddition of an acetylenic dienophile to cyclohexadiene-*cis*-1,2-ketaldiols **77**; the required cyclohexadienes may be prepared from arenes by biological oxidation of *Pseudomonas putida*. The thermolysis of **78** was achieved under mild conditions and gave the substituted arenes **79** (Scheme 18).



With diethyl acetylenedicarboxylate and ethyl propiolate, similar reactions of substituted 1,3-cyclohexadienes took place within 20 min on MW irradiation or in 1–9.5 h on conventional refluxing in toluene, which resulted in analogous formations of polysubstituted benzenes. The cycloadducts underwent elimination of ethylene and gave benzene derivatives as sole and pure products. MW procedures were found to be more effective and rapid than classical heating for these one-step DA/rDA reactions.[56]

The oxygen-bridged DA adduct **81** was prepared by the reaction of methyl coumalate with bis(methylthio)ethene. On heating, the adduct decomposed as monitored by ^{1}H-NMR. Among the other products, the substituted benzene derivative **83** was formed by the loss of CO_2 and further elimination of methanethiol from the intermediate cyclohexadiene **82** (Scheme 19).[57]

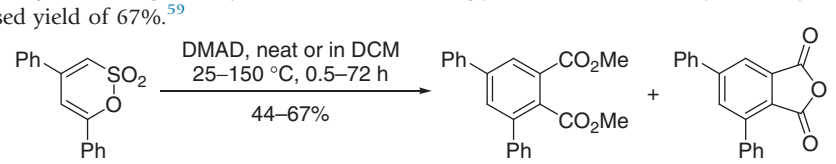
On conventional heating with acetylenic dienophiles **85** under MW-promoted conditions, the irreversible DA cycloaddition of 3-carbomethoxypyrone **84** improved the synthesis of substituted benzoates (Scheme 20).[58] The reaction of **84** with ethyl



Scheme 18

Scheme 19

propiolate (R = CO_2Et) proceeded with a product ratio **88**/**89** = 65/35 in 50% yield (Table 5). With phenylacetylene (R = Ph) **85** as dienophile, the reaction also gave a mixture with poor selectivity (**88**/**89** = 65/35) on extended heating in toluene at 250 °C (in a closed vessel). Solvent-free MW-assisted conditions were found to be best for the rDA aromatization processes. These reactions were generally irreversible because of the expulsion of CO_2 from the adducts.



Scheme 20

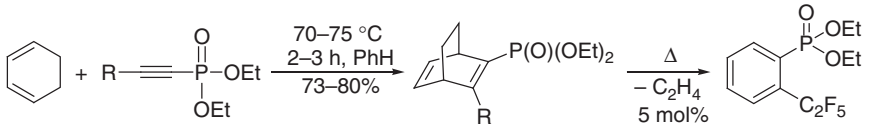
6	Ph	MW	–	150	3	64	100/0

When MW irradiation (100 W) was applied with an excess (5 or 8 equivalents) of dimethyl acetylenedicarboxylate (DMAD), the domino DA/rDA reaction of 1,3-dienic δ-sultone **90** resulted in the formation of phthalic diester **91** and the anhydride **92** in a ratio of ~3:1 (equation 13). The use of conventional heating in a solvent-free medium led to a **91**/**92** ratio of 3:2. In DCM at a high pressure (1300 MPa), the analogous DA/rDA reactions surprisingly produced the diphenyl dimethyl phthalate **91** as the sole product in an increased yield of 67%.[59]

90 **91** **92** (13)

The release of isocyanates **95** from the DA adducts of pyridones **93** can be used to generate highly substituted aromatic compounds **94** (Scheme 21). By trapping or isolation, the isocyanates may be separated from the product.[60]



93 **94** **95**

R = Me, Et, *n*-Pr

Scheme 21

The reactions of perfluoroacetylenephosphonates **97** with cyclohexa-1,3-diene **96** on heating furnished the bicyclic adducts **98** as fairly stable fluids in yields of 73–80% (Scheme 22). However, when R = C_2F_5, the product underwent an rDA reaction during distillation, with the splitting-off of ethylene and the formation of the aromatic diethyl 2-(pentafluoroethyl)phenylphosphonate **99** together with traces of isomeric cyclohexa-2,4- and -2,6-dienylperfluoroalkylphosphonates as confirmed by ^{31}P-, ^{19}F-, and ^{1}H-NMR spectroscopy.[61]

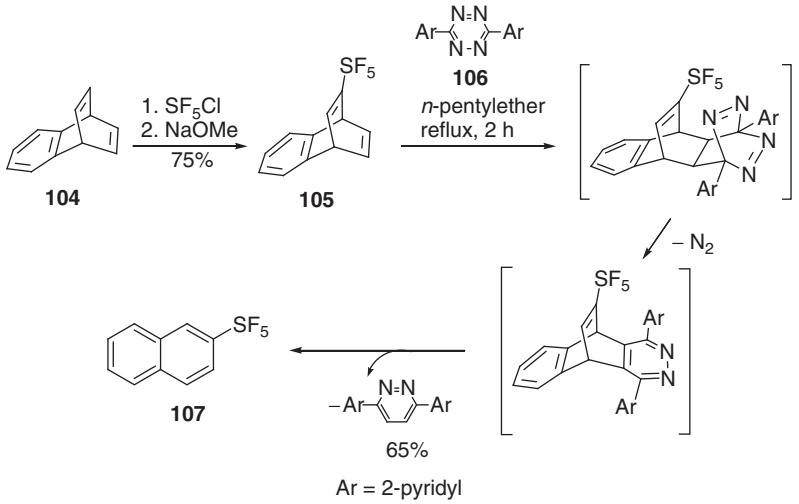
Scheme 22

Domino [4 + 2]/retro [4 + 2] cycloadditions of alkynyl-substituted pyridines and pyrimidines **100** with electron-rich dienes **101** afforded pyridyl- and pyrimidyl-substituted benzenes **103**. The reactions proceeded through the formation of bridged cycloadducts **102**, with the subsequent thermal extrusion of ethylene in a pressure tube (Scheme 23).[62]

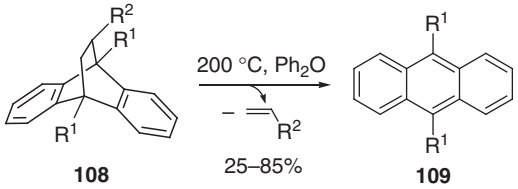


100 **101** **102** **103**

X = CH, N; R^1 = OMe, OEt; R^2 = H, OTMS; R^3 = H, OH

Scheme 23

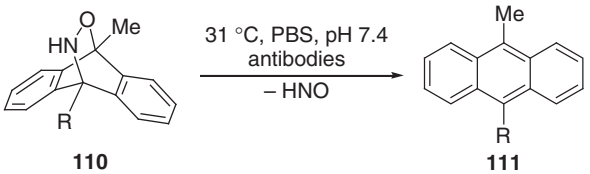
When 2-pentafluorosulfanylbenzobarralene **105** was heated with 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine **106,** the reaction involved elimination of the ethylene bridge, which prevented cycloaddition and retro reaction sequences and yielded 2-pentafluorothionaphthalene **107** (Scheme 24). Cycloadduct **105** was prepared by the addition of SF_5Cl to benzobarralene, followed by the base-promoted elimination of HCl.[63] The direct thermal rDA of the adduct **105** was unsuccessful, because it is sufficiently stable between 250 and 350 °C.



Scheme 24

The application of MW-mediated heating (90–120 W, max. 301–421 °C) of various anthracene DA adducts supported on graphite resulted in the recovery of the starting anthracene and dienophile (MA, fumaric diester, or 1,4-benzoquinone) in 56–80% yields.[64]

The kinetics, rate constants, enthalpies, entropies, and volumes of activation for the rDA reaction of the 9-chloroanthracene–tetracyanoethene cycloadduct were determined in different solvents (e.g., MeCN, DCE, benzene, toluene, or EtOAc). Complete decomposition was reached only in the presence of an appropriate reagent, used for irreversible trapping of the 9-chloroanthracene. It was found that cyclopentadiene combined rapidly and irreversibly with tetracyanoethene and gave more stable adducts.[65]



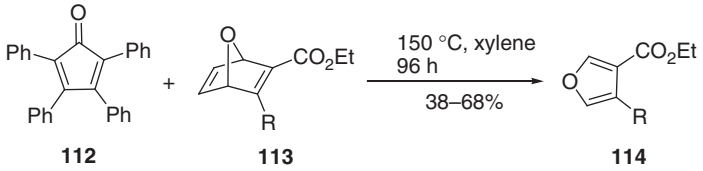
To accelerate the rDA splitting of other anthracene cycloadducts or adducts, compounds containing distal siloxy substituents were studied; the reactions were carried out in Ph_2O (equation 14). A comparison of the rate constants indicated a clean first-order kinetic process. On linear least-squares analyses, a 19-fold rate increase was observed for the siloxy compounds relative to other substituted derivatives.[66]

(14)

R^1 = H, Me, OSiMe; R^2 = CN, CO_2Et

To accelerate the rDA process in aqueous phosphate-buffered saline medium, nitroxyl synthase antibodies (10F11, 9D9, and 27C5), which catalyze the release of nitroxyl (HNO), were gained from the tricyclic prodrugs **110** (equation 15). The reaction led to 9-methyl-10-carboxy derivatives of anthracene **111**. Theoretical and experimental results relating to the catalytic effect of the antibodies were reported by Hugot et al. and Leach et al., who employed programs to calculate the docking modes of molecules into the protein-binding sites.[67,68]

(15)

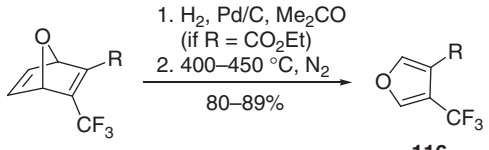


R = H, $(CH_2)_2CO_2H$, $(CH_2)_2CONH(CH_2)_2NH_2$, $CONH(CH_2)_2CO_2H$

Photo rDA reactions of a variety of [4 + 2] anthracene and tetracene cycloadducts have been studied extensively. The experimental results demonstrated that the photoreactivity depends on the electron-donating ability of the diene and the electron-withdrawing ability of the dienophile. The mechanism was investigated by means of fluorescence spectroscopy through trapping

of the reaction intermediate and measurement of the time-resolved absorption. For the photoreactivity (quantum yield), a wavelength of 254 nm was chosen, at which the polyaromatic ring systems absorb efficiently.[69]

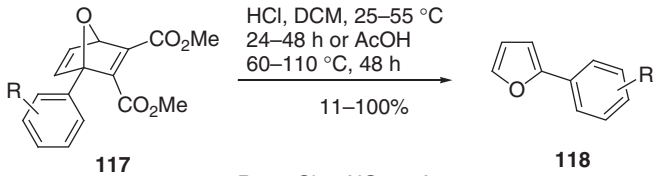
5.12.3.4 Furan as a Heteroaromatic 1,3-Diene



By cycloreversion, 3-perfluoroalkyl-4-ethoxycarbonylfurans **114** were prepared from 2-perfluoroalkyl-3-ethoxycarbonyl-7-oxabicyclo[2.2.1]hepta-2,5-dienes **113** with tetraphenylcyclopentadienone **112** as forceful diene (equation 16). This diene-exchange process was carried out in xylene.[70]

112 **113** **114**

R = CF_3, C_5F_9, C_7F_{15} (16)



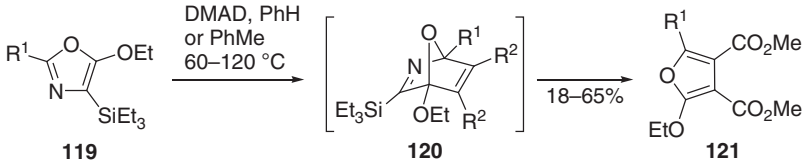
Thermolysis of 2,3-bis(trifluoromethyl)-7-oxabicyclo[2.2.1]hepta-2,5-dienes **115** yielded 3,4-bis(trifluoromethyl)furans **116** (R=CF_3) through the splitting-off of acetylene.[71] However, when R=CO_2Et, regioselective hydrogenation of adducts **116** was necessary in order to achieve complete pyrolysis at 400 °C (equation 17).[72]

115 **116**

R = CF_3, CO_2Et (17)

On reaction with Lewis acids (e.g., $ZnBr_2$ or ZnI_2), 7-oxabicyclo[2.2.1]heptadienes **117** could be converted easily to phenols or 6-hydroxyfulvenes, which, depending on their nature, reacted with Brønsted acids to give rearranged products. In the presence of gaseous HCl or glacial $MeCO_2H$, unique acid-promoted rDA processes were observed, leading to 2-phenylfurans **118** almost exclusively (equation 18, Table 6).[73]

117 **118**



R = 2-Cl, 4-NO_2, 4-Ac (18)

Table 6 Acid-catalyzed rDA transformation of 7-oxanorbornenes **117** (R=2-Cl) (equation 18)

No.	*Acid*	*Solvent*	*T (°C)*	*Time (h)*	*Yield (%)*
1	HCl (g)	DCM	25	48	100
2	HCl (aqueous)	DCM	55	24	50
3	AcOH	–	60	48	60
4	AcOH	–	90	48	75
5	AcOH	–	110	48	82

With electron-poor alkynes (e.g., DMAD), silylated oxazoles **119** underwent intermolecular and intramolecular DA/rDA reactions to generate polysubstituted furans **121** through unstable bicyclic [4 + 2] adducts **120** (Scheme 25). From these, nitriles were eliminated under mild conditions, the process resulting in the formation of furan derivatives **121** (Table 7). Similar reactions with other oxazoles (R^1=2-furanyl, NMe_2) were completely unsuccessful, possibly because of the electron-donating effect of these substituents; the yield of the methyl derivative was also poor, whereas with electron-withdrawing groups (e.g., Ph or CO_2Me) the yield increased. With DMAD, 2-furanyloxazole **119** gave a 1:1 cycloadduct, because the furan ring is more electron-rich than

the oxazole.[74] The highly electron-rich dimethylaminooxazole underwent a rapid reaction to furnish products that could not be isolated.

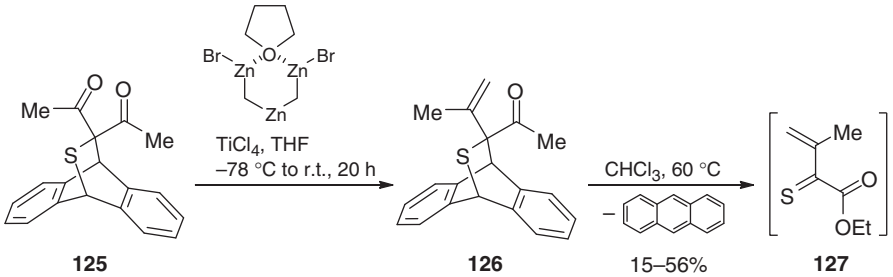
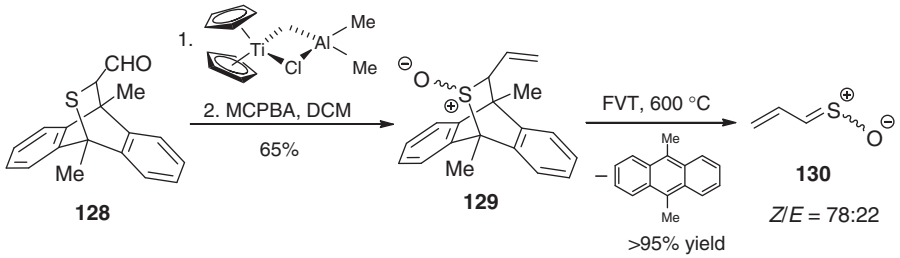
5.12.4 Formation of Small Molecules Containing C=X or X=Y Heteroatom Bonds



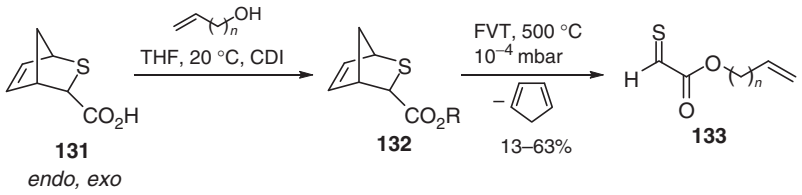
5.12.4.1 Unsaturated Thioaldehydes, Thioketones, and α-Thioxoesters

Lee et al. trapped ethyl thioxoacetate **124**, prepared by rDA fragmentation of the bicyclic precursor **123**, which in turn was obtained by a fascinating reaction of aminocrotonate **122** with SCl_2 (Scheme 26). For the trapping, 2,3-dimethyl-1,3-butadiene or 1,3-cyclohexadiene were used.[75]



Scheme 26

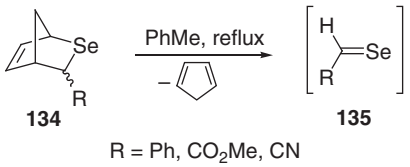
For the transformation of the oxo group to a methylene, the anthracene–α,α′-dioxothioketone cycloadduct **125** was treated with the Nysted reagent and a Ti compound. The resulting product **126** underwent thermal decomposition via rDA fragmentation to give the unstable α,β-unsaturated-α′-oxo derivative **127** (Scheme 27). This thioketone reacted as heterodiene or heterodienophile to furnish 5,6-dihydro-4 H- or 2 H-thiopyrans, respectively.[76]



Scheme 27

Through conversion of the formyl group to a methylene unit with the Tebbe reagent, the first synthesis of thioacrolein *S*-oxide **130** was achieved by means of a similar anthracene template. By selective and mild oxidation with *m*-chloroperoxybenzoic acid (MCPBA), **128** afforded sulfoxide **129** as a mixture of two stereoisomers (*Z*/*E* = 70/30 by ^{1}H-NMR). Flash vacuum thermolysis of **129** led to 9,10-dimethylanthracene, which was recovered (Scheme 28). The volatile **130**, trapped at − 196 °C and analyzed by NMR at − 60 °C, consisted of two isomeric sulfines in different *Z*/*E* ratios.[77]

Scheme 28

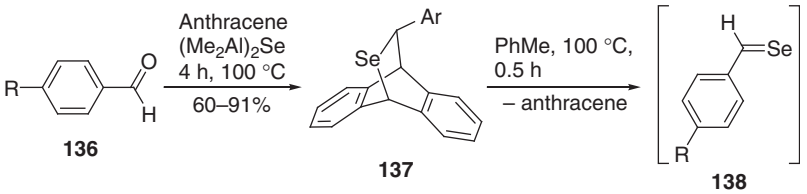


The cycloadduct of cyclopentadiene and thioaldehyde–acetic acid (HO_2C–CHS) **131** was converted to esters **132** on reaction with alkenols. When subjected to FVP, **132** gave alkenyl thioxoacetates **133** (Scheme 29), which then underwent spontaneous intramolecular reaction on silica in MeOH at 20 °C to give thia-alkenolides containing 6- to 11-membered rings.[78,79]

Scheme 29

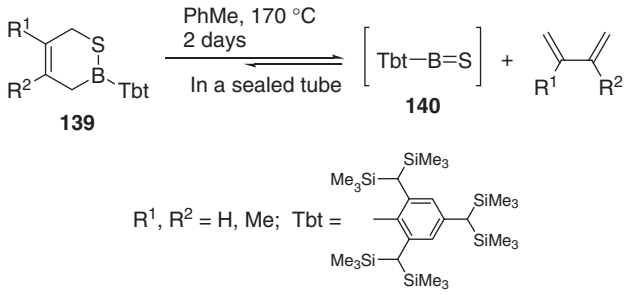
5.12.4.2 Unsaturated Selenoaldehydes

Bicyclic adducts **134** yielded selenoaldehydes **135** when refluxed in an inert solvent (equation 19). This procedure proved advantageous over other methods for the *in-situ* preparation of selenoaldehydes, which react with suitable Wittig reagents in a regular fashion to give the corresponding alkene products (e.g. cinnamate esters or fumarates). The adducts **134** in turn were prepared by simple mixing of a stabilized ylide and elemental selenium and heating of the mixture in the presence of cyclopentadiene.[80]



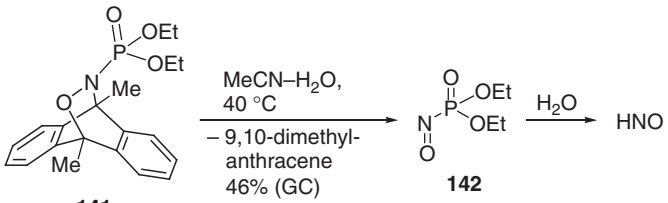
(19)

With bis(dimethylaluminum)selenide in the presence of anthracene, 4-substituted benzaldehydes **136** gave cycloadducts **137**, which could be cleaved to reactive selenoaldehydes **138** in a one-step reaction (Scheme 30). The latter were trapped by 2-silyloxy-1,3-butadiene, 2-methoxyfuran, or 5-ethoxyoxazoles to give the corresponding selenacyclic cycloaddition products.[81]



5.12.4.3 Compounds Containing X=Y Heteroatom Bonds

Regioisomeric (2:1) mixtures of adducts 4- and/or 5-methyl-1,2-thiaboracyclohex-4-enes **139** readily underwent [4 + 2] cycloreversion, but the starting compounds were recovered in 59% yield after cooling. ^{1}H-NMR spectroscopic monitoring showed that the initially formed thioxoborane (Tbt-B=S) **140** did not dimerize, but existed as a monomer even at a high temperature (170 °C). It therefore had a sufficient lifetime for a DA reaction with an equimolar amount of diene (isoprene), leading to the regeneration of a (1:1) mixture of the starting cycloadducts.[82]

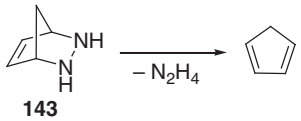


136 **137** **138**

Scheme 30

139 **140** (20)

P-nitrosophosphates reacted as *N*-*O* heterodienophiles with 1,3-dienes to give functionalized cycloadducts, which could be transformed directly to allylic phosphoramidates. With 9,10-dimethylanthracene, the *P*-nitrosophosphate gave rise to cycloadduct **141**, which underwent rDA dissociation to reform **142** (equation 21). In the absence of 1,3-dienes, the mild thermal decomposition of the DA adducts resulted in formation of NO, as evidenced by the presence of HNO. The yield of **142** (46%) was determined by GC. The results identified *P*-nitrosophosphates as the new species that react similarly to acyl nitroso compounds as useful synthetic intermediates and potential HNO delivery agents.[83]

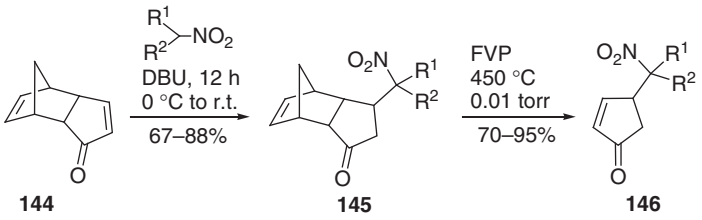


141 **142** (21)

The *N*-acylnitroso analogs were found to be photoinducible HNO-releasing agents, which were also prepared by [4 + 2] cycloaddition of 9,10-dimethylanthracene with nitroarylaminoacylnitroso (NO_2–Ar–NHCON=O) derivatives.[84] The reaction rate proved to be dependent on the intensity of the light source. Some derivatives were thermally stable and not activated by ultraviolet A irradiation. The results indicated that their stability was largely dependent on the steric hindrance of the substituents.

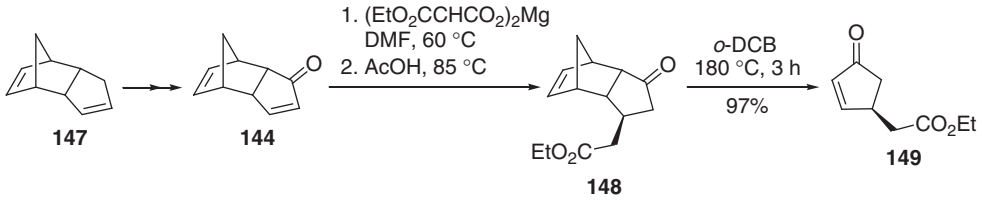
5.12.5 Production of Cycloalkane Derivatives

5.12.5.1 Cyclopentane Derivatives



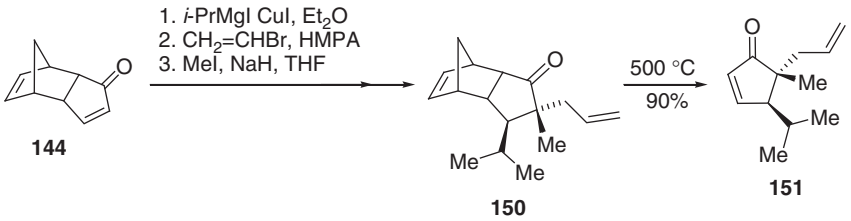
The first synthesis of 2,3-diazabicyclo[2.2.1]hept-5-ene **143** in 1993 was facilitated by the isolation of the biscarboxylates formed by the hydrolysis of biscarbamates. The rDA splitting to diimide and cyclopentadiene under mild conditions was explored (equation 22).[85]

143 (22)



1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) catalysis of the Michael addition of nitroalkanes to dicyclopentadienone **144** provided bicyclic nitroketones **145**, which were subjected to FVP to furnish cyclopentenones **146** (Scheme 31). Although organonitro derivatives are usually labile and have explosive properties at high temperatures, **146** proved to be fairly stable. Compounds **145** can be transformed via an Nef reaction to carbonyl derivatives (R^1=H and R^2=H, Me, Et) by the use of MeONa and $TiCl_3$ in aqueous MeOH. FVP of the resulting bicyclic ketones at 350 °C gave the expected 4-acetyl- and propionylcyclopentenones.[86]

A chemoenzymatic multistep synthesis was developed for the preparation of enantiomerically pure oxoester **149**, with rDA fragmentation as the key step. Dicyclopentadiene **147** was transformed to enone **144** in several steps via manganese

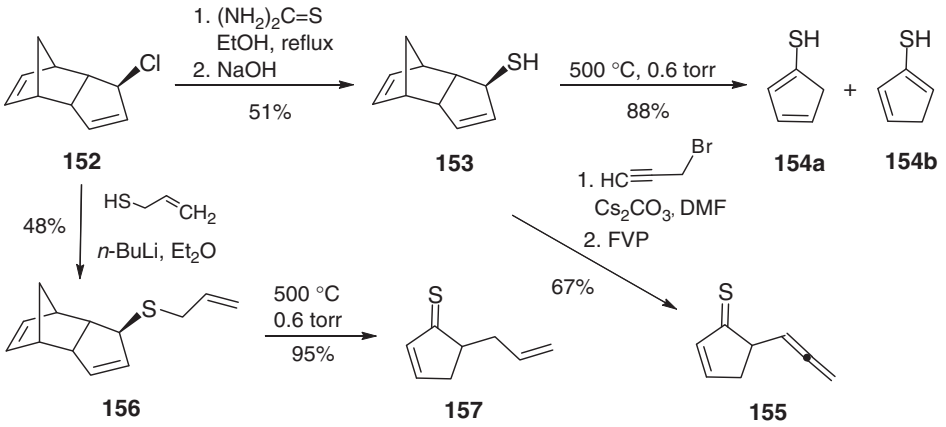


Scheme 31

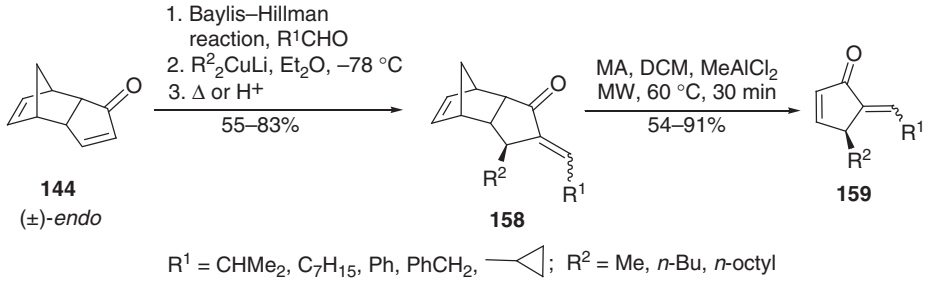
triacetate-mediated allylic acetoxylation, and the racemic mixture of acetates was then hydrolyzed to the corresponding alcohols. After enzymatic resolution with lipase polystyrene (PS), separation and oxidation with pyridinium chlorochromate afforded the enantiopure cyclic ketone **144**. With magnesium monoethyl malonate, the conjugate addition to **144** resulted in the corresponding Michael adduct as a single diastereomer. Acidic workup gave oxoester **148** through partial decarboxylation (Scheme 32). Refluxing of oxoester **148** in 1,2-dichlorobenzene resulted almost quantitatively in the cyclopentenone derivative **149** by an rDA reaction.[87]

Scheme 32

In studies aimed at the total synthesis of the biologically important natural product guanacastepene A, a new and concise route to a fully functionally endowed hydroazulenic core was devised. The strategy set the requisite stereochemical features on the *endo*-tricyclo[5.2.1.$0^{2,6}$]decane matrix followed by excision of the five-membered ring in an rDA reaction (Scheme 33). Specifically, enone **144** was alkylated and allylated regioselectively in multiple steps. The crowded ketone **150** was pyrolyzed to give product **151**.[88]



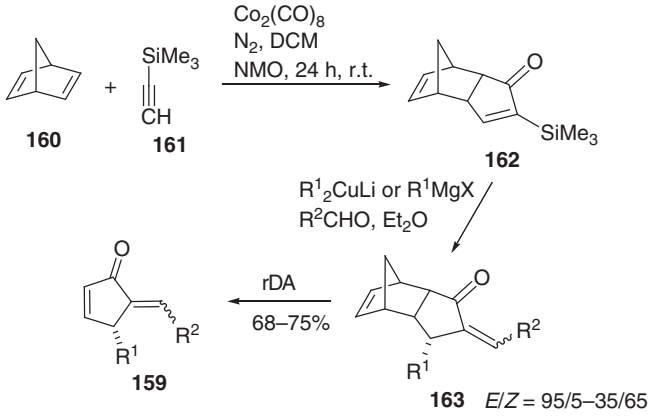
Scheme 33



By elimination of cyclopentadiene in an rDA reaction, the FVT of tricyclic allyl- (e.g. **156**) or propargyl-substituted sulfides led to mixtures of isomeric allylthio- or propargylthiocyclopentadienes (e.g. **157**), respectively (Scheme 34). However, the propargyl derivative underwent a thio-Claisen rearrangement, which resulted in the reactive 5-allenylcyclopentene-1-thione **155** (Scheme 34). The corresponding alkenyl- and alkinylthiobicycles were prepared by two different known routes from chlorodicyclopentadiene **152**. Possible retroene reactions involving the elimination of propene or allene from the allylthio or propargylthio moieties were not observed. Under FVT, the tricyclic thiol **153** afforded a mixture of isomeric cyclopentadienethiols **154a** and **154b**, which tautomerize to cyclopentenethione on warming.[89]

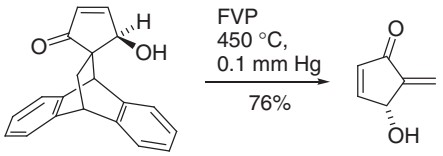
From racemic *endo*-dicyclopentadienone **144**, a straightforward and efficient synthesis yielded optically pure alkylidene- and arylidene-disubstituted cyclopentenones **159** via one-pot alkyl cuprate addition/aldol condensation/dehydration followed by an MW-mediated and Lewis acid-catalyzed rDA procedure.[90] An alternative route involved a modified Baylis–Hillman protocol followed by conjugate addition with alkyl cuprates at a low temperature, with the final cycloreversion step in an MW reactor under mild conditions (Scheme 35). For cyclopentadiene trapping, an excess of MA was used. The reactions, followed by means of ^{1}H-NMR spectroscopy, demonstrated exclusive *E* selectivity (>95%).

Similar preparations of cross-conjugated dienone 5-alkylidenecyclopent-2-enones **159** and prostanoids have been described through tandem conjugate addition–Peterson olefination, starting from 2-trimethylsilyltetrahydro-4,7-methanoinden-1-one **162**



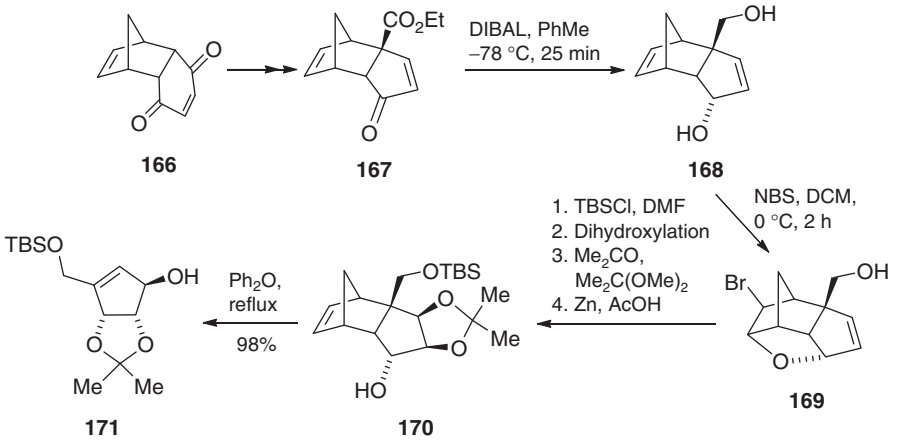
Scheme 34

Scheme 35



as the reactive intermediate obtained by a Pauson–Khand reaction. Compound **162** was prepared by treating norbornadiene **160** and trimethylsilanylacetylene **161** with $Co_2(CO)_8$, with subsequent addition of 10 equivalents of *N*-methylmorpholine-*N*-oxide (Scheme 36). The selectivity of the exocyclic alkenes was controlled by the use of an organometallic species in the conjugate addition step. Organocuprates led to the formation of *E*-exocyclic alkene adducts **163**, whereas Grignard reagents promoted the formation of the *Z*-alkenyl isomers. When adduct **163** was refluxed in hexane for 3–35 h or subjected to Lewis acid-catalyzed rDA cleavage, enantioenriched disubstituted cyclopentenones **159** were obtained.[91,92]

Scheme 36

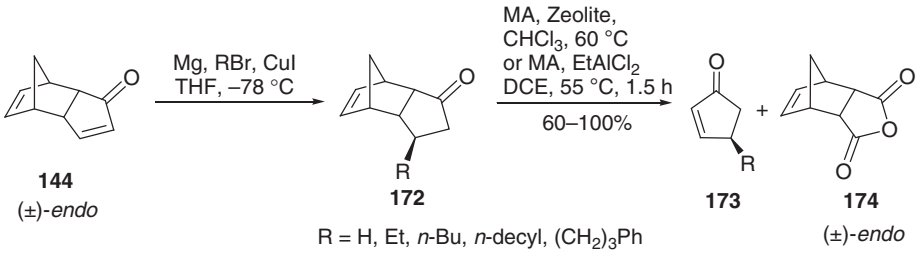


A short and simple chemoenzymatic synthesis of (–)-epipentenomycin I comprised a lipase-catalyzed kinetic resolution of the racemic pentacyclic alcohol followed by FVP of (–)**164**. In this way, enantiomerically pure 4-hydroxy-5-methylene-2-cylopentenone

165 was obtained without racemization or side reactions (equation 23). Epoxidation and hydrolytic ring opening of **165** then gave (–)-epipentenomycin I.[93]

164 **165** (23)

A silylated intermediate, prepared in a multistep and enantioselective procedure, was applied in the synthesis of neplanocin A, which displays a strong antitumor activity. This process started from optically active 2-hydroxymethyl-5-hydroxytricyclodecadiene **168** with rDA reaction as the key step. The readily available dione **166** was treated with aqueous H_2O_2, and the resulting product was warmed with NaOH. The oxoester **167** obtained was reduced with diisobutylaluminum hydride (DIBAL) to the dihydroxy derivative **168**. After bromination, the 9-bromo-5,8-epoxytricyclodecane was regioselectively silylated on the hydroxymethyl group with *tert*-butyldimethylsilyl chloride (TBSCl) and the double bond dihydroxylated. Acid-catalyzed protection with dimethoxypropane in acetone and transformation with active Zn and AcOH resulted in the acetonide derivative **170** (Scheme 37). Derivative **170** was refluxed in Ph_2O solution to give the rDA product **171** as required for the synthesis of neplanocin A.[94]

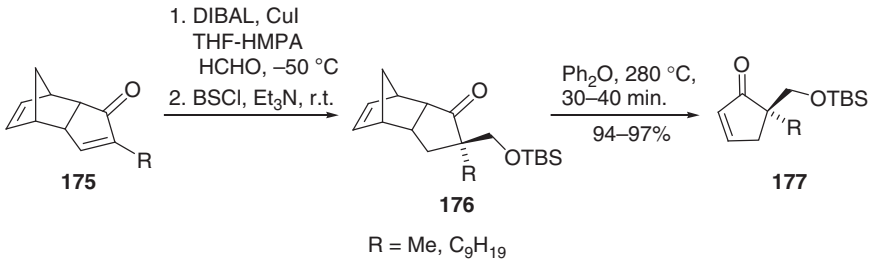


166 **167** **168** **169** **170** **171**

Scheme 37

A similar procedure led to the diastereocontrolled preparation of (+)-tanikolide, a toxic and antifungal marine natural product isolated from *Lyngbya majuscula*.[95]

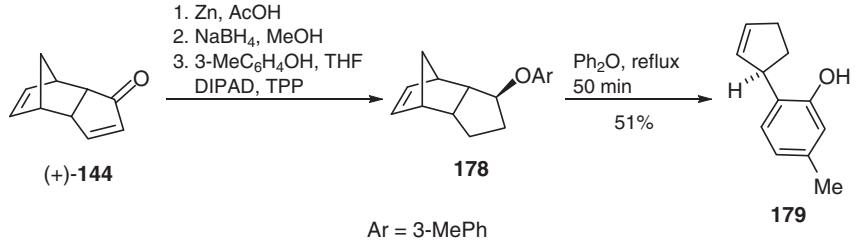
Zeolite H-Beta catalyzed the rDA reactions of a range of cyclopentadiene cycloadducts in the presence of an active dienophile. A screening of different zeolites suggested that the rDA fragmentation of tricyclodecenones **172** was catalyzed by Brønsted acid, and the high catalytic performance of H-Beta could be ascribed to the optimal balance between the number of acidic sites, their strength, and accessibility.[96] As an alternative to the Lewis acid-catalyzed rDA procedure, the methodology was applied to the synthesis of a series of 4-alkylcyclopentenones **173**, with MA being used to trap the dienophile (Scheme 38).



144 (±)-*endo* **172** **173** **174** (±)-*endo*

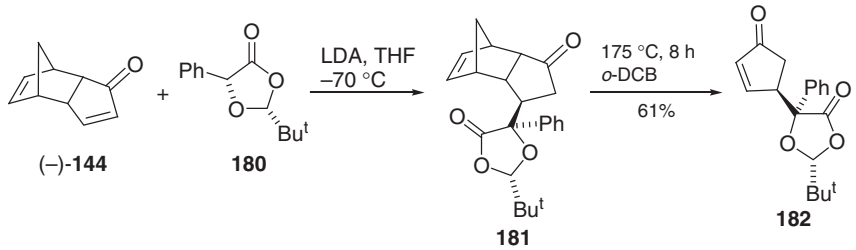
R = H, Et, *n*-Bu, *n*-decyl, $(CH_2)_3Ph$

Scheme 38



A [4 + 2] cycloreversion was applied as a key step for the synthesis of the pheromone (+)-frontalin and the structurally related marine antibiotic (–)-malyngolide. From 4-methyl- and 4-nonyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3-ones **175**, *O*-silylated

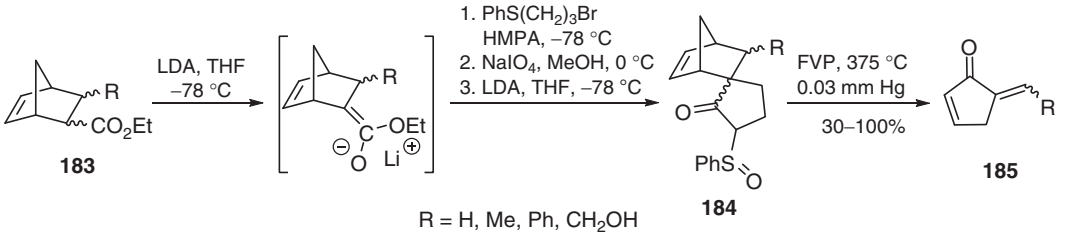
hydroxyketones **176** were obtained in a two-step procedure (Scheme 39). An rDA reaction then led to the required intermediate hydroxyketones **177**.[97]



Scheme 39

From the chiral ketone **144**, a new stereocontrolled route was developed to (+)-curcuphenol, a sesquiterpene from a marine sponge. The compound **144** was transformed by chemo- and stereoselective reduction with $NaBH_4$ to the chiral *endo*-tricyclic alcohol. The reaction with 3-methylphenol, diisopropylazodicarboxylate (DIPAD), and triphenylphosphine (TPP) furnished the *exo*-aryl ether **178**. After thermolysis, the chiral 3-arylcyclopentene **179** was obtained (Scheme 40) through a concurrent rDA reaction and Claisen rearrangement.[98] The phenolic compound **179** was used as the key precursor for the total synthesis of (+)-curcuphenol.

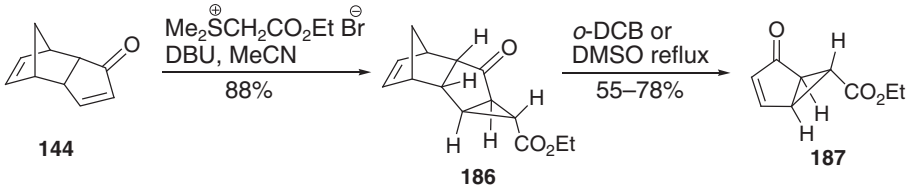
Scheme 40



The diastereoselective synthesis of 2-cyclopentyl-2-hydroxy-2-phenylacetic acid, a moiety of a new muscarinic M_3-receptor antagonist, was achieved through the Michael addition of the enolate of chiral dioxolane **180** to dicyclopentadienone **144** in the presence of lithium diisopropylamide (LDA) (Scheme 41). Adduct **181** was submitted to an rDA process by heating in 1,2-dichlorobenzene (*o*-DCB).[99]

Scheme 41

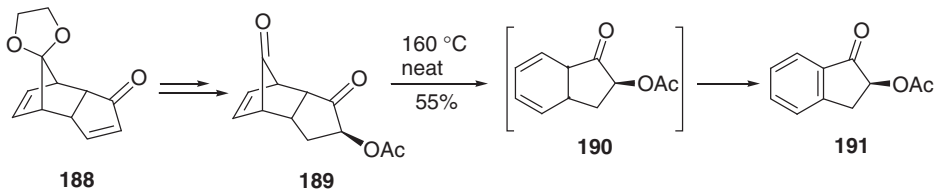
A general method for the preparation of 5-alkylidene-2-cyclopentenones **185** relied on the thermolysis of spiro-cyclopentanones **184**. The FVP step was reported to take place with *E*/*Z* selectivity (Scheme 42), resulting in the quantitative or high yielding release of **185** (>95% yield, R=H) (R=Me, Ph, *E*/*Z* ratio: 100/0–83/15) at 375–450 °C (0.03–0.05 mm Hg). When R was hydroxymethylene, the yield was low (30%), presumably due to decomposition under the pyrolytic conditions; only the *Z* isomer was obtained in this case.[100]



The rDA fragmentation of 1,4-benzoquinone-annelated spirobicyclo[2.2.1]heptenes was studied both experimentally and theoretically. On refluxing in MeCN or toluene, the reactions gave spirocyclopentadienes (spiro[2.4]hepta-4,6-dienes) in 35–87% yields through the decomposition of the cycloadducts during 8–28 h. The results were supported theoretically by computation of the activation barrier (with ΔE^{+}/kcal mol^{-1} calculated for the gas or solution phase at the B3LYP/6–31 G* level of theory).[101]

183 **184** **185**

Scheme 42

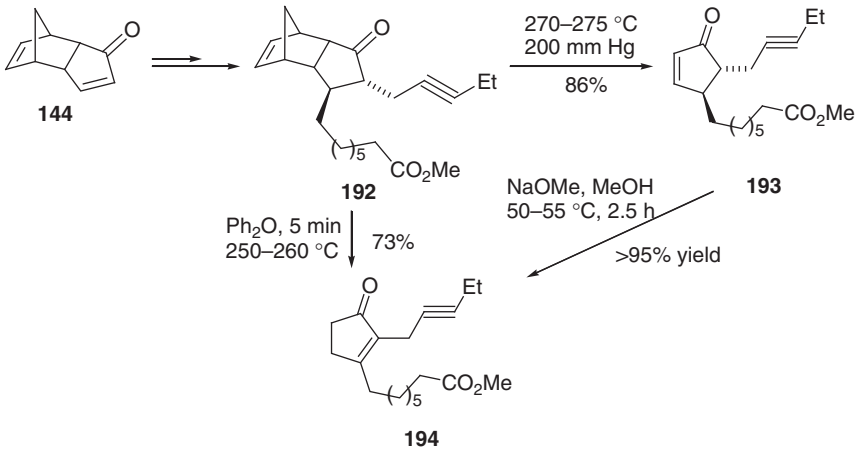


On cyclopropanation of dicyclopentadienone **144**, enantiomerically pure bicyclic cyclopentenone γ-ester **187** was prepared by a modification of Payne's sulfur ylide method. Thus, **144** was reacted with ethyl(dimethylsulfuranylidene)acetate to afford tetracycle **186** as a single diastereomer (Scheme 43). For the cycloreversion, this oxoester was refluxed under a blanket of N_2, which gave rise to **187** in moderate yield (55% after 23 h). The reaction could be carried out more rapidly and efficiently (with a yield of 78%) using dimethyl sulfoxide (DMSO) as the solvent (~189 °C, 8 h).[102]

144 **186** **187**

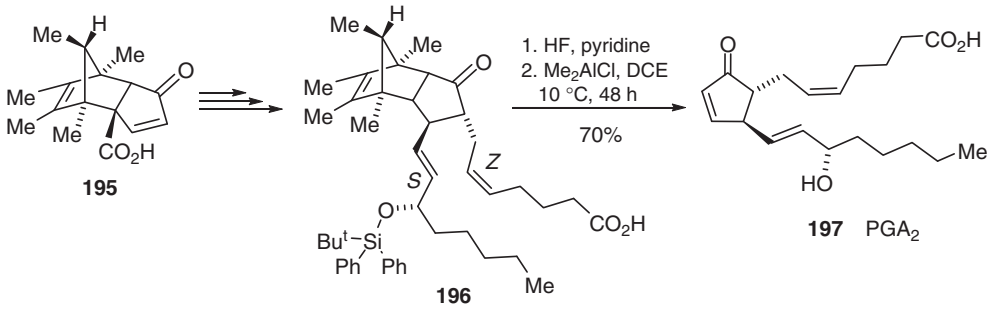
Scheme 43

Enantiomerically pure aminoindanol has drawn attention as the key component of the human immunodeficiency virus-protease inhibitor Indinavir and through its use in some chiral auxiliaries and catalysts for asymmetric reactions. The important precursor acetoxyindanone **191** was prepared by a multistep procedure. Starting from the protected dienone **188,** acetoxy diketone **189** was obtained as a single isomer in a regio- and stereoselective manner. The thermally induced extrusion of CO from (+)-**189** via rDA fragmentation and aromatization of the unstable diene intermediate **190** led to (2*S*)-acetoxyindan-1-one **191**, which could be readily converted to aminoindanol (Scheme 44).[103]



188 **189** **190** **191**

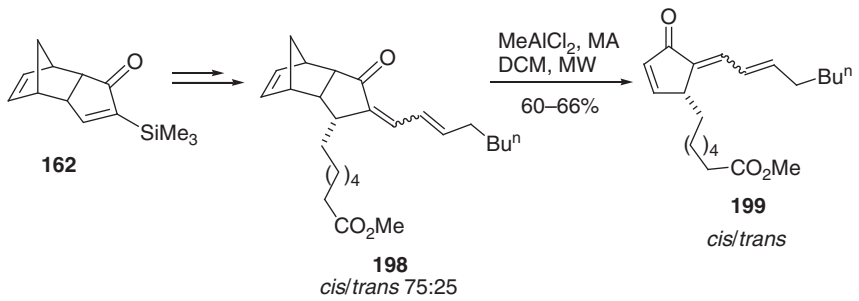
Scheme 44



The chromomoric acid family (chromomoric acid B and F methyl esters) as metabolites of linolenic acid, isolated from *Chromolaena morii* and *Chromolaena chasleae* but also found in other species, exhibits antibiotic and antihypertensive activities. A convenient total synthesis of these compounds with a cyclopentenone skeleton has been described starting from enone **144**. This compound was converted to the *trans*-4,5-dialkylated tricyclodecen-3-one **192**, which was subjected to thermolysis *in vacuo* with the splitting-off of cyclopentadiene to afford dehydrochromomoric acid B methyl ester **193** diastereoselectively (Scheme 45). When **192** underwent thermolysis, the rDA step resulted in a 2:1 mixture of **193** and **194**, which readily converged to enone **194** (intermediate to chromomoric acid F methyl ester).[104] Similarly, the total synthesis and structural revision of chromomoric acid D-I methyl ester were reported.[105]

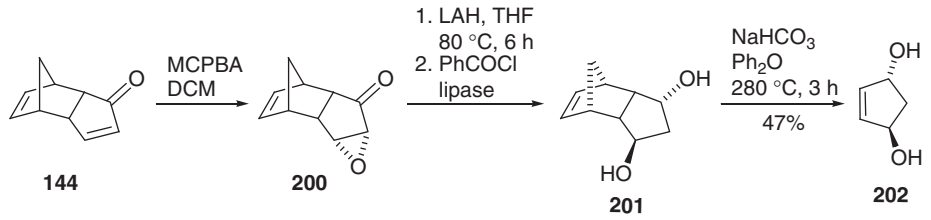
A facile rDA reaction of pentamethyltricyclo[5.2.1.$0^{2,6}$]decenone **196** led to the total synthesis of prostaglandin A_2 (PGA_2) **197**. The incorporation of methyl groups into **196** at positions C(1), C(7), C(8), C(9), and C(10) accelerated the retro process dramatically, which occurred under Lewis acid catalysis with Me_2AlCl. Subsequent deprotection of the hydroxy group (Scheme 46) permitted synthetic access to the natural PGA_2.[106]

Through conjugate addition/Peterson olefination, racemic $\Delta^{12,14}$–15-deoxyprostaglandin-J_1 was readily synthesized from trimethylsilyl ketone **162** in a multistep procedure. One-pot conjugate addition of the silyl-protected Grignard reagent under Cu(I) catalysis followed by addition of *trans*-2-octenal gave a mixture of *cis*/*trans* isomers, which were separated. With the Jones reagent or Dess–Martin periodinane sodium chlorite, oxidation of the primary –OH group to the methyl ester was possible, which yielded the precursor **198** (Scheme 47). Subsequent Lewis acid-mediated rDA fragmentation of adduct **198** in the presence of MA



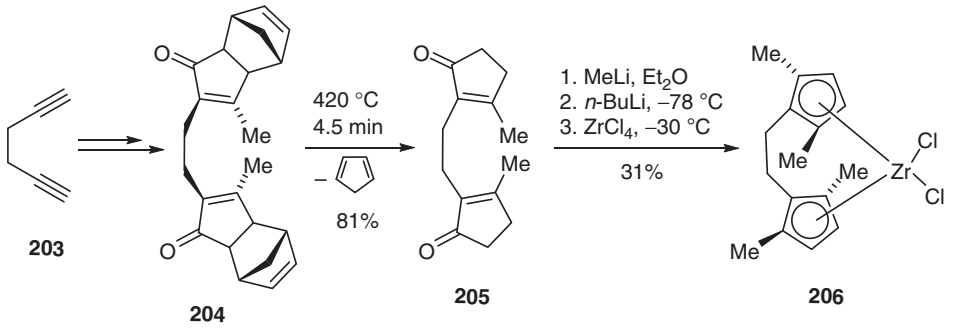
Scheme 45

Scheme 46



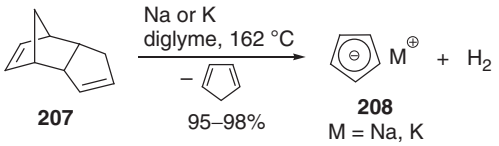
afforded both geometric isomers of cyclopentenone **199**. The thermal cycloreversion was optimized by means of short bursts (~200 s) of MW irradiation at 300 W at 110 °C.[107]

Scheme 47



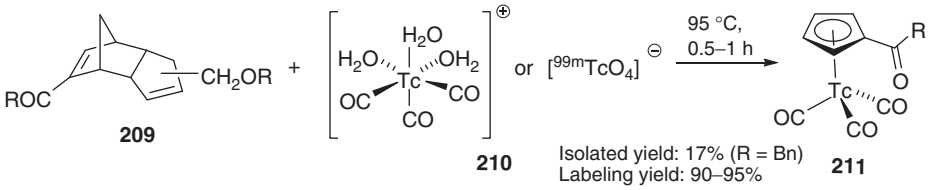
From racemic tetrahydro-4,7-methanoinden-1-one **144**, the optically pure C_2-symmetric 4-cyclopentene-1,3-diol **202** has been prepared in both enantiomeric forms by employing lipase-mediated kinetic resolution. The known (3a*S**,4*R**,7*S**,7a*S**)-3a,4,7,7a-tetrahydro-4,7-methano-1*H*-inden-1-one **144** was transformed to (1′*S**,3′*S**,3′a*R**,4′*S**,7′*R**,7′a*S**)-2′,3′,3′a,4′,7′,7′a-hexahydro-3′-hydroxy-4′,7′-methano-1′*H*-inden-1′-yl benzoate by stereo- and regioselective hydride reduction of epoxyketone **200** and sequential benzoylation, with resolution via transesterification in the presence of lipase. Hydride reduction of the benzoate or acetate gave chiral diol **201** (Scheme 48), which was transformed to both enantiomers of the C_2-symmetric 4-cyclopentene-1,3-diol **202** in an rDA reaction.[108] 4-Cyclopentene-1,3-diols are important intermediates for the synthesis of enantiopure prostaglandins and other natural products.[109–111]

When the symmetrical ethylene-bridged bisdicyclonorbornadienone **204** was heated, a rare double rDA reaction occurred to give ethylene biscyclopentenone **205**, which was transformed to a novel zirconium chloride complex. The ligand was prepared from 1,5-hexadiyne **203** by a Pauson–Khand reaction and rDA fragmentation (Scheme 49). The metallation of compound **205**,



Scheme 48

conducted in a trimethyltin-mediated step through the biscyclopentadiene intermediate, led to the isolation of **206** in a rather low yield (31%). The resulting zirconocene complex **206** was fully characterized by NMR spectroscopy and X-ray crystallography.[112] To obtain a 9-fluorenylmethyl-dicyclopentadienone skeleton, another unsymmetrical zirconocene complex with cyclopentadiene and fluorene moieties was prepared and decomposed by rDA cycloreversion at 300 °C.[113]

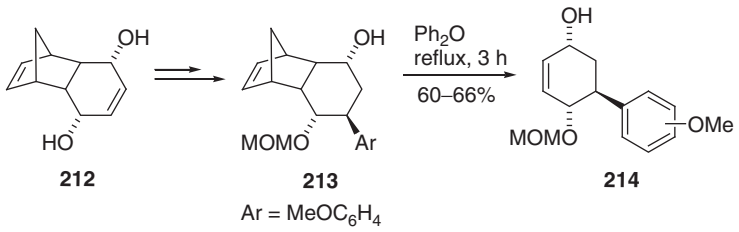


Scheme 49

By the direct reaction of dicyclopentadiene with alkali metals, a novel method for the synthesis of metal cyclopentadienides was developed. Unlike conventional methods, which use dicyclopentadiene **207** to first generate cyclopentadiene in an rDA reaction, the new preparation directly afforded metal cyclopentadienides **208** starting from dicyclopentadiene when the temperature reached the boiling point of the solvent (equation 24). During the addition of cyclopentadiene, the cessation of H_2 evolution indicated the end of the reaction, which furnished sodium or potassium cyclopentadienide adducts.[114]

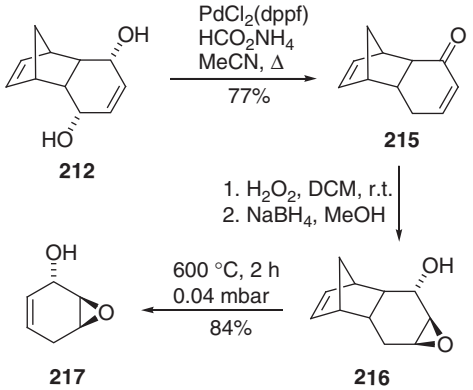
(24)

The metal-mediated rDA fragmentation of dicyclopentadiene derivatives (Thiele's acid, its ketone or amide) was studied, and their Tc and Re complexes were synthetized. DA dimers **209** are 'protected' cyclopentadienes. Although the thermal cracking of **209** required a high temperature (over 160 °C), the rDA complexes formed from Thiele's acid derivatives **209** in the presence of a group 7 transition metal (Mn, Tc, or Re) decomposed at a low temperature and resulted in the quantitative formation of complexes such as **211** (equation 25). Compound **211** could also be prepared directly from TcO_4^- in the presence of dimers **209** under the same conditions. This was particularly interesting, because they have been used to carry Tc-99 m (half-life 6 h), commonly employed in scanning procedures in nuclear medicine. For similar reactions, 'cold' Re was also applied because it was much more robust than technetium; the rhenium carbonyl complex $[Re(OH_2)_3(CO)_3]^+$ required longer reaction times or higher temperatures with Thiele's acid (R=OH).[115,116]



(25)

R = OH, Bn, $BnNH_2$, $NHCH_2CO_2H$

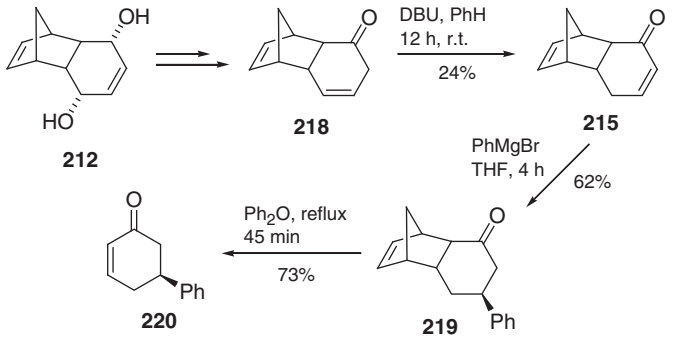


5.12.5.2 Cyclohexane Derivatives

Through the use of the chiral 5-phenylcyclohex-2-ene-1,4-diol, structural analogs of the potent nonopioid analgesic alkaloid epibatidine were prepared via an enantio- and diastereo-controlled route. These diol intermediates were obtained from cycloadduct **212** by rDA cleavage; protection of the methoxymethyl (MOM) ether and subsequent arylation followed by cleavage in refluxing Ph_2O gave **214** (Scheme 50). These 2-, 3- or 4-methoxyphenylcyclohexenols were suitable for further transformations to compounds containing an azabicyclo[2.2.1]heptane skeleton.[117]

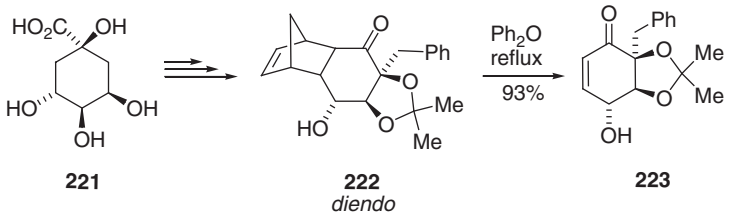
Scheme 50

From the readily accessible cyclopentadiene–p-benzoquinone cycloadduct, a synthetic route to 2-deoxystreptamine, a common moiety in many pharmacologically active aminoglycosides, was devised. Reduction under Luche conditions (with $NaBH_4$–$CeCl_3$ in MeOH at ~0 °C) led diastereoselectively to diol **212**, which was converted to enone **215** before being transformed into **216** by nucleophilic epoxidation (Scheme 51). To avoid a Payne rearranged product and other side reactions, the reduction was performed at a low temperature (−78 °C). The desired thermolytic rDA process was achieved by application of FVP, which furnished pure epoxycyclohexenol **217**.[118]



Scheme 51

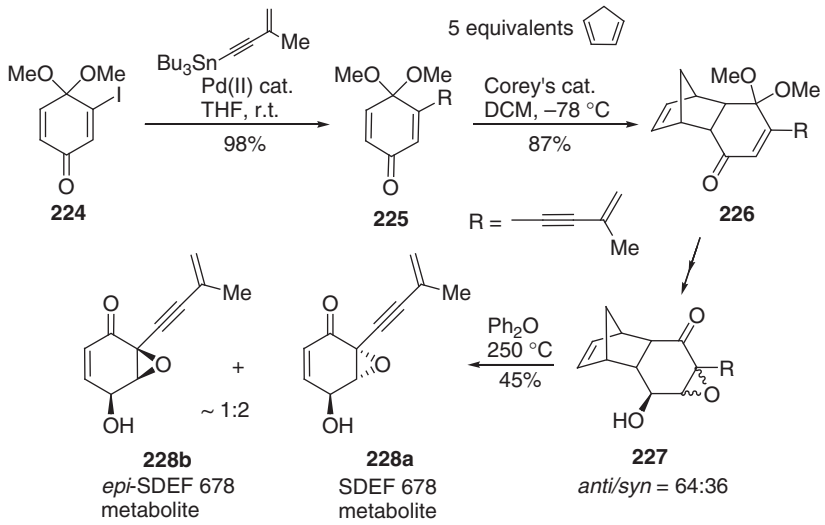
Norbornene-fused hexanediol **212** has also been used to obtain phenyl- and other aryl-substituted cyclohexenones **220**. By transesterification with a specific ester in the presence of lipase, the crude diol afforded an optically active derivative. Pure **212** was acylated by a conventional method and treated with Zn under ultrasonic waves to give deacyloxylated cyclohexenone **218**, which was isomerized to **215** with DBU. After purification by column chromatography over silica gel, a Grignard reagent was added to obtain the phenyl-substituted ketone **219** (Scheme 52). This tricyclic product readily afforded the rDA fragmented chiral ketone **220** as the target compound.[119]



With slight modifications, the discussed methods could be applied widely and successfully in other cases, when oxo, hydroxy, epoxy, or aryl(alkyl) moieties were built onto the cyclohexene skeleton. These usually diastereo- and/or enantioselective procedures furnished fairly good yields when side products were not observed in the course of the rDA fragmentations. The use of norbornene as the carrier part of the cycloadducts proved best, mostly in the rDA cleavage, because cyclopentadiene readily splits off from the molecule on thermolysis at different temperatures.[120–125]

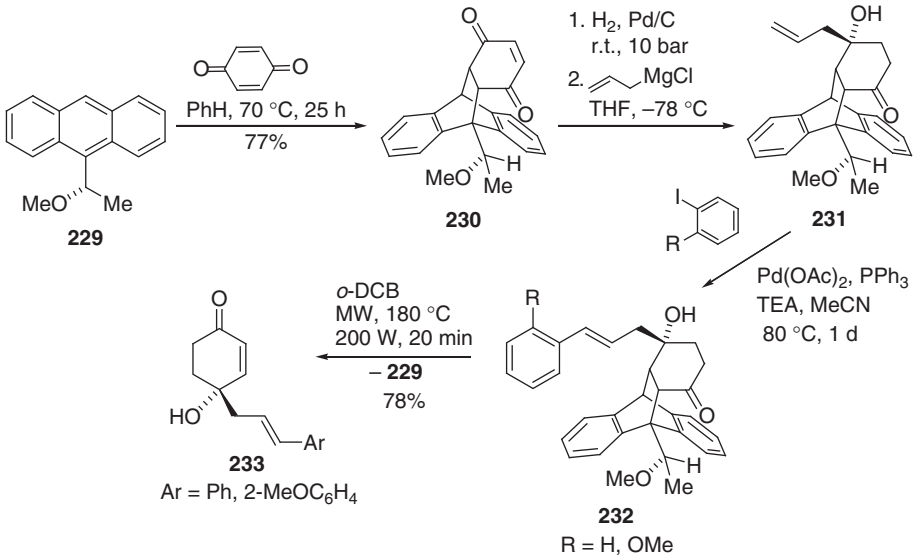
Multifunctional polysubstituted cyclohexene derivatives were synthetized through a similar enantiocontrolled route. 6-Benzyl-4,5-epoxy-6-hydroxy-2-cyclohexenone **223** was studied as the model compound for the epoxycyclohexenone moiety of scyphostatin. The starting material was obtained from the commercially available (–)-quinic acid **221**, which was converted to cycloadduct **222** in a multistep procedure. The thermolytic reverse cycloaddition of the tetracyclic ketone **222** proved to be critical. This finally provided pure acetonide **223** without decomposition or isomerization (Scheme 53).[126]

Through application of a DA/rDA sequence, the first synthesis of the antifungal and plant growth-promoting compound (±)-grass sterile dark ectotrophic fungus (SDEF) 678 was achieved; this compound was isolated earlier from the roots of an Australian



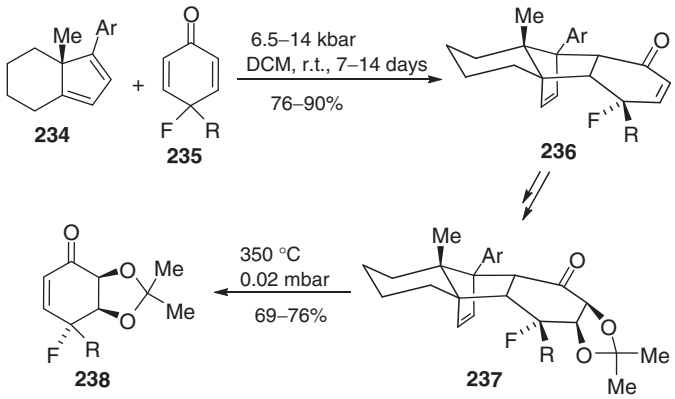
Scheme 52

Scheme 53



native SDEF.[127] The compound contains a 2-(but-1-en-3-ynyl) sidechain, which made the synthetic strategy somewhat problematic. Via the use of an alkynyl stannane and Stille coupling, iodocyclohexadienone **224** was converted to **225**. Corey's chiral oxazaborolidine in combination with triflic acid served to catalyze the cycloaddition of ketone **225** with cyclopentadiene to furnish norbornene-fused **226**. After reduction, deprotection and selective epoxidation, rDA reaction in boiling Ph_2O led to the metabolite SDEF 678 **228a** and the *epi* derivative **228b** (Scheme 54).[128]

Scheme 54

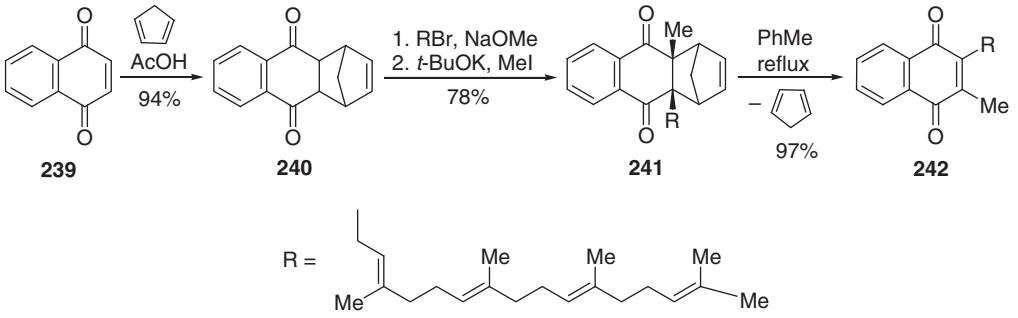


From cycloadducts with furan or anthracene, only a few examples have been reported for the preparation of cyclohexene derivatives. A rare and interesting procedure was reported by Jones et al., who used a chiral anthracene auxiliary and 1,4-benzoquinone for the DA/rDA methodology in the enantioselective synthesis of candenatenins B and C. They applied a highly diastereoselective cycloaddition of the 9-substituted anthracene **229** with 1,4-benzoquinone, which gave the chiral adduct **230**; after catalytic hydrogenation and a Grignard reaction, hydroxycyclohexanone **231** was obtained as the major product. Heck coupling with iodobenzene yielded the aryl ring; no *Z*-alkenes were formed in the reaction (Scheme 55). The cycloreversion of **232** was optimized in various solvents (chlorobenzene, 1,2-dichlorobenzene or DMSO), at different temperatures (75–230 °C)

and under MW irradiation (150–300 W); the catalytic effect of a Lewis acid [$Sc(OTf)_3$] was also studied. Best results were obtained under MW irradiation to give the chiral compounds **233**.[129]

Scheme 55

With the cyclopentadiene enantiomer **234,** a highly face-selective DA reaction took place under high pressure. Thus, 4-fluorocyclohexadienones, prepared in an improved Jacquesy process, underwent cycloaddition with fluoroketone dienes **235** and furnished adducts **236** under forceful conditions. The polycyclic fluoroketones **236** were reacted with $RuCl_3$–$NaIO_4$ through a 'flash-dihydroxylation', and an acid-catalyzed ketal was then formed using 2-methoxypropene or 2,2-dimethoxypropane (Scheme 56). FVP of the acetonide adducts **237** led to protected fluorocyclohexadienones **238**.[130,131]



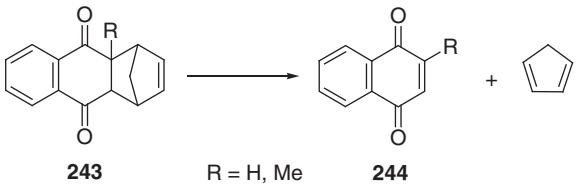
Scheme 56

From optically pure cyclopentadiene **234,** spiroisoxazolines (1-oxa-2-azaspiro[4.5]deca-2,6-dien-8-ones) were prepared in a DA/rDA procedure. These compounds are chromophore subunits of the marine antibiotics agelorin A and B isolated from the sponge *Agelas oroide*.[132,133]

5.12.5.3 Polycondensed Cycloalkanes

With cyclopentadiene, the DA cyclization of 1,4-naphthoquinone **239** afforded 1,4,4a,9a-tetrahydro-1,4-methanoanthraquinone **240**, which was alkylated with 3,7,11,15,-tetramethyl-2(*E*),6(*E*),10(*E*),14-hexadecatetraenyl bromide (RBr). A subsequent methylation gave anthraquinone **241**, refluxing of which in toluene resulted in the formation of vitamin K_2 (menaquinone) **242**

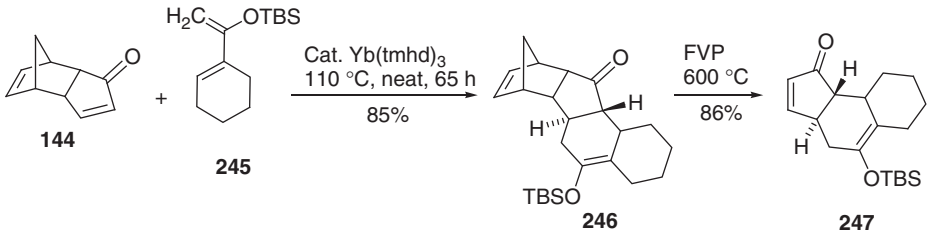
by an rDA process (Scheme 57).[134,135] Analogously, the DA reaction of the methyl anthraquinone followed by alkylation and the retrodiene reaction finally yielded vitamin K_1.[136]



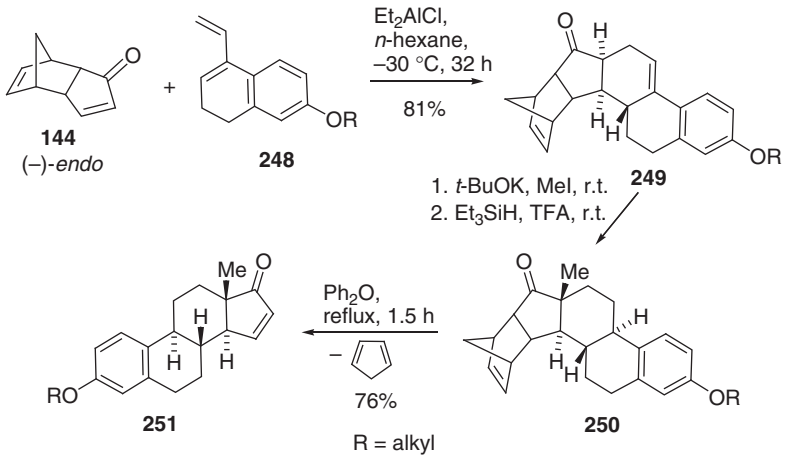
Scheme 57

The effect of the solvent on the rDA reaction of 1,4,4a,9a-tetrahydro-4a-methyl-1,4-methanoanthracene-9,10-dione–cyclopentadiene adduct **243** (R=Me) has been studied kinetically (Table 8). The hyperbolic relationship observed between the kinetic data and the acceptor number of the solvent was strong evidence for the fact that the solvent acts as an electrophile which lowers the activation energy of the reaction. The linearity clearly indicated that the nature of the solvent effect is the same in both the DA and rDA reactions. These relationships and the thermodynamic parameters suggest that the rDA process is a 'late transition state' pericyclic reaction, the solvent effect arising from the specific interaction between the solvent and the product **244**.[137] The rDA process of methanoanthracenedione proceeded considerably faster in aqueous solutions than in organic solvents (equation 26). The addition of organic solvents retarded the reaction. Data correlation demonstrated that the origin of the water-induced acceleration involved primarily the enhanced H-bonding of water to the activated complex for the rDA cleavage of methanoanthracenedione.[138]

Table 8 First-order rate constants and Gibbs energies for activation of the rDA reaction of **243** (R=Me) in different solvents at 40.0 °C (equation 26)



No.	*Solvent*	$10^8 \times k_1$ (s^{-1})	ΔG^0 (kJ mol^{-1})
1	*n*-Hexane	2.6	122.3
2	Benzene	6.6	119.9
3	DMSO	23	116.6
4	*i*-PrOH	27	116.2
5	AcOH	62	114.0
6	Water	359	109.5

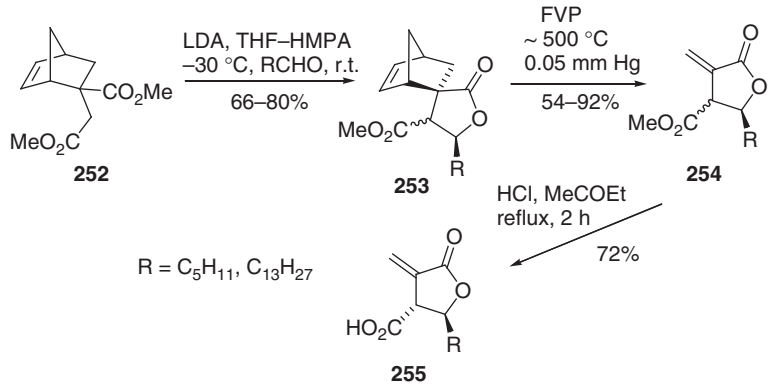


(26)

For the total synthesis of the *Galbulimima* alkaloid (±)-GB 13, a retrosynthetic strategy led to the pentacyclic framework, which, on incorporation of a piperidine moiety, furnished the alkaloid in the racemic form. The use of a rhodium(I)-catalyzed ketone–hydroarylation and a late-stage pyridine reduction afforded the target compound in a multistep procedure.[139] The carbotricylic unit **247** was synthetized from pentadienone **144** and silyloxydiene **245**. The ytterbium-catalyzed DA reaction proceeded via an *endo*-transition state, and epimerization *in situ* resulted in ketone **246**. FVP of adduct **246** afforded the condensed cyclopentenone **247** (Scheme 58), which was applied in further steps to obtain (±)-GB 13.

A novel method was described for the preparation of (+)-estrone derivatives. From dicyclopentadienone **144** and 4-vinyl-7-alkoxy-1,2-dihydronaphthalenes **248** in the presence of Lewis acids, the process led to DA polycylic enantiomeric adducts **249** (Scheme 59). Methylation on the neighboring carbonyl and then chemoselective reduction with a triethylsilane–trifluoroacetic acid (TFA) mixture gave **250**, which underwent rDA cycloreversion to give 3-methyl- or other 3-alkyl-substituted (+)-estrones **251**.[140,141]

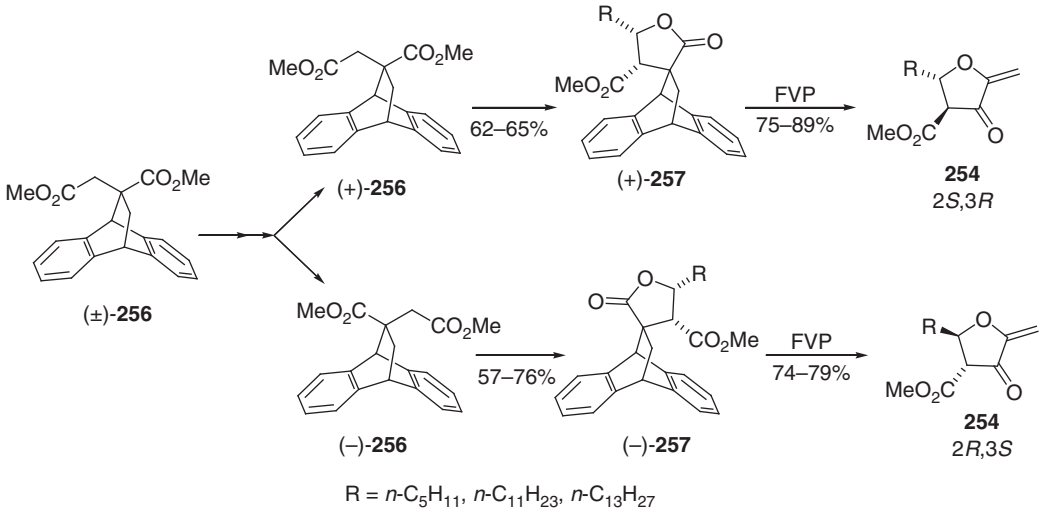
Scheme 58



Scheme 59

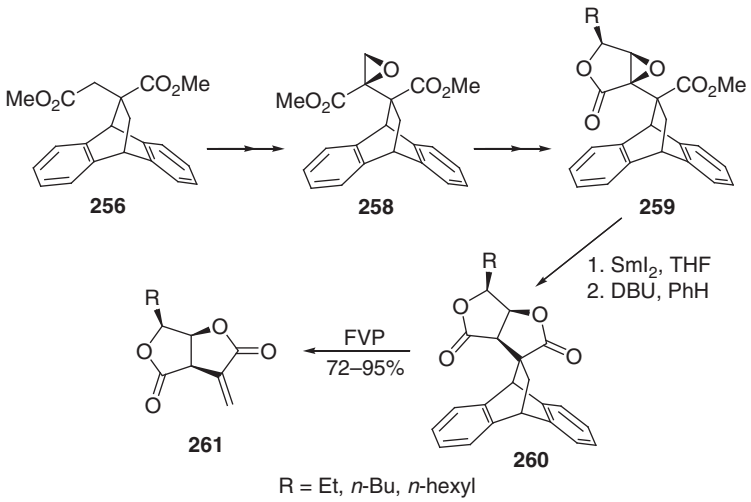
5.12.6 Syntheses of Unsaturated Heterocycles

5.12.6.1 Heterocycles Containing One Heteroatom



5.12.6.1.1 Oxygen-containing heterocycles

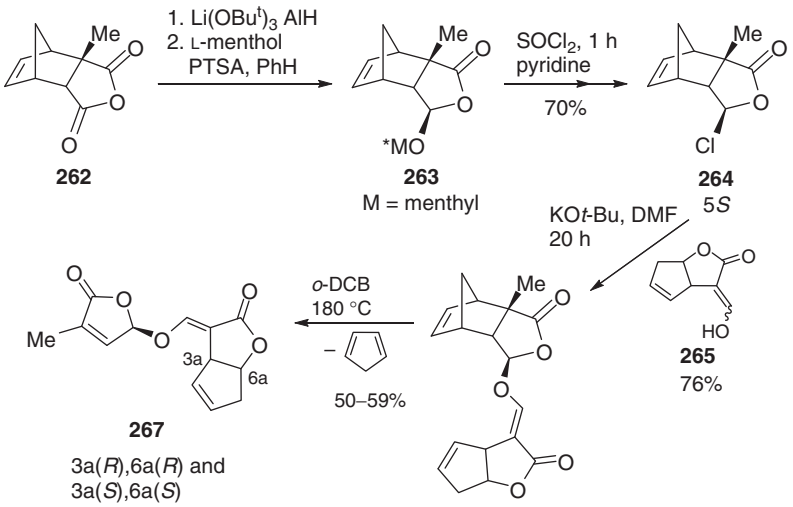
A facile preparation of β-carboxy-α-methylene-γ-lactones made use of an rDA reaction as the key step, leading to the total synthesis of the antibacterial and antitumoral (±)-methylenolactocin (**255**, R=C_5H_{11}) and (±)-protolichesterinic acid (**255**, R=$C_{13}H_{27}$). The preparation of these lactones involved some challenges, relating to the construction of the *exo*-methylene group and the susceptibility of the lactone to ring opening. In the coupling of the lithium ester enolate with the aldehyde, an unseparable mixture of diastereomeric spirolactones **253** was formed. The removal of cyclopentadiene by FVP resulted in a mixture of diastereomeric α-methylene lactones **254** in a smooth rDA process (Scheme 60). On refluxing in *n*-BuOH, the acid-catalyzed hydrolysis of the *exo*-methylenelactones gave rise exclusively to epimerization of the *cis*-acids to *trans*-methylenolactocin and protolichesterinic acid **255**.[142]



Scheme 60

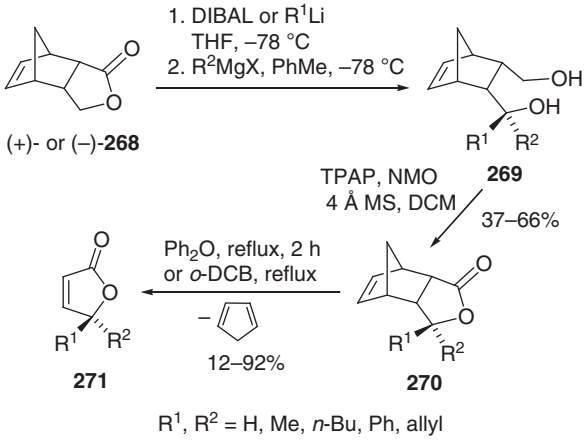
For the formation of both the enantiomers of methylenolactocin (R=C_5H_{11}), protolichesterinic acid (R=$C_{13}H_{27}$) and nephrosterinic acid (R=$C_{11}H_{23}$) **255**, an alternative cycloreversion was introduced, involving the application of itaconate–anthracene adducts (Scheme 61). Enantiomerically pure (+)- and (–)-**256** were prepared by partial hydrolysis of (±)-esters **256** with KOH in aqueous MeOH, followed by regioselective esterification with enantiopure menthol. Transesterification of the menthyl esters followed by tandem aldol lactonization by the previous method led to the optically active main adducts **257**, which by means of FVP provided enantiomers **254**; subsequent acidic hydrolysis afforded enantiomerically pure **255**.[143]

Scheme 61



The itaconate–anthracene adduct **256** served as a methylene-carbonyl equivalent in the synthesis of various other natural products. Treatment of adduct **256** with LDA in tetrahydrofuran (THF) at 0 °C or with lithium 2,2,6,6-tetramethylpiperidide (LTMP) at −78 °C generated the ester enolate. With various electrophiles such as aldehydes, the enolate anion reacted stereospecifically to afford **258** after epoxidation, which underwent consecutive aldol lactonization to give epoxy lactones **259**. The samarium iodide-catalyzed ring opening of the epoxide, followed by treatment with catalytic DBU resulted in *cis*-fused bislactones **260** via ring reclosure (Scheme 62). The FVP of **260** led smoothly to naturally occurring α-methylene-bis-γ-butyrolactones **261**, such as xylobovide (R=Et), canadensolide (R=*n*-Bu), and sporothriolide (R=*n*-hexyl).[144,145]

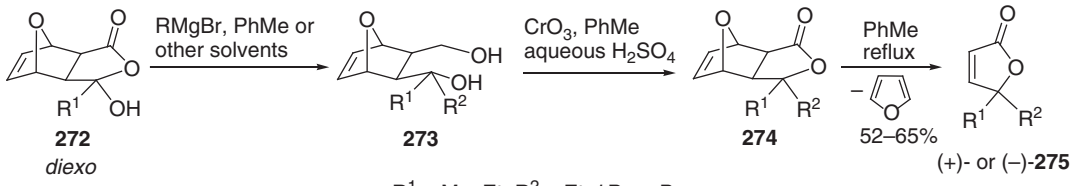
Scheme 62



Several natural products, such as (+)-strigol and the related compounds (sorgolactone and alectrol) or their analogs (GR7) contain a butenolide ring and display, for example, a germination-stimulant effect. From cyclopentadiene-'protected' butenolides as reusable DA adducts, asymmetric conversion of the D-ring synthon to strigol derivatives was accomplished. On partial

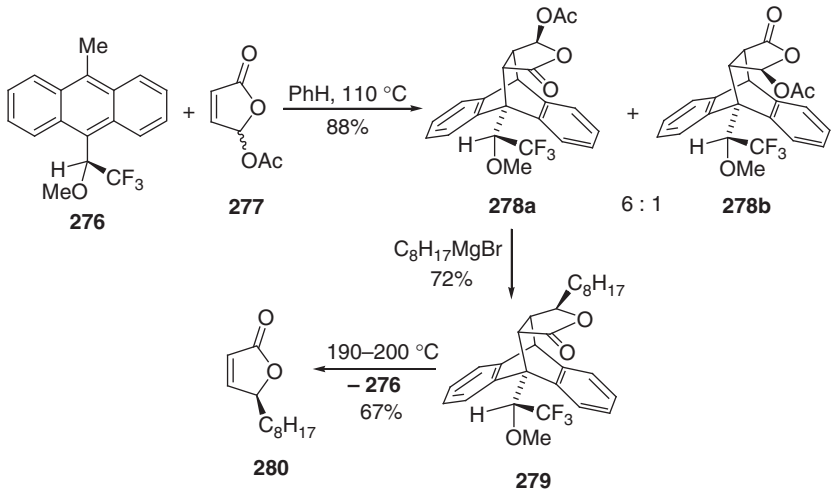
reduction with alkoxyaluminum hydrides (lithium tributoxyaluminohydride, LTBA), **262** gave the racemic hydroxylactone, which on treatment with L-menthol in the presence of *p*-toluenesulfonic acid (PTSA) as catalyst under azeotropic conditions furnished the separable diastereomers of menthyloxy lactone **263**. Acidic hydrolysis with 80% TFA and subsequent chlorination resulted in enantiopure chlorolactone **264**, which was coupled with racemic hydroxymethylenolactone **265** to give bislactone **266** (Scheme 63). When heated in *o*-DCB for 15 h, the DA adduct **266** underwent cycloreversion to diastereomers **267** (compound GR7) without epimerization.[146,147]

Scheme 63



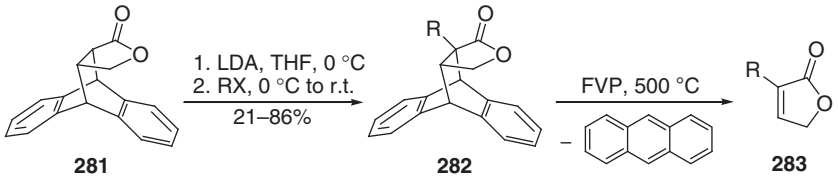
Appropriate norbornene adducts provided butenolides **271** by rDA cleavage. From tricyclic lactone **268**, a concise and enantiodivergent synthesis of (+)- and (–)-*trans*-quercus lactone,[148] γ-substituted butenolides with tertiary and quaternary asymmetric centers,[149] as well as a formal synthesis of (–)-ngaione via asymmetric synthesis of methyl- and allyl-disubstituted butyrolactone **271**[150] were achieved (Scheme 64).

Scheme 64



An unusually strong solvent effect on the diastereoselectivity of nucleophilic additions of alkylmagnesium bromides to the oxabicycloheptene-fused lactols **272** allowed the formation of 1,4-diols **273** in diastereoisomerically pure form. From these, γ,γ-disubstituted γ-butyrolactones **275** were obtained after oxidation with chromium(VI) oxide followed by a mild rDA process, without affecting the chiral center at C5 of the furan-2(5*H*)-one moiety (Scheme 65).[151]

A chiral anthracene template, 10-methyl-9-(1-methoxy-2,2,2-trifluoroethyl)anthracene **276**, underwent a highly diastereoselective cycloaddition with MA or 5-acetoxy-2(5*H*)-furanone **277** to give a chiral adduct of value for further transformations, for example, for the preparation of enantioenriched butenolides. The cycloaddition of dienophilic furanone **277** with anthracene **276** in a sealed tube yielded a mixture of the regioisomeric adducts **278a** and **278b**. Because of the difficulty in separation and the

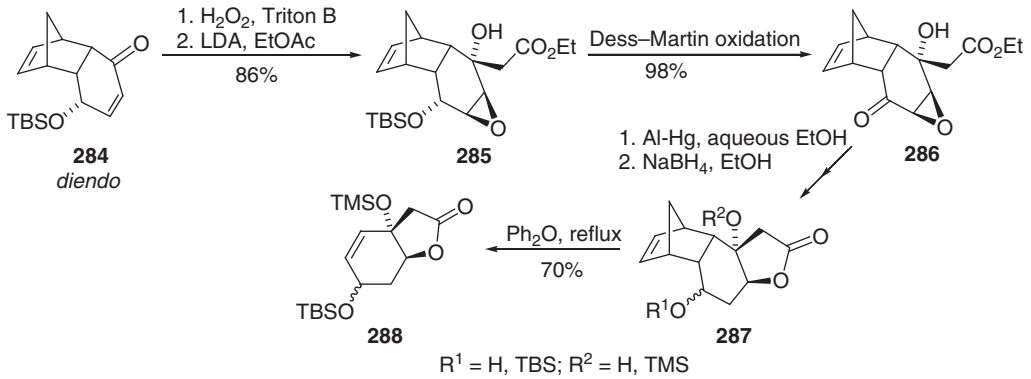


Scheme 65

instability of the adducts, this mixture was used in the subsequent step. Grignard reaction of the mixture of **278a** and **278b** resulted in the enantiopure lactone **279**, which by cycloreversion furnished optically active butenolide **280**, a precursor for the rove beetle pheromone (Scheme 66).[152]

Scheme 66

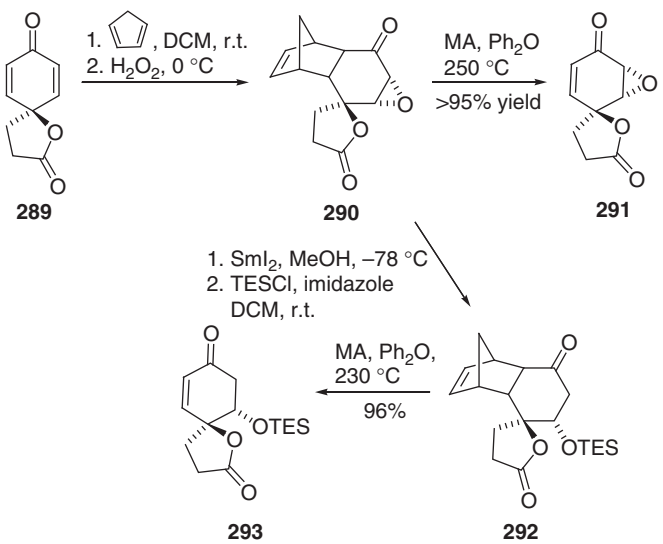
Deprotonation and electrophilic quenching of lactone **281**, derived from the DA adduct of anthracene and MA by $NaBH_4$ reduction, led to 3-substituted 2(5*H*)-furanones **283** after rDA cleavage of **282** by means of FVP. A low temperature (− 78 °C) precluded enolate formation; 0 °C was found to be the optimal temperature for the deprotonation of **281** with LDA. The addition of excess electrophile (1.5–3 equivalents) afforded *C*-alkylated lactones (Scheme 67), whereas the reaction with tributyltin chloride gave stannane **282** only in low yields (Table 9). On application of FVP, rDA fragmentation generally readily took place; for stannane **282**, however, it failed. This compound survived the MW irradiation, but application of FVP readily led to retrodiene cleavage and furnished the destannylated furanone **283**.[153]



Scheme 67

Some cyclohexane-fused butenolides are natural products (e.g., menisdaurilide and aquilegiolide and its dihydro derivatives), isolated from *Tamarindus indica* L. or *Sinomenium acutum* species. Honzumi and Ogasawara developed a straightforward synthesis, using an rDA method starting from norbornene-fused cyclohexenone. Enantiopure **284** was transformed to the *exo*-epoxide, and the oxo group was then converted to the *β*-hydroxy ester in **285** on reaction with the lithium enolate derived from ethyl acetate. The secondary hydroxy group was selectively oxidized to give **286** under Dess–Martin conditions, and the epoxide ring was cleaved by using aluminum amalgam. Finally, $NaBH_4$-mediated reduction of the oxodiol ester afforded the polycyclic

Table 9 Substitution and cycloreversion of the anthracene–furanone adducts **281** (Scheme 67)



No.	*RX (electrophile)*	*Yield of **282** (%)*	*Yield of **283** (%)*
1	MeI	76	78
2	$CH_2{=}CHCH_2I$	71	83
3	BnBr	78	79

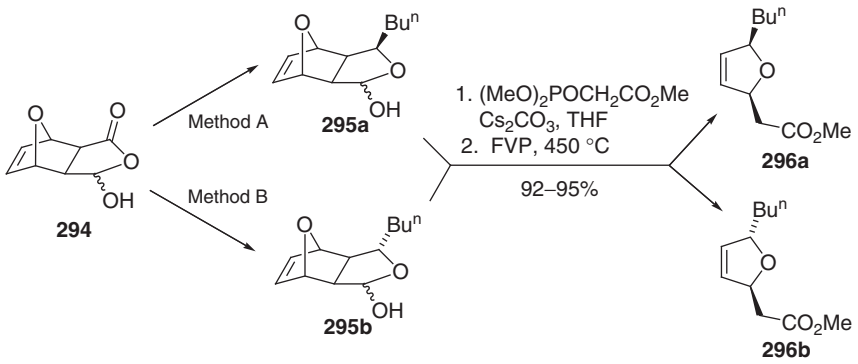
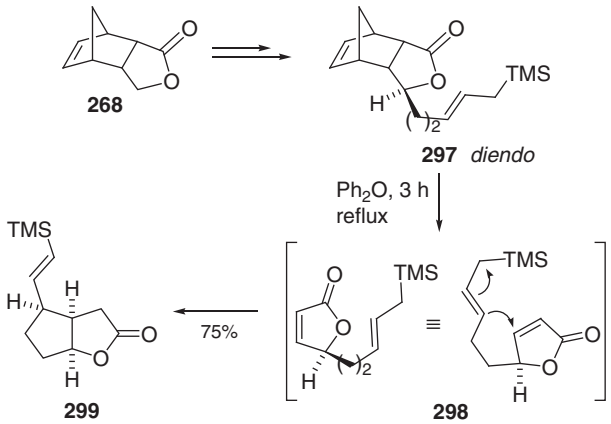
5	$(EtO)_2P(O)Cl$	74	67
6	Me_3SiCl	86	82

intramolecular lactone **287**, which, after protection, was refluxed to give cyclohexanenebutenolide **288** by cycloreversion (Scheme 68).[154]



Scheme 68

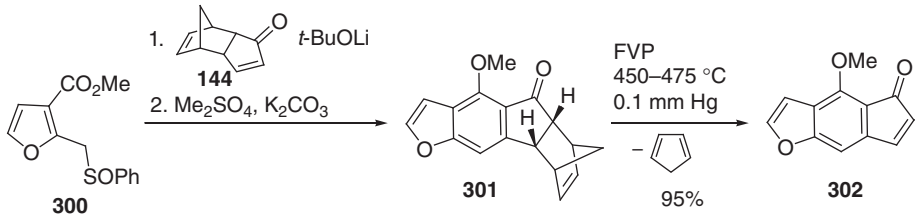
Scyphostatin was isolated from a mycelial extract of *Dasyscyphus mollissimus* SANK-13892, and numerous enantioselective and highly efficient methods were later developed for its total synthesis. In one retrosynthetic strategy, preparation of the hydrophilic 6-alkyl-4,5-epoxy-6-hydroxy-2-cyclohexen-1-one moiety was attempted by an rDA process. DA [4 + 2] cycloaddition of spirolactone **289** with cyclopentadiene furnished the adduct with a high π-facial selectivity. The epoxidation of the resulting dienone gave spirolactone **290**. The rDA process was carried out in the presence of MA to give product **291**. Treatment of epoxide **290** with samarium(II) iodide, reductive epoxide ring cleavage, protection with a triethylsilyl group (TES) and an rDA reaction afforded **293** (Scheme 69). This compound was later converted to 4,5-epoxy-2-cyclohexen-1-one bearing a spirolactone, which could be regarded as a Scyphostatin analog.[155,156]



Scheme 69

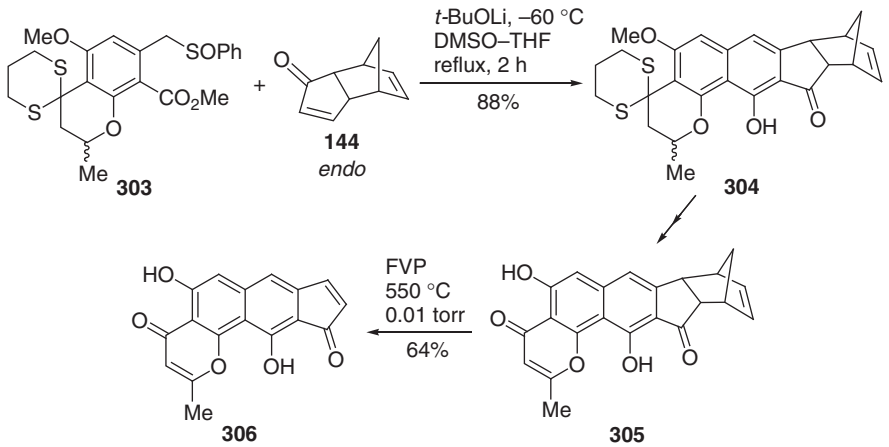
In a stereocontrolled process, the addition of *n*-BuMgBr to racemic *diexo*-lactol **294** either in Et_2O (method A) or in THF, in the presence of $ZnBr_2$ as additive (method B), resulted in the corresponding butyldiols. With 4-methylmorpholine *N*-oxide and tetrapropylammonium perruthenate, oxidation to the lactones followed by reduction with DIBAL hydride (DIBAL-H) led to lactols **295a** and **295b**. Tandem Wittig–Horner/intramolecular Michael reactions resulted in the methyl esters of the tricyclic ethers, which were heated for a very short time (1 ms) and gave the rDA products *cis*- and *trans*-2,5-disubstituted dihydrofuran **296a,b** in excellent yields (92–95%) (Scheme 70).[157]

Scheme 70



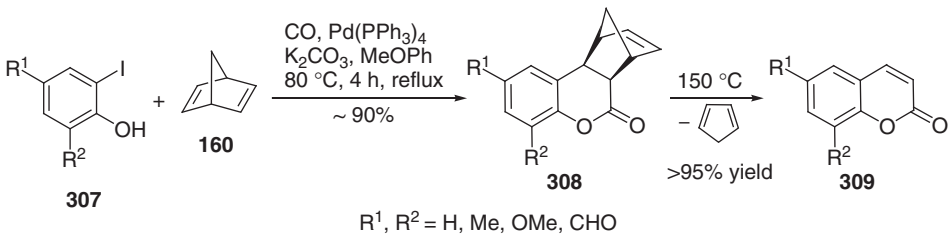
An enantiocontrolled synthesis of (–)-methyl 6-*epi*-cucurbate and (+)-methyl jasmonate proceeded from a chiral tricyclic lactone **268** via a new type of tandem rDA/ene-reaction activated by a trimethysilyl substituent. A solution of lactone **268** in toluene was successively treated with DIBAL at $-78\ ^{\circ}C$ and with the Grignard reagent prepared from 5-bromo-1-(trimethylsilyl)pent-2-ene. The resulting diol was cyclized oxidatively to lactone **297** by a known procedure with *N*-methylmorpholine-*N*-oxide (NMO)/tetrapropylammonium perruthenate (TPAP) at 0 °C. Finally, the rDA method gave intermediate **298** (Scheme 71). However, a tandem ene-type intramolecular cyclization occurred spontaneously in the course of the cycloreversion, which diastereoselectively yielded the cyclopentane-fused γ-lactone **299**.[158] This bicyclic lactone is an important precursor, for example, for the preparation of methyl jasmonate.

Scheme 71



In multistep reactions, similar diastereomeric cyclopentene-condensed γ- and δ-lactones were prepared by using a synthon containing the dicyclopentadiene skeleton for the rDA step. A tricyclic building block, chiral 3-(hydroxymethyl)cyclopenta-2,4-dien-1-ol, served as equivalent for the two iridoids, the (–)-iridolactone and (+)-pedicularis-lactone, which were synthetized in an enantio- and diastereocontrolled manner.[159]

A simple method for the total synthesis of coriandrin and psoralen precursors involved an anion [4 + 2] cycloaddition–rDA strategy, starting from sulfoxide ester **300** and bicyclic enone **144**. Addition and *O*-methylation resulted in the pentacyclic ketone **301** in good yields (>70%). The product underwent rDA fragmentation under FVP conditions to afford 4-methoxy-5*H*-indeno[5,6-*b*]furan-5-one **302** (Scheme 72). Epoxidation with H_2O_2/Et_3N followed by pyrolytic rearrangement led to demethylcoriandrin, an isocoumarin derivative. 8-Methoxypsoralen and its isostere were prepared analogously.[160–162]

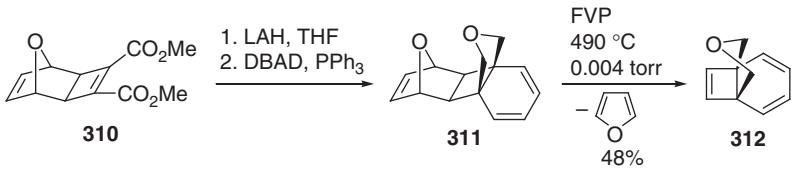


Scheme 72

The first total synthesis of the natural product euplectin, a metabolite isolated from *Flavoparmelia euplecta* lichen which contains a rare chromone (1,4-benzopyrone) ring-condensed indenone structure, comprised 17 steps, including a Hauser sulfoxide-annulation, chromone ring formation, and an rDA process. The preparation of sulfoxide ester **303** from methyl 2-hydroxy-4-methoxy-6-methylbenzoate in a multisequenced procedure proved to be a difficult and crucial task. The modified annulation of sulfoxide **303** with enone **144** yielded the target intermediate **304**, which, after desulfurization, dehydrogenation, and demethylation, afforded polycyclic pyrone **305** (Scheme 73). FVP of this adduct and cleavage of the cyclopentadiene ring led to euplectin **306**.[163]

Scheme 73

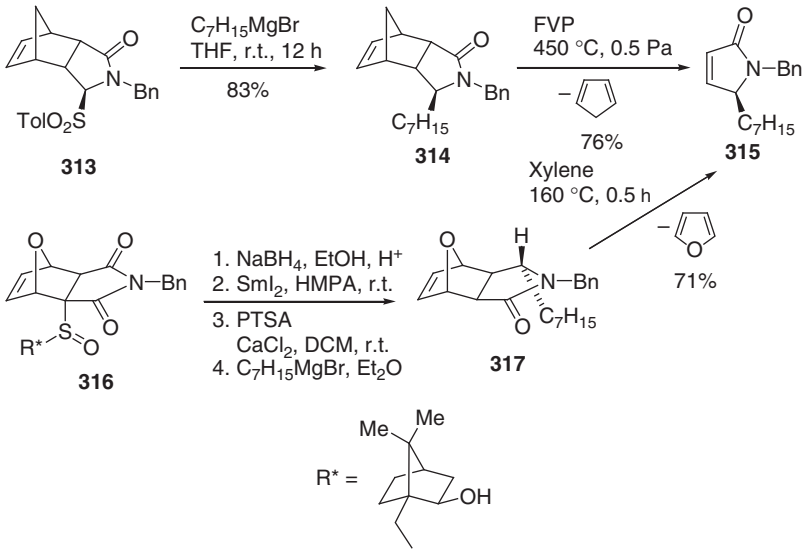
A variety of substituted coumarins have been prepared through Pd-catalyzed coupling of *o*-iodophenols **307** with internal alkenes. The reactions of norbornadiene **160** with *o*-iodophenols **307** in the presence of tetrakis(TPP)palladium gave norbornene-fused coumarins **308** with *diendo* selectivity (Scheme 74). On heating, the rDA reactions of adducts **308** readily led to substituted coumarins **309** by the elimination of cyclopentadiene.[164,165]



Scheme 74

Oxabicycloheptene-fused cyclobutenedicarboxylic ester **310** was reduced to the diol, which underwent the Mitsunobu reaction with dibenzyl azodicarboxylate (DBAD) and Ph_3P to furnish the pentacyclic tetrahydrofuran **311**. When subjected to FVP *in vacuo*, adduct **311** resulted in the unique oxygen-bridged bicycle[4.2.0]octa-2,4,7-triene **312** (Scheme 75).[166]

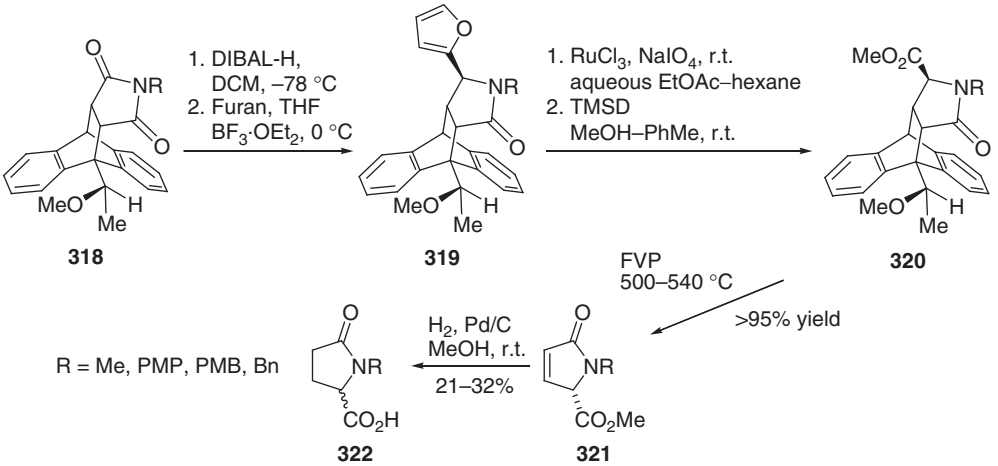
5.12.6.1.2 Nitrogen-containing heterocycles



From the bicyclo[2.2.1]heptene- or 7-oxabicyclo[2.2.1]heptene-fused pyrrolidinone **313**, a novel route was developed to furnish the 5-substituted 3-pyrrolin-2-one **315** in high optical purity (Scheme 76). The reaction of lactam **313** with heptylmagnesium bromide in the presence of $ZnBr_2$ gave the (+)-alkylated derivative **314**, FVP of which afforded (+)-5-heptyl-3-pyrrolin-2-one **315**, though the enantiomeric excess was only moderate (*ee* 74%). To increase the enantiopurity of **315**, an alternative method was

310 **311** **312**

Scheme 75

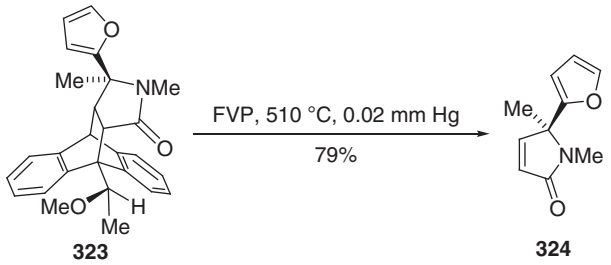


applied, using the enantiomerically pure *N*-substituted α-(2-*exo*-hydroxy-10-bornylsulfinyl)maleimide–furan adduct **316** as the starting compound. After reduction, desulfinylation with SmI_2 and two-step sequenced alkylation, lactam **317** was obtained; in contrast to the bicyclo[2.2.1]heptene, the nucleophile addition took place from the less-hindered *endo* face on the 7-oxabicyclo[2.2.1]heptene. On heating, the (+)-tricyclic lactam **317** gave (+)-**315** via rDA fragmentation in a similar yield (71%) but in high optical purity (*ee* >97%).[167]

313 **314** **315** **316** **317**

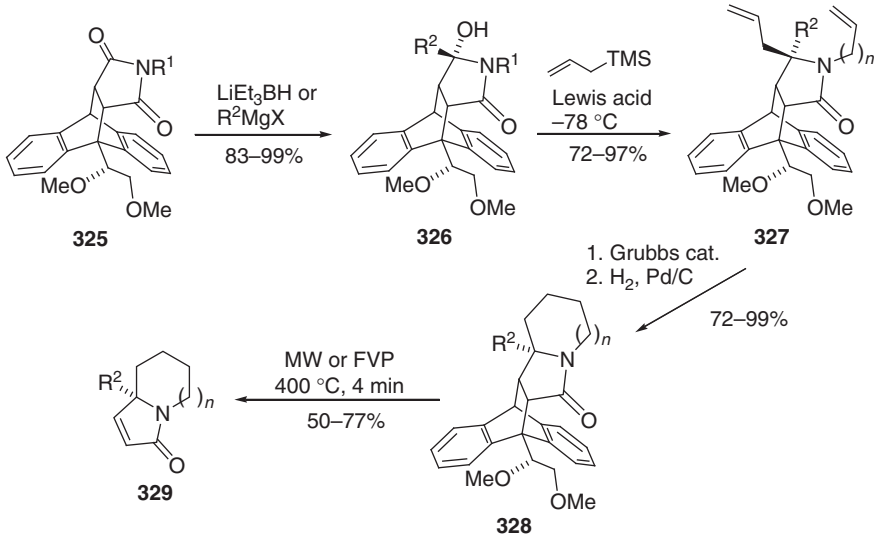
Scheme 76

On the basis of an anthracene chiral auxiliary, a new asymmetric synthesis of pyroglutamic acids **322** was reported (Scheme 77). Anthracene adducts **318** were prepared from chiral methoxyanthracene and maleimides. Introduction of the furan ring into these masked carboxylic acid units ensured excellent diastereoselectivity for **319**, and later allowed conversion to ester through oxidative steps and methylation on treatment with $RuCl_3$–$NaIO_4$ followed by trimethylsilyldiazomethane



318 **319** **320** **321** **322**

Scheme 77



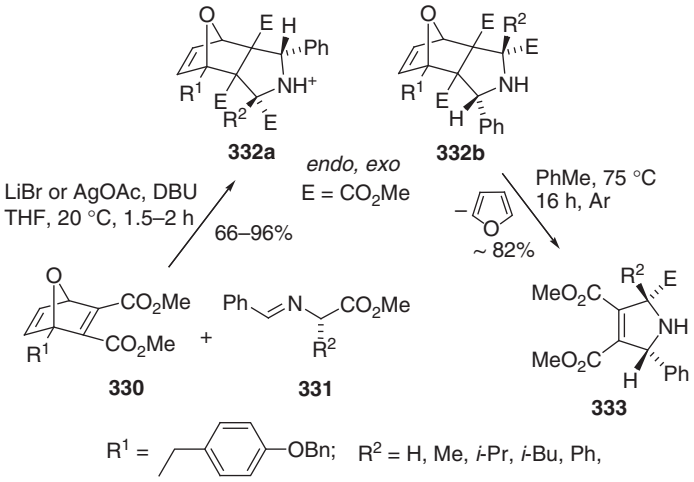
(TMSD). The obtained pyroglutamic ester adducts **320** were subjected to FVP, when rDA cleavage of the chiral anthracene templates occurred to give *N*-substituted 5-oxo-2,5-dihydro-1*H*-pyrrole-2-carboxylates **321** with a conversion of 100%. These products were directly hydrogenated to afford *N*-alkylpyroglutamates **322**, although complete racemization occurred under these conditions.[168]

Starting from the chiral anthracene template, an analogous rDA resulted in arylated or heteroarylated derivatives through the stereoselective intermolecular Friedel–Crafts reaction of the hydroxylactam derivative of **318** (R=Me). Thus, the 5-furanyl-1,5-dimethylpyrrolone enantiomer **324** was obtained by thermolysis of the dimethyl cycloadduct **323** via an rDA process (equation 27).[169]

323 **324** (27)

For the preparation of α,β-unsaturated lactams or bicyclic lactams, 9-(1,2-dimethoxyethyl)anthracene **325** was successfully employed as chiral template in DA/rDA sequences. The cycloadditions took place with complete diastereo- and regioselectivity; moreover, the cycloreversion allowed the use of an FVP method. Superhydride reductions or Grignard reactions of adducts **325** resulted in hydroxylactams **326**. Subsequent allylation furnished dialkenyllactams **327**, which were suitable for ring-closing metathesis in the presence of the Grubbs catalyst. Hydrogenation led to indolizidines **328** ($n=1$) or their seven-membered homologs ($n=2$), and subsequent FVP yielded bicyclic lactams **329** (Scheme 78). By means of cycloaddition, the 3-allyl-5-phenyl-substituted analog of **324** was also prepared from 9-(1,2-dimethoxyethyl)anthracene and *N*-methyl-2-bromomaleimide in several steps. The experimental results demonstrated that 9-(1,2-dimethoxyethyl)anthracene was more reactive (2.8 times) than anthracene itself.[170] Under other conditions (e.g., irradiation, acid catalysts, and a silica gel adsorbent), rDA cleavage with MW-promoted cycloreversion on graphite as a support at 150 °C proceeded with lower yields.[171]

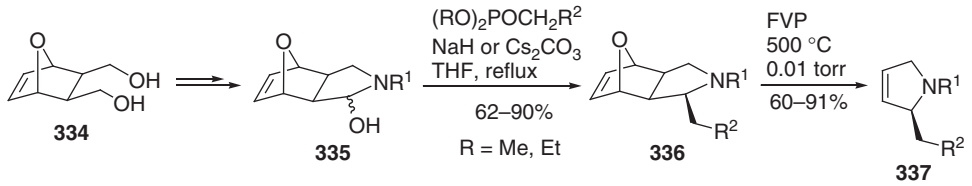
325 **326** **327** **328** **329**



R^1 = Me, vinyl, allyl, $(CH_2)_2CH{=}CH_2$; R^2 = H, Me, Ph; n = 1, 2

Scheme 78

In similar enantioselective syntheses of substituted α,β-unsaturated γ-lactams, 9-(2-phenylethyl)aminoanthracene proved to be a valuable chiral template in DA/rDA reaction sequences in terms of stereo- and regioselectivity.[172]

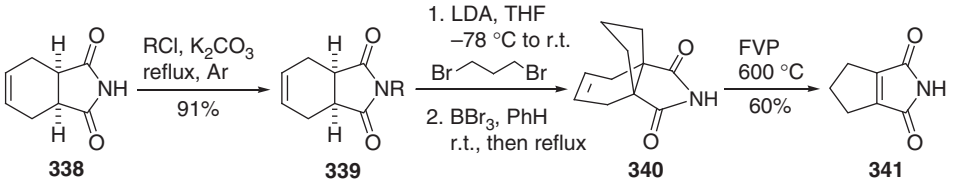


The [3 + 2] cycloaddition of *N*-methylated azomethine ylides derived from α-amino esters with dimethyl 7-oxabicyclo-[2.2.1]hepta-2,5-diene-2,3-dicarboxylates **330** was described for the production of 3-pyrrolines **333**. 1,3-Dipolar cycloaddition to the C=C bond, catalyzed by LiBr or AcOAg in the presence of DBU, afforded mixtures of the stereo- and regioisomeric adducts **332**. The Ag(I)-catalyzed reactions led mainly or exclusively to the *diexo* isomers of **332**. In contrast, the application of LiBr gave

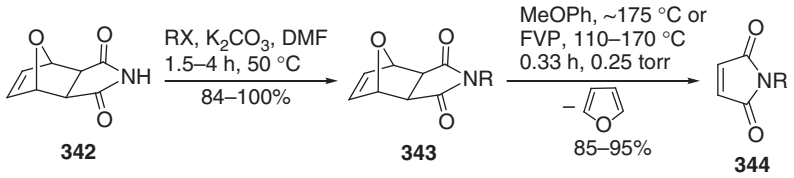
the tricylic products **332a** and **332b** through *diendo* transition states. The cycloreversions were generally carried out under argon in toluene (Scheme 79), which resulted in 5-phenyl-2,5-dihydro-1*H*-pyrrole-2,3,4-tricarboxylates **333**. For R=H, isomerization to 2-phenyl-3,4-dihydro-2*H*-pyrrole-3,4,5-tricarboxylate was observed, probably by a 1,3-hydrogen shift and a C=C double bond migration.[173,174]

Scheme 79

A general synthetic procedure for the preparation of optically active 2-substituted 2,5-dihydropyrroles was based on a highly stereoselective intramolecular Michael reaction, which afforded enantiopure dihydropyrroles after an rDA reaction (Scheme 80). For the key compound **336**, the commercially available *diexo*-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride was reduced with LAH to diol **334**, which was converted by transesterification in the presence of lipase to an optically active intermediate, followed by cyclization to an *N*-acetyl- or other *N*-protected (*tert*-butoxycarbonyl- or *N*-benzyloxycarbonyl) derivative **335**. The tandem Wittig–Horner/intramolecular Michael reaction of hemiaminals **335** with phosphonates in basic medium gave rise to tricyclic pyrrolidines **336** with considerable diastereoselectivity (82–90% *de*), depending on the phosphonate substituent R^2, the base and the *N*-protecting group. On FVP, the tricyclic pyrrolidines **336** underwent cycloreversion and furnished enantioenriched 2-substituted 3-pyrrolines containing an *N*-protecting group **337**.[175]



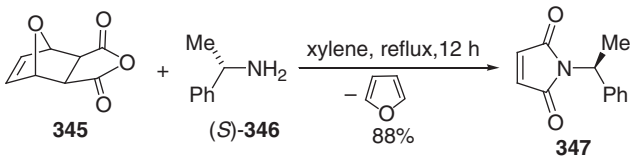
Scheme 80



A convenient synthesis of maleimycin, an antibiotic isolated from *Streptomyces showdoensis*, was based on the dianion-mediated reaction of *cis*-1,2,3,6-tetrahydrophthalimide **338**. The maleimycin precursor was constructed in four stages, including protection and deprotection steps. After protection of the imide with benzylchloromethyl ether, compound **339** was alkylated at the annelation sites with 1,3-dibromopropane, resulting in an 'azapropellane-like' propylene-bridged maleimycin moiety. The imide was deprotected under mild conditions with BBr_3 to give 7,9-dioxo-8-azatricyclo[4.3.3.0]dodec-3-ene **340**, which underwent an rDA process on FVP (Scheme 81) to afford the required skeletal framework **341** of the target molecule.[176]

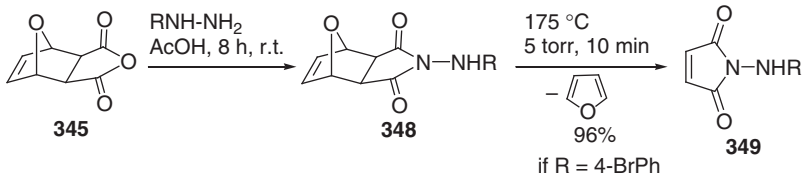
From the *diexo*-7-oxabicycloheptene adduct, *N*-alkylmaleimides **344** were easily prepared via rDA fragmentation on cleavage of furan. After alkylation of imide **342** by heating with alkyl, alkenyl or benzyl halides, the resulting alkylimides **343** were subjected to a thermolytic rDA reaction (Scheme 82) by means of FVP.[177] This method allowed the use of the widely available starting materials and gave maleimides in high purities and yields. It is noteworthy that the products were also of interest for potential thermo- and photo-setting polymerizations. Similar preparations of 2-hydroxyethyl-*N*-maleimide and the related compounds of biological interest were recently patented.[178]

A series of dicyanodihydrofuran (DCDHF) fluorophores containing a thiol-capturing maleimide function were prepared by the above strategy. Alternative and generally useful procedures involved the combination of the Mitsunobu reaction of a



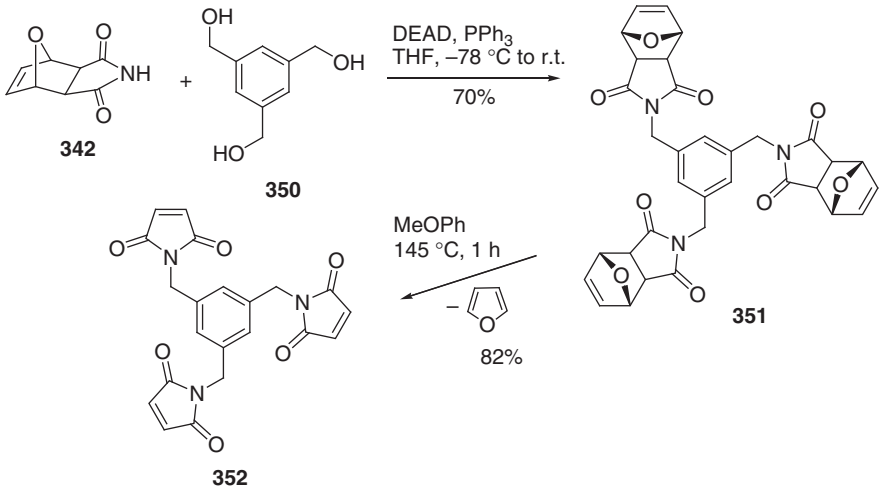
Scheme 81

Scheme 82



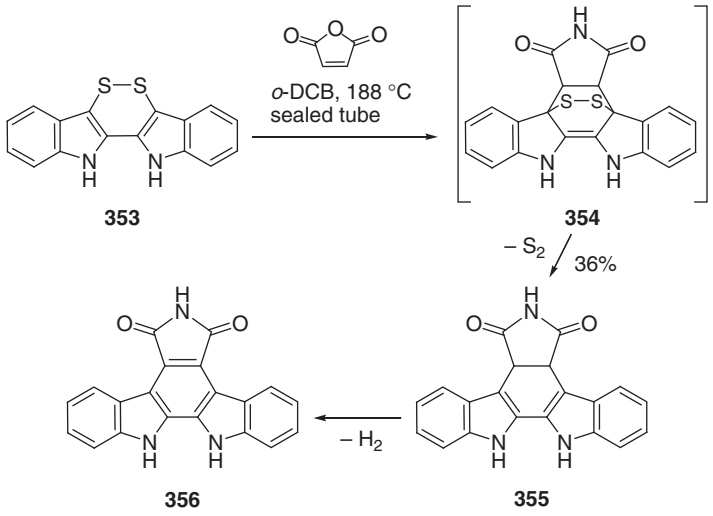
hydroxy-DCDHF with 7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic imide **342** and subsequent rDA cycloreversion in refluxing toluene or xylene, leading to maleimide derivatives in high yields.[179]

(1*S*)-*N*-(1-Phenylethyl)maleimide **347** was prepared through π-cationic cyclization. Its reactivity was studied and this compound was applied to the synthesis of the chiral pyrroloisothiochromane and pyrrolobenzo[*d*]thiepine.[180] The key compound was constructed from the commercially available *diexo*-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride **345** via a tandem amine–anhydride cyclodehydration/rDA reaction involving the release of furan in a one-pot procedure (equation 28). Compound **347** was obtained in another three-step reaction from MA, but in a lower overall yield (73%).



(28)

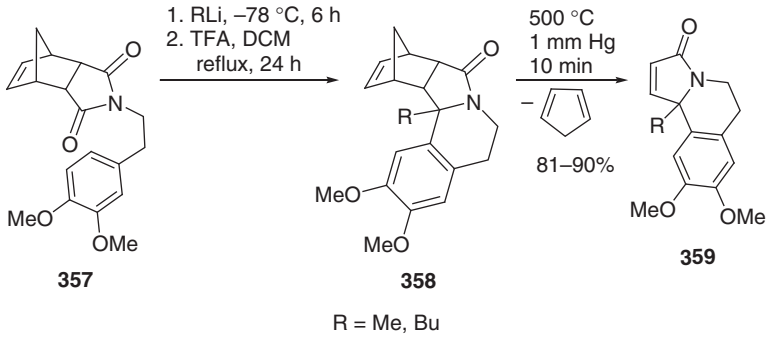
Thanks to the special behavior of MA, a new synthetic route to *N*-substituted aminomaleimides was devised through condensation of *diexo*-**345** with hydrazine or one of its derivatives. The mixture was stirred under nitrogen to give bicyclic alkyl- or aryl-substituted *N*,*N*′-maleimides **348** (Scheme 83). When the bicylic imide (R = 4-bromophenyl) **348** was heated, rDA decomposition to furan and the aryl-protected aminomaleimides **349** occurred.[181] In other cases, however, the cycloreversion failed.



Scheme 83

A novel homotrifunctional conjugation reagent, 1,3,5-tris-(*N*-maleimidomethyl)benzene, was synthetized in pure form and high yield, and its reactivity was examined by the application of L-cysteine as a model nucleophile. Use of the Mitsunobu reaction for the coupling of imide **342** with 1,3,5-tris(hydroxymethyl)benzene **350** under standard conditions (DEAD = diethyl azodicarboxylate) afforded trisubstituted benzene **351,** which underwent an rDA reaction on heating and led to the reactive maleimide **352** on cleavage of furan (Scheme 84). The reactivity of this unsaturated triimide **352** in thiol conjugation was studied using L-cysteine methyl ester hydrochloride as a simple but representative thiol-containing molecule for the demonstration of peptide conjugation.[182]

Scheme 84

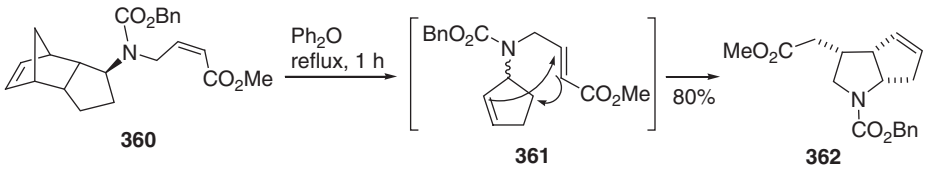


The DA/rDA sequence involving the formation and transformation of maleimide was applied in an approach to the natural product arcyriaflavin-A **356**, a potent inhibitor of CDK4/cyclin D1 (IC_{50} = 59 nM), which also inhibits the human cytomegalovirus in cell cultures (IC_{50} = 200 nM). Heating of the conformationally rigid dithiete **353** with maleimide furnished arcyriaflavin-A (Scheme 85) via [4 + 2] adduct **354**, which underwent an rDA process to yield S_2 and dihydroarcyriaflavin-A **355**. The latter presumably underwent dehydrogenation by dissolved oxygen and/or extruded sulfur to afford the targeted alkaloid **356**.[183]

Scheme 85

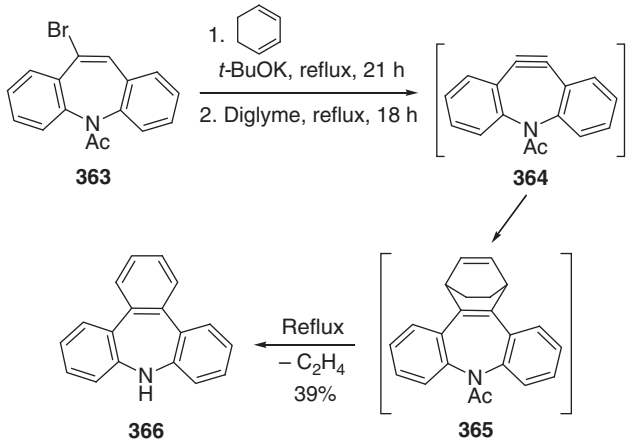
The reactions of organolithium compounds with *N*-phenylethylimides proved to be an effective means of accessing functionalized norbornene-fused dihydropyrrolo[2,1-*a*]isoindolones. Thus, imide **357**, prepared by condensation of the phenylethylamine with the bicyclic anhydride, was treated with MeLi or *n*-BuLi to afford α-hydroxylactam intermediates as diastereomeric mixtures in ratios of 88:12 and 85:15, respectively. Intramolecular cyclization with TFA gave methylene-bridged isoindoloisoquinolines **358**, which on heating resulted in the unsaturated pyrroloisoquinolinones **359** through an rDA procedure (Scheme 86).[184]

An enantiodivergent synthesis of 10b-substituted pyrrolo[2,1-*a*]isoquinolines (R = H, Me, *n*-Bu, allyl) **359** was developed from enantiomerically pure *N*-phenethylnorborn-5-ene-*diendo*-2,3-dicarboxyimide **357** with the 2-*exo*-hydroxy-10-bornylsulfinyl group as the chiral auxiliary. The key transformations resulted from the diastereoselective intramolecular cyclization of aryllithiums and α-amidoalkylation, wherein the ethylidene bridge of the norbornene directed the stereochemical outcome in either reaction. Hence, the organolithium addition–intramolecular α-amidoalkylation sequence on imides **359** afforded the *R* configuration stereoselectively, whereas the tandem Parham cyclization–intermolecular α-amidoalkylation on the iodinated imide led to the epimeric compound. Refluxing in *o*-DCB and the subsequent reductive removal of the chiral auxiliary followed by the rDA step afforded (10b*S*)- and (10b*R*)-pyrroloisoquinolines **359** in optical purities (> 99% *ee*).[185,186] This synthetic strategy was also used



Scheme 86

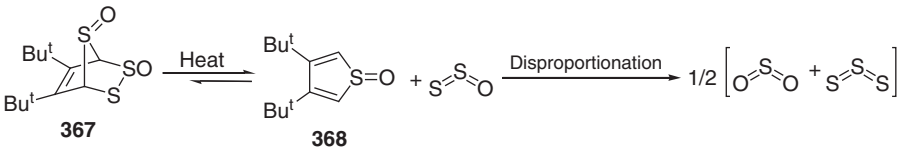
for the preparation of 10b-functionalized dihydropyrrolo[2,1-*a*]isoquinolines, serving as intermediates for the synthesis of the erythrinane ring systems.[187]



The application of Grignard reagents instead of organolithium compounds led to similar results in addition to carboximide **357**; the expected methyl- and pentenyl-substituted pentacyclic dihydropyrrolo[2,1-*a*]isoindolones were obtained in good yields (75–81%) and with complete diastereocontrol. Cycloreversions by heating in vacuum at 0.25 mm Hg gave the same heterocycles **359** in 65–90% yield.[188]

A stereocontrolled route to (–)-kainic acid, a representative of the kainoid amino acids which exhibit insecticidal, anthelminthic, and neuroexcitatory properties, was devised by enantioconvergent conversion of the *diendo*-bicyclopentadienone **144** to amine starting materials for concurrent rDA fragmentation and intramolecular ene reaction. The thermolysis of the amine diastereomers **360** gave best results in boiling Ph_2O at ~260 °C. However, an intramolecular ene reaction took place with high diastereo- and enantioselectivity (>99% *ee*) to give all-*cis* tetrahydrocyclopenta[*b*]pyrrole carboxylate **362** instead of the expected cyclopentenylamine **361** (Scheme 87). Compound **362** was transformed to a direct precursor of kainic acid in a multistep procedure by cyclopentene ring-opening reactions.[189]

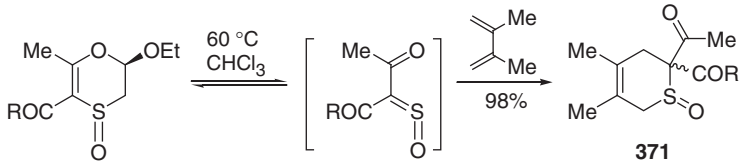
Scheme 87



By means of an rDA procedure, a new route to 9*H*-tribenz[*b,d,f*]azepine **366** was developed. As a reactive intermediate, 10,11-didehydro-5-acetyl-5*H*-dibenz[b,f]azepine **364**, prepared *in situ* with *t*-BuOK from 5-acetyl-10-bromo-5*H*-dibenz[*b,f*]azepine **363**, was reacted with 1,3-cyclohexadiene in a DA reaction. The resulting cycloadduct **365** underwent an rDA reaction on refluxing in diglyme (Scheme 88) and a simultaneous hydrolysis resulted in the targeted 9*H*-tribenz[*b,d,f*]azepine **366**.[190]

Scheme 88

5.12.6.1.3 Sulfur-containing heterocycles

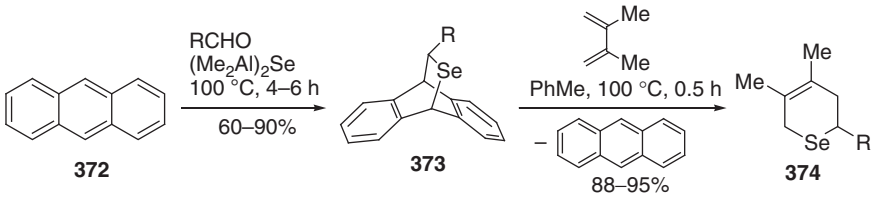


5,6-Di-*t*-butyl-2,3,7-trithiabicyclo[2.2.1]hept-5-ene-7-*endo*-oxide was prepared by the addition of S_2Cl_2 to 3,4-di-*tert*-butylthiophene-1-oxide. Oxidation with dimethyldioxirane gave a 7:1 isomeric mixture of 5,6-di-*t*-butyl-2,3,7-trithiabicyclo[2.2.1]hept-5-ene-2-*endo*-7-*endo*-dioxide **367** and the 2-*exo*-7-*endo*-dioxide. The thermally labile **367** underwent an rDA process, which produced S_2O and *S*-oxide **368** in a reversible way (Scheme 89). By trapping with dienes, S_2O gave 3,6-dihydro-1,2-dithiin-1-oxides. In the absence of dienes, the S_2O disproportionated to SO_2 and S_3, the latter participating in 1,3-dipolar cycloaddition with 3,4-di-*tert*-butylthiophene 1-oxide **368**, on its syn-π-face with respect to the S=O bond, to give a trithiolane derivative on hydrolysis. In the presence of excess norbornene, the 1,3-dipolar cycloadduct was produced. Thus, the rDA cycloreversion of **368** served as a source of S_2O and S_3.[191]

367 **368**

Scheme 89

When oxathiin-*S*-oxides **369** were heated, α,α′-dioxosulfines **370** were generated as unisolable electron-poor dienes by thermal rDA cycloreversion; they were reacted *in situ* with 2,3-dimethyl-1,3-butadiene or 1,3-cyclohexadiene as the dienophile. In direct DA reactions, sulfines were formed as dihydrothiopyran cycloadducts **371**, which could be isolated in almost quantitative yields (Scheme 90). However, a longer reaction time was required for the cycloaddition of α-oxo-α′-carbethoxysulfine (R=OEt) than for the corresponding dioxosulfine (R=Me) cycloreversion intermediate.[192,193]



369 **370** **371**

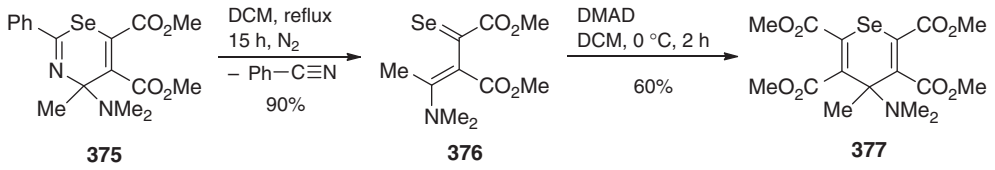
Scheme 90

5.12.6.1.4 Selenium-containing heterocycles

From alkylaldehydes or substituted benzaldehydes, the [4 + 2] cycloadducts **373** of anthracene **372** with selenoaldehydes were prepared using bis(dimethylaluminum)selenide as the reagent. *In-situ* regeneration from the selenoaldehyde adducts through a thermal rDA/DA process in the presence of 2,3-dimethyl-1,3-butadiene as the trapping agent afforded dihydroselenopyranes **374** (Scheme 91).[81]

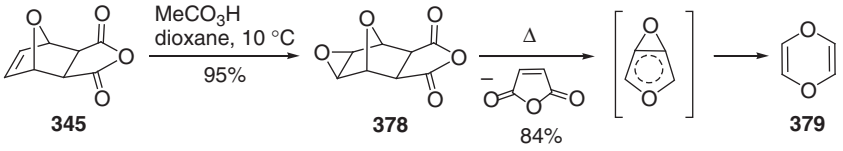


372 **373** **374**

R = *n*-Pr, Ph, 4-FC_6H_4, 4-$MeOC_6H_4$, $(CH_2)_2Ph$

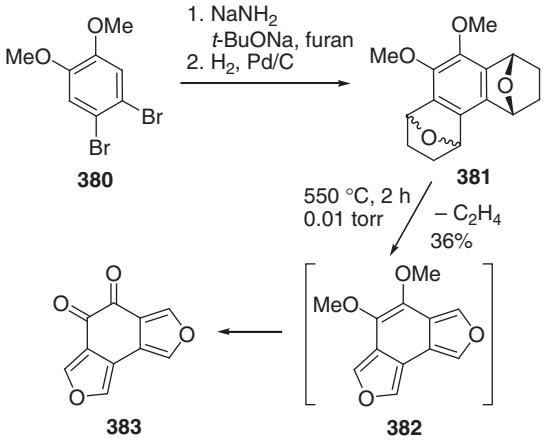
Scheme 91

The reactivities of *N*-selenoacylamidines as 4π heterodienic systems in [4 + 2] cycloadditions with electrophilic dienophiles have been reported. Selenoketone **376** was generated *in situ* from 4*H*-1,3-selenazine **375** through the release of benzonitrile via cycloreversion. When quenched with an excess of DMAD, this stable heterodienic diester **376** afforded 4*H*-selenopyrane **377** (Scheme 92) by [4 + 2] cycloaddition.[194]



Scheme 92

5.12.6.2 Heterocyclic Ring Systems Containing Two Identical Heteroatoms

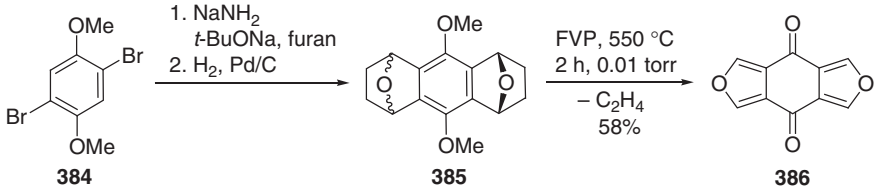


5.12.6.2.1 Heterocycles containing two oxygen atoms

The [4 + 2] cycloaddition of furan to MA opens access to 1,4-dioxin **379**. With peracetic acid, the unsaturated adduct **345** was converted to epoxide **378**, which underwent a thermal rDA reaction to give 1,4-dioxin **379** (Scheme 93) by the regeneration of MA. Compound **379** was then transformed to acrylaldehyde.[195]

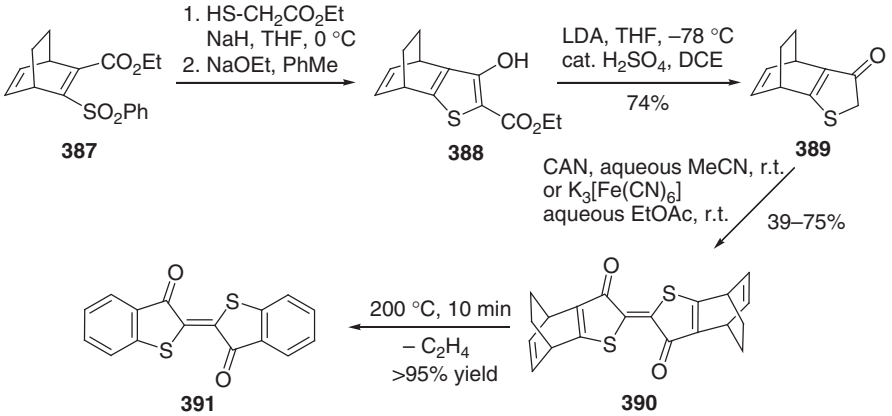
Scheme 93

Treatment of dibromide **380** with sodium amide and sodium *t*-butoxide (Caubère's superbase) in the presence of furan gave a mixture of *syn*- and *anti*-9,10-dimethoxydiepoxyphenanthrene, which afforded diepoxytetrahydrophenanthrene **381** in a yield of 97% on hydrogenation over a Pd catalyst. Pyrolysis of **381** led to the angular benzodifuran-4,5-dione **383** directly, though in poor yield. The formation of the *o*-quinone could be rationalized by double rDA extrusion of ethylene from phenanthrene **381** through intermediate **382** (Scheme 94), which underwent homolytic C–O bond cleavage of the methoxy groups.[196]



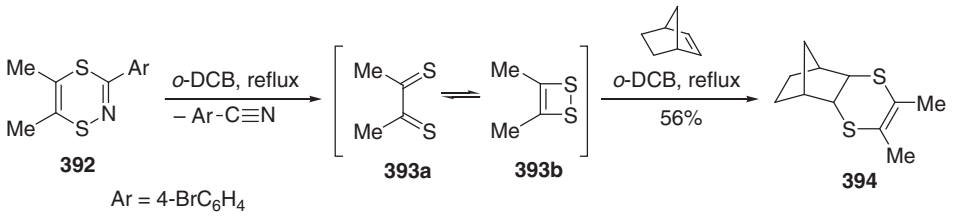
Scheme 94

Through a similar route, linear *p*-quinone analogs were synthetized from 1,4-dibromo-2,5-dimethoxybenzene **384** in a stirred one-pot reaction (Scheme 95) with superbase and dry furan. After workup, the corresponding diepoxyanthracene **385** was obtained from the mixture. Hydrogenation and FVP rDA fragmentation of **385** led to benzodifuran-4,8-dione **386**.



5.12.6.2.2 Heterocycles containing two sulfur atoms

Thioindigo **391**, a unique thio analog of the natural dye indigo, was synthetized by an rDA method from the symmetrical bisthiophenonylidene attached to two bicycle[2.2.2]octadiene (BCOD) units (Scheme 96). From commercially available ethyl propiolate, cycloadduct **390** was prepared in six steps by the construction of the DA adduct **387** with cyclohexadiene. The thiophene ring was formed by Dieckmann condensation followed by an intramolecular reaction, which directly afforded 2*H*-thiophen-3-one **389** after an acidic workup. The subsequent step led to oxidative dimerization to **390**, for which a variety of

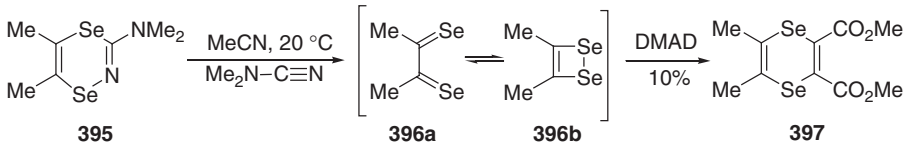


Scheme 95

conditions were studied: two-phase oxidation with potassium ferricyanide was found to be best, though the application of ceric ammonium nitrate (CAN) was also efficient. As the precursor adduct, compound **390** was obtained as a 1:1 mixture of diastereoisomers but as a single *E* isomer with regard to the newly formed C=C bond. Cycloreversion of dimer **390** on heating resulted in pure thioindigo **391**.[197]

Scheme 96

Under forcing conditions (refluxing in 1,2-dichlorobenzene at 180 °C), 5,6-dimethyl-3-*p*-bromophenyl-1,4,2-dithiazine reacted with dienophiles such as DMAD or with less reactive alkenes (e.g., norbornene). The mechanism of this reaction was not proven, but seemed to occur by cycloreversion of dithiazine **392** via the loss of nitrile to the butane-2,3-dithione intermediate **393a** or its ring-closed 3,4-dimethyl-1,2-dithiete tautomer **393b**, which was trapped by norbornene to give the stable and isolable hexahydro-5,8-methano-1,4-benzodithiine **394** (Scheme 97). However, thermolysis of **392** with an electron-rich substituent on the phenyl ring did not result in 1,4-dithiines but in isothiazoles formed by extrusion of elemental sulfur from the ring. Electron-withdrawing subtituents such as bromide on the phenyl group promoted the DA-type [4 + 2] cycloreversion/cycloaddition process at a reasonable temperature.[198]

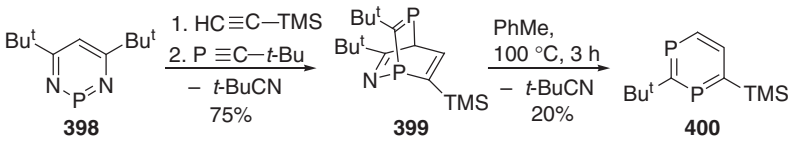


Scheme 97

5.12.6.2.3 Heterocycles containing two selenium atoms

1,3-Diselenolium salts reacted with ammonia and iodine to afford unstable 1,4,2-diselenazine **395**, which, similar to the thio analog, was fragmented under mild rDA conditions to furnish dimethylcyanamide and 1,4-diselenine **397**, presumably via the intermediate 1,2-diselenete **396b**, which is trapped with DMAD to give cycloadduct **397** (Scheme 98).[199]

5.12.6.2.4 Heterocycles containing two phosphorus atoms

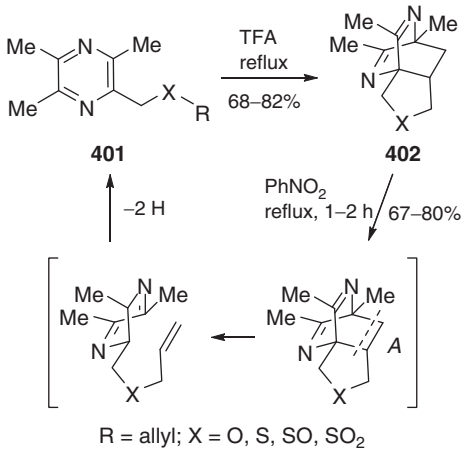


t-Butylphosphaethyne (*t*-Bu–C≡P) in combination with trimethylsilylacetylene underwent a DA reaction with 1,3,2-diazaphosphinine **398** to furnish azadiphosphabarrelene **399** by elimination of one molecule of pivalonitrile (Scheme 99). Through

395 396a 396b 397

Scheme 98

smooth [4 + 2] cycloaddition with other silylated acetylenes (e.g., ferrocenyl), the reaction also gave different azadiphosphabarrelenes in yields of 53–75%. Although the thermolysis of these barrelenes led exclusively to the starting compounds, the pyrolysis of **399** under the same conditions proceeded by [4 + 2] cycloreversion with concomitant elimination of a further molecule of pivalonitrile led to 1,3-diphosphinine **400**, unambiguously identified by an analysis of its tungsten complex.[200]

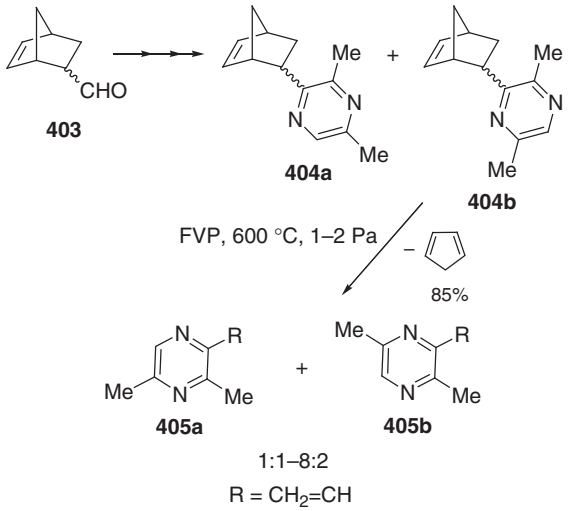


398 399 400

Scheme 99

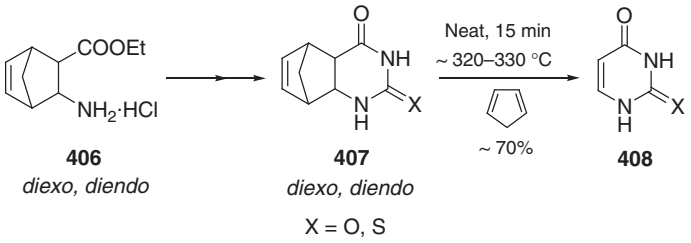
5.12.6.2.5 Heterocycles containing two nitrogen atoms

On heating in TFA (bp. 72 °C) for 1–8 h, the intramolecular DA cycloaddition of a series of pyrazines **401** with ω-alkenyl sidechains led to 3-oxa- and 3-thia-8,10-diazatricyclic dienes **402**. The cycloadduct **402** was converted into the starting pyrazines **401**, via rDA reaction at a higher temperature (~210 °C). Thus, the unstable DA adduct **402** was thermally cleaved at the site labeled 'A' in Scheme 100 and dehydrogenated by the hydrogen acceptor nitrobenzene (Scheme 100).[201]



401 402

Scheme 100

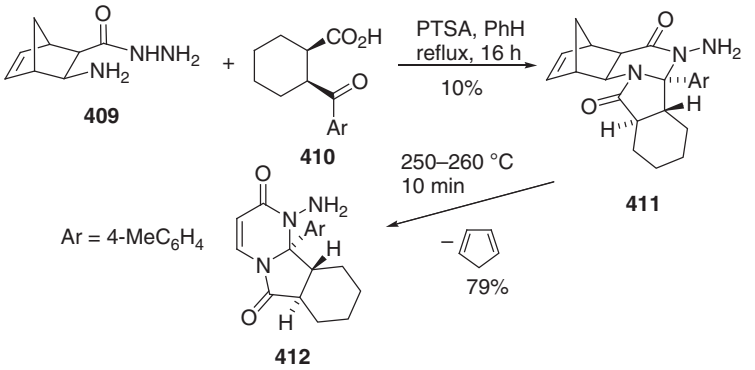


Regioisomeric 2-vinyl-3,5-dimethylpyrazine **405a** and 3-vinyl-2,5-dimethylpyrazine **405b** were obtained via norbornene-substituted derivatives **404a,b** in a multistep procedure (Scheme 101). These pyrazines were identified in ground or freshly roasted coffee beans and in volatile aromatic compounds of roasted peanuts. Earlier attempts at the total synthesis of these compounds were quite unsuccessful or the products were obtained in only very poor yields (1–5%). With the aid of a DA/rDA methodology, however, the dimethylpyrazine moiety was successfully built up from carboxaldehyde **403** by condensation with acetaldehyde, followed by oxidation in ethoxyethanol with Bi_2O_3 to a propanedione derivative. This diketone (a mixture of *exo* and *endo* isomers) was then reacted with 1,2-diaminopropane to yield 5,6-dihydropyrazines, which were subsequently oxidized to pyrazines **404** in the presence of MnO_2. The mixture of regioisomers **404a** and **404b** was pyrolyzed to pyrazines **405a** and **405b** in various ratios (equimolarly from *exo* isomer **404**, and in a ratio of 8:2 from the *endo* compound **404**) in a yield of 85% (and an overall yield of 14% over five steps).[202]

With KOCN, the reaction of 2-aminonorbornenecarboxylate hydrochlorides **406** gave urea ester intermediates, which were cyclized to norbornene-fused 5,6-dihydrouracils **407** (X = O). The *diexo* adduct **407** afforded 2,4-pyrimidine-2,4-dione (uracil) **408**

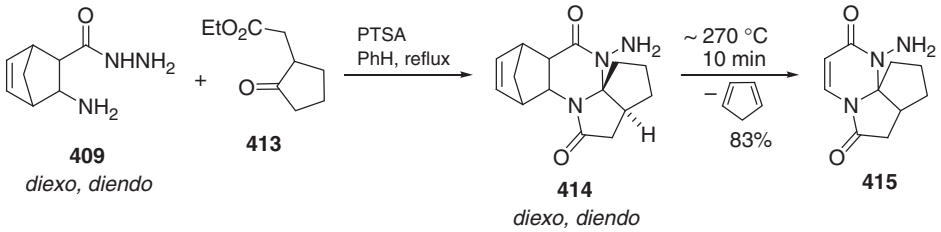
Scheme 101

(X=O) on heating at around the melting point through the release of cyclopentadiene (Scheme 102).[203] The transformation of the norbornene-condensed *β*-aminoester with thiophosgene resulted in an isothiocyanate, which, on reaction with NH_3 in MeOH and standing overnight at room temperature, cyclized spontaneously to *diendo*- or *diexo*-tricyclic dihydrothiouracils **407** (X=S). When **407** were heated to the melting point, a retrodiene decomposition took place with the cleavage of cyclopentadiene, resulting in pure thiouracil **408** (X=S).[204]



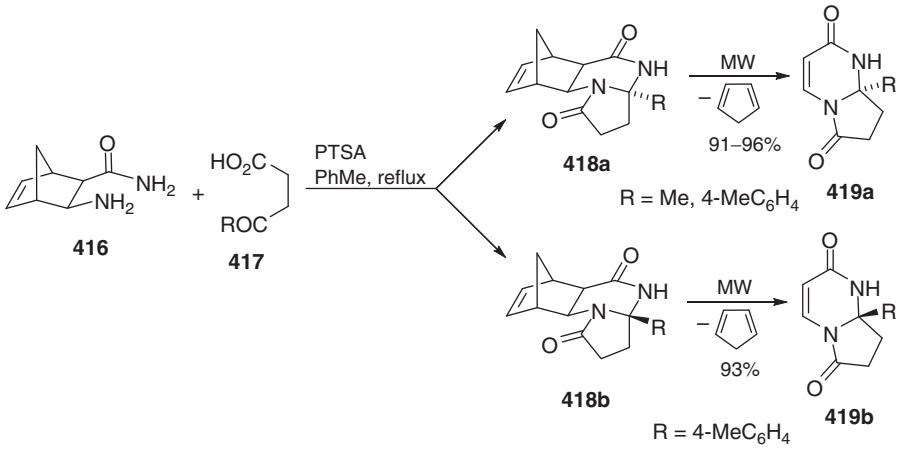
Scheme 102

The reactions of *diexo*-3-amino-2-norbornenecarbohydrazide **409** and *cis*-2-toluoyl-cyclohexanecarboxylic acid **410** or its aromatic analogs involved two unusual transformations (Scheme 103). When **409** and **410** were refluxed in benzene in the presence of a catalytic amount of PTSA,[205] the pentacyclic *N*-aminopyrimido[2,1-*a*]isoindole-2,6-dione **411** was obtained first, in contrast to the expected methylene-bridged decahydro-8*H*-phthalazino[1,2-*b*]quinazolin-8-one. At the same time, a *cis*→*trans* isomerization took place at the annelation carbons in the isoindolone moiety of **411**, which was followed by fragmentation via an rDA process to give cyclopentadiene and aminopyrimido[2,1-*a*]isoindole-2,6-dione **412** (Scheme 103).

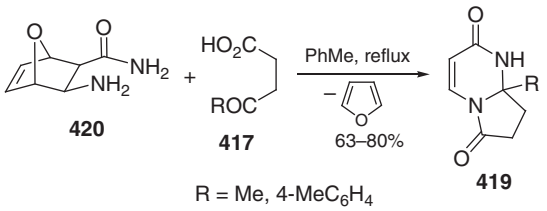


Similar reactions of *diexo*- or *diendo*-3-amino-2-norborneneaminocarbohydrazides **409** with ethyl (2-oxocyclopentyl)-acetate **413** afforded the pentacylic *N*-aminopyrrolo[1,2-*a*]quinazoline-1,5-dione **414**. On heating at temperatures between 270 and 275 °C, this compound gave tetrahydrocyclopenta[2,3]pyrrolo[1,2-*a*]pyrimidine-2,6-dione **415** in an rDA reaction (Scheme 104).[206]

From *diexo*-3-aminobicyclo[2.2.1]hept-5-ene-2-carboxamide **416** and levulinic acid or *p*-toluoylpropionic acid **417**, all diastereomers of the tetracyclic pyrrolopyrimidine derivatives **418a** and **418b** were prepared in a three-step domino reaction. When subjected to an MW-mediated rDA reaction, the tetracycles furnished bicyclic pyrrolo[1,2-*a*]pyrimidines **419a** and **419b** by loss of cyclopentadiene (Scheme 105). From enantiomerically pure *diexo*-3-aminobicyclo [2.2.1]hept-5-ene-2-carboxamide, the heterocyclic products were formed with *ee* >99%, demonstrating that the starting compound was an excellent chiral source.[207]

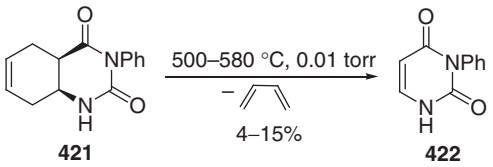


Through cyclization of *diexo*-3-amino-7-oxanorbornene-2-carboxamide **420** with *γ*-oxocarboxylic acids such as levulinic acid or *p*-toluoylpropionic acid **417**, pyrrolo[1,2-*a*]pyrimidinediones **419** were formed directly or indirectly, with the loss of furan by thermolysis (equation 29). When 2-formylbenzoic acid was used, the same sequence of condensation with **420** and cycloreversion led to the corresponding pyrimido[1,2-*a*]isoindoledione.[208]

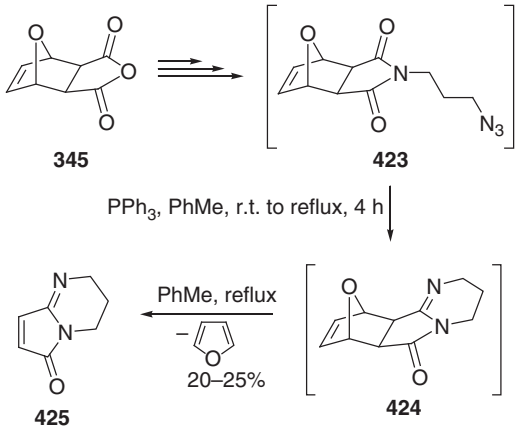


Scheme 103

Scheme 104



Scheme 105



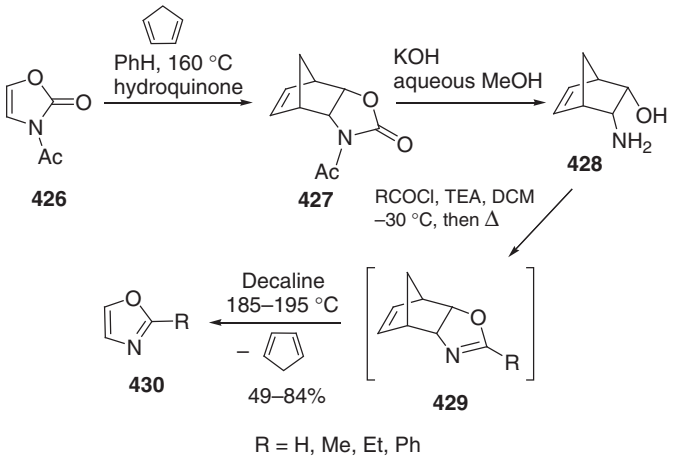
(29)

When *cis*-3-phenyltetrahydroquinazoline-2,4-dione **421** was subjected to FVP during a contact time of ~0.01 s, rDA cycloreversion took place at all the temperatures studied, furnishing uracil **422** as the main product, together with butadiene (equation 30).[209]

(30)

From commercially available 7-oxabicycloheptenedicarboxylic anhydride **345,** the bicyclic amidinium salt of the antibacterial and cytotoxic agent phloeodictine A1 (isolated from the sponge *Phloeodictyon* sp.) was synthetized in a convergent seven-step route, in an overall yield of 8%. The Eguchi-aza-Wittig reaction of **423** furnished the tetracyclic intermediate **424**, which, following an rDA reaction, liberated 3,4-dihydropyrrolo[1,2-*a*]pyrimidin-6(2*H*)-one **425** (Scheme 106). Specifically, with 3-aminopropanol, the furan–MA DA adduct **345** provided a cyclic hydroxypropyl-*N*-imide, which was converted to the mesylate and then azide **423** with NaN_3. When refluxed with polystyrene-supported PPh_3, **423** underwent the intramolecular Eguchi-aza-Wittig cyclization to **424**, spontaneous rDA cycloreversion of which gave **425**.[210]

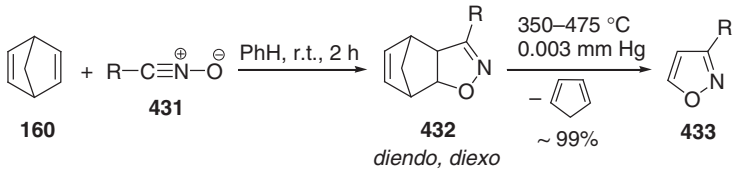
Scheme 106



5.12.6.3 Heterocycles Containing Two Different Heteroatoms

5.12.6.3.1 Heterocycles containing nitrogen and oxygen

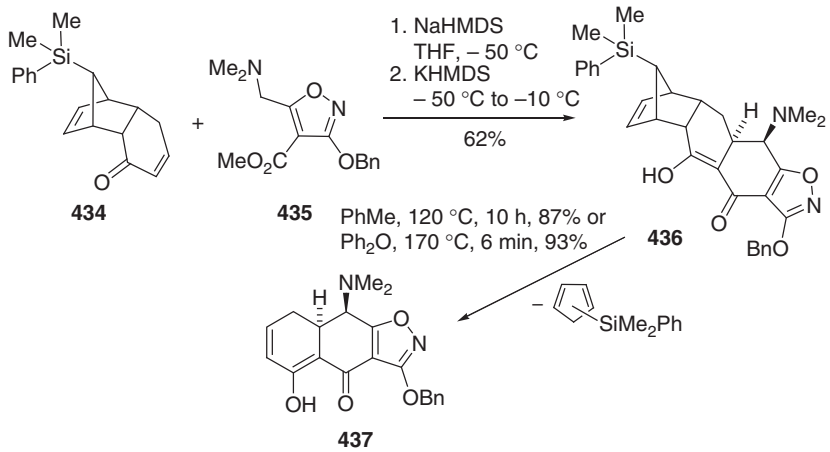
After earlier attempts to synthetize the oxazole moiety through classical condensation strategies had failed, a facile and mild rDA approach to prepare 2-substituted oxazoles was developed that involved a cycloaddition–cycloreversion method. For the preparation of norbornene-2-aminoalcohol **428,** cyclopentadiene was reacted with 3-acetyl-2(3*H*)-oxazolone **426** and the adduct **427** was hydrolyzed. Acylation and thermal cyclization allowed the simultaneous retrodiene reaction to afford oxazoles **430** (Scheme 107). Attempts at the cyclization of α-amino alcohol **428** to tricyclic oxazoles **429** by other methods, for example, with phosphoryl chloride or thionyl chloride, were ineffective.[211] The above method, however, was successfully applied to the preparation of analogs of disoxaril (Win 51711 and Win 54954), which inhibit the replication of poliviruses types 1 and 2 and display antirhinoviral activity against human rhinovirus type 14 (HRV-14).[212]



3-Vinyl- and 3-phenylisoxazoles **433** were prepared by a sequence involving the cycloaddition of nitrile oxides to norbornadiene **160**, followed by rDA cycloreversion on FVP (Scheme 108). The 1,3-dipolar addition was achieved *in situ* from acrylonitrile and benzonitrile oxides **431**, with an excess (5 equivalents) of norbornadiene, after which the reaction mixture was purified by column chromatography to afford *diexo* and *diendo* adducts **432** in different ratios (~3:1). Traditional thermal rDA fragmentation of the adducts in mesitylene at 163 °C for 19 h was unsuccessful, whereas FVP at temperatures between 350 and 400 °C (R=Ph) or at 475 °C (R=vinyl) gave complete conversion.[213]

A practical and convergent route to the key precursor (AB enone ring core) for tetracycline antibiotics from simple starting materials was developed using a diastereoselective Michael–Claisen coupling. Specifically, a Michael–Claisen cyclization of the dimethylphenylsilyl-substituted cyclohexenone **434** and the isoxazole ester **435** was effected with sodium hexamethyldisilazide (NaHMDS), and the resulting adduct then treated with potassium hexamethyldisilazide (KHMDS) to ensure rapid deprotonation of the Claisen product. In the preferred sequence, the Michael–Claisen cyclization product **436** was heated to induce the rDA reaction (Scheme 109), which resulted in a mixture of cleaved dimethylphenylsilyl–cyclopentadiene isomers in different ratios and the desired 9-amino-5-hydroxydihydronaphtho[2,3-*d*]isoxazolone derivative **437**. Two other rDA fragmentations of the adduct **436** under different conditions were also studied. Heating in diphenyl ether at 170 °C for 6 min provided tricyclic **437** in

426 **427** **428** **429** **430**

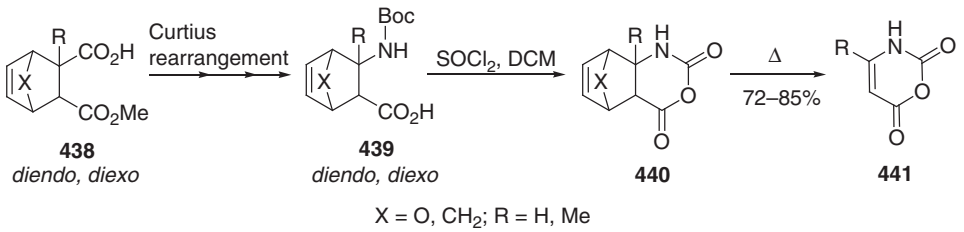


Scheme 107

160 **431** **432** *diendo, diexo* **433**

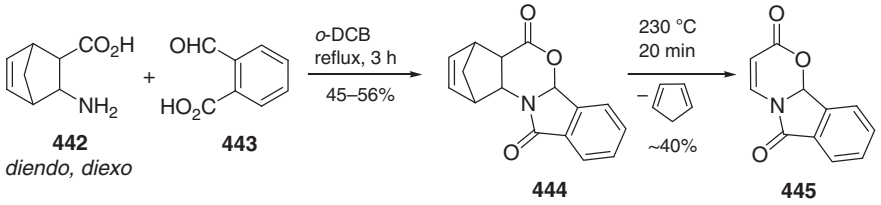
Scheme 108

93% yield, and heating of the hydrochloride of **436** in hexafluoroisopropanol under reflux (60 °C) for 12 h afforded the same product in 69% yield after the basic workup. However, the rDA process of the analogous nonsilylated cycloadduct **436** occurred only above 200 °C, and partial decomposition (55%) took place in the presence of dimethyl maleate when continuous-flow reaction conditions were applied.[214]



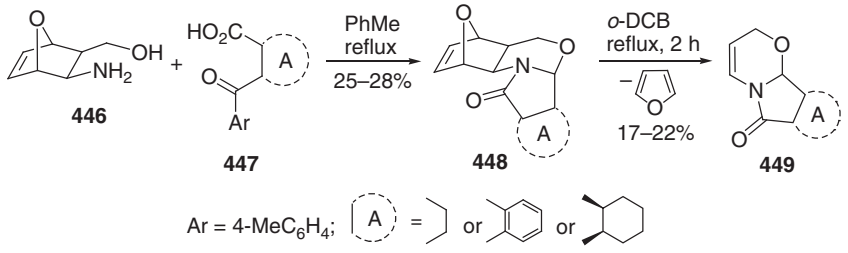
434 **435** **436** **437**

Scheme 109



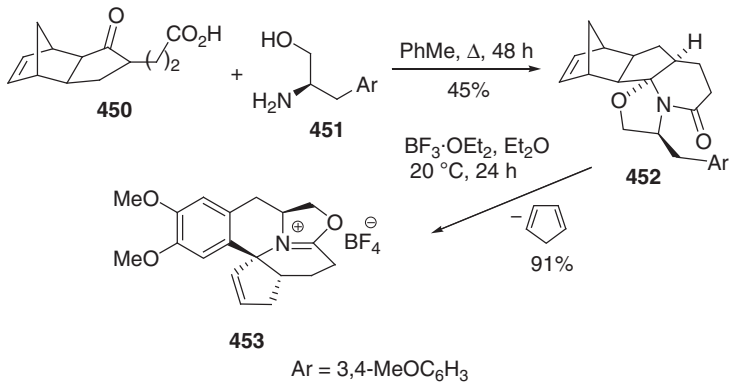
From bicyclic monoesters **438**, methylene- and oxygen-bridged bicyclic *N*-protected *β*-amino acids **439** were prepared diastereo- and regioselectively via Curtius rearrangement. Subsequent cyclization by $SOCl_2$ led to the fused 1,3-oxazinane-2,6-dione adducts **440** (Scheme 110), which provided versatile substrates for the synthesis of dipeptides and could be easily converted to 2*H*-1,3-oxazine-2,6(3*H*)-diones **441** by thermal [4 + 2] cycloreversion.[215] The conditions of the retrodiene reactions differed greatly, depending on the bridge atom: in the presence of a methylene bridge (X=CH_2), more forceful heating was required

(160 °C) than in the case of an oxygen bridge (refluxing in benzene). This proved that furan splits off more readily than cyclopentadiene in the course of the rDA reaction.



Scheme 110

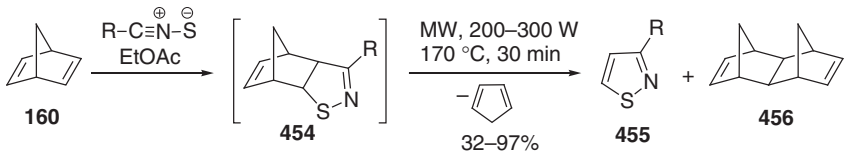
Methylene-bridged tetrahydroisoindolo[2,1-*a*][3,1]benzoxazine-6,12-diones **444** were isolated from the cyclocondensation of *diendo*- or *diexo*-3-aminobicyclo[2.2.1]heptene-2-carboxylic acid **442** and 2-carboxybenzaldehyde **443** on refluxing in 1,2-dichlorobenzene. Further heating of the pentacyclic isoindolone **444** at an elevated temperature led to 1,3-oxazino[2,3-*a*]isoindole-2,6-dione **445** in a retrodiene reaction (Scheme 111).[216]



Scheme 111

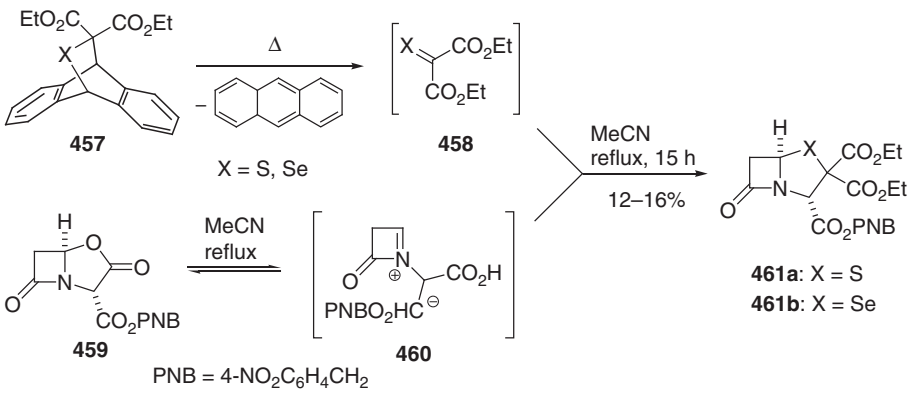
Through refluxing in toluene in the presence of PTSA as catalyst, the cyclocondensation of *diexo*-7-oxabicyclonorbornene-3-aminopropanol **446** with aliphatic, aromatic, or cyclohexane ring (A)-containing γ-oxocarboxylic acids **447** afforded oxanorbornene-fused pyrrolo[1,3]oxazine or isoindolo[1,3]oxazines **448**, together with the rDA products **449**, which could be separated by column chromatography (Scheme 111). When the same reaction was performed in refluxing *o*-DCB (bp. 180 °C), pyrrolooxazine and oxazinoisoindolones **449** could be obtained directly. On heating in chlorobenzene (bp. 131 °C), furan was released from the polycyclic 1,3-oxazines **448** and products **449** were formed in better yields (e.g., 57% vs. 17%).[217] The MW-assisted [4 + 2] cycloreversion for the direct preparation of **449** from *cis*-2-*p*-tolyl-cyclohexanecarboxylic acid **447** (ring A=cyclohexane) with the bicyclic aminoalcohol was achieved by reaction at 160 °C for 15 min, which afforded hexahydro-1,3-oxazino[2,3-*a*]isoindolone **449** in fairly good (67%) yields and in pure form Scheme 112.[218]

Scheme 112



For the preparation of polycyclic benzo[*a*]quinolizidines, a subunit of naturally occurring isoquinoline alkaloids, a facile asymmetric approach has been described. During the construction of functionalized derivatives, the generation of an iminium ether salt intermediate was observed by novel rDA/*N*-acyliminium cyclization cascade reactions (Scheme 113). With chiral β-aminoalcohols **451,** the tricyclic δ-oxocarboxylic acid **450** was cyclized to diastereomerically and enantiomerically pure pentacyclic oxazolidines **452**, from which cyclopentadiene could be split off under unusually mild conditions (at 20 °C) through an rDA process on treatment with BF_3. At the same time, *N*-acyliminium cyclization took place at the phenylethyl moiety, which gave the structural analog **453** of *Erythrina* and the related alkaloids.[219]

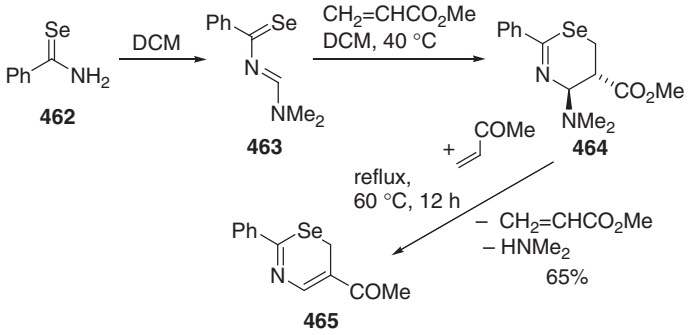
Scheme 113



5.12.6.3.2 Heterocycles containing sulfur or selenium and nitrogen

The 1,3-dipolar cycloaddition of nitrile sulfides generated by MW-assisted decarboxylation of 1,3,4-oxathiazol-2-ones has been studied. The reactions of aryl nitrile sulfides with norbornadiene **160** led to 3-arylisothiazoles via the proposed initial cycloadduct **454** (presumably as a mixture of *exo* and *endo* isomers), which on classical heating (e.g., at ~130 °C for 100 h) underwent DA cycloreversion to isothiazoles **455** with the expulsion of cyclopentadiene (Scheme 114). With MW irradiation, the reactions were complete in 30–60 min at 170 °C, with varying yields. The spectroscopic assignments indicated a common byproduct in all of the norbornadiene reactions; tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene **456** was obtained from the DA cycloaddition of norbornadiene, acting as a dienophile with the cyclopentadiene generated in the fragmentation of the fused 4,5-dihydro-1,2-thiazoles **454**.[220]

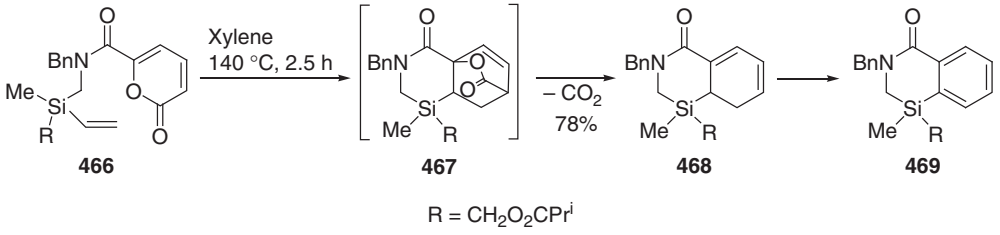
Scheme 114



The diethyl thioxomalonate (X=S) or selenoxo (X=Se) analog **458**, both produced by transient rDA reactions from **457**, underwent 1,3-dipolar cycloaddition (Scheme 115) with azomethine ylide **460** as the trapping agent (derived from *β*-lactam oxazolidinone **459**) to furnish *p*-nitrobenzyl (PNB)-protected penam **461a** and 2,2-disubstituted selenapenam **461b,** respectively.[221]

Scheme 115

On reaction with selenobenzamide **462**, *N*,*N*-dimethylformamide dimethylacetal (prepared from thiobenzamide) led to *N*-selenoacylamidine **463** in a yield of 30%, which, as a 4π heterodienic system, took part in [4 + 2] cycloaddition with electrophilic dienophiles. Thus, compound **463**, generated *in situ*, was quenched with an excess of methyl acrylate, which furnished 5,6-dihydro-4*H*-1,3-selenazine **464** in 91% yield in methyl vinyl ketone as the solvent. The thermal cycloreversion of **464** then

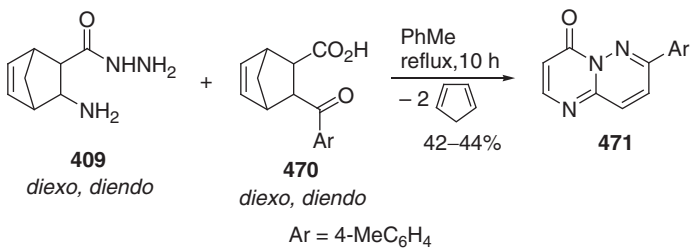


resulted in the release of heterodiene **463** which was trapped by the DA reaction with an excess of methyl vinyl ketone to afford 6*H*-1,3-selenazine **465** through *in-situ* elimination of the dimethylamino group (Scheme 116) from the intermediate cycloadduct.[194]

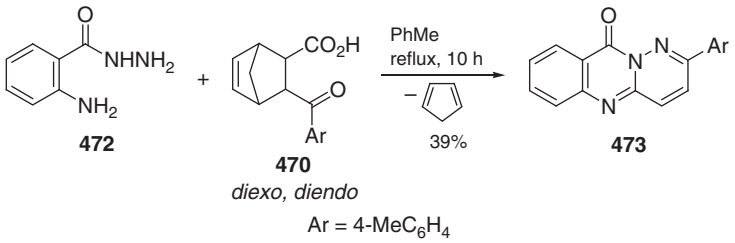
Scheme 116

5.12.6.3.3 Heterocycles containing silicon and nitrogen

The intramolecular DA reaction of pyran-2-one-6-carboxamide **466** linked to a vinyl dienophile by a chiral Si atom, followed by CO_2 extrusion in an rDA reaction, led diastereoselectively to 4-silatetrahydroisoquinolin-2-one **468** (Scheme 117). Specifically, carboxamide **466** produced 1-methyl-2,3,8,8a-tetrahydrobenzo[*d*][1,3]azasilin-4(1*H*)-one **468** on heating as a mixture of two diastereomers (36% *de*), which could not be separated by silica gel chromatography; no trace of the tricyclic intermediate **467** was observed. When the reaction was performed at 110 °C for 1 day, the yield of **468** decreased to 42% and 2,3-dihydrobenzo[*d*][1,3]azasilin-4(1*H*)-one **469** was isolated in poor yields, presumably as a result of oxidative aromatization in air.[222]



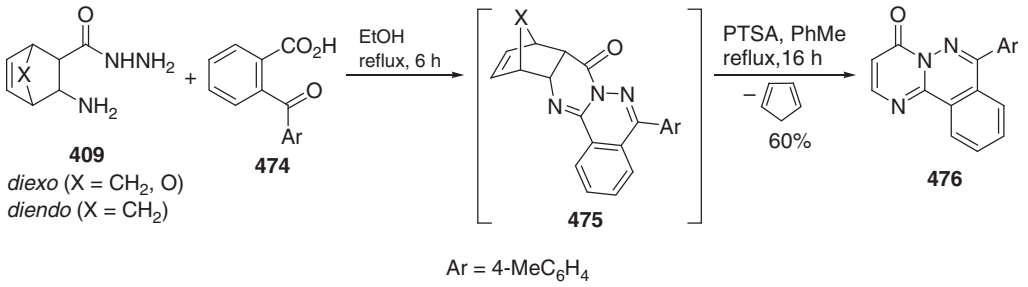
Scheme 117



5.12.6.4 Heterocycles Containing Three Heteroatoms

5.12.6.4.1 Heterocycles containing three nitrogen atoms

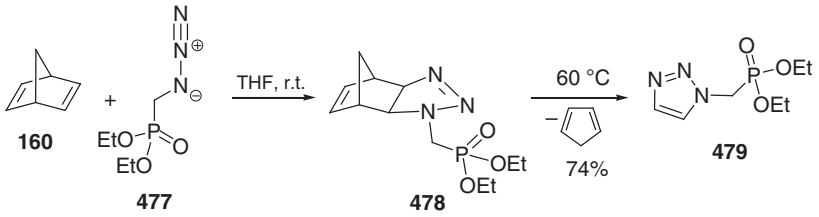
A facile method was developed for the synthesis of heteroring-fused pyrimidines, by using a rare double cycloreversion. The *diendo*- and *diexo*-2-aminobicyclo[2.2.1]hept-5-enecarbohydrazides **409** were allowed to react with norbornene-2-aroylcarboxylic acids **470** to yield pyrimido[1,2-*b*]pyridazine **471** directly, through the loss of two molecules of cyclopentadiene (equation 31). Analogously, anthranilic acid hydrazide **472** and bicyclic γ-oxocarboxylic acids **470** furnished 2-tolyl-10*H*-pyridazino[6,1-*b*]quinazolin-10-one **473** in a single cycloreversion (equation 32).[223]



(31)

(32)

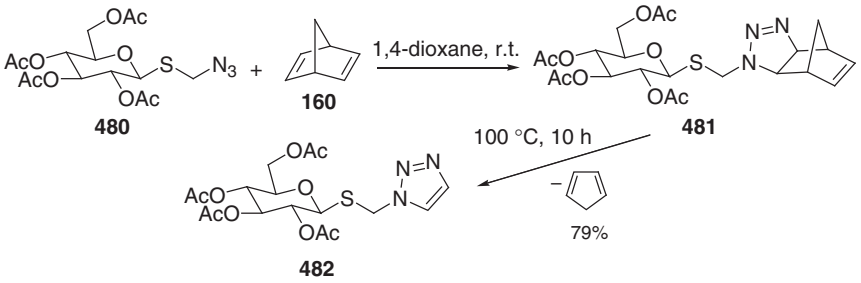
Similar reactions of bicyclic *diendo*- or *diexo*-2-aminocarbohydrazides **409** and 2-(4-methylbenzoyl)benzoic acid **474** and its *cis*-hexahydro analogs afforded tri- and pentacyclic ring systems, but rDA fragmentation also occurred, resulting in pyrimido[2,1-*a*]phthalazin-4-one **476**. Specifically, compound **476** was prepared by refluxing a mixture of *diendo*-2-aminocarbohydrazide **409** and oxoacid **474**, first in EtOH and then in toluene for a prolonged time, by cleavage of cyclopentadiene without isolation of the intermediate **475** (Scheme 118).[205]



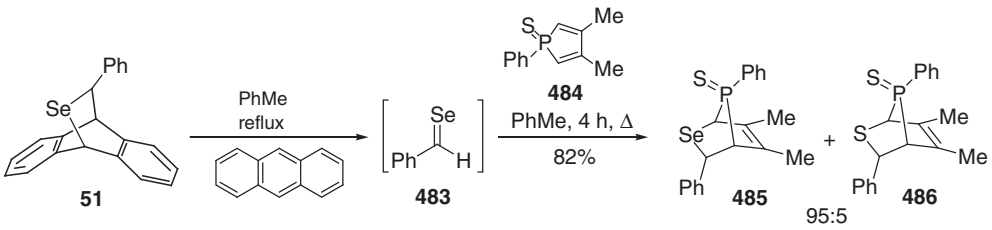
Scheme 118

Compound **476** was also prepared in a moderate yield (42%) from bicyclic 2-aminocarbohydrazides (X=CH_2) or oxacarbohydrazide (X=O) **409** by a similar cyclocondensation/rDA reaction, on heating of the norbornene or 7-oxanorbornane intermediates **475** (X=O) in refluxing toluene.[224]

On reaction with norbornadiene **160,** diethyl azidomethanephosphonate **477** gave triazoline **478** in 86% yield, which decomposed with the elimination of cyclopentadiene on heating to provide triazolylmethanephosphonate **479** (Scheme 119). The formation of this simple product containing a 1,2,3-triazole moiety was explained by a thermolytic reverse DA mechanism.[225]



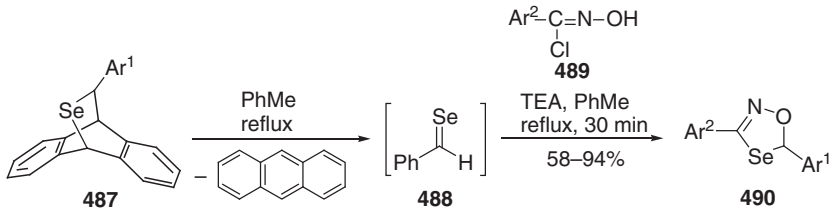
The reaction of *O*-acyl-protected glucosylthiol with dichloromethane readily afforded glucosylthiomethyl chloride, which, on treatment with sodium azide, gave glucosylthiomethyl azide **480**. The reaction with norbornadiene **160** led to a tandem 1,3-dipolar cycloaddition/rDA decomposition, which furnished the parent 1-glycosylthiomethyl-1,2,3-triazole **482**. Specifically, the norbornadiene underwent a 1,3-dipolar cycloaddition with the glucose-derived azide to give *diexo*-triazoline **481**. The following rDA process furnished triazole **482** through the extrusion of cyclopentadiene (Scheme 120).[226]



Scheme 119

The stereoselective [4 + 2] hetero DA cycloaddition of selenoaldehyde **483** (generated by thermal cycloreversion of the anthracene adduct **51**) with pentavalent 3,4-dimethylphosphole sulfide **484** at 110 °C afforded the 2-selena-7λ^5-phosphabicyclo[2.2.1]hept-5-ene-7-thione [4 + 2] cycloadduct **485** as a single diastereoisomer (*endo*), accompanied by a small amount of the heteroatom-exchanged thiin **486** as a side product (Scheme 121).[227]

As selenoaldehyde precursors, 16-aryl-15-selenatetracyclic compounds **487** underwent facile decomposition in an rDA reaction. Thus, unstable selenoaldehyde intermediates **488** were reacted with nitrile oxides (obtained *in situ* from the precursor



Scheme 120

Scheme 121

chlorides **489** with Et_3N) to give 3,5-diaryl-1,4,2-oxaselenazoles **490** (Scheme 122) in efficient 1,3-dipolar [3 + 2] cycloadditions at 110 °C (Table 10).[228]

Ar^1 = Ph, 4-$CF_3C_6H_4$, 1-naphthyl; Ar^2 = Ph, 4-$MeOC_6H_4$, 4-ClC_6H_4, 2,4,6-MeC_6H_2

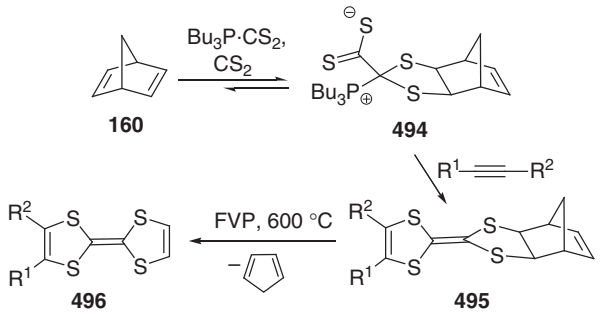
A new class of boron dipyrromethene (BDP) dyes with rigid BCOD units were prepared by conversion to benzo-BDP derivatives via rDA fragmentation of the BCOD moiety with the elimination of ethylene. 4,7-Ethanodihydroisoindolecarboxylate was converted to the tricyclic 2-methylpyrrole **491**, which was transformed to stable boron complexes **492** in several steps. On heating, these BCOD-fused complexes (Scheme 123) resulted quantitatively in fused 2,2-difluoro-1 λ^5,3-diaza-2 λ^4-bora-tricyclo[7.3.0.$0^{3,7}$]dodecapentaen-1-ylium derivatives **493**.[229]

In a direct reaction, norbornadiene **160** combined with tributylphosphine and CS_2 to give the stable adduct **494**, which underwent cycloaddition with acetylenic esters and furnished norbornene-fused dihydrotetrathiafulvalenes **495**, even though in



Scheme 123

fairly poor yields (5–21%). On FVP, the compounds decomposed to substituted tetrathiafulvalenes **496** (Table 11) in reverse DA reactions involving the release of cyclopentadiene in good to excellent yields (Scheme 124).[230]

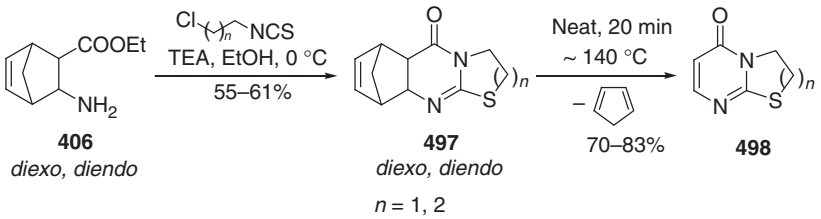


Table 11 Yields of tetrathiafulvalenes **496** (Scheme 124)

No.	R^1	R^2	*Yield of* ***496*** *(%)*
1	CO_2Me	CO_2Me	98
2	CO_2Et	CO_2Et	92
3	CO_2Me	H	97

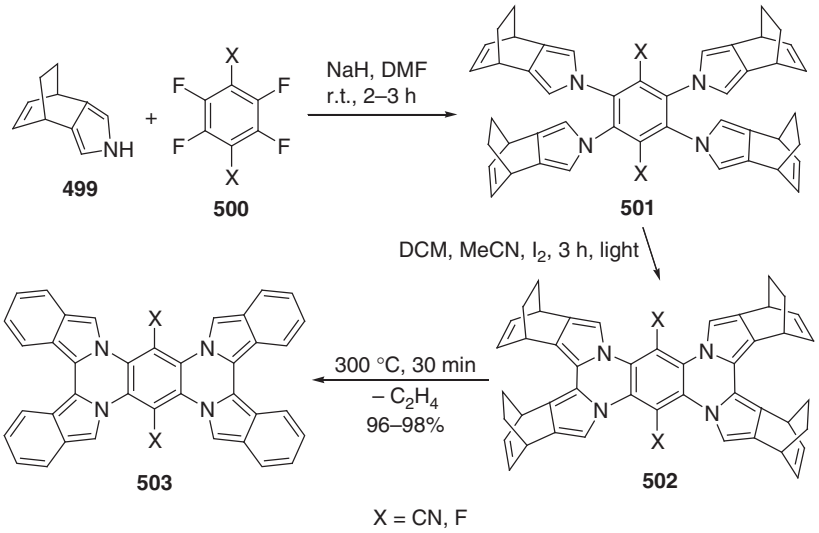
5	CO_2Me	Ph	77

Scheme 124

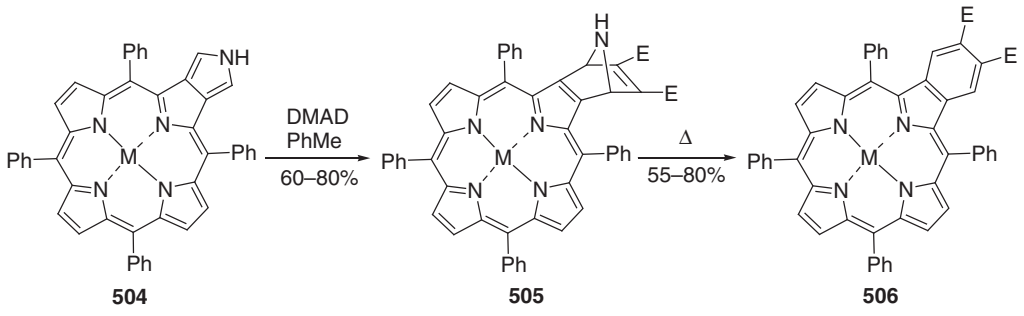


Ethyl 3-*exo*-aminobicyclo[2.2.1]hept-5-ene-2-*exo*-carboxylate **406** and its *diendo* counterpart reacted with ω-chloroalkyl isothiocyanates in the presence of triethylamine on stirring for 24 h to furnish tetracyclic norbornene-fused 6,7-dihydro-2*H*-thiazolo[3,2-*a*]pyrimidin-5(3*H*)-one ($n=1$) or tetrahydropyrimido[2,1-*b*][1,3]thiazin-6(2*H*)-one ($n=2$) **497**, respectively. On melting, these heterocycles underwent retrodiene fragmentation to give **498** by cleavage of cyclopentadiene (Scheme 125). The annelation mode (*diendo* vs. *diexo*) did not significantly influence the yield of products, but the decomposition of thiazolidine **497** ($n=1$) was faster than that of its homologs.[231]

Scheme 125

Substitution of 4,7-dihydro-4,7-ethano-2*H*-isoindole **499** with tetrafluoro-*p*-phthalonitrile (X=CN) or hexafluorobenzene **500** (X=F) under basic conditions afforded the tetrasubstituted derivatives **501** in good yields. On oxidative coupling with I_2

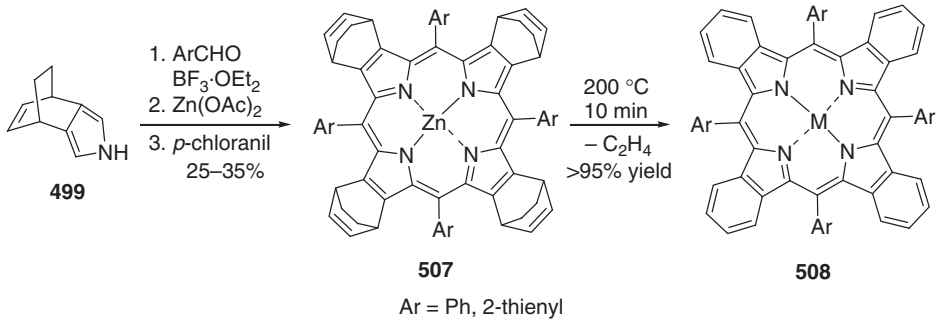
and irradiation with light, these compounds gave tetrapyrrolotetraazaanthracenes **502**, which were converted to tetraisoindolotetraazaanthracene derivatives **503** by cycloreversion (Scheme 126).[232]



Scheme 126

5.12.6.5 Porphyrins, Phthalocyanins, and Related Compounds

Porphyrins, which occur widely in nature, are composed of four modified pyrrole subunits interconnected at their α-carbons via methano bridges. One of the best known porphyrins is heme, a pigment in red blood cells. Phthalocyanins are structurally related macrocyclic pigments. They are intense blue–green colored compounds that are widely used as dyestuffs. In tetrabenzotetraazaporphyrins the pyrrole rings are coupled by four nitrogen atoms instead of methine bridges.



Benzoporphyrins **506** were obtained as the major products from the cycloaddition of fused metallopyrroloporphyrins **504** with DMAD. In the presence of excess dienophile, adduct **505** was obtained, which underwent an rDA reaction to produce **506**. When copper(II) or nickel(II) complexes **504** were refluxed with DMAD, the [4 + 2] cycloadducts **505** were obtained, which could be converted into benzoporphyrins **506** by prolonged reflux (Scheme 127).[233]

Scheme 127

When heated, 4,7-dihydro-4,7-ethano-2*H*-isoindole **499**, a key compound for porphyrin synthesis, underwent an rDA reaction to furnish the reactive and unstable isoindole, essentially in quantitative yield; this was used for the novel synthesis of tetrabenzoporphyrins and monobenzoporphyrins. The reaction of isoindole prepared *in situ* with aromatic aldehydes followed by subsequent oxidation gave *meso*-tetraarylated porphyrins **507** (Scheme 128), which were converted into benzoporphyrins **508** by retrograde thermolysis.[234]

From 4,7-dihydro-4,7-ethano-2*H*-isoindole as a masked isoindole equivalent, facile new syntheses of unsubstituted tetrabenzoporphyrins and their metal complexes, as well as of polysubstituted monobenzo- and dibenzo-fused derivatives were reported via a similar thermal retrodiene route.[235]

Scheme 128

From 4,7-dihydro-5,6-dimethoxycarbonyl-4,7-ethano-2*H*-isoindole **509**, benzoporphyrins **510** functionalized with eight ester groups and their water-soluble derivatives **511** were synthetized by a similar cycloreversion method (Scheme 129).[236,237]

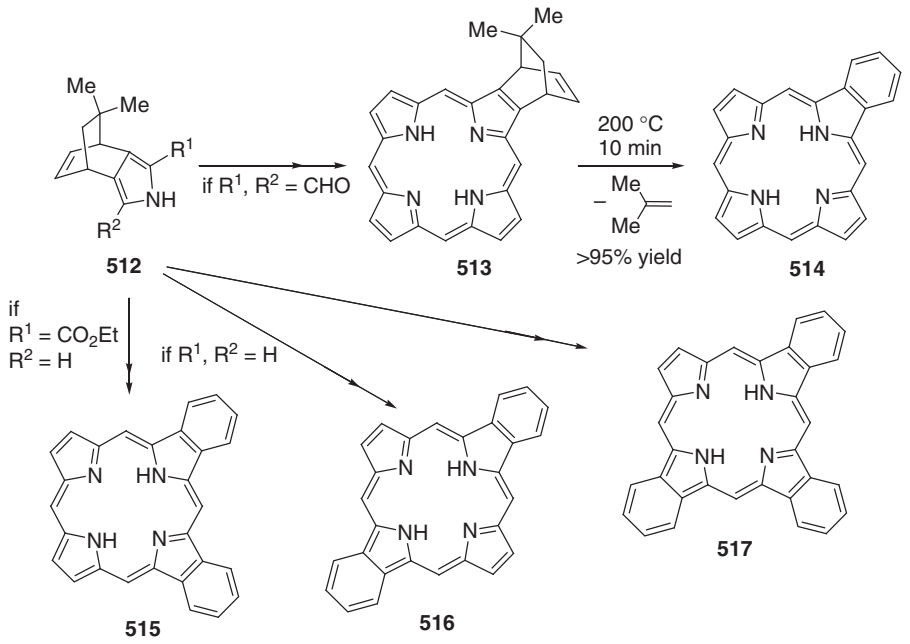
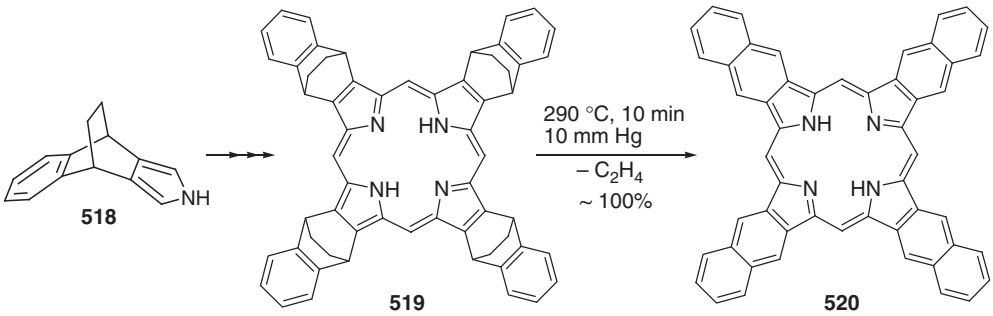
R^1 = H, Ph; R^2 = CO_2Me, CO_2H, CO_2Na

Scheme 129



The BF_3-catalyzed Rothemund condensation of phenylpropargylaldehyde with 4,7-dihydro-4,7-ethano-2*H*-isoindole **499**, followed by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone and rDA fragmentation of the resulting BCOD-fused porphyrin gave a quantitative yield of tetrakis(phenylethynyl)benzoporphyrin, which has special redox and spectroscopic properties.[238]

Although *β*-alkyl monobenzoporphyrins and *meso*-aryl dibenzoporphyrins were prepared from pyrrole fused with BCOD, the corresponding parent compounds could not be obtained by the usual methods. Only Okujima et al. have reported an appropriate synthesis of the parent mono-, di-, and tribenzoporphyrins **514–517**, from their soluble precursors by an rDA procedure. 4,7-Dihydro-8,8-dimethyl-4,7-ethano-2*H*-isoindole **512**, when treated with methyl orthoformate in TFA, gave the corresponding dialdehyde (R^1, R^2=CHO) in 55% yield. Subsequent condensation and oxidations led to the monoannelated porphyrin **513**, which on heating underwent an rDA reaction to result in monobenzoporphyrin **514** through cleavage of volatile isobutylene. The reactions to di- and tri-BCOD-annelated derivatives were based on analogous methodology. In this way, the bicyclic ester, pyrrole and carboxy ester derivatives were applied in further reactions (Scheme 130). The thermal decomposition was carried out in vacuum in a glass tube oven.[239]

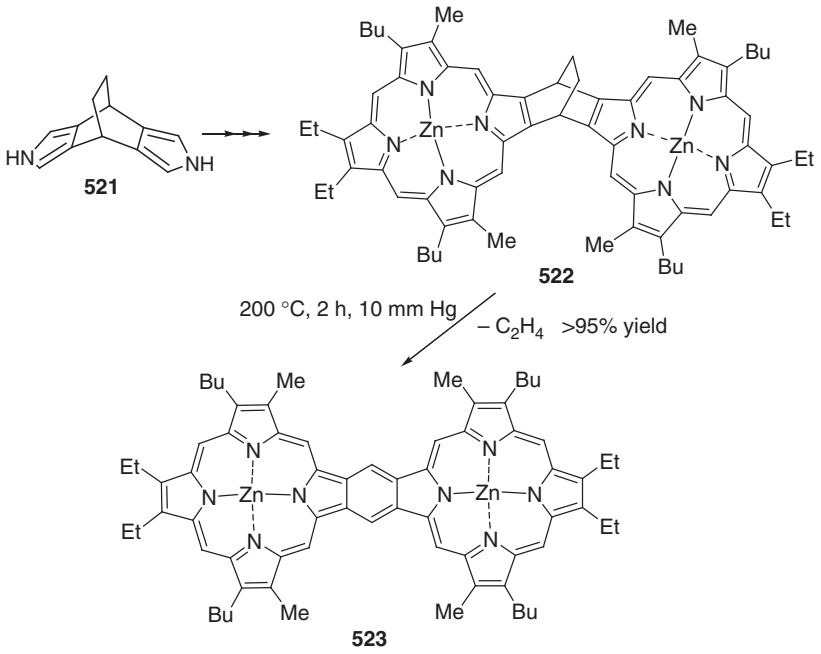


Benzporphyrins fused with acenaphthylene or fluoroanthene rings were prepared by the condensation of BCOD-annelated tripyrans with the appropriate pyrroledialdehydes followed by an rDA reaction.[240]

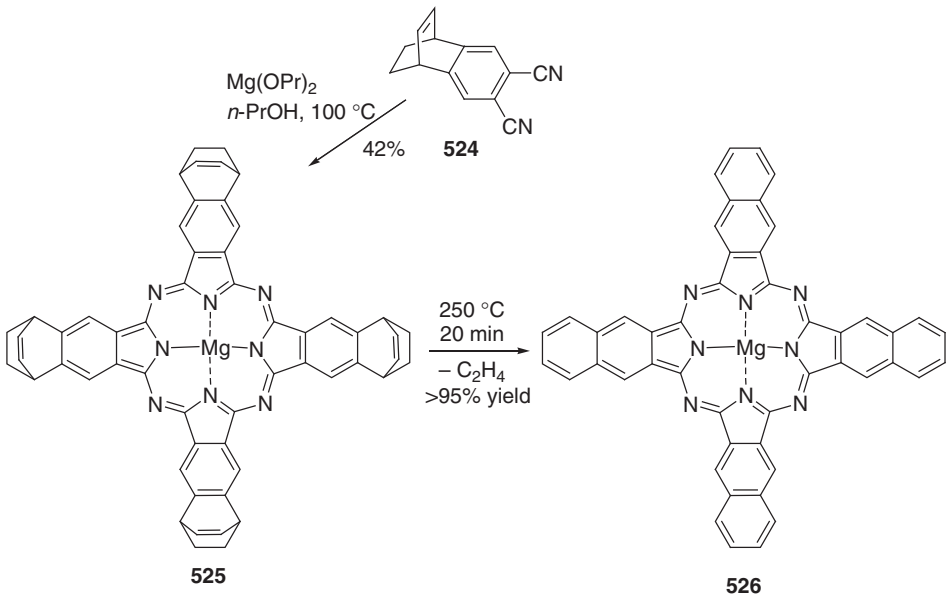
A method for the synthesis of fused porphyrins was developed starting from 4,9-ethano-2*H*-benz[*f*]isoindole **518**, which gave [2,3]-naphthoporphyrins. In a general multistep procedure, ethylene-bridged porphyrins were obtained through the tetramerization and oxidation of **518**. After the introduction of a Zn(II) ion into the tetrafused porphyrin, both the parent compound **519** and its Zn(II) complex could be converted to pure insoluble tetranaphthoporphyrin **520** in a retrodiene process by heating in vacuum (Scheme 131).[241] The use of MW-assisted heating allowed the reaction time and temperature in the rDA reaction used for the synthesis of the octamethoxy derivative of **520** to be reduced.[242] The benzene homolog of synthon **507** proved suitable for the construction of the linearly *π*-expanded tetraanthrophorphyrin analog of **520** via rDA methodology.[243]

A soluble gable bisporphyrin linked with a BCOD ring **522** was prepared and converted to the insoluble, conjugated, and planar bisporphyrin **523** through thermal cycloreversion. The synthetic strategy was based on the formation of dipyrrole **521** comprising a BCOD core, which was prepared from ethyl 4,7-dihydro-4,7-ethano-2*H*-isoindole-2-carboxylate in four steps as already reported.[244] The bisporphyrin **522** fused to a BCOD core was prepared by the usual procedure on application of a [3+1] approach. For the rDA fragmentation of the zinc(II)bisporphyrin complex, pyrolysis was applied (Scheme 132), which yielded the planar bisporphyrin **523** in pure form.[245]

Scheme 130



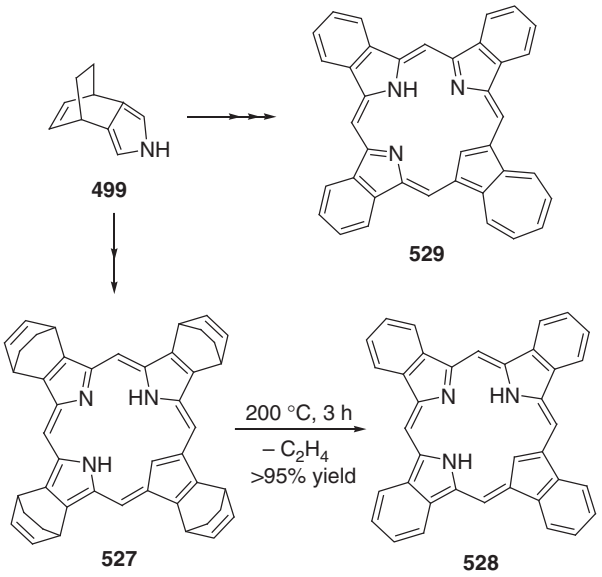
Scheme 131



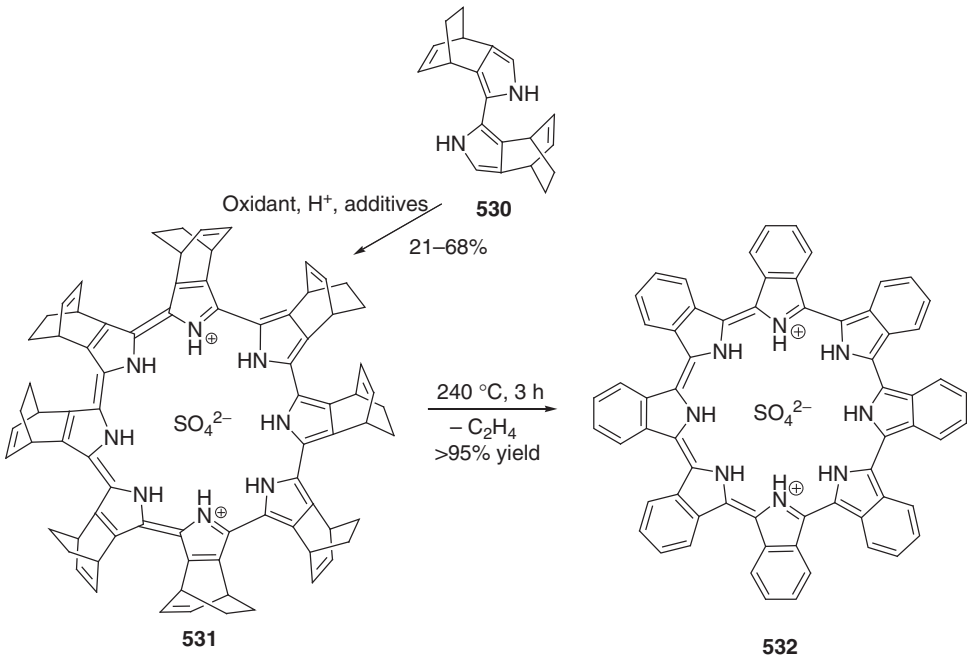
Phthalocyanines are formed on heating of phthalic acid derivatives containing functionalized nitrogen groups, such as the classical precursor phthalonitrile. Relatively few articles have dealt with the application of retrodiene reactions in phthalocyanin chemistry. One of them involved the use of the bicycle[2.2.2]octene-fused phthalonitrile **524** as a synthon for the construction of the tetrakis-bicyclooctene-annelated phthalocyanin **525**, which was obtained by treating derivative **524** with Mg(II) propoxide (Scheme 133). The purified Mg(II) complex **525** was heated in a glass tube under vacuum to give naphthalocyanin **526** with the release of four ethylene units.[246] A soluble precursor of the 2,3-naphthalocyanin derived from phthalonitrile **524** was prepared and converted into an insoluble semiconducting thin film by a similar rDA reaction.[247]

An efficient synthesis of the conjugation-expanded tetrabenzocarbaporphyrin **528** and tribenzoazuliporphyrin **529** was achieved using a BCOD-fused tripyrane as a versatile intermediate, and thermolytic cycloreversion of adduct **527** (Scheme 134). The key compound tripyrrane obtained from 4,7-dihydro-4,7-ethano-2*H*-isoindole **499** and its *t*-butoxycarbonyl derivative were condensed with diformylindene or azulene-1,3-dicarbaldehyde under acidic conditions; subsequent oxidation resulted in carba- and azuliporphyrin homologs, which were fragmented in an rDA process.[248]

The first successful synthesis of cyclo[8]isoindole **532** as a ring-expanded and annelated porphyrinoid was achieved from BCOD-fused 2,2′-bipyrrole **530** by oxidative coupling and rDA cleavage of the cyclo[8] BCOD-pyrrole **531** (Scheme 135) through the extrusion of ethylene molecules. For the preparation of the conjugated (octa)bicyclic system **531,** oxidative homocoupling of bipyrrole **530** was used and the oxidizing agents, acids, and additives were optimized (Table 12).[249]



Scheme 132



Scheme 133

By means of a cycloreversion strategy starting from 4,7-dihydro-4,7-ethano-2*H*-isoindole **499** as the precursor, five-membered porphyrin-homolog benzosapphyrins have recently been prepared.[250] Similar protocols were adapted for the syntheses of expanded porphyrins (penta-, hexa-, hepta-, and octaporphyrin), when ethanoisoindole **499** was reacted with pentafluorobenzaldehyde in the presence of $BF_3.OEt_2$ as the catalyst, followed by oxidation of the primary product. However, the rDA reaction at 170–200 °C under a reduced pressure (0.1 mm Hg) afforded rather complicated mixtures of multiple fluorine-eliminated products or structurally unusual benzoporphyrins in some cases.[251]

A series of core-modified tetrabenzoporphyrins with interesting optical properties, including thia-, dithia-, and oxathiatetrabenzoporphyrins, were synthetized in a simple procedure. The process for the preparation of BCOD-fused porphyrins **537** and their conversion to core-modified tetrabenzoporphyrins is outlined in Scheme 136. For the formation of different heteroatom-containing conjugated ring systems, the classical [3 + 1] construction was applied. Dipyrrole analog **535** with a central thiophene

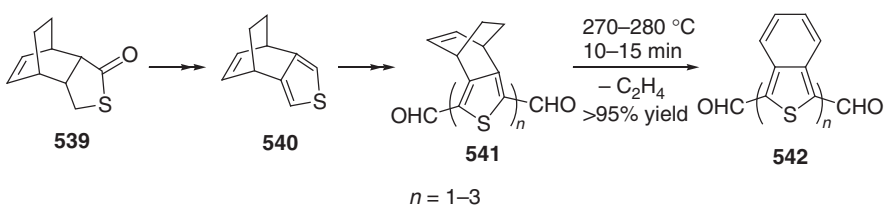
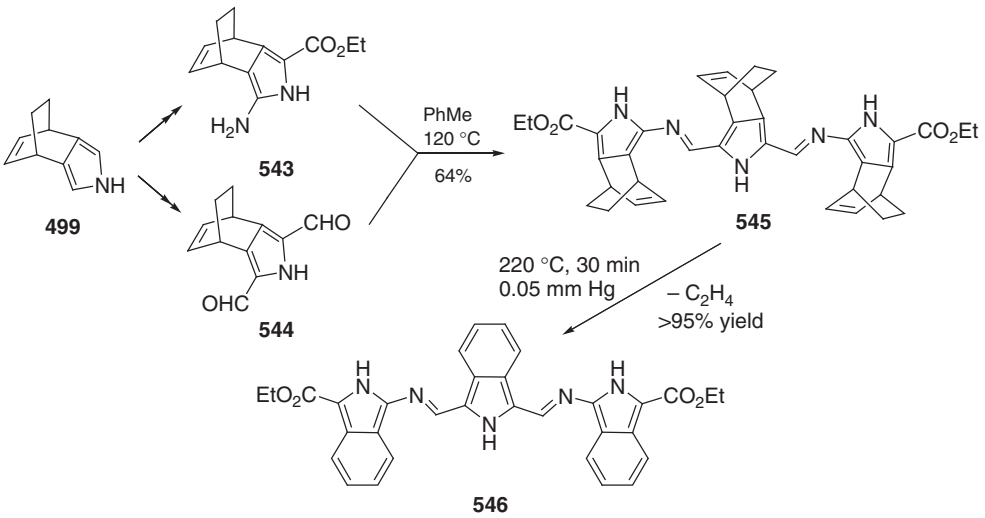
ring was prepared by acid-catalyzed condensation of diol **533** with the ethoxycarbonyl derivative **534**. Hydrolysis and cyclization with dialdehydes **536** and subsequent oxidation resulted in macrocycles **537** as diastereomeric mixtures in variable yields (23–42%). When heated, macrocycles **537** furnished the core-modified tetrabenzoporphyrins **538** by rDA reaction involving the cleavage of ethylene.[252,253]



An application of the [3 + 2] condensation strategy was described for the preparation of a BCOD-fused trithiasapphyrin. Following the condensation of BCOD-fused thiatripyrrane and BCOD-fused bithiophene with TFA in dichloromethane at room temperature and neutralization with triethylamin, the mixture was oxidized. The thermal rDA reaction of trithiasapphyrin at different temperatures demonstrated that pyrrolysis at 230 °C for 1 h achieved the total extrusion of all ethylene molecules and led to trithiapentabenzosapphyrin.[254]

5.12.7 Application of rDA Reactions in the Chemistry of Oligomers and Polymers

5.12.7.1 Synthetic Applications Involving Oligomers

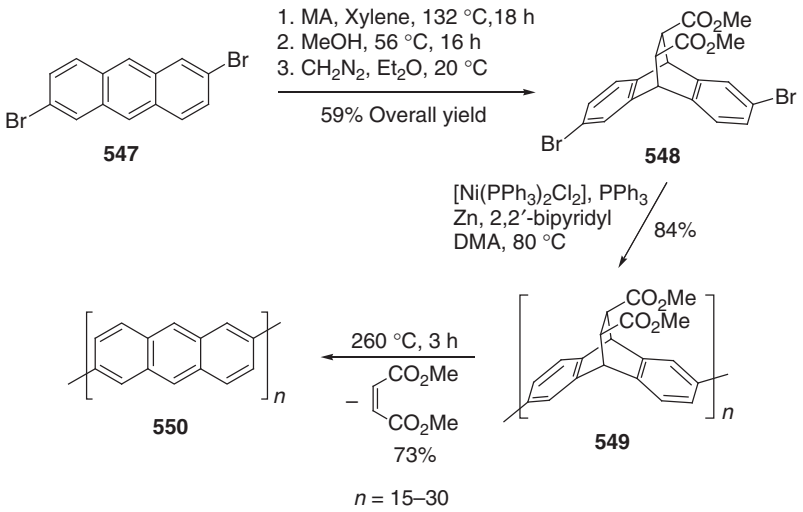


Oligomer molecules consist of a relatively small number of monomer units, in contrast to polymers, which, at least in principle, contain an unlimited number of monomers joined by repetitive covalent linkages. The units may involve one or more than one species, so that the oligomers can be dimers, trimers, or tetramers, etc.

A convenient synthesis of isothianaphthene oligomers **542** was presented and their electrochemical behavior was studied by Ono and coworkers, who used the rDA process as an important step in the decomposition of oligothiophens **541** annelated with BCOD rings. The method was based on the preparation of the stable tricyclic thiophene **540** from *endo*-4-thiatricycloundecenone, which was obtained simply by the DA reaction of 2-hydroxythiophene with 1,3-cyclohexadiene. Compound **540** was readily functionalized in the 1,3-positions and then oligomerized to the dimer and trimer ($n = 2$, 3) by various coupling methods. The rDA fragmentation of dialdehydes **541** proceeded very slowly, even at 200 °C for 3 h, and the cycloreversion conditions were therefore optimized. The procedure proved successful in a shorter time in vacuum (2 mm Hg), when the retrodiene process took place smoothly (Scheme 137) and the products **542** were sufficiently pure.[255]

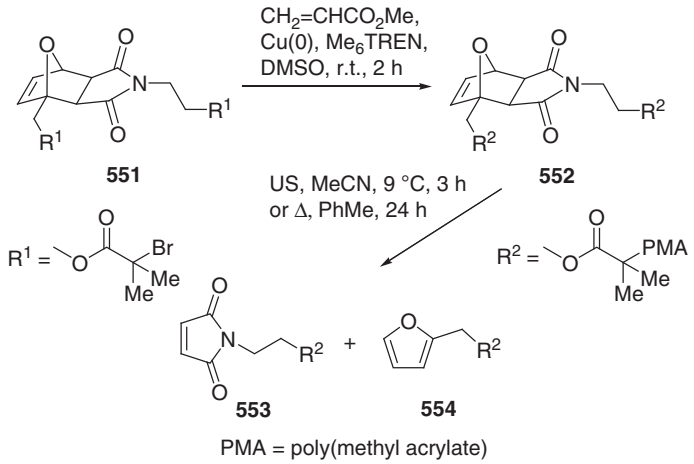
Scheme 137

In the coupling of aminopyrrole ester **543** with 1,3-dicarbaldehyde **544** (both compounds derived from dihydro-4,7-ethanoisoindole **499** in several steps), the BCOD trimer-fused bisimino pyrrole derivative **545** was obtained. Bulk conversion of BCOD-fused pyrrole was successfully performed under a reduced pressure, when trisisoindole **546** linked with methylideneamino units were obtained on extrusion of ethylene (Scheme 138). Thermogravimetric data indicated that the extrusion of ethylene from the BCOD-fused moiety was hardly affected by substituents on the pyrrole ring; the starting temperature of elimination was invariably at approximately 170 °C.[256]



Scheme 138

5.12.7.2 Synthetic Applications Involving Polymers

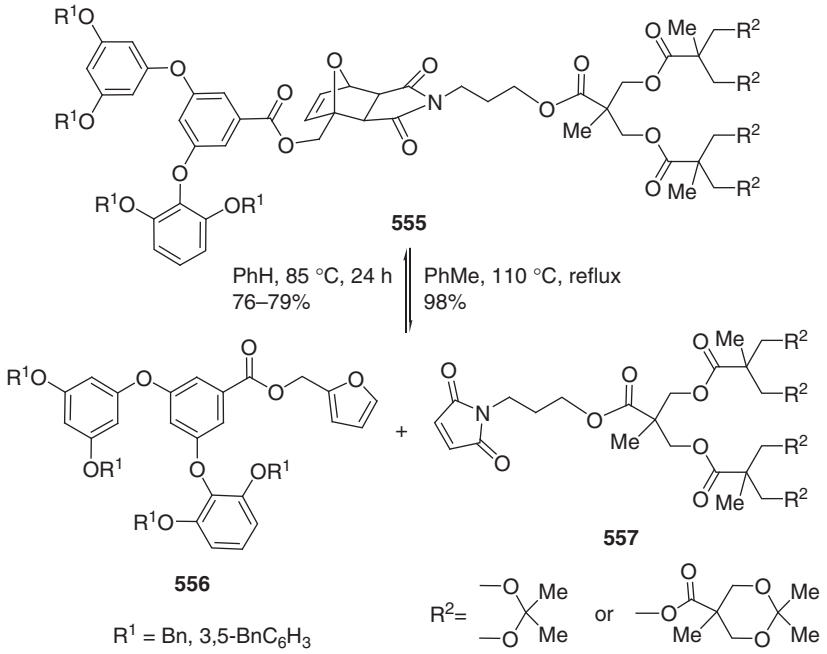


Polymers are large molecules (macromolecules) composed of repeating structural units. These subunits are typically connected by covalent chemical bonds. Although the term polymer is sometimes taken to refer to plastics, it actually encompasses a large class comprising both natural and synthetic materials with a wide variety of properties. Many commercially important polymers are synthetized by chemical modification of naturally occurring polymers. The identity of the monomer residues (repeat units) making up a polymer is its first and most important attribute. Polymer nomenclature is generally based on the type of monomer residues comprising the polymer. Polymers that contain only a single type of repeat unit are known as homopolymers, whereas polymers containing a mixture of repeat units are known as copolymers. An important microstructural feature determining polymer properties is the polymer architecture. The simplest polymer architecture is a linear chain, that is, a single backbone with no branches. A related unbranched architecture is a ring polymer. A branched polymer molecule is composed of a main chain with one or more substituent sidechains or branches. Special types of branched polymers include star polymers, comb polymers, brush polymers, dendronized polymers, ladders, and dendrimers.

Many anthracene compounds are photoluminescent, and the polymers containing these units as part of larger π-electron systems are also likely to be electroluminescent. Synthesis of such copolymers occurs via precursor polymers **549** or their *p*-phenylene-substituted homologs of poly(anthracene-2,6-diyl) **550**. The procedure exploited the rDA reaction. DA adduct **548** was conveniently obtained from 2,6-dibromoanthracene **547** by treatment with an excess of MA in xylene, followed by a two-step esterification to the corresponding dimethyl ester **548**. In a nickel(0)-mediated organometallic coupling in *N*,*N*-dimethylacetamide (DMA) as the solvent, adduct **548** resulted in precursor polymers **549** in 86% yield (Scheme 139). Conversion of **549** to the target polymers **550** was achieved in a thermal rDA process on heating at 260 °C for 3 h, which led to the elimination of dimethyl maleate to give the desired poly(anthracene-2,6-diyl)s.[257]

Poly(methyl acrylate)s (PMAs) with different molecular weights were grown from a DA adduct of maleimide with furan **551** containing two polymerization-initiating moieties. The initial efforts were directed toward polymerizing methyl acrylate from the oxanorbornane-based, difunctional brominated initiator derivative **551**, using a copper(0)-mediated single-electron transfer radical polymerization in DMSO in the presence of tris[2-(dimethylamino)ethyl]amine (Me_6TREN) as a very active ligand at room temperature (Scheme 140). At an initial monomer to initiator ratio of ~800:1, polymer **552** with a number average molecular weight (M_n) of 69 kDa was obtained. When the corresponding PMA (>30 kDa) chain was subjected to ultrasound (US), reverse [4 + 2] cycloaddition occurred, as observed by gel permeation chromatography (GPC) and labeling of the liberated maleimide **553** and furan **554** moieties. This is a rare example of mechanically induced retro [4 + 2] cycloaddition. The preliminary experiments with thermally activated rDA also led to a reduction in the molecular weight. After removal

Scheme 139



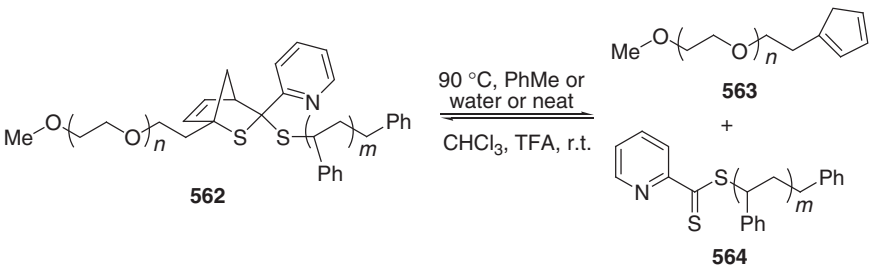
Scheme 140

of the solvent, the resulting material was determined by GPC to have $M_n = 35$ kDa, similar to that of the postsonification polymer.[258]

Another interesting application of the rDA process in polymer chemistry is the formation of thermally reversible networks. The use of [4 + 2] cycloadditions to polymers bearing furan moieties with either a monomaleimide or a bismaleimide has been reported. Spectroscopic evidence, supported by data from model compounds, indicated that the resulting linear and cross-linked products contained extensive percentages of adduct structures formed from the furan moieties. Both types of materials were heated in solvent containing a large excess of 2-methylfuran, in order to induce retrodiene reactions involving the furan rings contained in some styrene copolymers.[259]

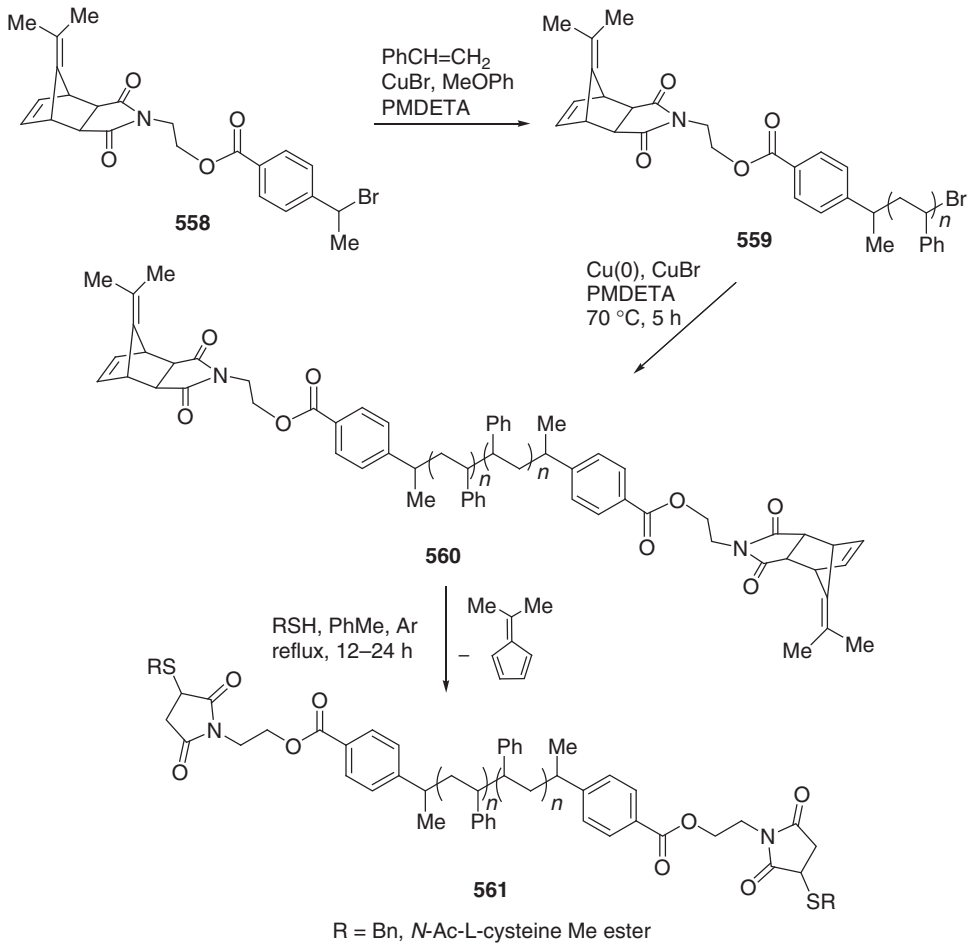
Poly(ethylene terephthalate) (PET) copolymers containing 2,6-anthracenedicarboxylate structural units were also prepared and modified by DA reactions with maleimides. This DA cross-linking reaction was thermally reversible, but at the required temperature (250 °C) the reverse reaction was slow and the PET–anthracene copolymer was therefore prone to thermal decomposition.[260]

Segment block dendrimers **555** consisting of polyester and polyaryl ether dendrons were synthetized through reagent-free DA cycloaddition by heating. Three generations of furan-functionalized polyaryl ether dendrons were reacted with maleimide-functionalized polyester dendrons of the same generation to obtain segment block dendrimers. The thermoreversible nature of macromolecules **555** was investigated by heating them at elevated temperatures to afford the corresponding furan **556** and maleimide derivatives **557** through an rDA process, in the absence or presence of anthracene as a scavenger diene (equation 33).[261]



(33)

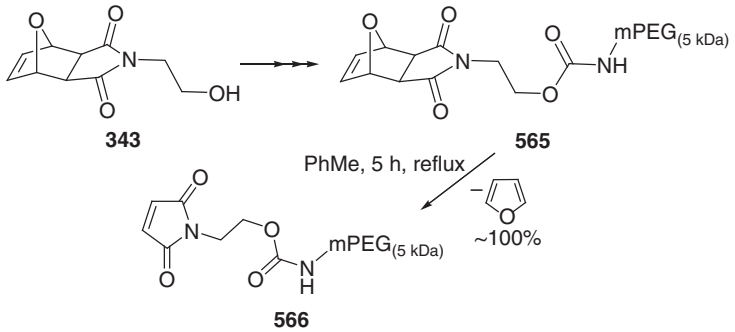
An invention for the synthesis and use of copolymers with furan and maleimide moieties in oilfield applications has been described, which involved rDA fragmentation to form a gel. Under appropriate conditions, the cycloreversion resulted in a decreased viscosity of this polymeric gel.[262]



A straightforward synthesis of the thiol-capturing telechelic polystyrene and conjugation of cysteine was achieved via the formation of dimethylfulvene-protected maleimide-functionalized atom transfer radical (ATR) polymerization initiator **559** in the presence of CuBr and pentamethyldiethylenetriamine (PMDETA) in anisole; the thermostability was compared with that of an analogous furan-protected initiator. Polystyrene with an M_n of 2530 Da was then prepared and subjected to ATR coupling with nanocopper(0) to form the bis-functionalized polymer **560** (**Scheme 141**). The reactivity of the polymer was demonstrated by *in-situ* rDA cleavage involving the elimination of dimethylfulvene and the formation of thioether adduct **561** with benzylmercaptan and *N*-acetyl-L-cysteine methyl ester.[263]

DA cycloaddition proved suitable as a convenient route for the formation of carbon–carbon bonds through a facile reaction under undemanding conditions that fulfilled the requirements of a click reaction. Moreover, such DA reactions are thermoreversible and this feature was exploited in the synthesis of self-healing polymers carrying functionalities, either as a polymer chain-end or among the repeating units. Hence, the preparation of novel well defined linear and star methyl methylacrylate polymers bearing DA adducts was devised from *N*-hydroxyethyl maleimide and furfuryl alcohol or 9-anthracenemethanol, and a preliminary evaluation was made of their thermolability. Refluxing of the polymers based on an oxabicyclonorbornene-skeleton in toluene led to cleaved copolymers through a retrodiene process. Heating of the anthracene–maleimide linker by refluxing in DMSO was unsuccessful, due to its high thermal stability.[264]

In a reversible DA/rDA process, poly(styrene)–block–poly(ethylene oxide) (PS–*b*–PEO) copolymers **562** were synthetized by a combination of reversible chain transfer (RAFT) polymerization and hetero DA cycloaddition. The resulting products could be cleaved on heating in the solid state or in solution by hetero rDA fragmentation to give nanoporous films. Cyclopentadienyl-functionalized poly(ethylene oxides) **563** were prepared by tosylation of monomethylated PEO, followed by conversion into the cyclopentadienyl derivative. Benzylpyridin-2-yldithioformate was used as a controlling agent to prepare poly(styrene) **564** by RAFT polymerization. A RAFT-hetero DA cycloaddition was carried out as outlined in equation 34. The successful formation of PS–*b*–PEO **562** was consistent with the estimated M_n. With regard to the thermal cleavage of the block copolymer in the solid state or in the solvent (toluene), the rDA reaction was essentially quantitative.[265]

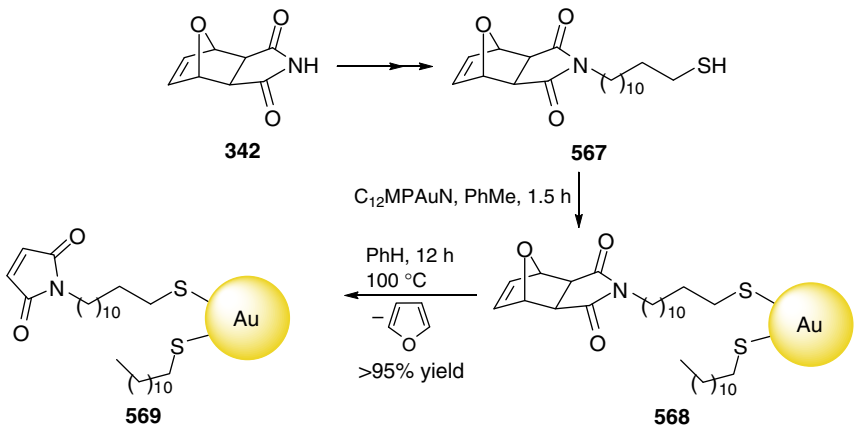


(34)

Scheme 141

The DA click reactions illustrated above are many-faceted methods for preparations and applications in polymer material science. The main [4 + 2] cycloaddition routes utilized in click chemistry take advantage of the thermal reversibility of DA/rDA reactions. Some DA reactions readily satisfy the requirements of click chemistry. The advantage of these reactions is clear: no metal catalyst is necessary. The results of the application of click reactions in polymer chemistry have been reviewed.[259–269]

A simple method for the construction of maleimide-functionalized polymers includes an rDA step. The thermally unstable oxanorbornene unit is used and a cycloalkyl group (e.g., a *trans*-1,4-cyclohexyl chain) is incorporated. The compound containing polyethylene glycol (PEG) spacers and a terminal amino group was reacted with the commercially available tricyclic oxabicycloheptenedicarboxylic anhydride in several steps to form the polymer intermediate **565**, which was heated in toluene to furnish the maleimide-functionalized polymer **566** and furan through a retrodiene reaction (Scheme 142).[270]

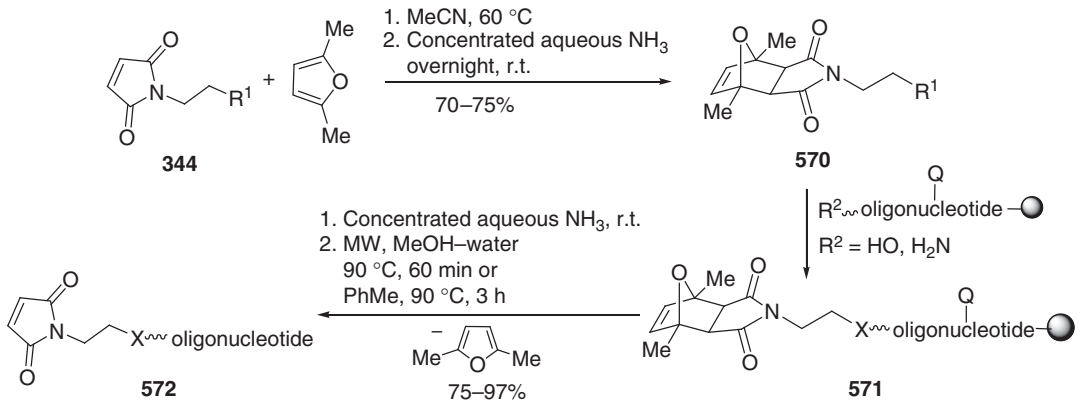


Scheme 142

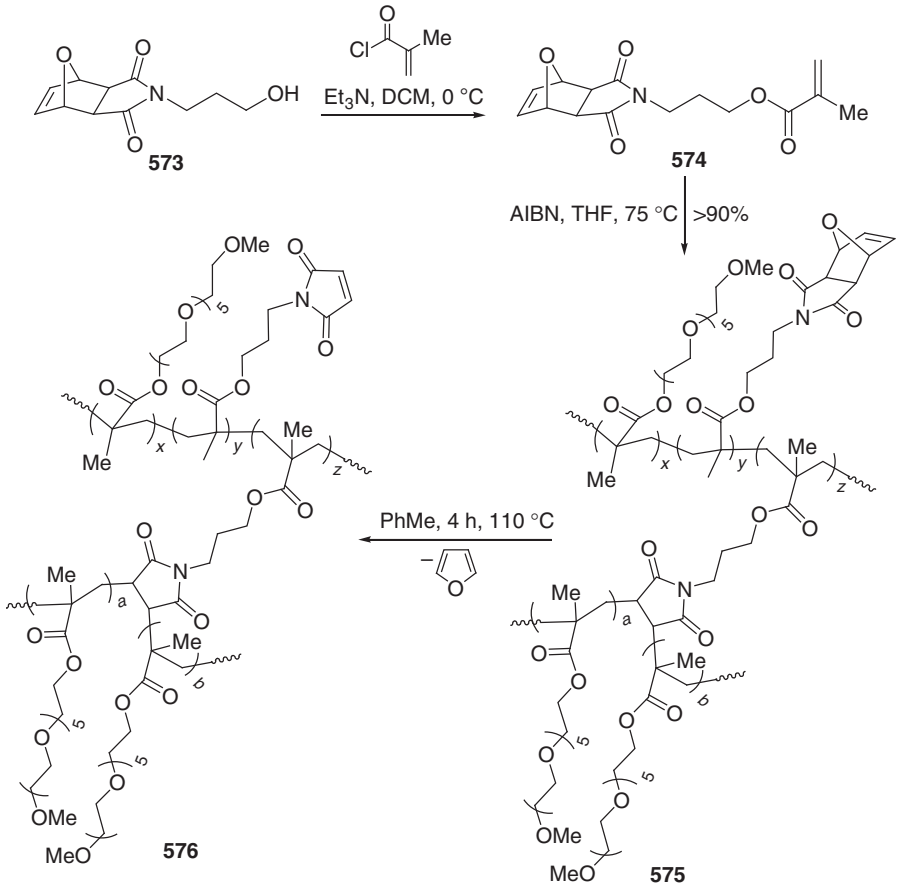
From *diexo*-*N*-hydroxyethylmaleimide **343**, a similar synthetic strategy was developed for the preparation of α-functional maleimide polymethacrylates (M_n = 4.1–35.4 kDa) via Cu-catalyzed living radical polymerization (LRP). The synthetic pathway involved an initiator containing a maleimide unit protected as a DA adduct. After polymerization, the maleimide functionality was released by application of an rDA reaction. These maleimido-terminated poly(methoxy)$PEG_{(475)}$, methacrylates and poly(-glycerol)methacrylates differed in behavior, size, and solubility in water. Such polymers can be ideal candidates for the synthesis of new polymer/(poly)peptide conjugate biomaterials.[271]

The 7-oxabicycloheptene moiety can serve as a convenient linker for solid-phase organic syntheses, and has been utilized in the preparation of a maleimide-functionalized neuropeptide Leu-enkephalin by standard peptide coupling techniques. Relatively mild conditions (≥150 °C for 8 h) were necessary for the rDA cleavage, which afforded the appropriate maleimide-tagged pentapeptide and a separable furfuryl resin.[272]

From furan–maleimide adduct **342,** maleimide-modified monolayer-protected Au nanoparticles (MPAuN) **569** were prepared by thermally reversible DA reactions under mild conditions (refluxing in benzene), with the release of a molecule of furan. Adduct **568** was prepared in a multistep procedure from the simple *diexo*-7-oxabicycloheptene-fused imide **342** through *N*-ω-bromo-alkylation with an excess of 1,12-dibromododecane in DMF. The resulting bromide was converted to thiol **567**, which was then incorporated into the dodecanethiolate-modified C_{12}MPAuN to afford **568** (Scheme 143) using the Brust–Schiffrin method starting from dodecanethiol and hydrogen tetrachloroaurate under reducing conditions. These maleimide-MPAuNs served as a general platform that allowed DA reactions with furan-modified MPAuN to reversibly provide larger 3D networks.[273]



Scheme 143



Maleimide-containing compounds **344** reacted with 2,5-dimethylfuran to give mixtures of *exo* and *endo* isomers in different ratios, from which the *diexo* cycloadduct could be easily isolated due to its stability in concentrated aqueous ammonia. The bifunctional dimethylfuran-protected maleimide (*exo* adducts) were attached to resin-linked oligonucleotide chains as in **571**. Removal of the protecting groups from the masked oligonucleotide functionalities followed by (MW-assisted or thermal) unmasking of the maleimide by rDA afforded maleimido-oligonucleotides **572** (Scheme 144) suitable for conjugation, as assessed by reactions with different thiols, lipophilic compounds such as thiocholesterol or water-soluble peptides (glutathione and other cysteine peptides).[274]

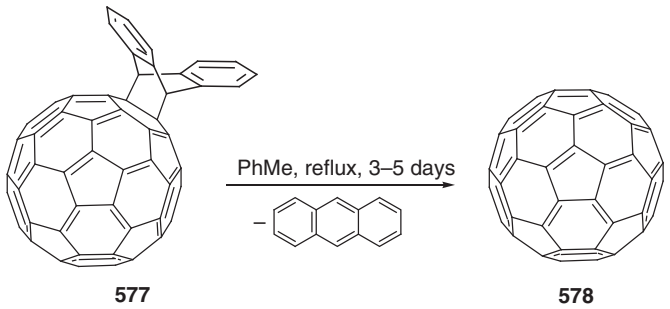
A novel DA cycloaddition/cycloreversion-based strategy allowed for the synthesis of poly(ethyleneglycol) methacrylate-based hydrogels containing thiol-capturing maleimide functional groups. Masked maleimide groups were directly incorporated into the hydrogel matrix during the gelation process by utilization of the furan-protected maleimide-containing methacrylate monomer **574**. During polymerization of this latent-reactive monomer **574** derived from *N*-hydroxypropylimide **573**, thermal deprotection of the maleimide groups led to compound **575** (AIBN = azobisisobutyronitrile). After gelation, the protected maleimide groups could be activated to their reactive gel forms **576** through thermal cycloreversion by the cleavage of furan (Scheme 145). The efficacy of gel formation, maleimide incorporation, functionalization, and bioconjugation of the hydrogel was investigated. These reactive hydrogels containing embedded maleimide groups could be readily derivatized with thiol-containing molecules such as fluorescent dyes. Likewise, thiolated biotin derivatives were covalently attached to these hydrogels under mild conditions.[275]

Thermally reversible polyethylene was synthetized by DA and rDA reactions from the furan–maleimide [4 + 2] cycloadduct as a cross-linking agent. The relative ease of adduct formation and rDA cleavage of furan–maleimide moieties permitted modulation of the properties of the grafted polymers. Various temperatures were applied in the solid or molten state to study the thermal reactivity by measuring the Fourier transform infrared spectroscopy absorption frequency at 700 cm^{-1} as the characteristic spectroscopic signature of the =C–H bond in maleimide. An original method was applied to graft the two molecules onto Lotader® poly(ethylene-co-glycidyl methacrylate) in a one-step procedure; the cycle of DA and rDA reactions was reproducible without significant polymer degradation.[276]

Scheme 144

Scheme 145

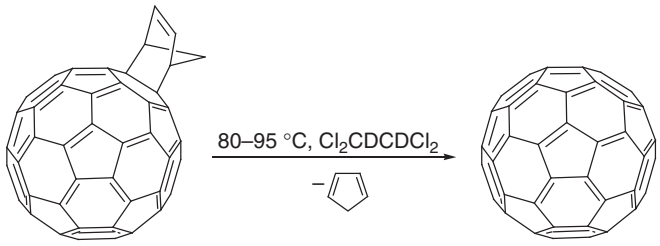
A smart poly(ethylene oxide) (PEO) polymer containing two thermally reversible groups located at the chain center (bisfuran–PEO) was prepared by a maleimide–furan [4 + 2] cycloaddition (DA) between one bis[(furan-2-yl)methyl]terephthalate and two maleimide-terminated poly(ethylene glycol) methyl ethers. These maleimide–furan adducts underwent rDA decomposition at high temperatures, with simultaneous maleimide–anthracene DA addition. Thus, when bisfuran–PEO and bis[(anthracen-10-yl]methyl) succinate were refluxed in toluene, the bisfuran–PEO cores were replaced by maleimide–anthracene adducts, which gave new polymers *in situ*. Moreover, when bisfuran–PEOs were mixed with molecules containing four anthracene units, cycloreversion of the maleimide–furan adducts and maleimide–anthracene addition took place in parallel, to generate a four-arm star arrangement of PEOs.[277]



Polymers have a limited lifetime and this can lead to the degradation of materials by cracking or breaking. Mending at a microscopic level may be done with adhesives, which, through a reversible polymerization process, can restore the original properties of the polymers, even repeatedly. The DA-based polymers (e.g., of furan–maleimide or anthracene–maleimide type) with important reversibility (DA/rDA) properties may solve this problem, and these polymers were named mendable polymers by Wudl et al.[278]

5.12.8 Fullerenes and Graphenes – New Perspectives

5.12.8.1 Synthetic Applications of rDA Involving Fullerenes and Carbon Nanotubes

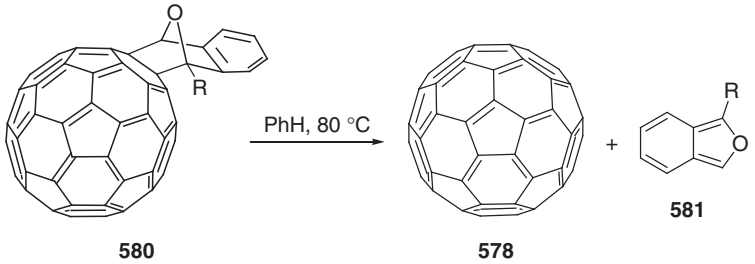


Cycloadditions are the most important amongst the reactions that allow the preparation of functionalized fullerenes, including [1 + 2], [2 + 2], [3 + 2], [4 + 2], [6 + 2], and [8 + 2] cycloadditions. However, only the reverse [4 + 2] reactions and DA adducts of fullerenes are discussed in this section.

Some [4 + 2] cycloadditions of C_{60} (**578**) and the related fullerenes and the reversibility of these reactions have been studied. Because the rDA reaction of the C_{60}–anthracene adduct **577** took place very easily, the resulting cycloadduct is relatively unstable. The preparation, purification, and characterization of the 1:1 adduct of C_{60} and anthracene were reported. The increased solubility of this adduct (in comparison with the parent C_{60} molecule) in common organic solvents facilitated crystallization with organic donors, creating a new class of charge-transfer salts with novel electronic and magnetic properties. Cycloadduct **577** was prepared by the reaction of a high excess (10 equivalents) of anthracene with 1 equivalent of C_{60} when the mixture was refluxed in toluene for 3 days. If a different excess of anthracene was used, the equilibrium shifted toward the starting materials, which caused low product yields. The 1:1 adduct remained stable for some weeks when stored in a freezer (at −10 °C). However, refluxing of purified **577** in toluene for several days resulted in degradation with the formation of neutral C_{60} (**578**) and anthracene by an rDA reaction (equation 35).[279]

577 **578** (35)

The kinetic thermal stability of the C_{60}–cyclopentadiene DA adduct **579** was studied via the rate of cycloreversion in the temperature range of 80–95 °C (equation 36). At 80 °C and at 95 °C, half-lifetimes of 97 min and 18 min, respectively, were measured.[280]

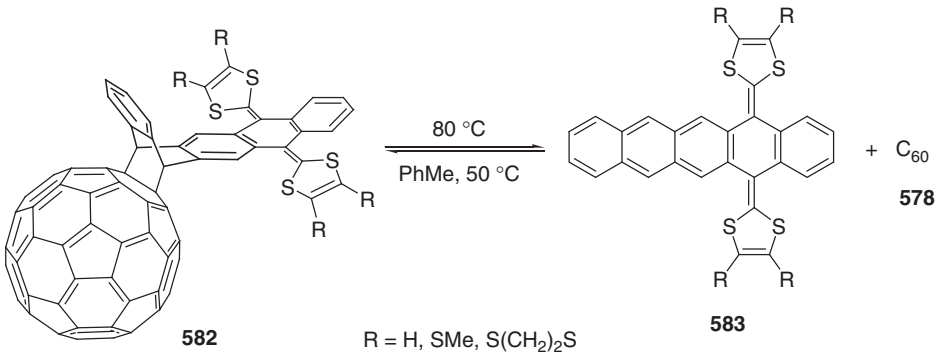


579 **578** (36)

Fullerene adducts with perfluoroalkylated 1,3-cyclopentadiene were also synthetized and studied. The perfluorinated substrates were less reactive toward C_{60} than cyclopentadiene itself, likely because of the electron-withdrawing effect of their side-chain. For the same reason, the rDA reactions of the fluorinated adducts required a lower temperature (70 °C) than that for the cyclopentadiene adducts with C_{60} (95 °C).[281]

Similar DA adducts of C_{60} with anthracene derivatives readily underwent cycloreversion to the component molecules on heating. The thermal dissociation of the DA adducts of C_{60} with amphiphilic anthracenes bearing a carboxylic acid group was utilized to prepare Langmuir–Blodgett films. Furthermore, 9-substituted anthracenes and bis(9-anthranylmethyl)adipate were studied as model compounds to evaluate the DA reactions with fullerene (C_{60}) and the thermostability of the cycloadducts formed.[282] Reversible DA reactions of anthracenes bearing a dendritic substituent with C_{60} were observed as new examples of the

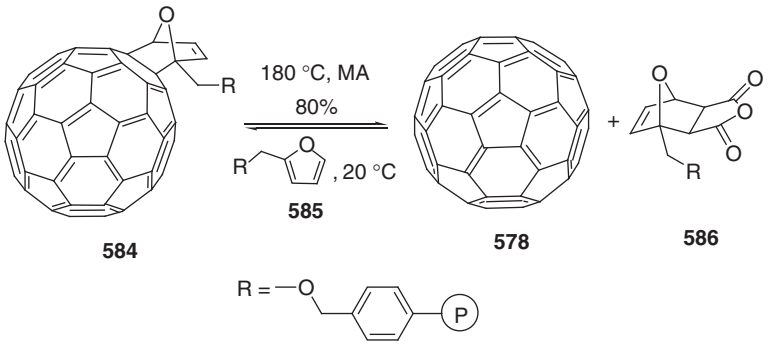
chemistry of poly(amidoamine) dendrimers grafted to fullerene, a novel class of photosensitive water-soluble fullererenes.[283] A racemic mixture of trisdi(ethoxycarbonyl)methanofullerenes Bingel trisadducts[60] was prepared by malonate addition and a subsequent rDA reaction starting from a C_{60}-tris-*e,e,e* adduct of anthracene as precursor. Because the anthracene protecting groups directed the orientation of new additions, specific and particular geometrical polyadducts were obtained. In the event, the DA cycloaddition of fullerene and anthracene led to a trisadduct, which was cyclopropanated in a Bingel reaction to form a hexaadduct. Finally, cycloreversion was applied to remove the anthracene.[284] The reactions of anthracene malonates with C_{60} in a 1:1 M ratio in toluene resulted in mono DA adducts. However, when the purified cycloadduct was refluxed in toluene for several hours, C_{60}–anthracene malonate and anthracene malonate were formed through rDA cycloreversion.[285]



With fullerene C_{60}, the reactions and kinetic stability of 1,3-disubstituted isobenzofurans were examined. A variety of substituted isobenzofurans **581**, generated by the reactions of 1,4-substituted 1,4-epoxynaphthalenes with 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine or 1,2,4,5-tetrazine, underwent addition to C_{60} to afford DA adducts **580**. The thermal stability of these adducts *vis-a-vis* rDA fragmentation in solution and the solid state differed greatly. In solution, the relatively facile rDA fragmentation of monoadducts **580** gave C_{60} and isobenzofurans **581** (equation 37) with rate constants (and activation barriers) of $k = 9.29 \times 10^{-5}\ s^{-1}$ at 70 °C ($E_a = 32.6$ kcal mol^{-1}) and $k = 1.36 \times 10^{-4}\ s^{-1}$ at 40 °C ($E_a = 33.7$ kcal mol^{-1}), indicating that the addition of isobenzofurans to C_{60} was readily reversible at these temperatures. However, the TGA of adduct **580** (R=H) in the solid state indicated that its decomposition occurred only within the temperature range of 220–300 °C. Thus, **580** in the solid state can be stored at room temperature for some weeks without significant decomposition, but it must be handled within only a few hours in solution.[286]

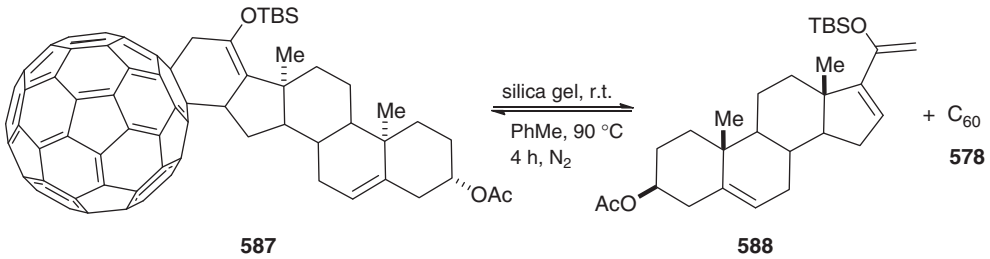
580 **578** **581**

R = H, CO_2Me (37)



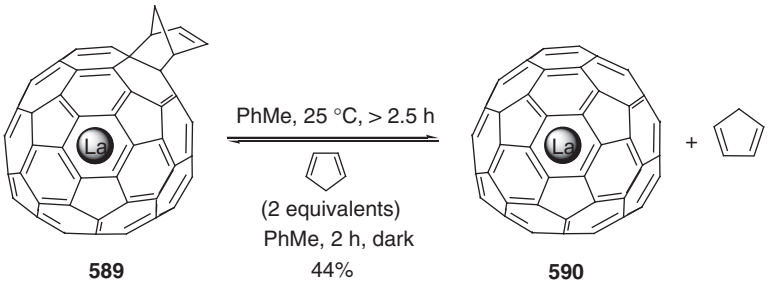
The DA cycloadducts of C_{60} and anthracene derivatives bearing fused π-extended tetrathiafulvalenes (TTF) behaved as thermally reversible donor–acceptor materials (dyads), which functioned as molecular fluorescence on/off switches. Dyads **582** could be obtained in poor yields (10–12%) from the [4 + 2] cycloaddition of equimolecular amounts of fullerene C_{60} and 5,14-bis(1,3-dithiol-2-ylidene)-5,14-dihydropentacenes **583**, with purification by column chromatography. The rDA decomposition of dyads **582** was studied at different temperatures by means of ^{1}H-NMR. The rDA process started at approximately 50 °C and continued up to 80 °C, when the decomposition of adducts **582** to TTF derivatives **583** and fullerene **578** was almost quantitative (equation 38). Increase of the temperature in 10 °C intervals from room temperature to 80 °C led to a gradual reactivation of the fluorescence-excited state.[287]

582 **583** **578**



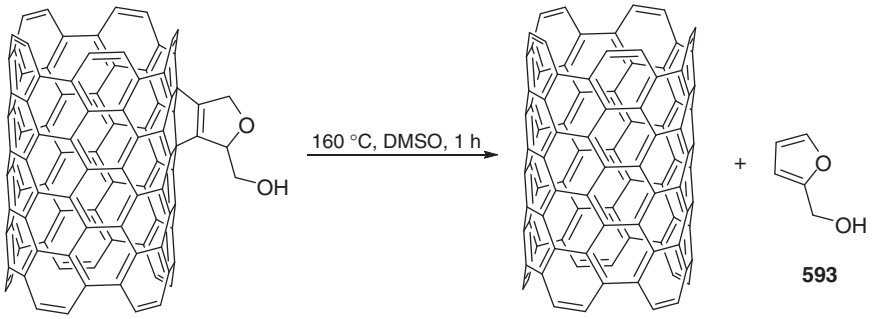
R = H, SMe, $S(CH_2)_2S$ (38)

The furan-functionalized polymer resin **585** reacted rapidly with C_{60} at room temperature, furnishing fullerene-substituted polymer **584** in a reversible DA covalent coupling reaction. This resin proved to be twice as efficient as the previously reported cyclopentadiene-substituted resin. Moreover, polymer **584** exhibited better reversibility on heating in the presence of the MA dienophile as the trapping agent (equation 39).[288]



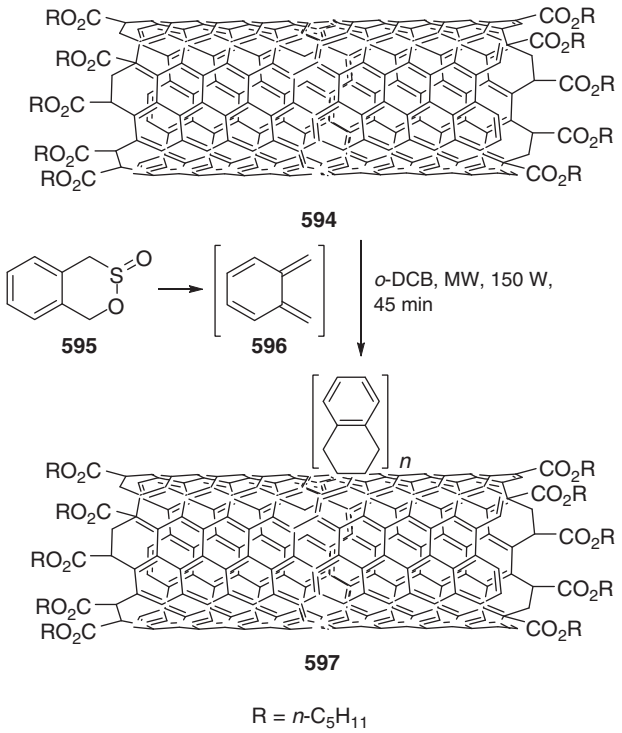
(39)

Certain novel fullerene–steroid adducts displayed activity on sarcoplasmic reticulum Ca^{2+}-ATPase. From commercially available 3β-acetoxypregna-5,16-dien-20-one, the corresponding *tert*-butyldimethylsilyl ether **588** was prepared and used as a diene. Its [4 + 2] cycloaddition with C_{60} was carried out in toluene. During attempted purification through chromatography on a silica gel column, adduct **587** unexpectedly suffered an rDA reaction (equation 40) under mild conditions.[289]



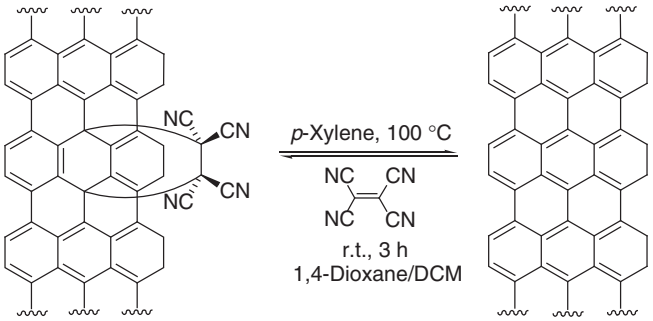
(40)

Endohedral fullerenes are a new and special class of carbon clusters which contain one or more atoms inside the hollow fullerene cage. This type of metallofullerenes has useful and unique electronic properties, such as low oxidation and reduction potentials which permit valuable applications. Reversible DA cycloaddition is therefore a useful method for the separation or protection of endohedral metallofullerenes. Kinetic analysis revealed that the rDA decomposition of cycloadduct **589** to La@C_{82} endohedral metallofullerene **590** and cyclopentadiene took place even in toluene (equation 41). The cleavage was much faster than that of the parent C_{60}–cyclopentadiene adduct (half-lifetime $\tau \sim 1.8$ h for **589** and $\tau \sim 1.8 \times 10^3$ h for **579**).[290]



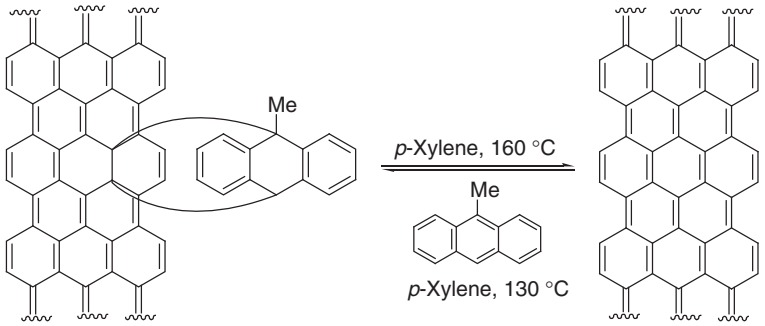
(41)

Carbon nanotubes (CNTs) are well known members of the fullerene structural family, which also includes the spherical buckyballs; the ends of a nanotube may be capped with a hemisphere with a buckyball substructure. They are categorized as single-walled nanotubes (SWNTs) or multiwalled nanotubes (MWNTs). The chemical bonding of nanotubes involves only sp^2 bonds, similar to those in graphite. These bonds, which are stronger than the sp^3 bonds in alkanes, provide nanotubes with their unique strength. Because of their unique properties, the functionalization of CNs through DA reactions offers a new perspective in the search for new and special materials. As compared with fullerenes, the CNTs are less reactive in direct cycloadditions, but the reactivity of SWNTs toward dienes in DA reactions can be promoted with transition metal catalysts under high pressure, by fluorination, by the use of reactive dienes (e.g., furan) or dienophile (maleimide) agents, among others. Studies of the functionalization of MWNTs demonstrated that these CNTs can serve either as dienophiles or as dienes. Further, the adducts can undergo a reverse DA reaction on heating. Thus, MWCNT–furfuryl alcohol adduct **591** formed CNTs **592,** which were collected by filtration in pure form (equation 42). The cycloreversion of the MWCNT–*N*-(4-hydroxyphenyl)maleimide adduct was carried out similarly.[291]



591 **592** **593** (42)

MW-assisted sidewall functionalization was first performed through an rDA/DA sequence involving cycloaddition of *o*-quinodimethane to SWNT ester **594**. Diene **596** was generated *in situ* from 4,5-benzo-1,2-oxathiin-2-oxide (sultine) **595** in an rDA reaction under MW irradiation. Repeated cycloaddition was achieved when a mixture of sultine **595** and ester-functionalized SWNT **594** was irradiated in a focused MW reactor. On workup, the reaction mixture gave the modified nanotube **597** (equation 43), opening up an access to a new family of modified SWNTs.[292]



(43)

Graphene, a carbon allotrope, consists of one-atom-thick planar sheets of sp^2-bonded carbon atoms densely packed in a honeycomb crystal lattice. Graphene is a basic structural element of certain forms of carbon, including graphite, charcoal, CNTs, and fullerenes. It can also be regarded as an indefinitely large aromatic molecule, the limiting case in the family of flat polycyclic aromatic hydrocarbons. Furthermore, graphene as an electronic material is of great potential thanks to its excellent transport properties, stemming from the unique Fermi surface and ballistic conductance. The zero-band-gap electronic structure of graphenes enables them to act either as diene or as dienophile in DA reactions and related reversible modification processes. Haddon et al. made a detailed study of the DA and rDA chemistry of graphite and graphene. When the tetracyanoethylene dienophile was reacted with graphene, a DA reaction occurred on addition of a few drops of 1,4-dioxane at room temperature. The cycloaddition was reversible when adduct **598** was heated at 100 °C in xylene, and starting graphene **599** was recovered after the rDA reaction (equation 44). The similar formation of graphene adducts with MA proved to be sensitive to the nature of the graphene sample and the reaction temperature (80–120 °C), but at ~150 °C the rDA reaction was complete.

598 **599** (44)

Investigations were also made into the use of graphite and graphene as dienophiles in DA cycloadditions involving 9-methylanthracene and 2,3-dimethoxy-1,3-butadiene, and the reversibility of the reaction was also examined. After optimization, the 9-methylanthracene–graphene cycloadduct **600** could be obtained in high yields. However, when the temperature was increased to 160 °C, the reverse DA reaction took place to regenerate graphene **601** and 9-methylanthracene (equation 45). The wide-ranging scope of DA/rDA chemistry and the dual nature of the reactivity of graphene with various dienophiles and dienes led to modifiable chemical functions and ready reversibility of the cycloadducts. The covalent functionalization of graphene by DA and/or rDA procedures is therefore a simple and valuable approach for optical and electronic applications.[293]

Glossary

Aldol condensation A reaction in which an enol or enolate ion react with a carbonyl compound to form a β-hydroxyaldehyde or β-hydroxyketone, followed by a dehydration to give a conjugated enone.

Asymmetric transformation The conversion of a racemate into a pure enantiomer or a mixture in which one enantiomer is present in excess, or of a diastereoisomeric mixture into a single diastereoisomer or into a mixture in which one diastereoisomer predominates.

Diels–Alder A cycloaddittion reaction between a conjugated diene and substituted alkene, commonly termed the dienophile, to form a substituted cyclohexene system. The reaction can proceed even if some of the atoms in the

newly formed ring are not carbon (hetero-Diels–Alder reaction). The cycloaddition reaction is allowed by the Woodward–Hoffman rules.

Endo, exo *Endo* and *exo* are descriptors of the relative orientation of groups attached to nonbridgehead atoms in a bicyclo[x.y.z]alkane ($x \geq y > z > 0$). If the group is orientated towards the highest numbered bridge (z bridge, e.g., C-7 in example below) it is given the description *exo*; if it is orientated away from the highest numbered bridge it is given the description *endo*.

Favorskii rearrangement The Favorskii rearrangement is mainly a rearrangement of cyclopropanones and α-halo ketones which leads to carboxylic acid derivatives. In the case of cyclic α-halo ketones, the Favorskii rearrangement involves a ring contraction.

Friedel–Crafts The Friedel–Crafts reactions are a set of reactions developed by Charles Friedel and James Crafts in 1877 to attach substituents to an aromatic ring. There are two main types: alkylation and acylation reactions, both proceeding by an electrophilic aromatic substitution pathway.

Nazarov electrocyclization The Nazarov cyclization reaction is a chemical reaction used for the synthesis of cyclopentenones. It was originally discovered by Ivan Nikolaevich Nazarov (1906–57) in 1949 while studying the rearrangements of allyl vinyl ketones. As originally described, it involves the activation of a divinyl ketone using a stoichiometric Lewis acid or protic acid promoter. The key step of the reaction mechanism involves a cationic 4π-electrocyclic ring closure which forms the cyclopentenone. Variants involving substrates other than divinyl ketones and catalytic promoters or others than Lewis acids have also been reported under the same name due to a similar mechanistic pathway.

Oxyallyl cation It refers to allylic cations substituted at the 2-position with an oxygen substituent. This type of 2π components participate in cycloadditions with dienes (4π) yielding cycloheptenones as adducts.

Transition state The transition state of a reaction is defined as the state corresponding to the highest potential energy along its reaction coordinate. It is often marked with the double dagger ‡ symbol.

Trialkylsilylenol ethers A type of enol ether in which the oxygen atom is linked to a trialkylsilyl group.

Vinyl oxocarbenium A type of oxocarbenium ion (canonical form of a carbocation, real or hypothetical, which places a formal positive charge on an oxygen atom) that incorporates a vinyl group attached to one of their atoms.

5.13.1 Introduction

Seven-membered rings are present in the structural core of many biologically relevant natural products and, in general, are more difficult to construct than the five- and six-membered congeners. Indeed, syntheses of products featuring seven-membered rings as key skeletal elements are much scarcer than those leading to cyclic products bearing smaller rings.

From the practical point of view, one of the best ways to construct seven-membered rings consists of the use of cycloaddition reactions owing to the intrinsic increase in complexity that can be achieved in just one step, from simple acyclic precursors. Among the different cycloaddition alternatives,[1] the more common are based on (5 + 2) and (4 + 3) assembling strategies. (It should be noted that in this chapter the authors use the (4 + 3) rather than the more frequent [4 + 3] notation. The designation (m + n) is used here in accordance with Woodward–Hoffmann/IUPAC conventions for describing cycloadditions based on the number of atoms, as opposed to the bracketed [m + n] designation, which indicates the number of electrons involved.) (5 + 2) Cycloadditions usually make use of alkynes or alkenes as two-carbon partners and vinylcyclopropanes, cyclopropyl imines, pyrones, pyranulose acetates, betaines, and quinones as five-atom components.[2] However, (4 + 3) cycloadditions are mainly based on the use of highly accessible conjugated dienes as four-carbon components, and different types of three-atom precursors.

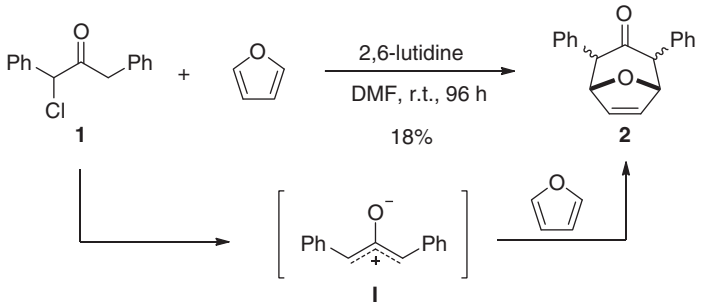
In many cases (4 + 3) annulation strategies rely on the reaction between allyl cation precursors and dienes, because the overall reaction involves a thermally allowed 4π + 2π cyclic rearrangement, homologous to that occurring in Diels–Alder cycloadditions. Nevertheless, in recent years other very interesting alternatives for this type of cycloadditions have been developed. Herein, the authors try to collect classical as well as more recent (4 + 3) cycloaddition approaches so that the reader can easily assess the evolution and current potential of this constructive strategy. They have tried to avoid excessive discussions on reactions that are already collected in previous reviews and, in particular, those already included in the first edition of Comprehensive Organic Synthesis. To facilitate reading and understanding, the different cycloaddition strategies are organized into sections according to common mechanistic features and/or related hypothetical intermediates. Thus, the (4 + 3) cycloaddition of allyl cations (e.g., oxyallyl, aminoallyl, metal-allyl, etc.), donor–acceptor strained cycles, metallacyclic intermediates, or Pd-trimethylenemethane (TMM) species, are collected in different sections. A final section on (4 + 3) cycloaddition strategies leading to seven-membered rings that involve sequential processes have also been included, occurring via well established and even isolable organic intermediates.

Finally, a number of synthetic applications have been collected in specific sections so that the reader can learn, at a glance, the potential of the technology to make biologically relevant cyclic targets.

5.13.2 (4 + 3) Cycloadditions Between Dienes and Allyl Cation Precursors

5.13.2.1 Introduction

Considering that cycloadditions involving 4π + 2π electron rearrangements are allowed by the orbital symmetry rules, it is not surprising that allyl cations can react with dienes to make seven-membered rings. It also makes sense that the transformation



should be favored by substituents in the 3C precursor that favor the formation of the allyl cation intermediate and stabilize the resulting carbocation of the cycloheptenic ring.

In the following sections the authors will discuss the most relevant methodologies thus far described to generate cycloaddition-active allyl cations. Each section discusses the chemistry of allyl cation intermediates bearing a specific type of substituent at the central carbon atom. The first section, devoted to oxyallyl cations, is organized based on the type of precursors used for their generation and, therefore, complements other very recent reviews that use a different organization.[3]

5.13.2.2 Reactions Involving Oxyallyl Cation Intermediates

5.13.2.2.1 Introduction

The success of a (4 + 3) cycloaddition strategy mainly depends on the facility for generating suitable three-carbon species capable of undergoing a cyclocondensation with a 1,3-diene (four-carbon partner). Among the different types of three-carbon allyl cations, those substituted at the central position with an oxygen substituent, termed 'oxyallyls', are the most common.[3] In 1951, Anston and Newkirk proposed for the first time the formation of oxyallyl cations as transient intermediates in the Favorskii rearrangement.[4] However, it was not until 1962 when Fort provided the first example of a (4 + 3) cycloaddition involving an oxyallyl cation intermediate (**I**) (equation 1). The reaction was accomplished by treatment of chloroketone **1** with 2,6-lutidine (4 equivalents) in the presence of excess furan (2.5 equivalents), and gave the oxacyclic products **2** in a modest 18% yield (equation 1).[5]

(1)

Since the discovery of Fort, many other (4 + 3) cycloadditions, which have been proposed to involve oxyallyl cation intermediates, have been reported. Although these key intermediates can be generated in different ways, there are some basic rules for the (4 + 3) cycloaddition of oxyallyl cations, which are applicable in most of the cases, and useful to understand, and even predict, the outcome of the reaction.

The (4 + 3) cycloaddition of dienes to oxyallyl cations, analogous to the Diels–Alder reaction, can be viewed as a [4π + 2π] process between a diene and a dienophile (Figure 1). However, in these cycloadditions, the dienophile works as a three- rather than as a two-carbon component as is the case of Diels–Alder reactions. Like for (4 + 2) cycloadditions, the (4 + 3) annulation can be explained in terms of the interaction between the highest occupied molecular orbital (HOMO) of the diene and the lowest unoccupied molecular orbital (LUMO) of the dienophile (oxyallyl cation). Whereas in Diels–Alder reactions the energy level of the LUMO is lowered by electron-withdrawing groups (EWGs) in the alkene or alkyne partners, the LUMO orbital of an oxyallyl cation is of lower energy when the O–M bond features a higher covalent character. Therefore, the electrophilicity of oxyallyl cationic intermediates decreases along the series M = alkyl or H > iron > silyl > zinc ≥ lithium > sodium > cyclopropanone ('oxidoallyl') (Figure 1).[3b,f]

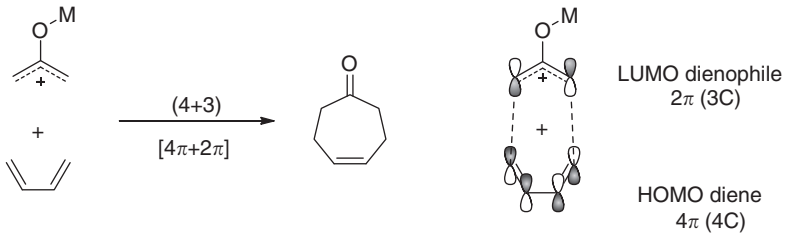


Figure 1 [4π + 2π] Cycloaddition between an oxyallyl cation and a conjugated diene.

The regioselectivity of the cycloaddition is controlled by the coefficient of the frontier molecular orbitals at the edge carbons of the oxyallyl moiety, which, in many cases, tend to be quite similar.

Substituted oxyallyl cations can, in principle, adopt different geometries, but we can consider that there are three basic structures: U-, sickle-, and W-shaped (Figure 2). The W form is usually proposed for acyclic substrates because it represents the conformation of lowest energy; the U-shaped conformation is the only one possible in case of cyclic structures (although the

'sickle' form could be an alternative for large rings). With regard to the dienes, the most reactive and commonly used are furan and its derivatives, as well as cyclopentadiene, owing to their enforced *s-cis* conformation. Other cyclic dienes such as pyrroles, cyclohexadienes, anthracenes, or fulvenes have also been used; however, they usually give rise to less efficient and selective reactions. Acyclic dienes can also work as four-carbon partners, albeit they generally provide modest cycloaddition yields, probably because of the low concentration of the reactive *s-cis* conformers.

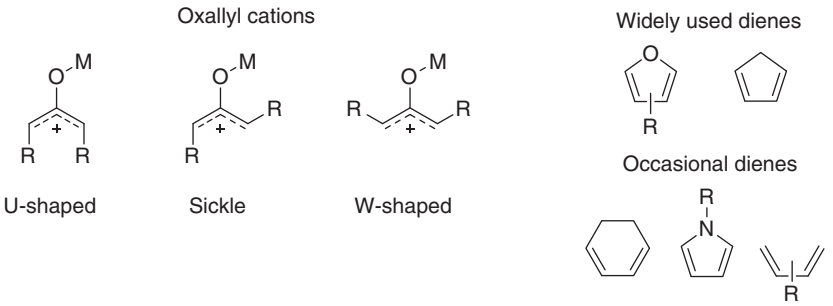

Figure 2 Oxyallyl cations and their diene counterparts.

Although from the above discussion it could be inferred that the (4 + 3) cycloaddition between oxyallyl cations and dienes is a concerted pericyclic process, this is not always the case, and in many instances it has been reported to take place in a stepwise manner. The mechanism depends on the reaction conditions, with stepwise processes being more favored for electron-rich dienes such as pyrrole and furan derivatives, because of the higher stability of cationic intermediates of type **II** (Figure 3). The stepwise mechanism is also more favored in the case of electrophilic oxyallyl cations featuring more covalent O–M bonds. Cramer and coworkers have recently investigated the mechanism of the (4 + 3) cycloaddition using computational methods, and agree that it depends on the electrophilicity of the oxyallyl cation and the nucleophilicity of the diene. These authors also suggest that in some cases the reaction may involve a (3 + 2) cycloaddition followed by Claisen rearrangement of intermediates like **III**.[6]

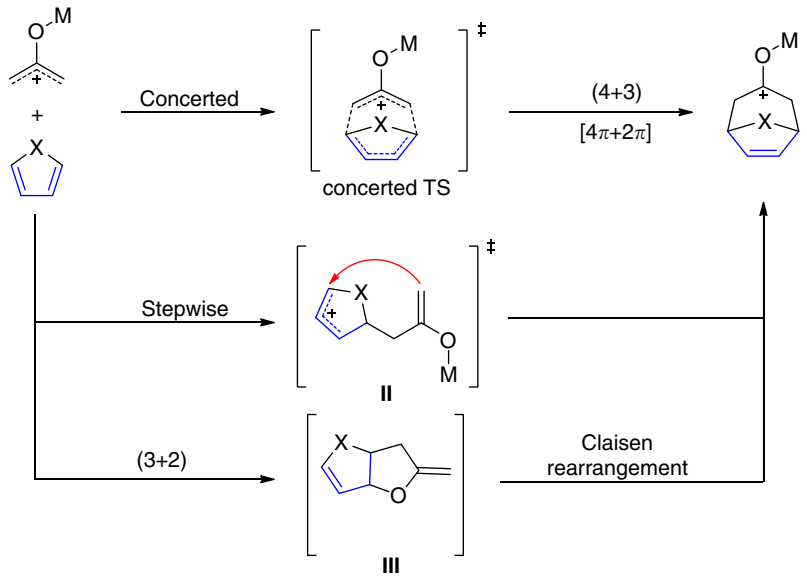

Figure 3 Mechanistic possibilities for the (4 + 3) cycloaddition of oxyallyl cations and dienes.

With regard to the stereochemistry, the cycloaddition can proceed for concerted processes through two topologically distinct transition states, called 'compact' or 'extended'. The 'compact' transition state (**TS-I**) is 'boat-like' and is related to the *endo* transition state of the Diels–Alder processes. The alternative is an 'extended' transition state (**TS-II**), which is 'chair-like' and is related to the *exo* transition state. In the case of substituted acyclic oxyallyl cations with a preferred 'W-shaped' conformation, reactions through compact transition states lead to diequatorial type of products (Figure 4), whereas those proceeding through extended transition states give products with the substituents R in a diaxial orientation. The formation of axial-equatorial products could be explained in terms of stepwise mechanisms, at least in those cases where the oxyallyl cation adopts a 'W-shaped' conformation (Figure 4). In general, oxyallyl cycloadditions are less stereoselective than Diels–Alder reactions, although in some cases impressive selectivities can be achieved.

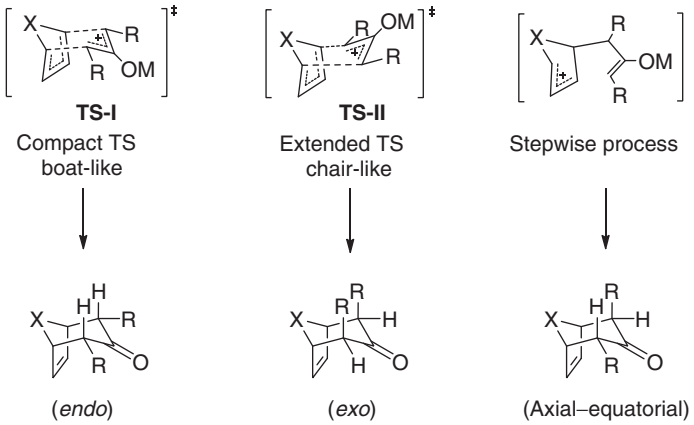

Figure 4 Stereochemical possibilities in the cycloaddition of acyclic oxyallyl cations with W-shape conformation.

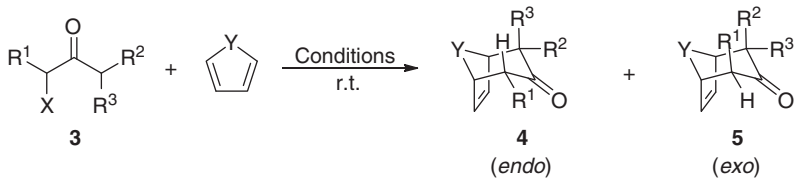
In the following subsections, the authors present different examples of (4 + 3) cycloadditions mediated by oxyallyl cations which, as commented above, have been organized according to the type of precursors employed to generate the reactive allylic species. Given the large literature body on this topic and the previous review of 1991 in Comprehensive Organic Synthesis, the authors will mainly cover work published after 1990.

5.13.2.2.2 α-Haloketones

5.13.2.2.2.1 Acyclic precursors

The first example of an oxyallyl-diene cycloaddition, reported by Forth in 1962, was based on the generation of the allyl cationic intermediate by treatment of an α-chloroketone with a base (see equation 1). The method represents a rather attractive approach to generate oxyallyl cations because of the mild conditions and the relative simplicity of the starting materials. Although the efficiency of these preliminary transformations was limited, subsequent improvements on reactions conditions by Föhlisch and coworkers, based on the use of ethereal lithium perchlorate or fluorinated solvents like trifluoroethanol (TFE), or 2,2,3,3-tetrafluoropropanol (TFP) brought an important enhancement of the efficiency and scope of the methodology.[3a]



Most of the work on this type of (4 + 3) cycloadditions of acyclic haloketones and dienes was developed in the 1970s and 1980s and is detailed in the first edition of Comprehensive Organic Synthesis.[3e] However, some representative examples are included in Table 1. Simple 1-chlorobutan-2-one (**3a**) only reacts with furan in a testimonial 5% yield. However, reaction of 2-bromopentan-3-one (**3b**) or 2-chloropentan-3-one (**3c**) with furan led to the corresponding oxabicycles in good yields and good selectivities in favor of the *endo* cycloadducts (**4**). Interestingly, the cycloaddition of 2-chloropentan-3-one (**3c**) with furan or cyclopentadiene could be performed even in water, using triethylamine as the base (conditions C, entries 4 and 9) and only require a smaller amount of diene (2 equivalents). A further increase in the substitution of the starting haloketone (**3e**) led to fully stereoselective processes (entry 6).[7d] In general, when the diene is furan (Y=O), good yields and selectivities can be achieved under different conditions. However, with cyclopentadiene, although the overall yield is good, the *endo*:*exo* selectivity drops (entries 3 vs. 8 and 4 vs. 9).

5.13.2.2.2.2 Cyclic precursors

Cyclic α-chloro- or α-bromoketones also participate in (4 + 3) cycloadditions with dienes under 'basic conditions,' providing interesting carbon-bridged bicyclic structures. Inspired by the work of Föhlisch with α-bromocyclohexanones (**6a**) and α-bromocyclopentanones (**6b**),[7a,d] Cha and coworkers reported in 1995 that treatment of substituted α-chlorocyclohexanones **6c–f** with cyclic dienes (2–4 equivalents) and Et_3N (2 equivalents) leads to the expected tricyclic cycloadducts (Table 2).[8] Although yields are from moderate-to-good, selectivities are generally very good, favoring the formation of *endo* products of type **7** even with cyclopentadiene (entries 4 and 7). In these cases, the reaction involves the formation and subsequent cycloaddition of 'U-shaped' cyclic oxyallyl intermediates like **IV**. The stereoselection observed in these intermolecular cycloadditions of cyclic oxyallyl cations with furans has been rationalized in terms of secondary orbital interactions and steric effects.

The same group reported an interesting asymmetric version of the transformation based on the use of cyclohexanone substrates **8**, bearing a chiral center in an adjacent position. These allyl cation precursors were prepared by chlorination (SO_2Cl_2) of ketones which, in turn, were ensembled by aldol condensation of cyclohexanone with an appropriate aldehyde and subsequent silylation. The cycloaddition reaction is proposed to proceed through a compact transition state which favors formation of the *endo* product resulting from the approach of the diene to the oxyallyl cation from its less-hindered face, opposite to the bulky alkoxy group, thus leading to the exclusive formation of cycloadduct **9** (equation 2). Interestingly, running the same reaction with the unprotected precursor **10** leads to products of complementary stereochemistry (**11**). This result is explained in terms of an internal hydrogen bonding, which favors a complementary facial approach to that observed in case of **8** (equation 3).[9]

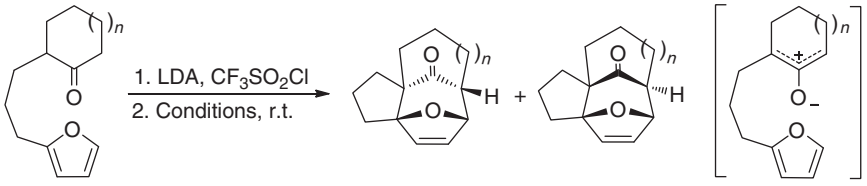
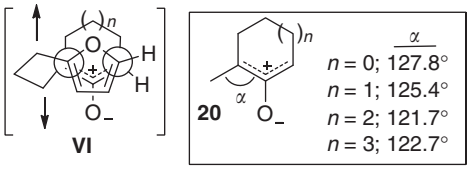
5.13.2.2.2.3 Intramolecular cycloadditions

As expected, this type of base-induced cycloadditions can also be implemented in an intramolecular manner. Therefore, treatment of the furan-tethered chloroketone **12** with Et_3N induces the formation of the expected carbobicyclic product **13**, but the reaction takes place in very low yield (equation 4). Remarkably, a simple incorporation of a methyl substituent at the ketone α-position, such as in **14**, increases the stability of the putative allyl cation intermediate, thus leading to a clear improvement in the yield (equation 5).[10] Nevertheless, the products are formed as a mixture of up to four diastereoisomers, and an *exo* (**15**) : *endo* (**16**) selectivity of 76:24 (equation 5).



(4)



(5)

In the mid-1990s, Harmata et al. reported a detailed study on the intramolecular cycloaddition of furan-tethered cyclic α-chloroketones prepared by *in situ* chlorination of **17** under standard conditions (equation 6).[11] Although the yields are moderate, the reaction offers substantially better selectivities compared with the intramolecular cycloaddition of acyclic precursors mentioned earlier (equations 4 and 5). The reaction was proposed to take place through U-shaped oxyallyl cations (**V**), which react preferentially via extended transition states (thus leading to *exo* products), except in the case of cyclopentenyl oxyallyl cations, which prefer to approach the diene in a compact mode (that leads to the *endo* product). The authors explained this result on the basis of the induced strain on the endo transition state (VI) when the angle α increases.

(6)

In the case of substrate **21**, the formation of cycloadducts **22** and **23** can be better explained assuming that the intermediate cyclic oxyallyl cation adopts a sickle-shaped conformation of type **VII**.[11]

21 **22** **23** **VII** (7)

Precursors featuring less nucleophilic acyclic dienes instead of furans are less prone to participate in this type of cycloaddition. Therefore, substrate **24a** did not give the expected cycloadducts, but mainly cyclopentenone **27a** (equation 8). It is, however, possible to promote the cycloaddition, although in modest yield and with poor *endo–exo* selectivity, by increasing the substitution of the diene, like in **24b**. In this case, such substitution probably favors a *s-cis* conformation. The yield can be improved using TFE as the solvent, but the selectivity is negligible.[12] It is interesting to note that, although this transformation is a (4 + 3) cycloaddition, it can alternatively be viewed as a [4C + 4C] annulation and therefore allows one to construct very interesting carbon-bridged cyclooctane systems.

5.13.2.2.3 Polyhaloketones

Although *polyhaloketones* are generally more expensive and difficult to make than monohaloketones; these oxyallyl cation precursors (di-, tri-, tetra-, and pentahaloketones) were shown to be excellent cycloaddition partners in a broad range of intermolecular oxyallyl cation (4 + 3) cycloadditions. They often provide advantages in terms of reactivity and selectivity compared with the much simpler monohaloketones.[3]

5.13.2.2.3.1 α,α- and α,α′-Dichloroketones

Both α,α- and α,α′-dichloroketones are useful three-carbon partners in (4 + 3) intermolecular cycloadditions with furans.[13] Apparently, the presence of extra chlorides in the α-position of the carbonyl groups is beneficial for their reactivity as oxyallyl cation precursors. Thus, although treatment of a monochloroketone **28a** with methylfuran under 'basic conditions' leads to a 1:1 mixture of regioisomeric cycloadducts **29a** and **30a** in modest yields, α,α′-dichloroketone **28b** reacts under the same conditions to generate oxyallyl cations such as **VIII**, which reacts with methylfuran to mainly produce regioisomer **29b** with good *endo*:*exo* selectivity (13:1) (equation 9). Similar results were achieved in the cycloaddition of α,α-dichloroketone **31** (equation 10). The regiocontrol seems to be grounded in both steric and electronic effects.

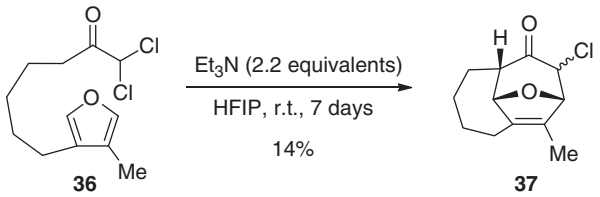
[a] *endo* : *exo* ratio.

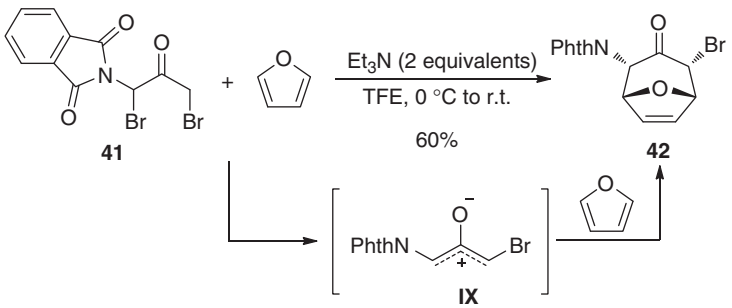


(10)

Similarly, beneficial effects of additional chloride atoms in the oxyallyl precursors were observed in the case of intramolecular processes. Although the cycloaddition of monochloride **12** (see equation 4, Section 5.13.2.2.2.3) is low yielding, dichloroketone **34** undergoes an efficient reaction to give the tricyclic product **35** in good yield and almost complete diastereoselectivity (equation 11).[14] Interestingly, it is even possible to accomplish the topologically difficult cycloaddition of substrates like **36**, which yields interesting bridged carbobicyclic products **37**, although in low yields (equation 12).[15]

(11)

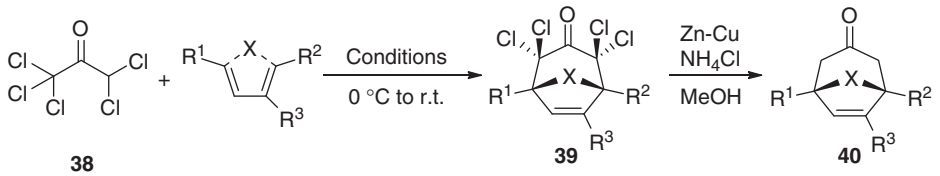
(12)



5.13.2.2.3.2 Polychloroketones

Trichloroacetone derivatives can also be used as precursors of oxyallyl cation intermediates with good results (e.g., the formal synthesis of Phorbol, Scheme 14, Section 5.13.2.6). Similarly Föhlisch and coworkers demonstrated that 1,1,1,3,3-pentachloro-2-propanone **38** (pentachloroacetone (PCA)) also participates in a variety of (4 + 3) cycloadditions with dienes to produce tetrachlorobicyclic adducts **39**.[16] These cycloadditions of PCA are advantageous over other related processes owing to the symmetry of the intermediate oxyallyl cations, and hence only one type of oxabicyclic products can be formed. The cycloaddition provides good yields for a variety of substituted furans (Table 3, entries 1–6). The polyhalogenated products can be readily converted to halogen-free, synthetically appealing oxabicycles **40** on treatment with zinc or zinc–copper, according to the standard procedures.[16a] It is also possible to perform the cycloaddition of PCA with acyclic-substituted dienes (entries 7–9), although in these cases the yields are moderate and the dehalogenation of the resulting products under standard conditions is inefficient.[16b]

5.13.2.2.3.3 α,α′-Dibromoketones



Similar to dichloroketones, α,α′-dibromoketones can also be used as precursors for oxyallyl cations. However, their use has been rather limited due to their frequent instability and lachrymatory properties. Some examples of the use of cyclic α,α′-dibromoketones in the synthesis of natural products can be found in Section 5.13.2.6 (Schemes 15 and 16).

In 1995, Walters and coworkers demonstrated that the readily available α,α′-phthalimidoyldibromide **41** reacts with furan on treatment with Et_3N in either TFE or $LiClO_4/Et_2O$, to give the expected seven-membered cycloadduct *endo*-**42** in 60% yield.[17] The reaction must involve the intermediacy of an *N*-substituted oxyallyl cation **IX** that prefers to react in a W-conformation (equation 13). Substituted furans and cyclopentadiene are also accepted; however they lead to mixtures of isomers with poor selectivity. A related strategy to generate *N*-stabilized oxyallyl cations from allene-amides will be discussed in Section 5.13.2.2.9.

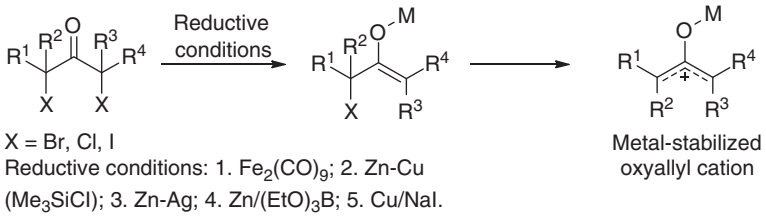
[c]Only small amounts were obtained.

Although this example by Walters made use of basic conditions to generate the reactive cationic intermediate, it is pertinent to comment that the generation of oxyallyl intermediates from α,α′-dibromoketones is most often achieved using reductive, rather than basic conditions. These reductive conditions involve the treatment of α,α′-dihaloketones (or polyhaloketones) with metal-based reducing agents to give metal enolates, which evolve by loss of the second halide to generate metal-bound oxyallyl cations (Figure 5). Therefore, and in contrast to the base-promoted cycloaddition of dibromoketones, these reductive methods produce bromide-free cycloadducts. Some typical reaction conditions involve the use of copper/sodium iodide in acetonitrile, zinc dust/triethyl borate in THF, zinc–copper couple in DME or [$Fe_2(CO)_9$] in benzene.[3b]



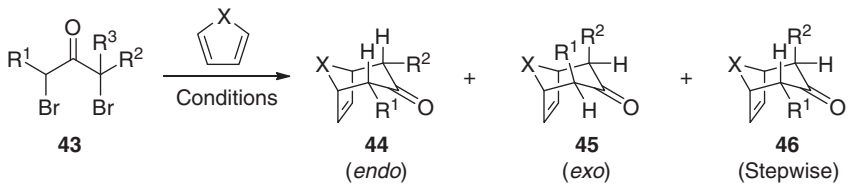


Figure 5 Oxyallyl cation generation from α,α′-dihaloketones under reductive conditions.

As shown in Table 4,[18] treatment of 2,4-dibromopentan-3-one (**43a**) with furan (2.5 equivalents) in the presence of Cu/NaI gives preferentially the *endo* cycloadduct **44a**, arising from a compact transition state (Table 4, entry 1). When the same reaction is carried out with Zn/Cu, the *endo*/*exo* selectivity drops, and some amount of epimer **46a** is isolated, probably arising from a stepwise pathway (entry 2). Finally, using an excess of $Fe_2(CO)_9$ as well as of the diene (solvent or in large amounts), the reaction produces a mixture of cycloadducts **44a** and **46a** in good yield (entry 3). The different stereochemical results can be explained in terms of an increasing electrophilic character of the oxyallyl cation when moving from Cu/NaI to $Fe_2(CO)_9$, owing to a greater covalent character of the O–M bond. Polybromoketone **43b** and the diphenyl derivative **43c** gave similar results (entries 4 and 5). Cyclopentadiene and *N*-methylpyrrole can also efficiently participate in the cycloaddition, although the resulting *endo*/*exo* selectivities were moderate (entries 6 and 7). The case of the pyrrole is interesting because this substrate tends to give products of electrophilic substitution instead of cycloadditions when other methods are used.

Acyclic dienes do also participate in this type of (4 + 3) cycloadditions. Indeed, the first examples reported by Noyori[18c] as early as 1978 showed that symmetrical α,α-dibromoketones of type **43** react with butadiene, isoprene or 2,3-dimethylbutadiene in the presence of stoichiometric amounts of $Fe_2(CO)_9$ to give the corresponding cycloheptenones **47**, although the yields were generally low (Table 5).

It was later shown that better overall yields can be obtained, even with the simplest dienes, if they were precoordinated to the metal and hence locked in the *s-cis* arrangement required for the cycloaddition (equation 14).

(14)

Cyclic α,α′-dibromoketones also participate in (4 + 3) cycloadditions with cyclic dienes, but the yields are lower than those obtained by the alternative methodologies described above based on α-haloketones (see Section 5.13.2.2.2.2, Table 2, entries 1 and 6). Interestingly, in the case of oxyallyl cation precursors embedded in large rings ($n=7$), the formation of cycloadducts **50** arising from a sickle-shaped allyl cation conformation is preferentially observed (equation 15).[18c,f]

(15)

In 1996, Lautens and coworkers reported an interesting asymmetric version of this type of (4 + 3) cycloadditions.[19] Thus, treatment of 3 equivalents of the enantiopure furan derivative (*S*)-**51** with diethylzinc (2 equivalents) in the presence of 2,4-dibromopentan-3-one (**43a**, 2 equivalents) produces the oxabicycle **52** in good yields and with excellent diastereocontrol. The formation of the product can be explained in terms of a chelation-controlled extended transition state **X**, which justifies both the facial and the *exo* diastereoselectivities (Scheme 1).

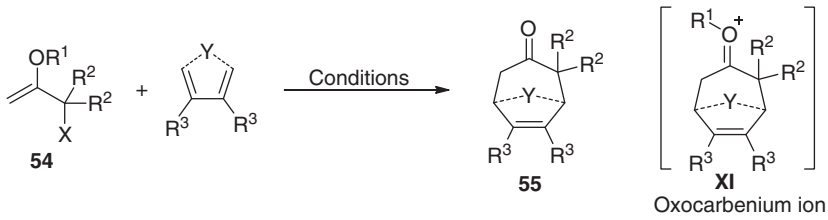
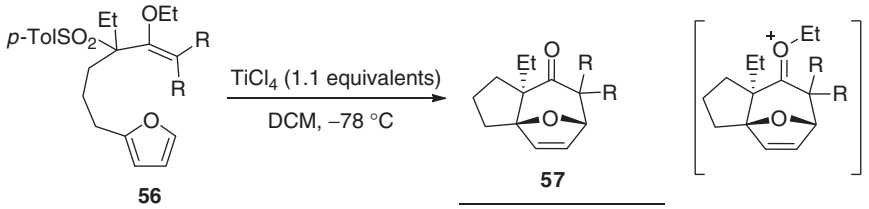


Scheme 1

5.13.2.2.4 2-Alkoxy- and 2-silyloxyallyl halides and related compounds

As might be envisioned, 2-alkoxyallyl halides and related 2-silyloxyallyl halides of type **54** participate in (4 + 3) cycloaddition reactions with dienes when treated with suitable Lewis acid promoters. Some examples are shown in Table 6. The transformation was investigated by several groups in the 1970s and 1980s, most notably those of Hoffmann,[20] Hosomi,[21] or Shimizu,[22] and has been proposed to involve the formation of oxyallyl cationic intermediates. From the practical point of view, the methodology is not the most appealing because making and handling of the required precursors is not so trivial and the cycloaddition yields are quite variable depending on the specific substitutions of the substrates. Initial results reported by Hoffmann with simple enol ethers (Table 6, entries 1–2) led to poor yields in the reactions with furan. Most probably the reactions produce oxocarbenium intermediates of type **XI**. Later, Hosomi and Shimizu reported that good yields and selectivities could be achieved when the oxyallyl intermediates are generated from crowded silyl enol ethers using $ZnCl_2$ (Hosomi) or $AgClO_4$ (Shimizu) as promoters (entries 3–6). Under these conditions acyclic dienes also can participate in the cycloaddition with moderate efficiency (entries 7–8).



Harmata and coworkers have extensively studied a variant in this type of chemistry based on the use of sulfones instead of halides as leaving groups. The method was mainly explored in intramolecular processes.[23] The required 2-alkoxyallyl sulfones can be prepared in a relatively simple manner from sulfonylallenic precursors. As an example, treatment of precursors **56a** or **56b** with stoichiometric amounts of $TiCl_4$ promotes their intramolecular cycloaddition to give the expected cycloadducts of type **57** in good yields and excellent diastereoselectivity (equation 16).

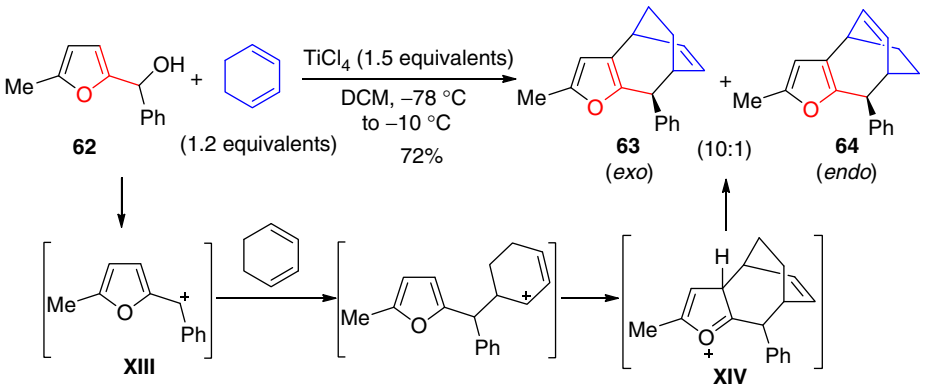
(16)

Unfortunately, the method fails for substrates with less substituted allyl cation precursors. To circumvent this problem, Harmata et al. designed precursors with a terminal sulfur-based substituent that could stabilize the incipient positive charge of the allyl cation through the formation of vinylthionium intermediates.[24] These authors showed that treatment of compound **58** (1:1 mixture *E*/*Z* isomers) with triflic anhydride and 2,6-lutidine affords the expected cycloadduct **59** as a single stereoisomer in good yield. In this case, the vinylthionium ions are generated by means of a Pummerer rearrangement (equation 17, intermediate **XII**).

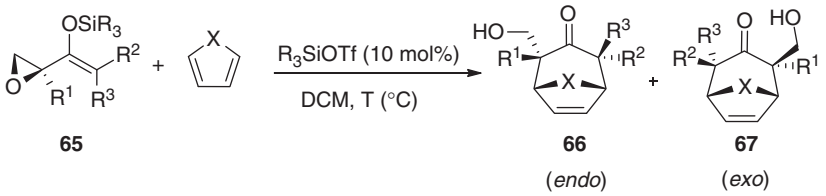


(17)

Hydroxy groups can also work as leaving groups in the generation of allyl cations, which are further stabilized by the presence of sulfur substituents. Thus, vinylsufide **60** reacts intramolecularly with simple dienes to form bicyclic products such as **61** as a mixture of diastereoisomers (equation 18).[25]

(18)

Equation 19 shows another example of a cycloaddition involving a hydroxyl function as the leaving group to generate stable carbocations. Furfuryl alcohol **62** reacts with dienes in a (4 + 3) manner when activated with Lewis acids to give the interesting bicyclic adducts **63** (major) and **64** (minor).[26] The presence of a Lewis acid most probably generates a furfuryl cation intermediate **XIII** that can be viewed as an oxyallyl or oxocarbenium ion. DFT calculations suggested that the reaction then takes place through a stepwise process involving an initial electrophilic addition to the furfuryl cation followed by a 7-*endo*-trig cyclization to yield **XIV**. A final deprotonation leads to the observed products (equation 19). Although this is the most probable mechanism, a concerted [6π + 4π] combination between the furfuryl cation and the diene to form the intermediate **XIV** cannot be fully discarded.



(19)

5.13.2.2.5 Epoxyenol silanes

Epoxides can also work as leaving groups in the generation of reactive oxyallyl carbocations. Indeed, Eguchi and coworkers demonstrated in 1990 that epoxy enol silanes of type **65** engage in intermolecular (4 + 3) cycloaddition reactions with dienes such as furan or cyclopentadiene when treated with Lewis acids, albeit the cycloadducts are produced in low yields and with low diastereoselectivities (Table 7, entries 1 and 2).[27] Importantly, the reaction can be carried out using catalytic amounts of a Lewis

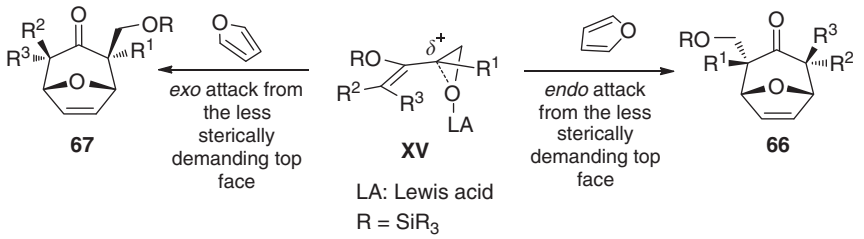
[f]20 mol% of TESOTf was used.

acid, with trimethylsilyl triflate (10 mol%) being the most effective. Almost 20 years later, Chiu and coworkers demonstrated that the yield of this type of intermolecular (4 + 3) cycloadditions could be dramatically increased by appropriate selection of the epoxy enol silane and the reaction conditions.[28] In particular, using a triethylsilyl enol ether in combination with triethylsilyl triflate as catalyst (10 mol%), and performing the reaction at a significantly lower temperature (− 94 °C), the cycloadducts are obtained in good yields (entries 3–5). Although the diastereoselectivity is generally low, it is possible to obtain better results by using epoxy enol silanes bearing silyl groups with higher steric demand. Thus, the cycloaddition of TBDPS-substituted enol ether **65c** with spirocyclopentadiene provided the corresponding *endo*-cycloadduct **66** which was isolated in a 46% yield (entry 6).[28b] The reaction can be extended to other alkene-substituted vinyl epoxides as can be deduced from entries 9–11. In all cases, only one pair of diastereoisosomes (**66** and **67**) was detected, suggesting that the reactions are stereospecific.

From a mechanistic point of view, it has been suggested that the transition state of the cycloaddition is reactant-like, with a significant epoxide and alkene character; therefore there is no generation of a neat allyl cation. Accordingly, the activated epoxide adopts a conformation resembling **XV** (Figure 6), which is approached by the diene from the less sterically demanding face, *anti* with respect to the epoxide, in both the *exo* and *endo* cycloaddition modes. As in other reactions with oxyallyl cation intermediates, the cycloadditions to furan are proposed to be quite asynchronous.



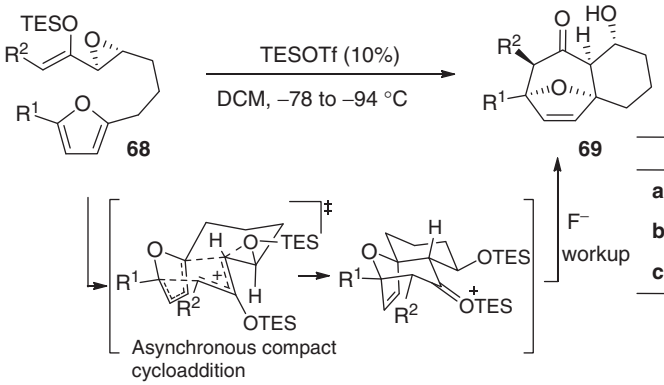


Figure 6 Mechanistic proposal for the epoxy enol silane cycloadditions with furans.

In contrast to the general lack of *endo*/*exo* diastereoselectivity in the intermolecular processes, the related intramolecular cycloadditions between furans and epoxy enol silanes **68** afford good yields of the corresponding cycloadducts **69**, which are obtained as single diastereoisomers and in a sterospecific manner with respect to the epoxy enol silane. Therefore, using a single enantiomer of the epoxy enol silyl ether **68a** provides optically pure cycloadduct **69a** (equation 20).[28a] The high diastereoselectivity of the intramolecular process could be explained on the basis of a compact transition state, in which the tether adopts a chair-like conformation and the silyloxylallyl cation adopts a W-type configuration (equation 20). This strategy has been recently used as key step in a concise and asymmetric synthesis of the pentacyclic framework of steroidal alkaloid Cortistatins (see Section 5.13.2.6, Scheme 20).[29]

5.13.2.2.6 α,α-Dialkoxy trialkylsilylenol ethers and related

In 1988, Föhlisch and coworkers demonstrated that α-chloro-α-alkoxy ketones of type **70** serve as satisfactory oxyallyl cation precursors in base-promoted (4 + 3) cycloadditions.[30] In this case, the oxyallyl cation is stabilized by the alkoxy group which generates a vinyloxocarbenium resonance form (equation 21). Shortly after this report, the group of Albizati reported that α,α-dialkoxy trialkylsilylenol ethers such as **73** are very good three-carbon cycloaddition partners in a Lewis acid-induced (4 + 3) reaction with furan derivatives.[31] Although several Lewis acids successfully promoted the reaction in a stoichiometric fashion (e.g., $SnBr_4$, $SnCl_4$, $TiCl_4$, BCl_3, etc.), TMSOTf is effective in substoichiometric amounts, typically 40 mol%. Most probably the reaction involves the generation of vinyloxocarbenium ion intermediates as shown in equation 22. Despite the similarities between this method and that of Föhlisch,[30] different diastereoselectivities and regiochemical outcomes were sometimes observed (equations 21 and 22), suggesting that slightly different mechanistic scenarios might be operative.

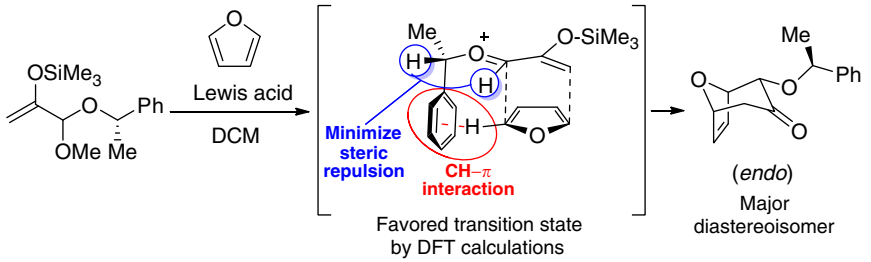
(22)

A few years later, the groups of Hoffmann and Harmata extended this type of chemistry to more elaborated allyl acetals equipped with additional substituents at the alkene and/or at the acetal group.[32] Additionally, in 1998 Hoffmann and coworkers developed an interesting asymmetric variant of these cycloadditions, based on the use of mixed chiral allyl acetals derived from α-methyl benzylic alcohols (equation 23).[33] In this case, treatment of **76** with the Lewis acid promoter generates a chiral oxyallyl cation **XVI**, which preferentially reacts with furan through an *endo* transition state providing good or even complete levels of diastereoselectivity depending on the solvent, temperature and the choice of aryl group at the acetal stereogenic center. In the case of a 2-naphthyl group, the (4 + 3) cycloadduct was formed as a single diastereoisomer, when the reaction was carried out in CH_2Cl_2 at $-95\ ^{\circ}C$.[34] The reaction is also possible with furans containing bromine, silicon, tin, or sulfur substituents at their 3-position; however 2,5-disubstituted furans react with poor diastereoselectivities.[35]



Ar	R	*de*	Yield (%)[a]	Ref
Ph[b]	H	76[c]	67	33a

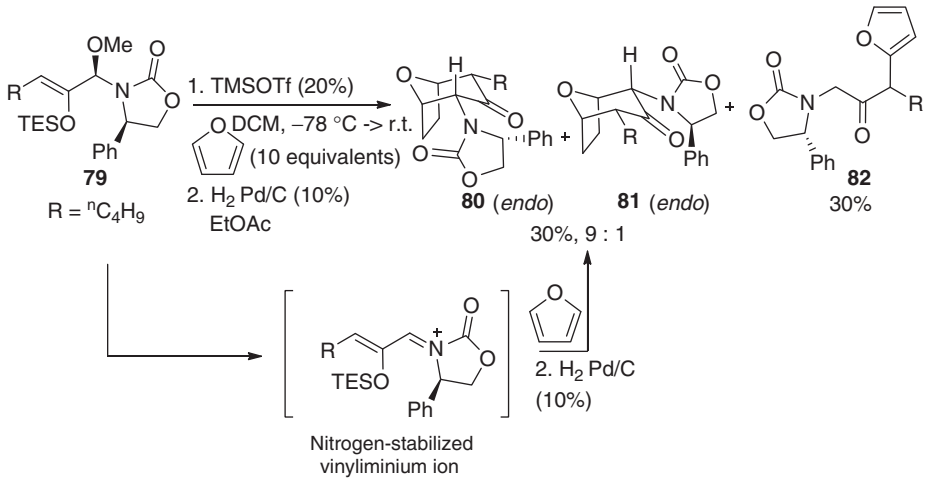
Ph	Me	87	53	34
2-Napht	Me	82	91	34

[a]Combined yield of **77** and **78**. [b]Experiments were carried out with (*R*)-1-(2-naphthyl)ethanol and (*S*)-1-(2-phenyl)ethanol as chiral auxiliaries, therefore providing opposite absolute configurations. Stereochemistry exemplified for Ar = Ph. [c] **77**:**78** ratio = 7.5 : 1.

(23)



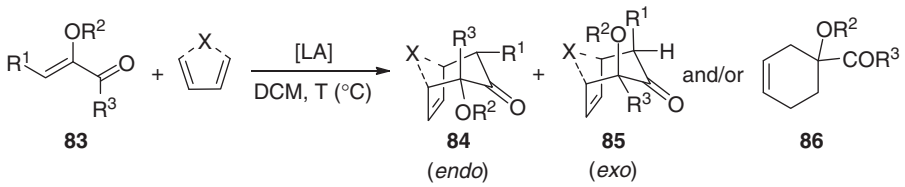
The stereochemical outcome of these asymmetric reactions with furans was originally rationalized by Hoffmann by assuming a silicon–oxygen chelation in the allyl cation. However, a more recent theoretical study by Houk and Harmata[36] suggests that it can be better explained by an *endo* cycloaddition pathway, which is a stepwise process, in which the approach of the reaction components is governed by two main factors: the minimization of repulsive interactions between the allyl cation and the methyl group of the chiral auxiliary, which fixes a preferred conformation for the dienophile, and the presence of an attractive edge-to-face

CH–π interaction between the aryl ring of the chiral auxiliary and the hydrogens of the furan moiety. The calculations based on this model also predict the increase in selectivity observed when going from a phenyl to a 2-naphthyl group in the chiral auxiliary, as well as the low diastereoselectivity observed with 2,5-dimethylfuran, which cannot establish stabilizing CH–π interactions at the C-2 or C-5 positions of the furan (equation 24).

(24)

Related asymmetric cycloadditions were developed in 2002 by Hsung and coworkers, who demonstrated that enol silyl ethers such as **79**, incorporating a chiral aminal instead of an acetal, could also be used in asymmetric (4 + 3) cycloaddition reactions with dienes. Thus, the activation of **79** with TMSOTf (20 mol%) in CH_2Cl_2 produces a chiral nitrogen-stabilized vinyliminium ion, which can be trapped by furan in a (4 + 3) way.[37] Although the reaction was fully *endo* selective and the diastereofacial selectivity was also high (**80**:**81** = 9:1), the yield of the (4 + 3) adducts was moderate (30%, equation 25), mainly because of the formation of a nondesired acyclic byproduct **82**. The generation of related chiral amido-stabilized oxyallyl cations from allenamides and their subsequent (4 + 3) cycloaddition reactions with dienes was extensively developed by the same authors and it is discussed in Section 5.13.2.2.9.

(25)



Finally, it is worth mentioning that the formation of vinyloxocarbenium ions from allyl acetals and their subsequent use in (4 + 3) cycloadditions was successfully exploited in natural product synthesis by several authors. Particularly noteworthy is the work of Cha and coworkers on the total synthesis (–)-colchicine, imerubrine, and grandirubrine,[38] Hoffmann and coworkers in the synthesis of functionalized scopolines,[39] and more recently by the Watanabe group in a stereoselective synthesis of (±)-urechitol A.[40] The methodology has also been applied to the synthesis of carbohydrates and chiral ketones.[41] For more details on these synthetic applications see Section 5.13.2.6.

5.13.2.2.7 α-Silyloxy-α,β-unsaturated carbonyls and vinylogous congeners

Vinyloxocarbonium species related to those proposed above should be, in principle, also accessible from α-silyloxy-α,β-unsaturated carbonyls. Indeed, in the early 1980s, Sasaki and Childs independently reported that 2-(trimethylsilyloxy)propenal **83a** and 3-(trimethylsilyloxy)-but-3-en-2-one (**83b**) react with dienes such as furan, cyclopentadiene, or 1,3-butadiene in a (4 + 3) manner in the presence of stoichiometric amounts of Lewis acid promoters (Table 8, entries 1–4).[42] Although the reactions were not particularly efficient and in general provided mixtures of the *endo* and *exo* (4 + 3) adducts **84** and **85**, and/or (4 + 2) adducts like **86**, these results set the basis for further developments in the area. In 2000, Harmata demonstrated that 2-(triisopropylsilyloxy) propenal **83c** reacts with selected dienes in the presence of catalytic amounts of scandium(III) triflate to afford the (4 + 3) cycloadducts **84** and/or **85** in good-to-excellent yields (Table 8, entries 5–7).[43]

The required dienophile precursor **83c** can be easily prepared by reaction of triisopropylsilyl triflate and 2-methoxy-2-methyl-[1,3]dioxan-5-one (**87**) in the presence of triethylamine (equation 26). Nearly contemporaneously, Funk and coworkers

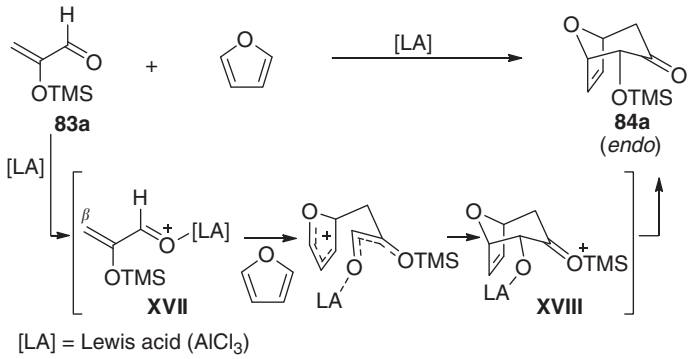
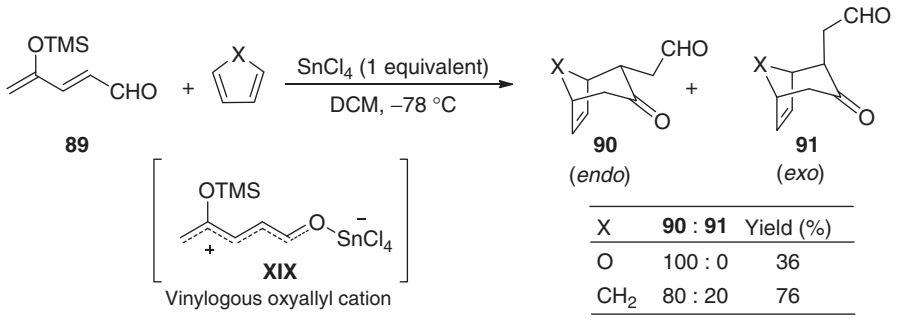
demonstrated that 2-(trialkylsilyloxy)-2-enals of type **83** could also be generated with high stereoselectivity by retrocycloaddition reactions of substituted 4*H*-1,3-dioxins (**88**, equation 26).[44] The higher stability of dioxins of type **88**, compared with dioxanones **87**, allows for their more facile functionalization and eventually for a more ready access to 3-substituted silyloxyalkenals such as **83d** ($R^1 \neq H$, Table 8), thereby, increasing the potential and the scope of the resulting (4 + 3) cycloaddition processes.



(26)

87, R = OMe, R^1 = H
88, R = Me, R^1 = H or alkyl

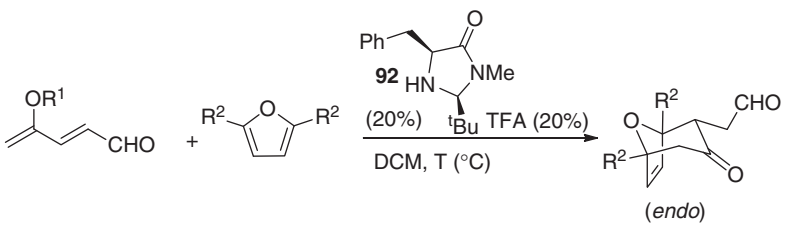
(a) R^2OTf, Et_3N, benzene (R^2 = TIPS, TES, TBS);
(b) i, R^2Cl, NaHDMS; ii, toluene, 110 °C (R^2 = TIPS, TES, TBS)



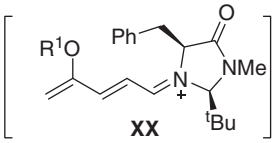
More recently, Harmata and coworkers expanded the versatility of the methodology, by showing that silyloxydioxins of type **88** undergo direct (4 + 3) cycloadditions with furan on treatment with catalytic amounts of $AuCl_3/AgSbF_6$.[45] The potential of the cycloaddition chemistry of α-silyl-α,β-unsaturated carbonyl derivatives was recently demonstrated by Funk et al. in the total synthesis of (±)-cortistatin J (see Section 5.13.2.6).[46]

With regard to the mechanism of these cycloadditions, recent theoretical calculations by Domingo et al.[47] suggest that the reaction is indeed initiated by coordination of the Lewis acid to the carbonyl group to generate an oxonium-stabilized form of a silyloxyallyl cation (**XVII**). In the case of furan, the cycloaddition begins by the attack to the dienophile's β position to give a zwitterionic intermediate, which evolves to the *endo* oxabicycle (**XVIII**). Finally, a silyl migration affords the experimentally observed (4 + 3) *endo* product of type **84**, which is favored over the *exo* one (equation 27).

(27)



4-(Trimethylsilyloxy)-2,4-pentadienal (**89**), which can be viewed as a vinylogous congener of enal **83a**, does also work as a precursor of oxyallyl cations. Thus, the addition of $SnCl_4$ (1 equivalent) to **89** in CH_2Cl_2 at $-78\ ^\circ C$, in the presence of an excess of furan or cyclopentadiene, provides the cycloheptenyl adducts of types **90** and **91**.[27] The reaction is suggested to involve the formation of an oxyallyl cationic intermediate such as **XIX** (equation 28).



X	**90** : **91**	Yield (%)
O	100 : 0	36
CH_2	80 : 20	76

(28)

Quite recently, Harmata and coworkers developed an elegant enantioselective version of these (4 + 3) cycloadditions of silyloxy pentadienals, based on the use a chiral amine organocatalyst **92**, previously developed by MacMillan for enantioselective Diels–Alder and Friedel–Craft reactions. Although the yield and enantioselectivity of the (4 + 3) cycloadditions of silyloxy pentadienals with furan were quite low, the analogous reactions with 2,5-disustituted furans provided the corresponding adducts with moderate or good yields and good enantioselectivities (typically 80–90% *ee*) (equation 29).[48] Also importantly, most reactions were completely diastereoselective, leading to the exclusive formation of *endo* adducts. Mechanistically, the authors proposed that the organocatalyst initially reacts with the aldehyde to generate a chiral unsaturated iminum ion (**XX**) which subsequently participates in an asymmetric (4 + 3) cycloaddition reaction with the furan derivative. The isolation of acyclic secondary products in the cycloadditions of C-2 monosubstituted furans suggests that these (4 + 3) annulations might occur by stepwise mechanisms (equation 29).

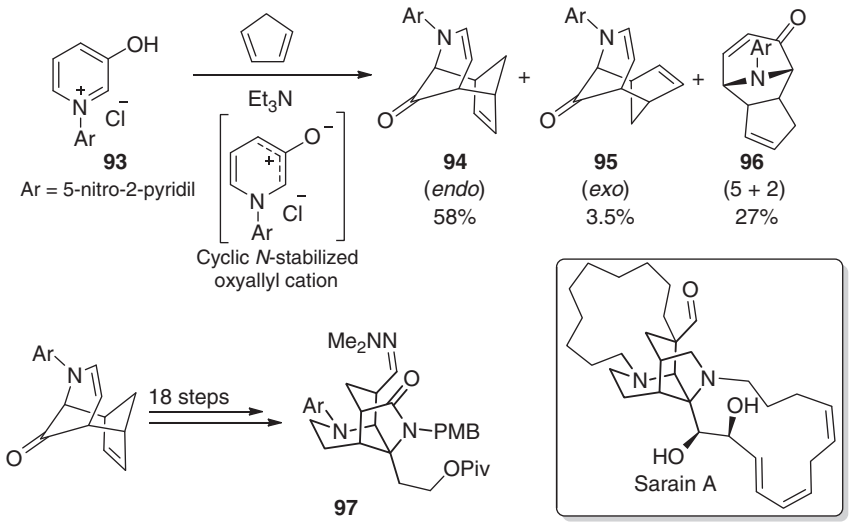
(29)

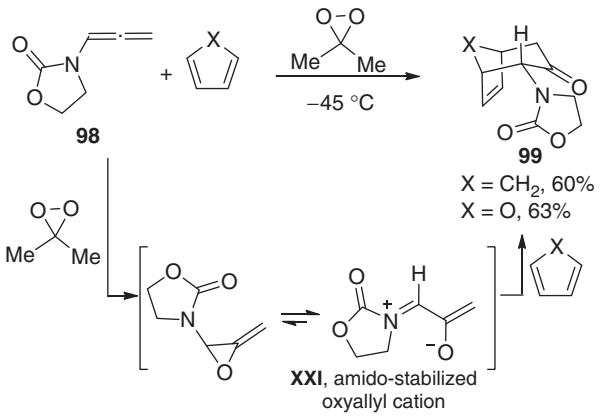


5.13.2.2.8 3-Oxidopyridinium betaines

During the 1970s and 1980s, the cycloaddition chemistry of 3-oxidopyridinium ions was extensively studied.[49] Although this type of heteroaromatic betaines usually participate in dipolar (5 + 2) cycloadditions with carbon–carbon double bonds, the groups of Nye and Katritzky independently demonstrated that they could also participate in formal (4 + 3) cycloadditions with dienes such as cyclopentadiene or 2,3-dimethyl butadiene.[50] Indeed, although oxidopyridinium ions are cyclic aromatic species, they can be alternatively viewed as cyclic *N*-stabilized oxyallyl cations capable of undergoing [3C(2π) + 4C(4π)] cycloadditions (equation 30).

(30)

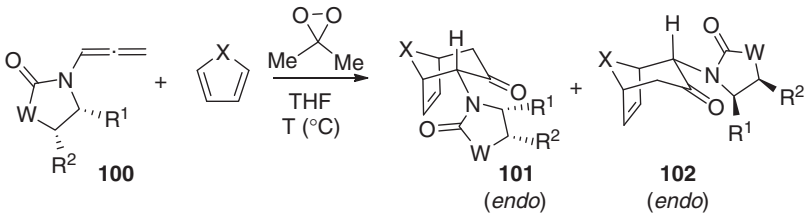
Interestingly, in 1999, Cha and coworkers applied this relatively unexplored (4 + 3) cycloaddition reaction as the key step for the synthesis of the tricyclic core of Sarain A, an alkaloid present in the marine sponge *Reniera sarai*.[51] In particular, a slight modification of Katritzky's cycloaddition, consisting of a slow addition of Et_3N into a mixture of pyridinium salt **93** and cyclopentadiene at room temperature, provided the *endo* and *exo* (4 + 3) adducts **94** and **95** in 58% and 3.5% yields, respectively, together with the (5 + 2) adduct **96** (27% yield, **Scheme 2**). Importantly, the reaction was robust enough to be performed on large scale, so that the *endo*-cycloadduct **94** could be further manipulated in a sequence of 18 steps to afford compound **97**, which incorporates the tricyclic core of Sarain A.



Scheme 2

5.13.2.2.9 Allenamides

5.13.2.2.9.1 Intermolecular examples



As shown above, nitrogen-stabilized oxyallyl cations have been shown to work as effective partners in (4 + 3) cycloadditions to dienes (see Sections 5.13.2.2.3.3 and 5.13.2.2.6).[17,37,52] In 2001, Hsung and coworkers demonstrated that treatment of oxazolidinone-substituted allenamides such as **98** with dimethyldioxirane (DMDO) provides an allene oxide, which subsequently opens to give the nitrogen-stabilized oxyallyl cation **XXI**. This oxyallyl cationic species could be trapped by cyclic dienes such as furan or cyclopentadiene in a standard (4 + 3) annulation (equation 31).[53] This cycloaddition chemistry has been extensively studied and optimized by Hsung during the past decade, and can be considered among the most versatile, selective, and efficient (4 + 3) cycloaddition methodologies relying on allyl cation intermediates.[54]

(31)

In their original report,[53] the authors demonstrated that by incorporating chiral oxazolidinones in the allene moiety, the (4 + 3) cycloaddition with dienes can take place with good-to-high levels of diastereoselectivity, depending on the chiral oxazolidinone used (Table 9). The reactions were completely *endo* selective and the best results (*dr* up to 96:4) were obtained with allenamides that incorporate a phenyl group at the nitrogen α-position, using $ZnCl_2$ (2.0 equivalents) as additive. Notably, these intermolecular cycloadditions can also be carried out in good yields and selectivities using *N*-protected pyrroles as diene counterparts, providing an efficient and direct entry to tropinone alkaloids.[55] The potential of the methodology has been demonstrated by its application to the synthesis of the tricyclic core of parvineostemonine (see Section 5.13.2.6).

Table 9 (4 + 3) Cycloadditions of allenamides with dienes

Numbers	Allenamide (**100**)				Diene	Temperature (°C)	Yield (%)[a]	**101**:**102**	References

5[b]	**100a**	O	Ph	H	*N*-Bz	−45	86	83:17	55

[a]Conditions: DMDO (2.0–3.0 equivalents), $ZnCl_2$ (2.0 equivalents) and diene (10 equivalents) in THF at the corresponding temperature unless otherwise noted.
[b]Reactions carried out with DMDO (6 equivalents) and diene (4–6 equivalents) in DCM with 4 Å MS.

Based on experimental data and DFT-theoretical calculations, Houk and Hsung have recently proposed a mechanistic model that accounts for the regio- and stereoselectivities of these cycloadditions.[56] The authors analyzed the different possible conformations of the amido-stabilized oxyallyl cation **XXII** derived from the oxidation of the allenamide. Contrary to the original hypothesis,[53] these studies revealed that the most stable allylic intermediate presents an (*E*)-configuration, in which the oxazolidinone carbonyl (C=O) and the oxyallyl oxygen are *anti* to each other in order to minimize electronic repulsions ((*E*)-**XXII**, Figure 7). Similarly, the calculations revealed that this conformation is maintained in the transition state of the (4 + 3) cycloaddition. The incorporation of a Lewis acid, such as $ZnCl_2$, decreases the activation barrier of the cycloaddition but does not change the conformation of the (*E*)-oxyallyl cation (*E*)-**XXII′** to a (*Z*)-chelate structure (*Z*)-**XXII′**, as had been initially hypothesized (Figure 7).[53]

The (4 + 3) cycloadditions between these oxyallyl cations and dienes were found to be *endo*-type concerted processes, in which the bond development at the transition state is most advanced at the most electron-rich CH_2 terminus of the oxyallyl cation.[56a] With regard to the diastereoselectivity, when chiral oxazolidinones incorporate a phenyl group at carbon atom adjacent to the nitrogen (**100a**), the calculations predict that there is an important stabilizing C–H–π interaction between the phenyl ring of **100a** and the hydrogen atom located at the C-3 position of the furan moiety. This interaction is strong enough to favor the cycloaddition through the more crowded face of the oxyallyl cation. On the contrary, with chiral oxazolidinones lacking aromatic groups

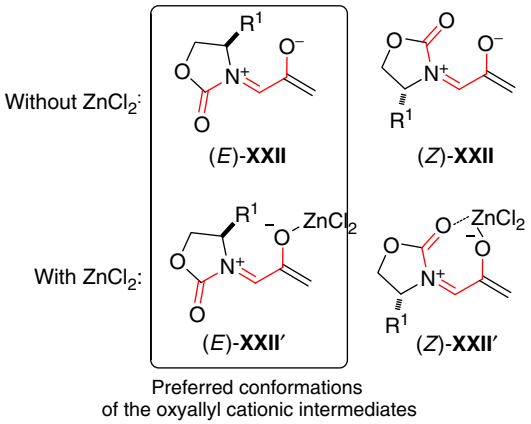

Figure 7 Preferred conformations of the *N*-stabilized oxyallyl species.

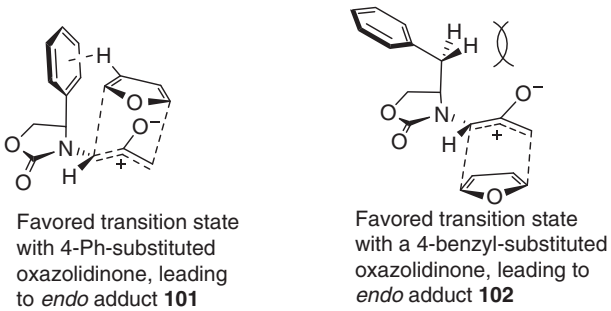
at this position, the stabilizing C–H–π interaction is not viable, so that the stereoselectivity is strictly controlled by steric factors, favoring an approach through the opposite, less crowded face of the oxyallyl cation (Figure 8).



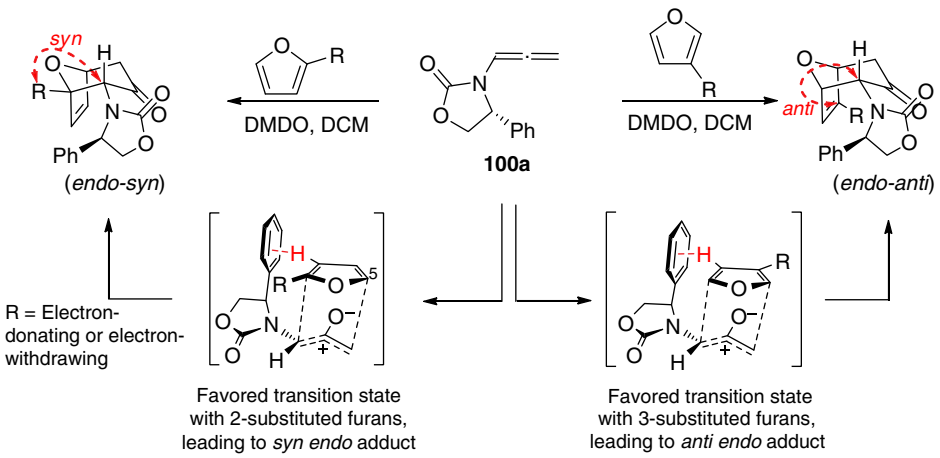


Figure 8 Favored transition states for the formation of products of types **101** and **102**.

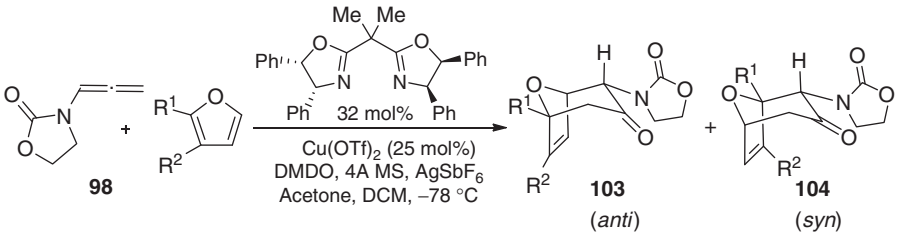
The existence of C–H–π interactions also helps one to understand the regioselectivities of these cycloadditions.[56a] Reactions of **100a** with 2-substituted furans gave *syn* cycloadducts selectively, with the oxazolidinone and furan substituents at the same face of the adduct (Scheme 3). On the contrary, cycloadditions with 3-substituted furans gave selectively *anti* cycloadducts, in which the oxazolidinone and furan substituents are on the opposite sides of the cycloadduct. In both cases, the major diastereoisomer is derived from the addition of the furan to the more crowded face of the oxyallyl, favored by stabilizing C–H–π interactions. When a substituent at the 2-position of the furan is present, the preferred orientation that determines the regiochemistry is that which leads to bond formation between the more nucleophilic CH_2 terminus of the oxyallyl intermediate and the less-substituted carbon (C-5) of the furan (Scheme 3).



Scheme 3

DFT calculations also explained the good regioselectivities observed when achiral oxazolidinones (e.g., **98**) were used, both with 3- and 2-substituted furans.[56c] Like in the asymmetric cases, as a general trend, reactions of allenamide **98** with 3-substituted furans gave predominantly *endo-anti* products, whereas 2-substituted furans, such as 2-methyl furan or 2-furoate, predominantly provided the opposite *endo-syn* cycloadducts.

In an important advance, the same authors have recently disclosed a catalytic and highly enantioselective version of this intermolecular cycloaddition using a chiral Lewis acid derived from $Cu(OTf)_2$ and a chiral C_2 symmetric bisoxazoline ligand (Table 10).[57] This is one of the few reports on catalytic and asymmetric (4 + 3) cycloadditions between allyl cations and dienes (see Sections 5.13.2.2.7 and 5.13.2.5 for other examples).

5.13.2.2.9.2 Intramolecular examples

The group of Hsung has also studied and developed efficient intramolecular versions of these (4 + 3) cycloadditions, which provide synthetically appealing polycyclic systems incorporating seven-membered carbocycles.[58] The authors developed four different strategies depending on the way the carbon chain that holds the diene unit is linked to the allene moiety: (1) to its proximal position (equation 32), (2) to its terminal position, (3) to the oxazolidinone backbone (equation 33), or (4) to the nitrogen atom of the allenamide (equation 34). As can be observed in the corresponding equations, these strategies provided excellent yields and good or very good diastereoselectivities in many cases.

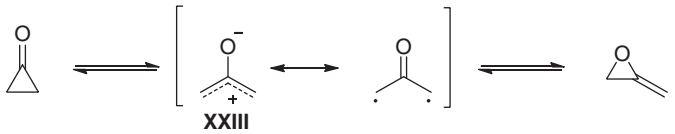
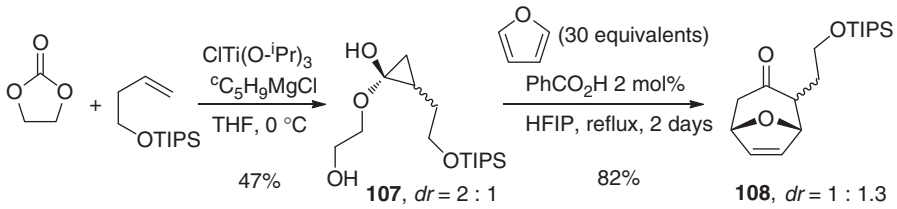
(34)

5.13.2.2.10 Cyclopropanone derivatives

Parent oxyallyl cations like **XXIII** might hypothetically exist in equilibrium with a closed oxidoallene or cyclopropanone form (Figure 9).[59] Therefore, cyclopropanones can be envisioned as potential oxyallyl cation precursors. However, cyclopropanones are not easy to prepare and handle, and therefore have almost not been used as three-carbon precursors for (4 + 3) cycloadditions.[3b]





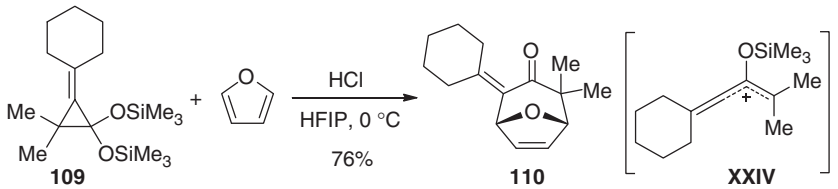


Figure 9 Oxyallyl forms of cyclopropanone.

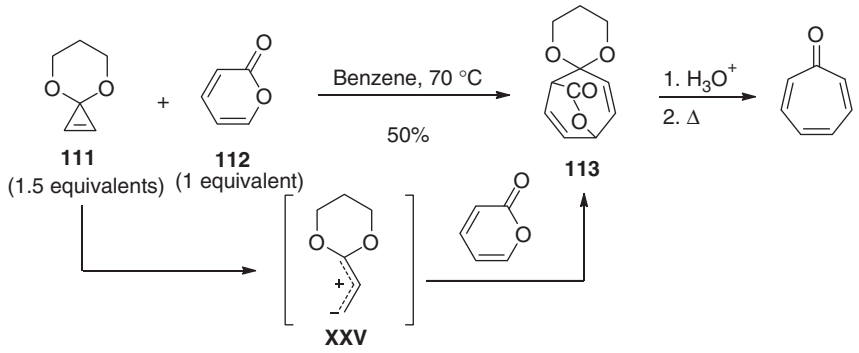
However, some stable derivatives of cyclopropanones, such as their hemiacetals, can be used as oxyallyl cation precursors. For instance, Cha and coworkers reported that hemiacetals of type **107** react with furan (30 equivalents) when treated with a catalytic amount of benzoic acid to give (4 + 3) adducts of type **108** (Scheme 4).[60] The reaction most probably takes place through the *in situ* generation of an oxyallyl cation species. The required hemiacetals (**107**) are synthesized in one step from the corresponding alkenes using a Kulinkovich cyclopropanation.

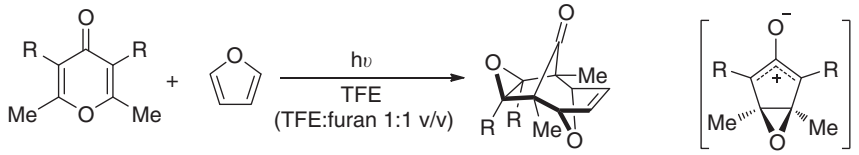
Scheme 4

The group of Fujita has shown that alkylidenecyclopropanone acetals such as **109** react with furan under acidic conditions, to give interesting oxabridged cycloheptenes **110** in good yields.[61] It is quite probable that the reaction involves a silyloxyallyl cation intermediate **XXIV** (equation 35).



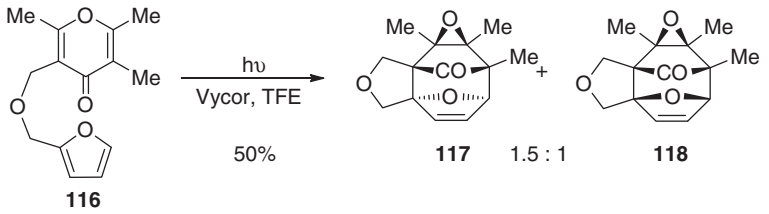
(35)

Finally, it is interesting to note here that cyclopropene acetals like **111** also participate in (4 + 3) cycloaddition with dienes such as **112** to form cycloheptadienes **113**.[62] However, the reaction does not involve the generation of a standard oxyallyl cation, but probably a delocalized singlet vinylcarbene such as **XXV** (Scheme 5).



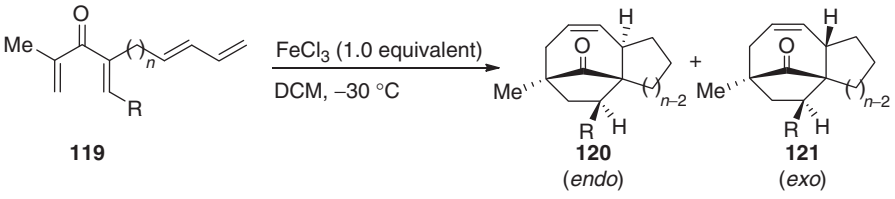
5.13.2.2.11 4-Pyrones

Oxyallyl cation intermediates can also be generated from less obvious precursors, such as 4-pyrones, using photochemical techniques. For instance, Barltrop demonstrated that pyrones **114a** react photochemically with excess furan to provide cyclic cyclooctanoids **115a** with moderate efficiency, which formally results from a (4 + 3) cycloaddition (equation 36).[63] West and coworkers found similar results with tetrasubstituted pyrone **114b**.[64] These results can be explained by assuming the formation of the cyclic oxyallyl cation **XXVI** on irradiation of the pyrone. Unfortunately, the efficiency and scope of the transformation is rather

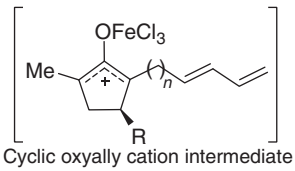


Scheme 5

limited. A related intramolecular version allowed highly functionalized cyclooctanoids (**117** and **118**) to be constructed, although with poor *endo*/*exo* selectivity (1.5:1) and moderate yield (50%) (equation 37).[64]



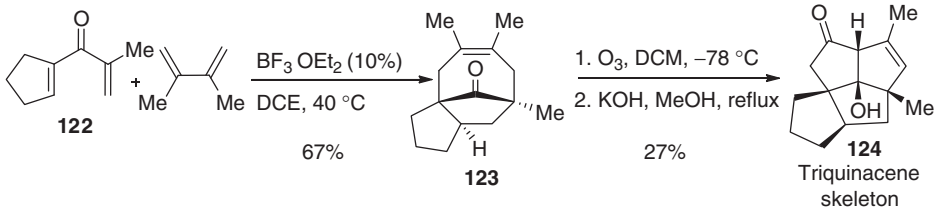
(36)



(37)

5.13.2.2.12 Conjugated dienones

Other nonobvious oxyallyl precursors are cross-conjugated dienones such as **119**, because they can undergo a Nazarov electrocyclization when treated with appropriate Lewis acid activators. The resulting cyclic allyl cations, similar to those previously discussed in Sections 5.13.2.2.2.2 and 5.13.2.2.2.3, can be intramolecularly intercepted by a conjugated diene linked to the α-position of the dienone.[65] Interestingly, the stereocenter generated during the electrocyclization controls the facial selectivity of the subsequent (4 + 3) cycloaddition, with a preferred approach of the diene from the less hindered face of the cyclic oxyallyl cation. The process is efficiently promoted at low temperatures by Lewis acids such as $FeCl_3$, providing keto-bridged cyclooctene derivatives **120** and **121** with moderate-to-high *endo*–*exo* selectivities, depending on the length of the connecting chain (equation 38). Importantly, the authors also demonstrated, in a specific case, that the loading of $FeCl_3$ can be reduced to 0.2 equivalent without affecting the yield or selectivity of the process. Overall, the reaction converts achiral acyclic reactants into tricyclic products by concomitant formation of three new carbon bonds and four stereocenters.



R	*n*	**120** : **121**	yield (%)[a]

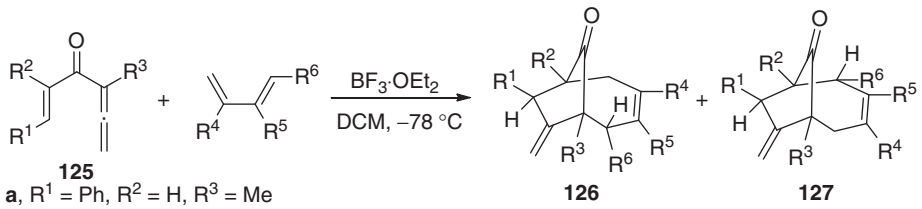
Me	4	0 : 1	67
Ph	4	0 : 1	75

[a]Combined isolated yield. [b]An identical result was obtained using 0.2 equivalent of $FeCl_3$.

(38)



The analogous intermolecular (4 + 3) cycloaddition is also effective with a variety of simple dienones and cyclic or acyclic 1,3-dienes.[66] In these cases, optimal conditions consisted of the use of 2 equivalents of diene and 1 equivalent of $BF_3 \cdot OEt_2$. In some particular cases, however, such as the one shown in Scheme 6, the cycloaddition could be carried out under catalytic conditions, using 0.1 equivalent of $BF_3 \cdot OEt_2$, to give the corresponding cycloadduct in a good 67% yield as a single diastereoisomer. The skeletal and functional richness of this type of bicyclic adducts facilitates their straight transformation into relevant targets such as centro-substituted triquinacene skeletons of type **124** (Scheme 6).[67] The cycloadditions could also be carried out with unsymmetrical 1,3-dienes such as isoprene; however, in these cases, regioisomeric mixtures of products were obtained with a selectivity up to 5:1.

Scheme 6

Quite recently, Burnell and coworkers demonstrated that certain allenyl vinyl ketones of type **125** are also suitable precursors for these Nazarov-interrupted (4 + 3) cycloadditions.[68] In particular, allenyl vinyl ketones **125a–c**, with alkyl substituents at the ketone α position on either the allene or the alkene, react efficiently with 1,3-dienes in the presence of $BF_3 \cdot OEt_2$ to provide the expected (4 + 3) adducts (**126** and/or **127**) with moderate-to-good yields. The best results were achieved with acyclic dienes such as isoprene, *trans*-piperylene, and 2,3-dimethylbutadiene (Table 11). The reactions proceeded with excellent diastereofacial selectivity, complete *exo* selectivity (Table 11, entries 2, 5, and 8) and, in general, with very good regioselectivity. Curiously, electron-rich cyclic dienes such as furan did not provide the expected (4 + 3) adducts, but addition products arising from trapping of the cyclic oxyallyl cation by electrophilic substitution.[68a]

[b]In this case **126** and **127** are the same product.
[c]An additional (3 + 2) cycloadduct was also isolated in 37% yield.

In 1999, Matlin and coworkers described an interesting cycloaddition example also based on a photochemically promoted Nazarov cyclization.[69] Relying on previous work, which had shown that irradiation of *cis,cis*-2,7-cyclooctadienone **128** results in

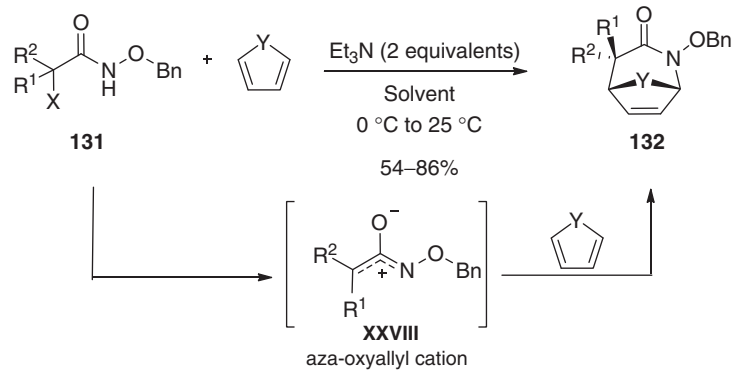
its isomerization to (*Z*,*E*)-2,7,cycloactadienone **129**,[70] these authors demonstrated that this intermediate, which is only stable at temperatures below −70 °C, readily undergoes a conrotatory Nazarov cyclization above −30 °C to give the cyclic cyclopentyl cation **XXVII**. This oxyallyl intermediate – which might be better described as a polarized single diradical according to the author's DFT calculations – reacts *in situ* in a concerted cycloaddition to simple acyclic dienes to give bicyclic products of type **130**. Only two isolated examples of this (4 + 3) cycloaddition were reported (equation 39).

(39)

5.13.2.2.13 α-Halo benzyloxyamides

In this section the authors show the only example so far reported dealing with the generation and (4 + 3) cycloaddition reaction of an aza-oxyallyl cation, a nitrogen analog of standard all-carbon oxyallyl cations. Thus, in 2011, Jeffrey et al. reported the development of an aza-(4 + 3) cycloaddition reaction between cyclic dienes and aza-oxyallyl cations, *in situ* generated from α-haloamides.[71] In this report, the authors demonstrate that, similarly to the base-mediated dehydrohalogenation of α-haloketones (see Section 5.13.2.2.2), the dehydrohalogenation of an *N*-alkoxyhaloamide like **131** affords *aza*-oxyallyl cations (**XXVIII**) which can participate as three-atom components in (4 + 3) cycloadditions with appropriate dienes (i.e., furan or cyclopentadiene). The corresponding (4 + 3) lactam cycloadducts **132** could be isolated in moderate-to-good yields (Table 12). Interestingly, related α-haloamides with alkyl, instead of alkoxy groups at nitrogen, did not afford the desired (4 + 3) adducts, suggesting that the electron-donating group at nitrogen (OBn) is essential for the cycloaddition.

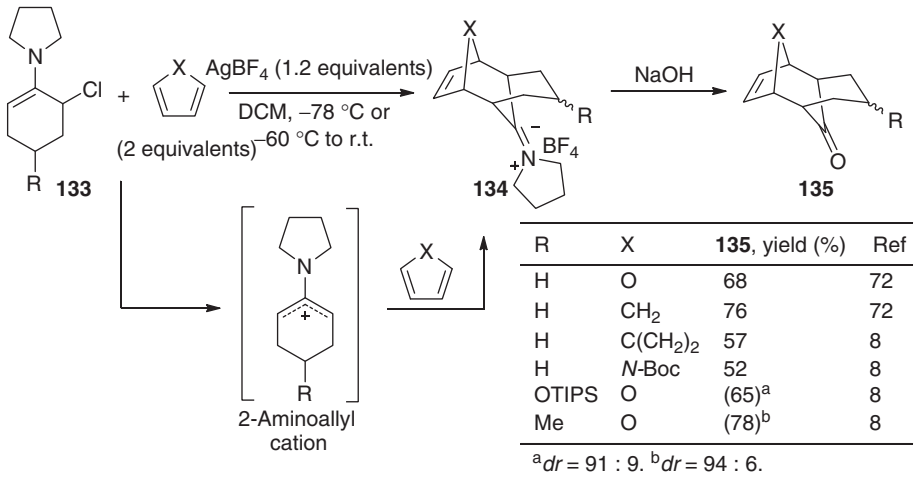
Experimental data and DFT calculations carried out by the same authors support a mechanism consisting of dehydrohalogenation of the α-haloamide to generate the reactive *aza*-oxyallyl cationic intermediate. The requirement of an OR group at nitrogen is also reproduced by the calculations, because it stabilizes the proposed aza-oxyallyl cationic species. Further developments on this approach, including intramolecular versions and asymmetric variants are expected.



5.13.2.3 Reactions Involving 2-Aminoallyl Cation Intermediates

2-Amino-stabilized allyl cations are less common that their oxyallyl counterparts, perhaps because of the difficulties for their generation. In a pioneering work, Schmid demonstrated that cyclic enamines **133** derived from cyclohexanone reacted very efficiently with furan or cyclopentadiene with complete *endo* selectivity, leading to the formation of the cyclic cycloheptanones after hydrolysis (Scheme 7).[72] More recently Cha expanded the scope of this reaction and demonstrated that this methodology is particularly efficient when the cyclohexenyl ring is substituted with alkyl or silyloxy groups, and when *N*-Boc-pyrrole or spirocyclopentadiene are used as diene partners.[8]

α-Haloimines can also work as precursors of amino-allyl cations. In 1997, Kende et al. took advantage of the presence of a chiral center in the α-position of an imine to develop the first asymmetric cycloaddition of 2-aminoallyl cations.[73] Unfortunately, the efficiency and the asymmetric induction achieved with this method were modest (Scheme 8). The authors suggest that the diastereoselectivity could be explained by assuming a preferred reactive conformation of the allyl cation due to the existence of cation/π-interactions with the phenyl ring, forcing the dienes to preferentially attack the less hindered *Re* face.



As might be expected from related reactions with oxidoallenes hypothetically formed in the oxidation of allenamides (see Section 5.13.2.2.9), Lewis acid promoted ring opening of strained alkylideneaziridines generate 2-aminoallyl cations capable of undergoing a standard (4 + 3) cycloaddition with dienes.[74] The authors propose that the intramolecular cycloaddition of substrates **138**, which feature a three-carbon tether, proceed via a compact transition state with the tethering arm orientating itself *anti* to the bulky Lewis acid (U-form of the allyl cation). An extended transition state may prevail in the case of precursor **140**, which has a longer linking tether (Scheme 9). In any case, the authors did not fully rule out other explanations based on mechanistic alternatives.

5.13.2.4 Reactions Involving (Trimethylsilyl)methyl Allyl Cation Intermediates

Although allyl cations, which feature oxygen or nitrogen groups at the C-2 position (oxyallyl and aminoallyl cations, see Sections 5.13.2.2 and 5.13.2.3), are the most common three-carbon reactants in thermal (4 + 3) cycloadditions, there are other interesting alternatives that do not incorporate a heteroatom at the central position of the allylic system. In particular, a variety of cycloaddition strategies relying on the generation of 2-(trimethylsilyl)methyl allyl cationic intermediates have been developed (Scheme 10).[75] Importantly, the seven-membered carbocycles resulting from these (4 + 3) cycloadditions contain an *exo* methylene carbon substituent, which is an attractive functionality for further synthetic manipulations.

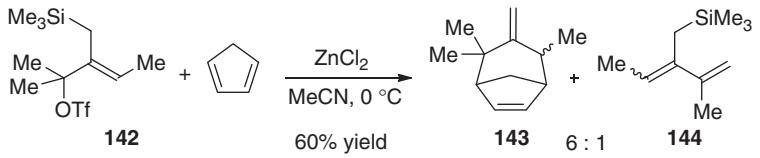
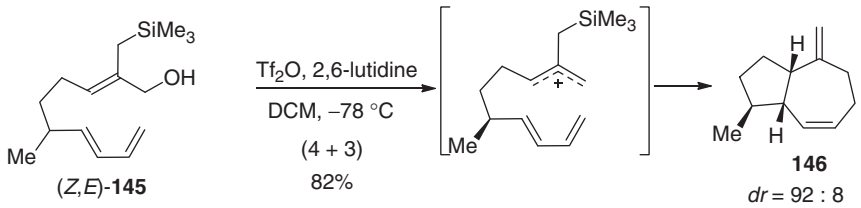
Scheme 8

Scheme 9



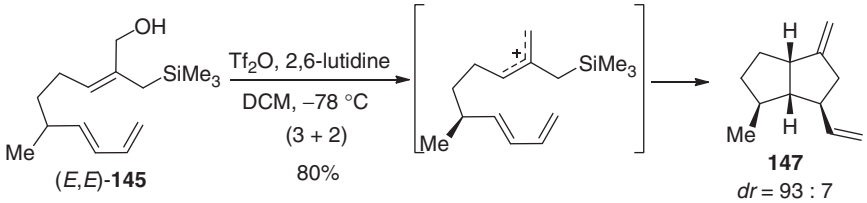
Scheme 10

5.13.2.4.1 (Trimethylsilyl)methyl allyl alcohols and acetates



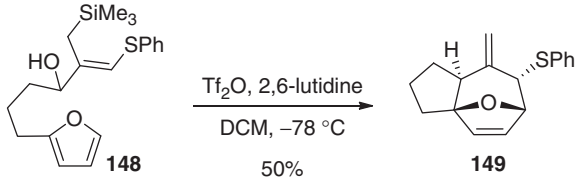
At the beginning of the 1980s, Hoffmann and coworkers reported pioneering examples of inter- and intramolecular (4 + 3) cycloadditions of (trimethylsilyl)methyl allyl trifluoroacetates such as **142** with dienes (i.e., cyclopentadiene or furan). It is proposed that these precursors are readily converted to the reactive (trimethylsilyl)methyl allyl cations on treatment with an

appropriate ionization promoter ($ZnCl_2$ or $TiCl_4$/PhNHMe, equation 40).[76] Despite the novelty of the approach, its versatility and efficiency were not that good.

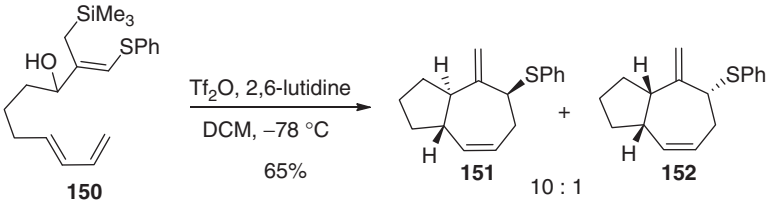


(40)

A few years later, Giguere and coworkers made an additional seminal contribution to this area by establishing more effective conditions to promote direct intramolecular cycloadditions between (trimethylsilyl)methyl allyl alcohols (the triflate is formed *in situ*) and acyclic dienes (equation 41).[77] Moreover, these authors established a relationship between the configuration of the allyl cation precursor and the chemoselectivity of the process. Thus, the reaction of alcohol (*Z*,*E*)-**145**, in the presence of triflic anhydride and 2,6-lutidine at -78 °C afforded the (4 + 3) cycloadduct **146** in 82% yield in a regio- and stereoselective manner. On the contrary, reaction of the configurational isomer (*E*,*E*)-**145** under the same conditions provided the (3 + 2) cyclopentyl adduct **147** in 80% yield (equations 41 and 42). These results suggest that the configuration of the allyl cation played an essential role in the selectivity of the process, and that the relative rate of seven-membered ring closure versus allyl silane rotation determines which cycloadduct is obtained.



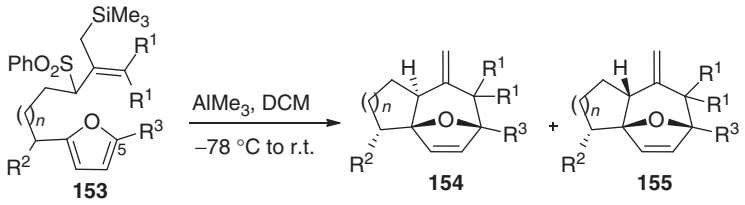
(41)



(42)

More recently, in 2001, Harmata and coworkers studied the reactions of (trimethylsilyl)methyl-substituted vinylthionium ions, which are generated *in situ* from appropriately substituted allyl alcohols.[78] Thus, treatment of **148** with Tf_2O and 2,6-lutidine at -78 °C afforded the corresponding cycloadduct **149** in 50% yield as a single diastereoisomer. The related cycloaddition of **150**, which incorporates an acyclic diene instead of the furan, afforded a 10:1 mixture of the diastereoisomers **151** and **152** in a combined 65% yield (equations 43 and 44).

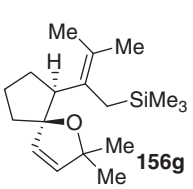
(43)



(44)

5.13.2.4.2 (Trimethylsilyl)methyl allyl sulfones

In consonance with the work carried out using alkoxyallyl sulfones (see Section 5.13.2.2.4), Harmata and coworkers also studied the use of the trimethylsilylmethyl group instead of the alkoxy substituent as terminator of the (4 + 3) cycloaddition.



Cycloaddition precursors such as **153** can be prepared from readily accessible sulfonyl allenes in a few steps. Importantly, the cycloaddition of **153a** proceeded efficiently on treatment with $AlMe_3$ in CH_2Cl_2 at room temperature to give a 1.7:1 mixture of the (4 + 3) cycloadducts **154a** and **155a** in a combined 71% yield (Table 13, entry 1). Therefore, there is a substantial improvement with respect to the same reaction from secondary alkoxyallyl sulfones which afforded poorer results.[75] As can be seen in Table 13, the method worked well for a broad range of substrates and, in some cases, high diastereoselectivities could be obtained.[79] Also relevant, a high degree of relative facial stereocontrol could be achieved with substrates such as **153e** equipped with stereocenters in the tether, although the *endo*/*exo* selectivity is low (Table 13, entry 5). This might arise by coordination of trimethyl aluminum to the furan; which forces the methyl group away from the oxygen to avoid steric repulsions. This induced-conformational bias has no effect on the *endo*/*exo* selectivity. Limitations of the methodology are the requirement of a cyclic diene as four-carbon partner (simple butadienes do not trap the allylic intermediate). Moreover, furans incorporating substituents at their C-5 position ($R^3 \neq H$) cannot be used. In these cases, alternative cyclization products derived from a stepwise interception of the allyl cation were detected (**156g** and **157h**) (Table 13, entries 7 and 8).

5.13.2.4.3 (Trimethylsilyl)methyl allyl acetals

The group of Harmata has also studied the use of 2-trimethylsilylmethyl substituted allyl acetals as precursors of active allyl cations. In 1997, these authors demonstrated that allyl acetals **158** could undergo intermolecular (4 + 3) cycloadditions with furan or cyclopentadiene in moderate-to-good yields when treated with suitable Lewis acids.[33b] Among the different promoters studied, $TiCl_4$, in CH_2Cl_2 at −78 °C, provided the best results (equation 45). The reactions exhibit high diastereoselectivity to give products arising from a preferred *endo* approach of the diene to the putative oxocarbenium ion intermediate.

(45)

Importantly, the use of chiral allyl acetals enabled the development of asymmetric transformations. As an example, the reaction of allylic acetal **160** with furan in nitroethane, in the presence of stoichiometric amounts of $TiCl_4$, gave rise to the (4 + 3) cycloadducts **161** and **162** in good yield and with excellent diastereoselectivity (**161**:**162** = 17.3:1). When cyclopentadiene was used as diene, the diastereoselectivity dropped significantly (equation 46).[80] Importantly, the reaction of chiral dioxolanes such as **163** can also be induced using catalytic amounts of the Lewis acid, affording good yields of cycloadducts **164** and **165** and high diastereoselectivities[81] (equation 47).

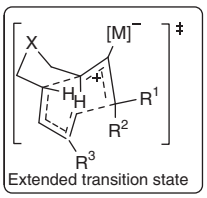
(47)

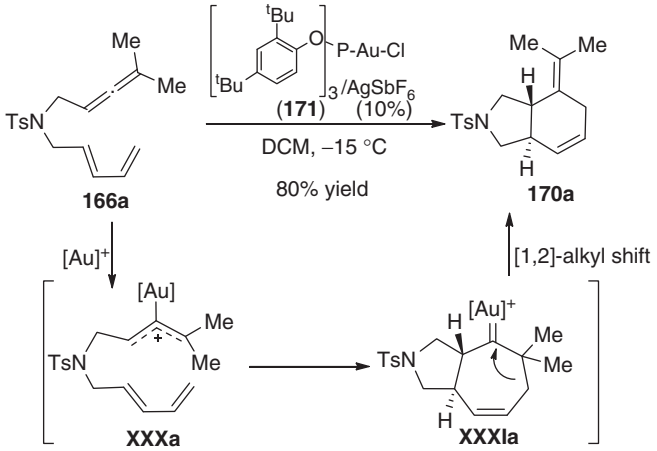
5.13.2.5 Reactions Involving Metal-allyl Cation Intermediates

In recent years, platinum and, particularly, gold complexes have emerged as excellent catalysts for promoting novel types of cycloaddition reactions, usually involving nonactivated C–C unsaturated systems (e.g., alkynes, allenes, alkenes, or 1,3-dienes).[82] The excellent reactivity of these group 11 catalysts can in part be explained in terms of relativistic effects,[83] which confer singular characteristics, like a high carbophilicity (affinity for C–C π-unsaturated systems) and a low propensity to participate in typical redox processes characteristic of other transition metal catalytic cycles. In this context, several research groups have demonstrated that some of the metal intermediates arising from the activation of designed unsaturated compounds can participate in cycloaddition reactions. In this section, metal-catalyzed (4 + 3) cycloadditions suggested to involve metal-allyl cation intermediates are discussed.



Based on several reports demonstrating the ability of gold(I) and platinum(II) catalysts to induce reactions of allenes through allyl cationic intermediates, Mascareñas and coworkers investigated the possibility of using allenes as allyl cation surrogates, so that they could participate in [4C(4π)–3C(2π)] cycloadditions with conjugated dienes. Initially, it was found that $PtCl_2$ was an excellent catalyst for promoting these intramolecular (4 + 3) cycloadditions of allenedienes **166** (equation 48).[84] DFT calculations as well as experimental data agreed with a mechanistic pathway based on the metal activation of the allene to afford a metal-allyl cation intermediate of type **XXX**, which subsequently undergoes a concerted (4 + 3) cycloaddition reaction with the diene moiety.

Finally, the resulting metal carbene species (**XXXI**) evolves through a 1,2-hydrogen shift, leading to seven-membered carbocycles of type **167** and regenerating the catalyst ($PtCl_2$). DFT calculations also suggested that gold catalysts should equally work and be even more active than $PtCl_2$. Accordingly, the use of a cationic Au^I catalyst containing a σ-donating *N*-heterocyclic carbene ligand (**168**/$AgSbF_6$, equation 48) allowed these reactions to be performed at lower temperatures than with $PtCl_2$, which increased the scope and synthetic utility of the process.[85] As in other cases of intramolecular allyl cation/diene cycloadditions, the reactions are completely *exo*-selective. The groups of Toste and Gung also demonstrated that other gold(I) complexes, for example, complexes containing a highly donating biaryl di-*tert*-butylphosphine ligand (**169**), are also effective for these cycloadditions.[86] In general, the reactions tolerate a wide variety of substituents in the allene and the diene, providing the corresponding bicyclo[5.3.0]decane systems in good yields (equation 48).



R^1	R^2	R^3	[M]	T (°C)	Yield (%)	Ref
Me	Me	H	$PtCl_2$	110	92	85

$-(CH_2)_5-$		H	**169**	r.t.	81	87a

X = $C(CO_2R)_2$

(48)

Curiously, allenediene, when disubstituted at the distal position of the allene as in **166a**, on treatment with a gold(I) catalyst bearing a π-acceptor ligand such as a triarylphosphite, give rise to (4 + 2) cycloaddition products **170a** instead of the (4 + 3) adducts (equation 49).[85,86a,87] Several experimental data as well as theoretical calculations suggest that the observed cyclohexene cycloadducts **170** are indeed the result of a ring contraction event (1,2-alkyl shift) in the initially formed cycloheptenyl gold carbene intermediate **XXXIa**, that results from the (4 + 3) cycloaddition pathway (equation 49). Thus, the ligand at gold determines the fate of this carbenoid intermediate to give either the (4 + 3) or the (4 + 2) adducts.

(49)

Mascareñas and López have also discovered that it is possible to achieve these allene–diene cycloadditions in a highly enantioselective manner using gold complexes with chiral phosphoramidite ligands, in particular **172**, bearing anthracenyl substituents at the 3- and 3′-positions of the binaphthol moiety (Figure 10). The (4 + 3) or (4 + 2) fate of the reactions is mainly determined by the substitution pattern of the allene (Table 14), and hence in some cases it is possible to obtain the

bicyclo[5.3.0]decane systems with very high *ee*'s (Table 14, entries 2–6).[87,88] The groups of Toste and of Fürstner independently reported related phosphoramidite–gold complexes, as well as the chiral phosphite gold catalyst **175**, which are also capable of inducing excellent enantioselectivities in intramolecular (4 + 2) allene diene cycloadditions (Table 14, entries 7–9).[89]

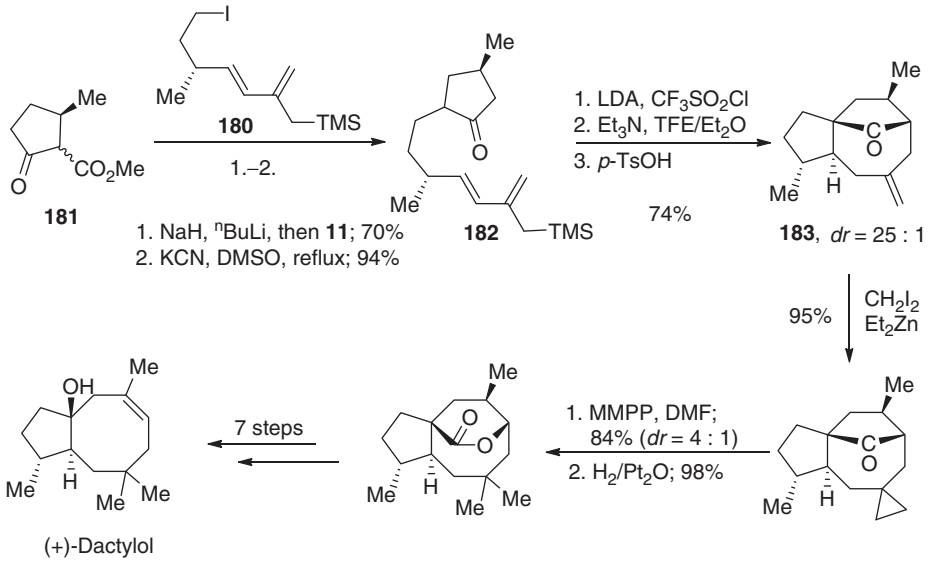
5.13.2.6 Synthetic Applications of (4 + 3) Cycloadditions of Allyl Cations

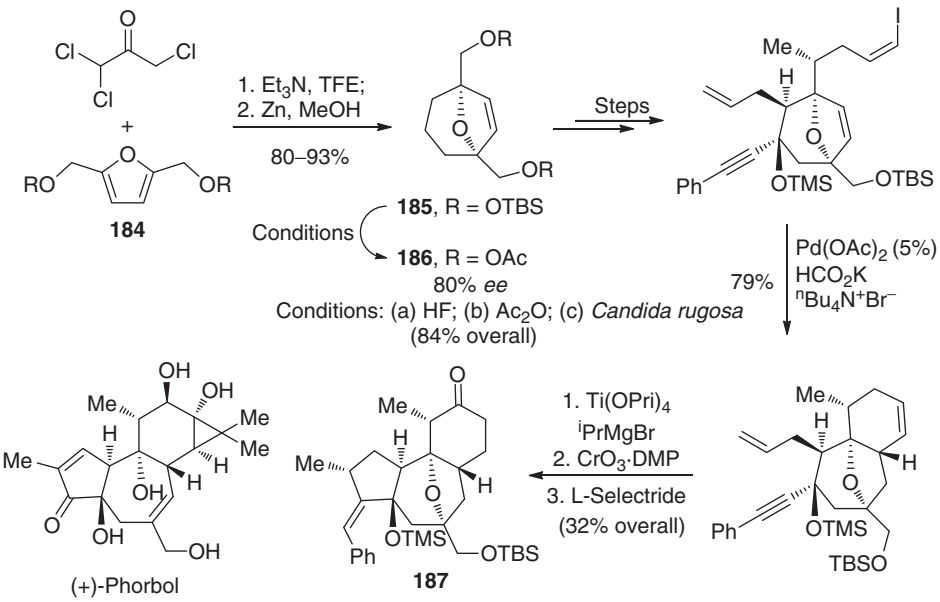
Some of the (4 + 3) cycloaddition approaches described above have been successfully applied to the total synthesis of cyclic natural products featuring cycloheptane rings, and in other cases to the partial assembly of their basic cyclic cores. In 1995, Cha and coworkers published the enantioselective synthesis of (+)-*cis*-lauthisan from oxabicycle **176**.[90] This compound was prepared using a (4 + 3) cycloaddition of 2-chlorocyclohexanone and furan under Föhlisch conditions as the key step. The same compound could also be efficiently prepared from a Schmid (4 + 3) cycloaddition of the 3-chloro-2-pyrrolidinocyclohexene and furan. The enantioselectivity was introduced using an enzyme-catalyzed acetylation of the *meso* intermediate **177** (Scheme 11).

Scheme 11



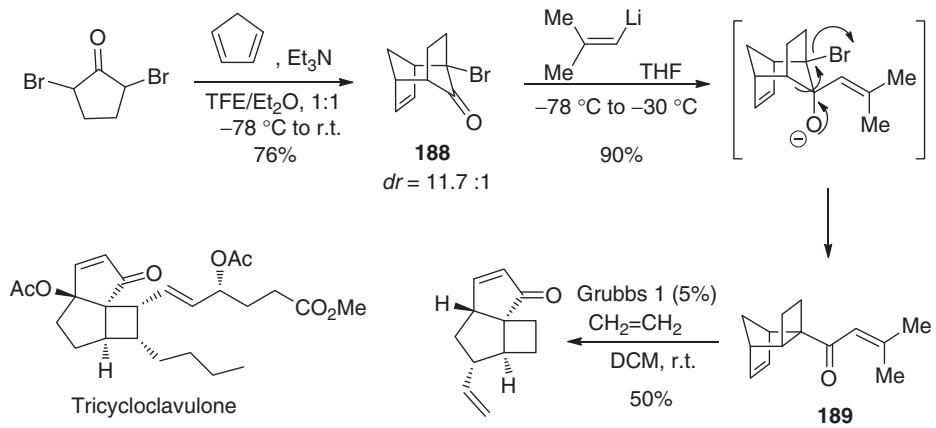
In 1997, Harmata et al. described the total synthesis of racemic aphanamol I, using as the key step an intramolecular (4 + 3) cycloaddition of the 2-ethoxyallyl alcohol precursor **179**, which was synthetized from readily available aldehyde **178** relying on phosphorous chemistry to construct the double bonds. Although the cycloaddition reaction is low yielding, it establishes the core of the molecule in a single step, and therefore allows for a short synthetic approach (Scheme 12).[91]

Scheme 12



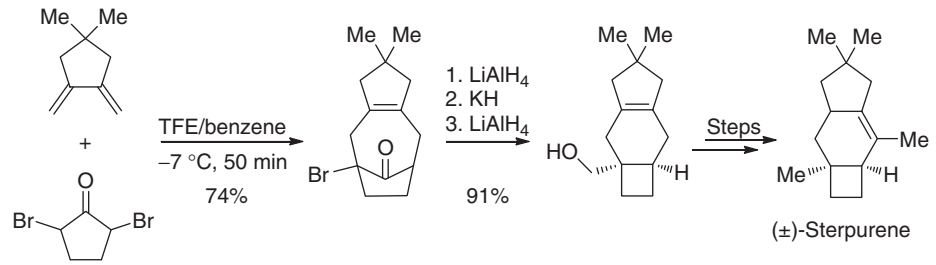
In 2000, the group of Harmata reported another interesting example of a synthetic application of a (4 + 3) intramolecular cycloaddition via allyl cation intermediates in the synthesis of (+)-dactylol.[92] In this case the reactive oxyallyl cation is embedded

in a cyclopentane ring, so that the cycloaddition is indirectly producing a cyclooctanic system. The process started by alkylation of the dianion of the ketoester **181**, prepared in a straightforward fashion from (*R*)-pulegone, with iododiene **180**, followed by decarboxylation using the Krapcho procedure (Scheme 13). Chlorination of **182**, followed by treatment of the resulting chloroketone with triethylamine and work up with *p*-TsOH afforded the tricyclic cycloadduct **183** with excellent diastereocontrol and 74% yield. Simmons–Smith cyclopropanation reaction followed by a Baeyer–Villiger oxidation with magnesium bis(monoperoxyphthalate (MMPP) afforded a 4:1 mixture of two regioisomeric compounds, the major isomer being that which resulted from migration of the less substituted carbon atom. Hydrogenative cleavage of the cyclopropyl ring to establish the required skeleton followed by several functional group transformations yielded enantiomerically pure (+)-dactylol (Scheme 13).



Scheme 13

In 1999, Cha and coworkers demonstrated that the intermolecular (4 + 3) cycloaddition of 1,1,3-trichloropropan-2-one to the symmetrical furan **184**, followed by dehalogenation, generates the oxabicycle **185**, which constitutes the central seven-membered ring of (+)-phorbol.[93] The other two rings were installed in consecutive reactions through a palladium-catalyzed intramolecular Heck reaction and a $Ti(OPr^i)_4$-promoted cyclization (Scheme 14). Straightforward manipulations then led to the formation of compound **187**, a known intermediate in the synthesis of (+)-phorbol previously reported by Wender.

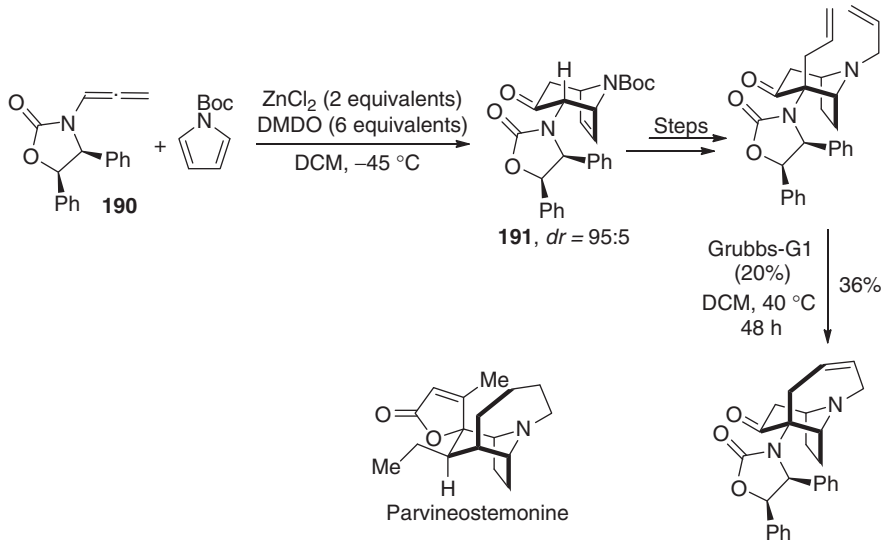


Scheme 14

An interesting protocol based on a (4 + 3) cycloaddition of cyclic oxyallyl cations precursors followed by a Favorskii rearrangement has been successfully used by Harmata for the synthesis of target-relevant fused cyclobutanic derivatives. Thus the (4 + 3) cycloaddition of 2,5-dibromocyclopentanone and cyclopentadiene gives the cycloadduct **188** in 76% yield and with high diastereoselectivity.[94] Addition of (2-methylprop-1-en-1-yl)lithium generates an alkoxide which undergoes a quasiFavorskii rearrangement to give the cyclobutane product **189**. Subsequent ring closing metathesis generates the basic tricyclic core of tricycloclavulone (Scheme 15). The same strategy of a tandem cycloaddition–quasiFavorskii rearrangement was used to synthesize the tricyclic natural product (±)-sterpurene (Scheme 16).[95]

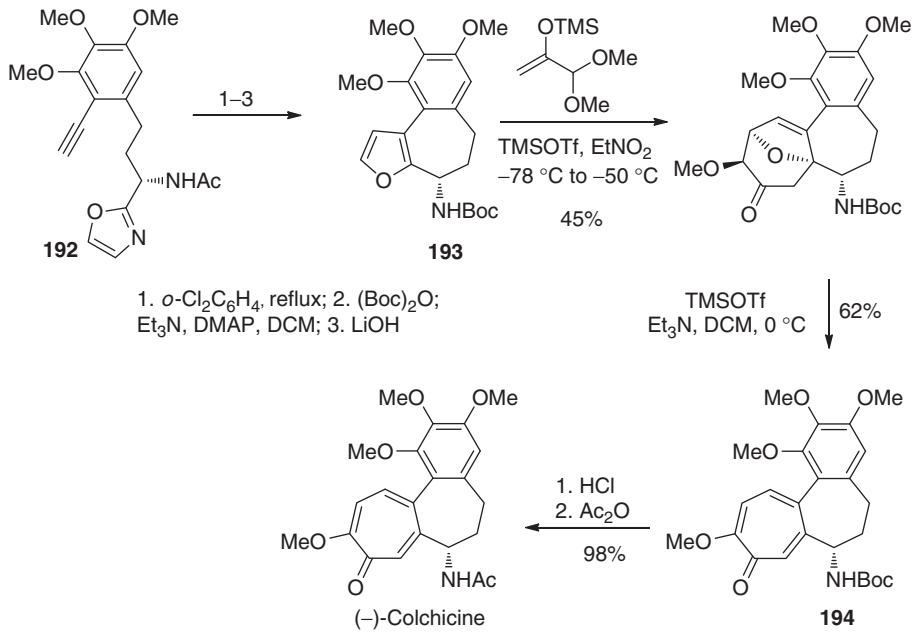
Scheme 15

Scheme 16



Hsung and coworkers have successfully used their allenamide (4 + 3) cycloaddition methodology in the synthesis of the sketetal core of parvineostemonine. The key step of the process is a (4 + 3) annulation between the allenamide **190** and a *N*-Boc-protected pyrrole, which takes place with good yields and excellent diastereoselectivity. The other ring of the natural product was installed by means of a ring closing metathesis with the first generation Grubbs catalyst (Scheme 17).[55]

Another interesting synthetic application of (4 + 3) cycloadditions involving oxyallyl cations was reported by Cha in the context of a total synthesis of alkaloids such as colchicine.[38] In this case the four-carbon cycloaddition component is a furan embedded into a tricyclic system (**193**), which itself is prepared by thermolysis of compound **192**, whereas 3,3-((dimethoxyprop-1-en-2-yl)oxy)trimethylsilane was used as the oxyallyl precursor. The diastereoselectivity derives from the dienophile approaching from the less hindered face of the furan in a 'compact' mode. Double elimination to the tropone **194** and final Boc deprotection and acetylation generated (–)-colchichine with ~90% *ee* (Scheme 18).[38a] A related methodology has been used by the same group for the synthesis of the isoquinoline alkaloids imerubrine, grandirubrine, and isoimerubrine.[38b]

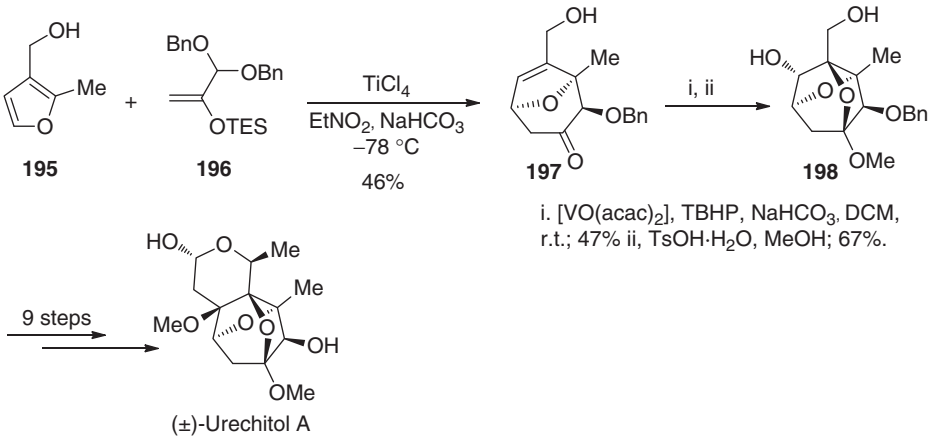


A Lewis acid-promoted cycloaddition of the oxyallyl cation precursor **196** and furan **195** was used by Watanabe et al. to synthetize the oxabridged cycloheptane derivative (±)-urechitol A in racemic form (Scheme 19).[40] The oxafunctionalization of the cycloheptane adduct resulting from the cycloaddition is well poised to ensemble the required cycloheptyl system of urechitol in just two steps, consisting of a Sharpless epoxidation and a methanol-assisted intramolecular epoxide opening. The product **198** was converted to the natural product in nine steps (Scheme 19). Thus the synthesis of racemic urechitol A was eventually achieved in 12 steps with an overall yield of 2.3%

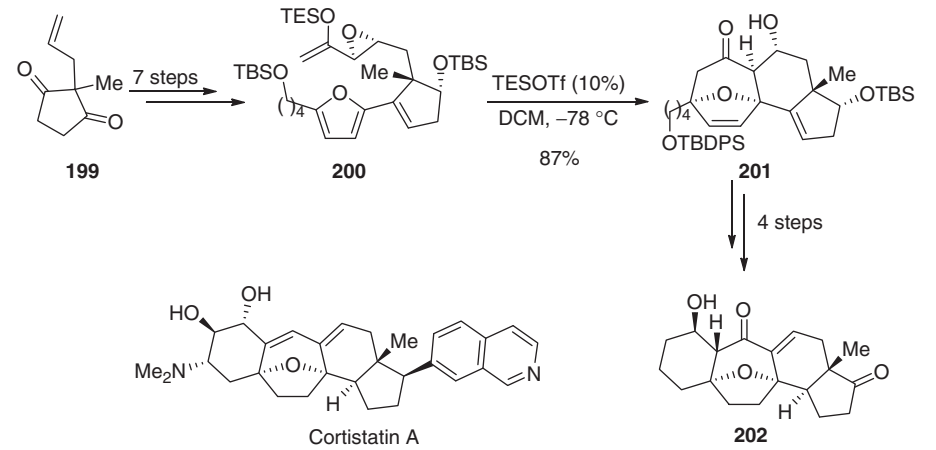
Recently, several allyl cation-based approaches have been reported to streamline the synthesis of the antitumoral polycyclic products of the cortistatin family. Chiu and coworkers accomplished an asymmetric synthesis of the pentacyclic core of this molecule (**202**) using a highly efficient and diastereoselective intramolecular (4 + 3) cycloaddition of the enantiopure epoxy enol silane **200** as the key step (see Section 5.13.2.2.5), which was prepared in seven steps from cyclopentadienone **199** (Scheme 20).[29]

Finally, very recently Funk et al. reported a 20-step total synthesis of (±)-cortistatin J involving an intramolecular (4 + 3) cycloaddition between a disubstituted furan and a (*Z*)-2-(trialkylsilyloxy)-2-enal as the key transformation. The reaction takes

Scheme 17

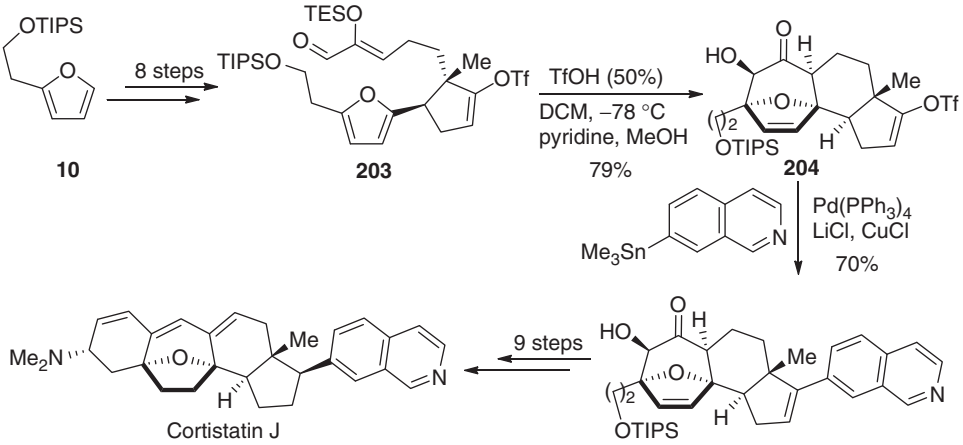


Scheme 18



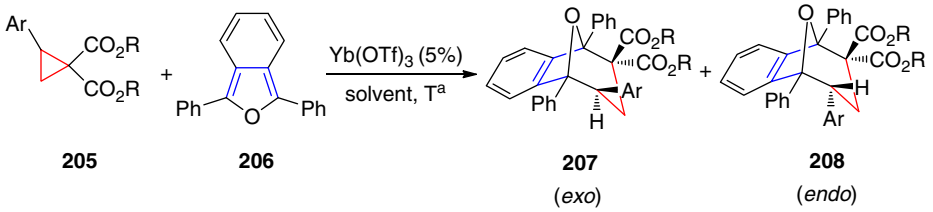
place in good yield and with total diastereoselectivity, forming four new stereocenters of the tetracyclic compound **204**, which is very similar to the compound **201** prepared by Chiu (Scheme 20) in racemic form (Scheme 21).[46]

5.13.3 (4 + 3) Cycloadditions of Donor–Acceptor Strained Cycles



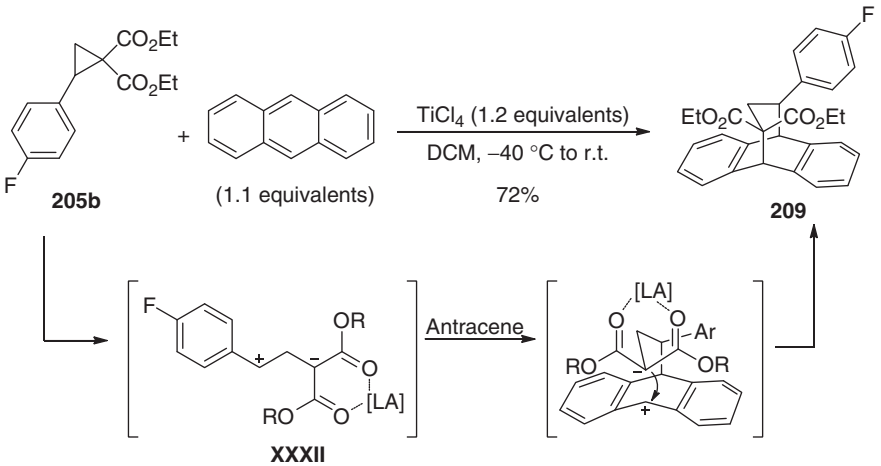
The presence of both electron-donating and electron-withdrawing substituents on a cyclopropanic ring favors ring opening to generate 1,3-carbon dipoles capable of engaging in cycloaddition reactions. In this context, Ivanova et al. have shown that 2-aryl-1,1-cyclopropanic diesters such as **205** react, on simple thermolysis, with specific dienes such as 1,3-diphenylisobenzofuran **206** to give oxabridged cycloheptanes **207** and **208** derived from a formal (4 + 3) cycloaddition.[96] This reaction provides good yields of the corresponding products, but poor *endo*:*exo* selectivities, and is restricted to cyclopropanes bearing appropriate functionalities that stabilizes the putative dipole intermediate (Table 15).

Scheme 19



Scheme 20

Scheme 21



This type of 2-aryl-1,1-cyclopropane diesters also react with anthracene on treatment with a Lewis acid catalyst to give (4 + 3) adducts **209**.[97] In this case it is proposed that the reaction proceeds in a stepwise manner, consisting of initial ring opening of the cyclopropane to form a 1,3-zwitterionic species **XXXII**, followed by nucleophilic attack of the anthracene and ring closure (equation 50).

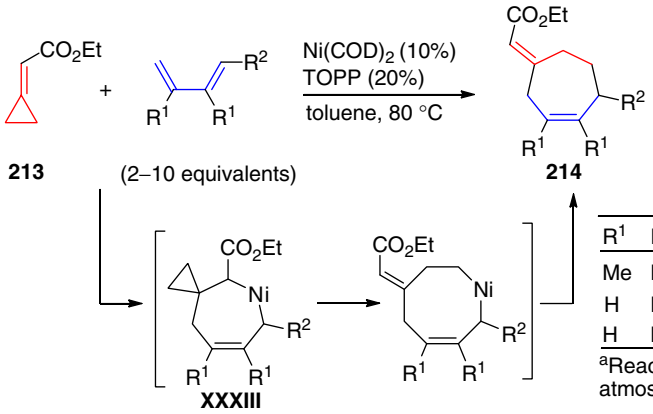
(50)

Donor–acceptor (DA) cyclobutanes share with cyclopropanes also a high degree of strain and can therefore undergo ring-opening processes to give 1,4-carbon dipolar type of synthons. In this context, Pagenkopf demonstrated that DA-cyclobutanes like **210** participate as four-carbon components in (4 + 3) cycloadditions to nitrones (**211**), when treated with $Yb(OTf)_3$.[98] The reaction allowed structurally unique oxazepines (**212**) to be assembled in moderate-to-high yield, tolerating a wide range of nitrones. An example is shown in equation 51.



(51)

5.13.4 (4 + 3) Cycloadditions Involving Metallacyclic Intermediates

The standard mechanism of many metal-catalyzed cycloadditions of unsaturated substrates involves the formation of metallacyclic intermediates that evolve to the final cycloadduct by reductive elimination of the metal catalyst. One can envision a similar type of mechanism for achieving (4 + 3) annulations, provided suitable three-atom reaction partners are found.

Alkylidenecyclopropanes, owing to the simultaneous presence of a metal coordinating position (the double bond) and a strained ring, have been shown to work as three-carbon synthons in different types of metal-promoted (3 + 2) intermolecular and intramolecular cycloadditions to alkenes and alkynes.[99] In 2007, Saito et al. demonstrated that ethyl cyclopropylideneacetate is able to react with 1,3-dienes in presence of catalytic amounts of $Ni(COD)_2$ and tri-*o*-biphenylyl phosphate (TOPP) to give formal (4 + 3) cycloaddition products.[100] The reaction provides moderate yields of the resulting adducts and requires a controlled slow addition of both substrates to the reaction medium. The proposed mechanism involves the initial formation of a Ni–butadiene complex, followed by insertion of **213** to generate a seven-membered nickelacycle **XXXIII**. A cyclopropylmethyl-butenyl rearrangement of this intermediate followed by reductive elimination generates the observed cycloheptenyl products **214** (equation 52).

(52)

Alkylidenecyclopropanes can also engage in intramolecular cycloadditions to dienes in the presence of Pd catalysts, as demonstrated by Mascareñas and coworkers.[101] The cycloaddition of substrates **215** provides better results with dienes bearing EWGs at their terminal position (R^3 = EWG, **Table 16**). In some cases, the formation of small proportions of five-membered adducts, resulting from a competitive (3 + 2) cycloaddition between the alkylidenecyclopropane and the internal double bond of

the diene, is also observed (Table 16). Preliminary studies on the development of an asymmetric version of this reaction using chiral phosphoramidite ligand **217** led to the isolation of the (4 + 3) adducts in 45–64% *ee*. Mechanistically, it has been proposed that the reaction might proceed by initial formation of palladacycles **XXXIV**, which undergo a σ–π rearrangement to palladacyclooctenes followed by reductive elimination. Reductive elimination from **XXXIV** would explain the formation of the (3 + 2)-cyclopentanic side products.[102]

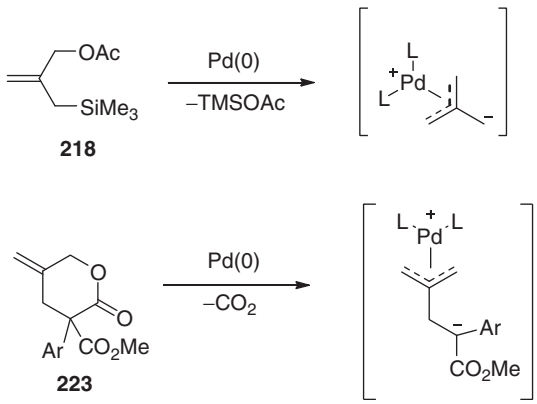
5.13.5 (4 + 3) Cycloadditions via Pd–TMM and Related Species

Pd–TMM complexes have been proposed as intermediates in a variety of (3 + 2) cycloaddition reactions leading to five-membered rings.[103] Examples on the utilization of Pd–TMM complexes in (4 + 3) cycloaddition reactions with dienes are much scarcer, and restricted to dienes blocked in a *cisoid* conformation and featuring electron-withdrawing substitutents.[103] In particular, Trost et al. have shown that treatment of 3-acetoxy-2-trimethylsilylmethyl-1-propene (**218**) with a Pd(0) catalyst in the presence of excess diene **219** generates the cycloadduct **220** in good yield. Formation of five-membered ring products in addition to the seven-membered adducts is taken as evidence for a stepwise process, as outlined in equation 53.[104] Similarly, conjugated imines (**221**) also participate in the (4 + 3) cycloaddition to give the corresponding azepines (**222**), although this reaction is only efficient when the competitive (3 + 2) cycloaddition to the alkene is clearly disfavored (equation 54).[105]

(53)

(54)

Recently it has been shown that γ-methylidene-δ-valerolactones (**223**) react with Pd(0)-complexes to generate zwitterionic species related to the Pd–TMM, but with one additional carbon atom (Figure 11).



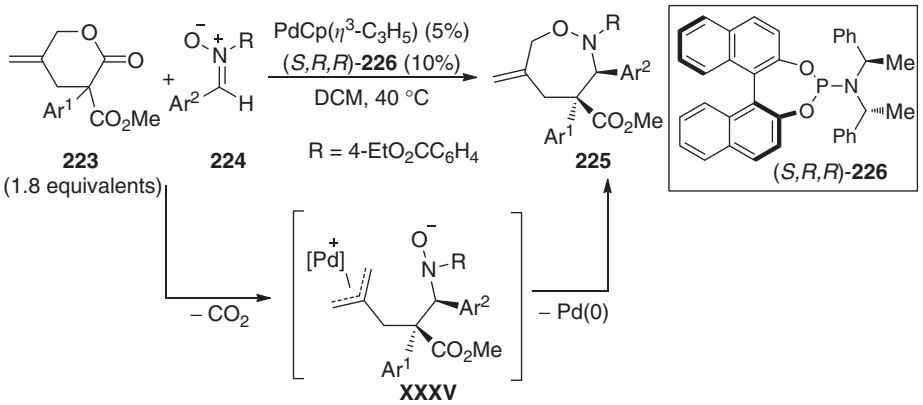


Figure 11 Zwitterionic species related to Pd–TMM from γ-methylidene-δ-valerolactones.

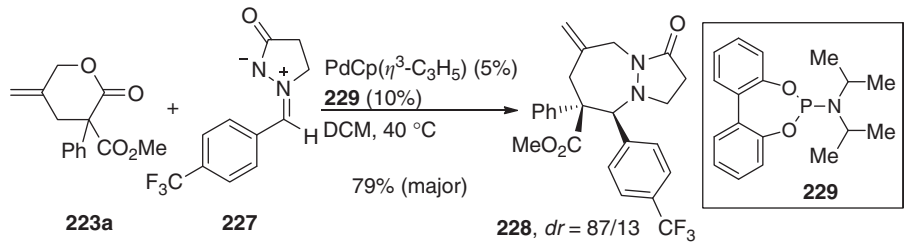
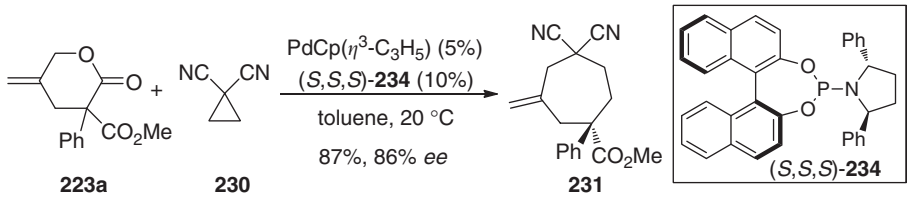


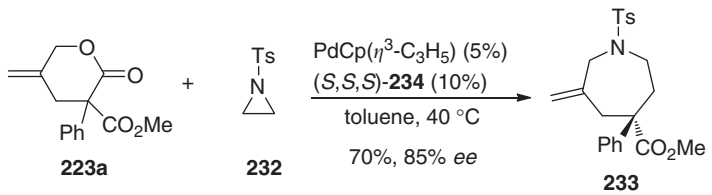
Interestingly, Hayashi and Shintani demonstrated that these precursors can behave as four-carbon components in palladium-catalyzed (4 + 3) cycloaddition with aromatic nitrones of type **224**. The reactions produce 1,2-oxazepines such as **225** in

good-to-excellent yields and with moderate-to-good diastereoselectivities. Moreover, good-to-excellent enantioselectivities could be obtained with the chiral phosphoramidite ligand (*S,R,R*)-**226**. Electron-deficient, heteroaromatic, and naphthyl valerolactones are tolerated as well as different types of aryl-substituted nitrones (Table 17). The reaction was suggested to proceed in a stepwise fashion through intermediate **XXXV**. The same palladium-catalyzed decarboxylative (4 + 3) cycloaddition was also achieved in good yield and moderate selectivity using azomethine imines such as **227** as coupling partners instead of nitrones (equation 55).[106]

Table 17 (4 + 3) Cycloadditions of γ-methylidene-δ-valerolactones with nitrones



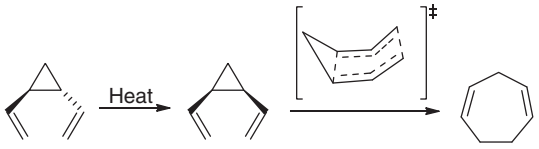
Numbers	***223***	*Ar*^{1}	*Ar*^{2}	*Yield (%)*	dr	ee *(%)*
1	**223a**	Ph	4-$CF_3C_6H_4$	98	81:19	83
2	**223b**	1-Napthtyl	4-$CF_3C_6H_4$	98	80:20	96
3	**223b**	1-Napthtyl	4-MeC_6H_4	99	70:30	89



(55)

This type of γ-methylidene-δ-valerolactones **223** can also react with 1,1-dicyanocyclopropane (**230**) or *N*-tosyl aziridines (**232**) to give seven-membered ring products resulting from (4 + 3) cycloadditions. The use of a chiral phosphoramidite ligand such as (*S,S,S*)-**234**, in combination with a Pd(0) source, allowed reasonably good enantioselectivities to be obtained in these processes (equations 56 and 57).[107]

(56)

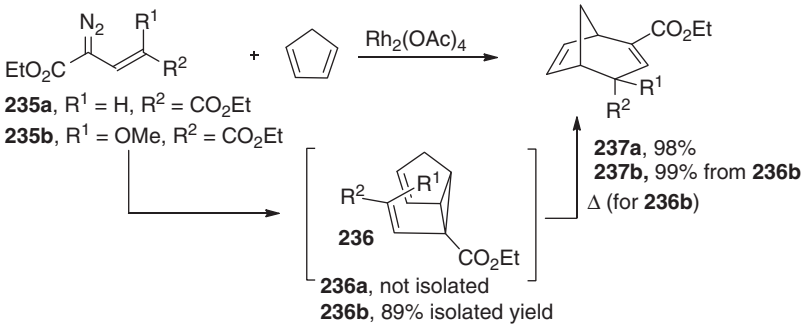


(57)

5.13.6 'Formal' (4 + 3) Cycloadditions Involving Sequential Processes

In the previous sections different types of pericylic and 'formal' (4 + 3) cycloadditions that take place in one or several steps, and involve the temporary formation of highly reactive intermediates are discussed. Now alternative annulation methodologies that rely on the formation of well-defined and relatively stable organic intermediates that can further evolve under the reaction conditions are described. Overall, these sequential transformations allow acyclic components to be converted into seven-membered cycles in a 'formal' (4 + 3) manner. Most of the examples described are based on a cyclopropanation/rearrangement sequence, but some other methods relying on the expansion of smaller rings are also discussed.

5.13.6.1 Sequential Cyclopropanation/Cope Rearrangements



The Cope rearrangement of *cis*-divinylcyclopropanes is a well-established manner of assembling seven-membered rings.[108] The first examples of the transformation go back to the early 1960s, when Vogel discovered that 1,2-divinylcyclopropane can thermally rearrange to cycloheptan-1,4-diene (equation 58).[109] Ensuing mechanistic studies suggested that the rearrangement requires a *cis*-disposition of the cyclopropane vinyl substituents, which allows the rearrangement to proceed through a boat-like transition state. *Trans*-divinylcyclopropanes can also undergo the reaction but, in general, at much higher temperatures, most probably required to induce epimerization to the reactive *cis*-configuration (equation 58). The fact that the reaction proceeds through a well-defined transition state has important consequences in terms of predictable stereoselectivity of the process, which allows the installation of up to three stereogenic centers in the resulting cycloheptadiene.

(58)

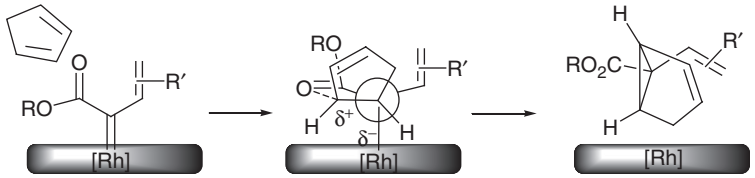
One of first synthetic uses of the strategy was published in the late 1970s by Wender and coworkers as part of their effort to develop efficient synthesis of terpenoid skeletons.[110] In this as well as in other applications, the required divinylcyclopropane precursors were usually assembled by reacting cyclopropylmetal derivatives with appropriate acceptors. A more practical way to obtain the required substrates consists of the cyclopropanations of dienes using vinylcarbenes. Although achieving this transformation with good control of reactivity and selectivity is not trivial, Davies et al. has extensively demonstrated that vinylcarbenoids equipped with adjacent EWGs promote highly stereoselective cyclopropanation of dienes. The approach allows for a great variety of 'formal' (4 + 3) annulations between dienes (four-carbon components) and vinylcarbenes (three-carbon partners).[111]

Key to the success of this chemistry is the use of alkenyldiazoalkanes containing EWGs as sources of relatively stable carbene moieties, and rhodium(II) carboxylates as catalysts responsible of inducing the decomposition of the diazo compounds. Early results demonstrated that rhodium(II) acetate catalyzes the decomposition of the vinyldiazomethane **235a** in the presence of cyclopentadiene to give the bicyclo[3.2.1]octane system **237a** in 98% yield under mild conditions. The exclusive formation of the *endo* product is consistent with a mechanism involving a stereoselective cyclopropanation following Cope rearrangement. The mechanism could be confirmed by isolation of the *cis*-divinylcyclopropane **236b**. This derivative rearranges to **237b** more slowly than **236a** (i.e., it requires heating in toluene) because of the steric interference of the methoxy substituent (equation 59).[112]

(59)

The high degree of stereoselectivity of the cyclopropanation, which only gives the *cis*-divinylcyclopropane derivative, is not so unusual in the carbenoid area. Although there is no definitive explanation, the outcome can be interpreted in terms of a nonsynchronous mechanism with charge-buildup in the transition state. The diene approaches the carbene 'side-on' from the side of the EWG group and avoiding steric collisions with the catalyst; the EWG substituent of the carbene contributes to favor a preferred orientation to give *cis*-dialkenylcyclopropane products.[113] The model also explains the lower reactivity of *trans*-alkenes because they have a substituent which unavoidably points directly toward the rhodium catalyst surface (**Figure 12**).

The nonsynchronous nature of the reaction appears also to be consistent with other observations, such as the higher diastereoselectivities of the cyclopropanation reactions in the case of electron-rich alkenes. Apparently, in carbenoid systems lacking the combination of donor (i.e., alkene) and acceptor (i.e., EWG) functionalities, the trajectory for the alkene approach is less rigorously defined, leading to a lower overall diastereoselectivity.



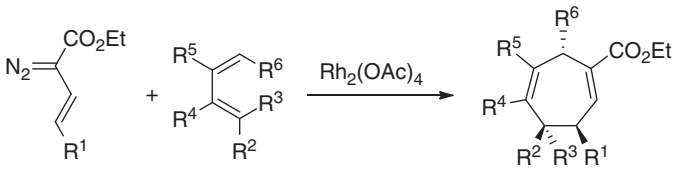


Figure 12 Mechanistic view of the tandem Rh-catalyzed cyclopropanation/Cope rearrangement.

Nonsymmetric acyclic dienes are also effective partners in the formal cycloaddition to α-ester alkenyldiazo compounds of type **235**; however, in some cases the efficiency of the reaction is lower than with cyclopentadiene because of the formation of a higher proportion of unproductive *trans*-cyclopropane intermediates. In any case, a wide range of dienes participate in the process to give an interesting variety of substituted cycloheptadienes **238** (Table 18). The regioselectivity of the reaction is very good, because of the preferred cyclopropanation of the less-substituted double bond of the diene.[113b]

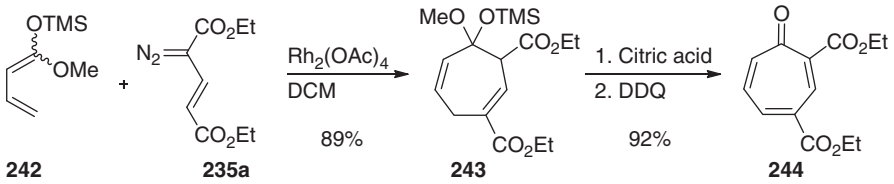
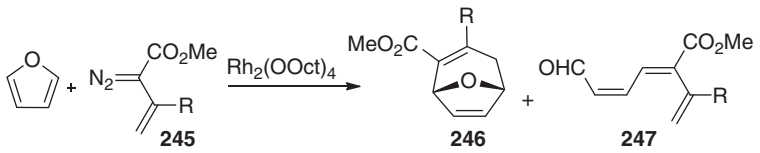
[a] $Rh_2(OAc)_4$ (1–5%), refluxing DCM.
[b] The formation of 13–14% of the *trans*-cyclopropane is also observed.



The performance of the diazoderivative **235c** with a series of sterically defined dienes provided a great deal of information on the regioselectivity and stereoselectivity of this type of vinylcarbenoid reactions (Scheme 22). In the case of (*E*)- and (*Z*)-1,3-pentadiene, the transformation provides cycloheptadienes **239** and **240**, respectively, resulting from the cyclopropanation of the most accessible double bond of the diene and a stereospecific Cope rearrangement. As already commented, cyclopropanation with vinylcarbenes is sensitive to steric hindrance in the alkene, and (*E*)-alkenes are less effective to capture the carbene than the related (*Z*)-counterparts. Therefore, reaction of **235c** with (*E*,*E*)-2,4-hexadiene failed to generate a cycloheptadiene product, whereas the reaction with (*E*,*Z*)-2,4-hexadiene proceeded smoothly to generate the cycloheptadiene **241**, the stereochemistry of which is consistent with exclusive cyclopropanation of the *cis* double bond to give intermediate **XXXVI**.[113b]

Oxygenated dienes are also excellent partners in the (4 + 3) cycloaddition with vinyldiazoacetates, because their initial cyclopropanation is more stereoselective than that of alkyl-substituted dienes. The use of highly oxygenated dienes like **242** offers a direct approach to tropones and tropolones. The cycloadduct **243** is formed in a very good 89% yield,[114] and can be readily transformed into the tropone **244** by hydrolysis with citric acid followed by DDQ oxidation (92% overall yield, Scheme 23).

Particularly interesting from the constructive point of view is the (4 + 3) cycloaddition chemistry of cyclic dienes like furans or pyrroles with alkenyldiazo derivatives. The annulation provides highly functionalized oxa- or azabicyclic systems, which are of considerable synthetic and biological interest. In the case of the cycloaddition of furans, care must be taken for the competitive formation of triene products such as **247**, arising from ring opening of a zwitterionic-like intermediate **XXXVII**. This side reaction



Scheme 22

Scheme 23

depends on the furan substituents, but can be avoided to some degree with the vinylcarbenoid **245b**, which is equipped with a *β*-silyloxy group that favors the ring closure to **246b** (equation 60).[115]

245	R	246[a]	247[a]

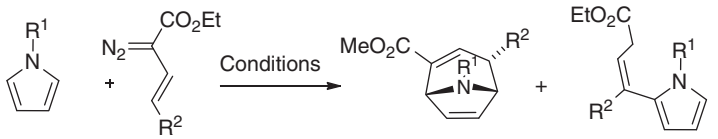
[a]Isolated yields.



(60)

In the case of pyrroles it is important to note that the direct reaction of vinyldiazomethane with pyrrole leads to addition (i.e., **249**) rather than the cycloaddition products **248**. However, acylation of the nitrogen to decrease the electron richness of the pyrrole unit allows for efficient (4 + 3) cycloadditions (Table 19, entries 1–4).[116] The products are formed as *endo* isomers, consistent with the stereochemistry expected for a tandem cyclopropanation/rearrangement sequence. In the case of vinyldiazomethanes in which R^2 = H, the reaction gives a mixture of the cycloaddition and addition products (entry 4), but the use of slightly different reaction conditions (rhodium hexanoate/hexane) increases the proportion of the tropanic products (entry 5).[117]

Davies et al. has also extensively studied different approaches to induce asymmetry in the above (4 + 3) cycloadditions. The presence of an ester group in the vinyldiazoacetates can serve as a linking position for introducing chiral auxiliaries such as lactate or pantolactone. The strategy has allowed the annulation of silyloxy-substituted vinyldiazomethanes **250** with different furans, with very high diastereoisomeric excesses (Table 20).[115c]

The asymmetric induction can be rationalized by assuming that the carbonyl group of the auxiliary (e.g., (*R*)-pantolactone) interacts with the carbenoid as shown in Figure 13. This array allows efficient transfer of chiral influence to the carbenoid position, because one of the faces of the carbene is blocked and the furan will approach the carbene from the other, more accessible face.

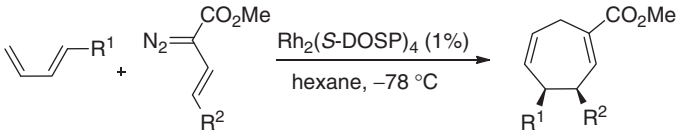
Figure 13 Mechanistic rationale for the asymmetric induction.

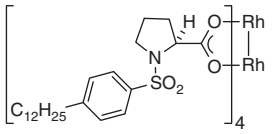
Even more relevant is the possibility of inducing asymmetry in the (4 + 3) cycloaddition of achiral diazoderivatives, by using chiral rhodium catalysts. Initially, the best reaction yields with the chiral Rh(II) catalyst Rh_2(*S*-TBSP)$_4$ were obtained with *β*-silyloxy-diazovinylderivatives (**245b**), but the enantioselectivity of the reaction was modest (46% *ee*) (equation 61).[115c]



245a, R = H
245b, R = OTBS

246a (64%, 80% *ee*)
246b (94%, 46% *ee*)

(61)



Subsequent research showed that the related rhodium(II) (*N*-dodecylbenzenesulfonyl)prolinate [Rh_2(*S*-DOSP)$_4$] is able to catalyze a highly enantioselective (4 + 3) cycloaddition of alkenyldiazoacetates with a variety of acyclic dienes. Some examples of this synthetic technology are included in Table 21.[118]

These types of catalysts are also effective in promoting the enantioselective cycloaddition of hetereodienes such as 1,2-dihydropyridines,[119] and importantly, of *N*-Boc-pyrroles,[120] which provides a straightforward enantioselective entry to the 8-azabicyclo[3.2.1]octane framework of tropanes. In this case, the best results were obtained with the catalyst Rh_2(*S*-PTAD)$_4$, and using smooth heating to improve the conversions. Importantly, the reaction can be conducted with the pyrrole as a limiting agent, which provides the opportunity to use more complex pyrroles. Indeed, 2-, 2,3-, and 2,5-substituted pyrroles do also participate in the cycloaddition, leading to good yields of the adducts **252** and excellent levels of enantioselectivity (equation 62). Later on, this same catalyst was found to be also very efficient for the cycloaddition of acyclic dienes.[121]

As might be expected, isolable metal vinylcarbenes can also participate in formal stoichiometric cycloadditions with dienes. Therefore, Wulff et al. demonstrated that Fischer chromium vinylcarbene **254** reacts with 1-methoxy-3-(dimethyl-*tert*-butylsilyloxy)-1,3-butadiene **253** to give the (4 + 3) adduct **255** (23%) together with the *trans*-cyclopropane derivative **256**, which can quantitatively evolve to the cycloadduct **255** on heating at 90 °C. Curiously, although the chromium carbene yields these seven-membered adduct **255**, the analogous tungsten complex leads to the Diels–Alder product **257**. Therefore, the nature of the metal has a dramatic influence on the product distribution, with the chromium derivative preferring to react as a carbene instead of as a Diels–Alder dienophile (Scheme 24).[122]

Scheme 24

Barluenga and coworkers have extended this chemistry to 2-amino-1,3-butadienes **258**, a particularly useful and readily available diene unit. Hydrolysis of the initially formed enamine cycloadduct generates cyclohepta-1,3-diones **261** with total regio- and stereoselectivity in a one-pot process (Table 22).[123] When the amino group is part of a prolinol derivative, the corresponding cyclic diketones are obtained with very high enantiomeric excesses.[123b] The same group demonstrated that 2-azadienes can also participate in the reaction, which is particularly relevant given that the strategy provides access to azepinones.[124]

Obviously, the above formal cycloadditions can also be performed in an intramolecular manner. Tethering the vinylcarbene and the diene ensures highly stereoselective cyclopropanations and hence very efficient cycloadditions. In contrast to the intermolecular cases, the cyclopropanation of the internal *trans*-double bond can now take place effectively.[115b] The stereoselectivity of the cyclopropanation is controlled by the alkene geometry: *trans*-dienes **262a–c** (Table 23, entries 1–3) give the seven-membered products **263** in good yield, whereas *cis*-stereoisomers such as (*Z*)-**262c** provide stable *trans*-cyclopropanes **264c**, which do not evolve to the seven-membered adduct (e.g., entry 4).

In an interesting tandem version of this transformation, Barluenga et al. has shown that acylchromates **265** react with *β*,*γ*-*δ*,*ε*-unsaturated acyl chlorides to directly give cycloheptadiene derivatives (**268**) in good yields. The reaction takes place by initial formation of *cis*-divinyl cyclopropanes **267**, which are obtained with complete selectivity and can even be isolated in some specific cases (Scheme 25).[125]

A rather interesting alternative to generate the vinylcarbenes required for the cyclopropanation reactions relies on a metathesis reaction between alkynes and Fischer carbenes. In this context, Harvey et al. demonstrated that alkyl methoxy molybdenum carbene complexes react with alkynes to generate vinylcarbenes which can be trapped by electron-poor olefins to produce vinylcyclopropanes.[126] On this basis, the group developed a quite appealing approach to 5,7-bicarbocyclic systems from

1,5-dien-8-ynes (**269**) and molybdenum carbene complexes (**270**). Formally, instead of (4 + 3) annulations, the reactions could be considered as (4 + 2 + 1) processes (Table 24).[127] Interestingly, although the use of molybdenum carbenes produces the seven-membered systems **271** and **272** via the corresponding divinylcyclopropanes, chromium carbenes lead to the preferred formation of products arising from insertion of CO into intermediate **XXXVIII**.

Relying on a similar strategy, Montgomery et al. developed a very interesting catalytic version of the annulation process. In this case, the initiator is a nickel carbene species generated from trimethylsilyldiazomethane. These authors demonstrated that treatment of dienynes like **273** with trimethylsilyldiazomethane in THF with 10% of $Ni(COD)_2$ at 60 °C produces the corresponding carbocyclic or heterocyclic bicycles in good yields and excellent diasteroselectivities. Mechanistic studies suggested that the reaction proceeds by the formation of *cis*-dialkenylcyclopropanes and subsequent sigmatropic Cope rearrangement. An example is shown in equation 63.[128]

Before ending this section, it must be noted that some isolated examples of related (4 + 3) annulations involving alternative ways of generating the required *cis*-1,2 alkenylcyclopropanes have been reported. Cha and coworkers used a Kulinkovich reaction to install the cyclopropane system,[129] whereas Yoshii's group published a (4 + 3) annulation based on the reaction of lithium enolates of unsaturated methyl ketones with (*β*-(trimethylsilyl)acryloyl)silanes.[130] However, this chemistry has not been further pursued.

More recently, the magic of gold catalysis has also touched this type of (4 + 3) annulations. This is a consequence of the well-known ability of gold complexes to convert unsaturated units, mainly alkynes and propargylic systems, into vinylgold carbenes.[82] Thus, Nevado's group has shown that propargyl acetates **275** react with 1,3-dienes in the presence of gold catalysts to give good yields of cycloheptadiene products **276** resulting from a formal (4 + 3) annulation (Table 25).[131]

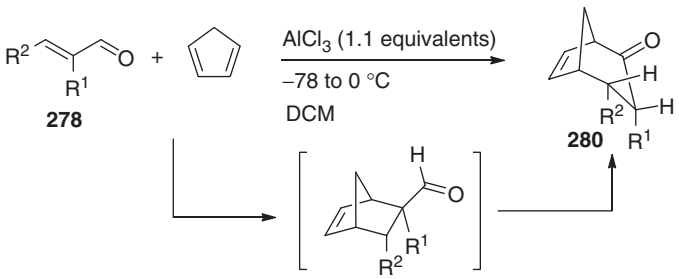
A possible mechanism for these transformations might consist of a gold-mediated 1,2-acyloxy migration of the propargyl ester to generate a gold carbenoid species (**XXXIX**), which reacts with the olefinic reactant to form a *cis*-cyclopropane intermediate. Subsequent gold-catalyzed Cope rearrangement through a boat-like transition state delivers the *cis*-2,3-disubstituted cycloheptenyl acetates of type **276** (equation 64).



(64)

5.13.6.2 Cycloaddition/Ring Expansion Processes

As shown in Section 5.13.2.2.7, α-silyloxy-α,β-unsaturated carbonyls can participate as three-carbon partners in (4 + 3) cycloadditions with furans when treated with Lewis acid promoters. Such reactions can be classified as belonging to the group of oxyallyl cation/diene annulations.[43,44] In 2004, Davies and Dai reported that analogous α-alkyl-α,β-unsaturated aldehydes such as **278** also undergo efficient (4 + 3) cycloadditions to cyclopentadiene in presence of one equivalent of $AlCl_3$, to yield the *endo* diastereoisomers **280** with excellent stereocontrol (Table 26). The presence of an alkyl substituent in the unsaturated system (R^1 = alkyl) as well as the use of a strained diene like cyclopentadiene seems to be required. Curiously, if the temperature is kept low (−78 °C), the reaction gives (4 + 2) cycloadducts **279** instead of the seven-membered products, which on heating to 0 °C rearrange to the (4 + 3) cycloadducts. On this basis, the authors suggested that the formal (4 + 3) annulation indeed takes place in two consecutive steps, namely by a Diels–Alder (4 + 2) process followed by a ring expansion (Table 26). The most likely mechanism for the ring expansion consists of a 1,2-alkyl shift to form a tertiary cation **XL** with the alkoxide at the *endo* position. A suprafacial 1,2-hydride migration would then generate the observed *endo* (4 + 3) cycloadduct (Scheme 26).[132] This hypothesis was supported by control experiments which demonstrated that with an enantioenriched (4 + 2) adduct of type **279**, the ring-expanded seven-membered product **280**, obtained after treatment with $AlCl_3$, retains the optical purity.

Moreover, the mechanism was further confirmed by theoretical calculations carried out by Domingo and coworkers, who analyzed the role of the Lewis acid in the competitive formation of the formal (4 + 2) and (4 + 3) cycloadducts of 2-methylacroleins with cyclopentadiene (Scheme 26).[133]

Scheme 26

Barluenga et al. found an interesting related cycloaddition/ring expansion sequence using alkynyl tungsten carbenes **281** and fulvenes **282** as cycloaddition partners (Table 27).[134] The reaction was tentatively explained in terms of an initial Diels–Alder cycloaddition to give species **XLI**, followed by a two-step ring expansion. This intermediate is stable under the reaction conditions and affords cycloadduct **283** after treatment with silica gel.

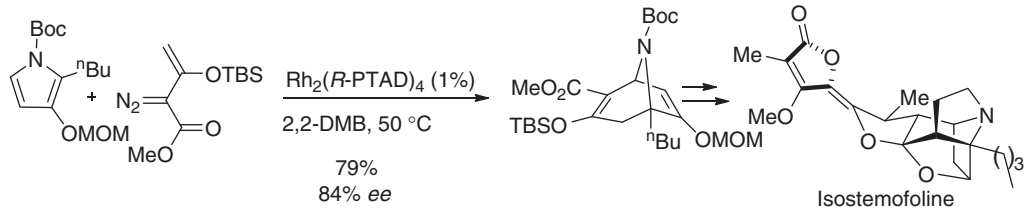
5.13.6.3 Synthetic Applications of 'Formal' (4 + 3) Cycloadditions

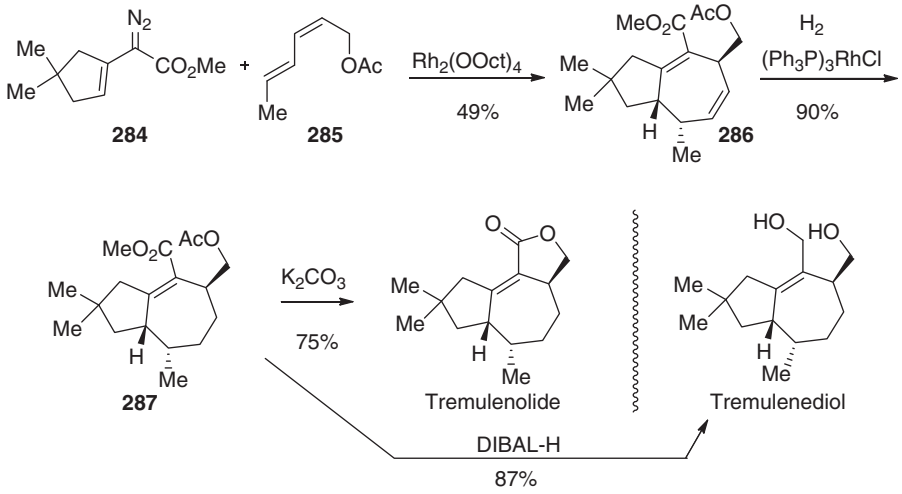
The relative simplicity of the above-mentioned annulation methodologies has led to the development of a variety of rather rapid and efficient synthetic approaches to different types of natural products featuring seven-membered rings. In particular, the cyclopropanation/Cope rearrangement sequence using metal-catalyzed decomposition of alkenyldiazo compounds has found important applications, most of them developed by Davies and coworkers.[135]



An early example of the use of this chemistry is the total synthesis of ferruginine, first in a racemic (Scheme 27) and later in an enantioselective version.[117]

More elaborated starting pyrroles can be readily converted into highly functionalized azabicyclic intermediates that have been used for the first total synthesis of complex polycyclic products such as Isostemofoline,[136] even in an enantioenriched form (Scheme 28).[120]

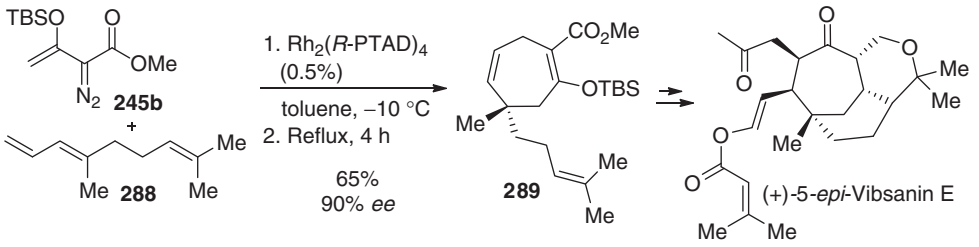
Aside from the construction of tropanes, more remarkable examples on the use of this annulation chemistry concern the synthesis of sequiterpenes like tremulenolide and tremulenediol (Scheme 29). The key step is a rhodium-catalyzed reaction of



Scheme 27

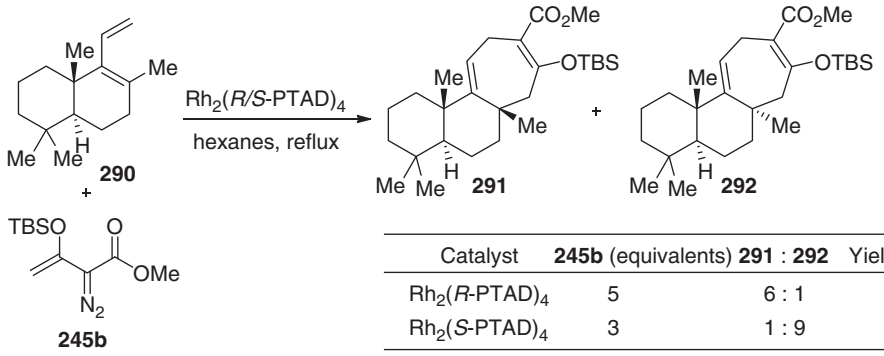
Scheme 28

vinyldiazoacetate **284** with the (*E*,*Z*)-diene **285**, which generates the cycloheptadiene **286** as a single regioisomer and diastereomer in 49% yield. As previously commented, donor/acceptor carbenes such as **284** are very sensitive to steric influences during cyclopropanation. Therefore, a selective cyclopropanation of the (*Z*) double bond to generate the corresponding *cis*-divinylcyclopropane was observed in this case (see Section 5.13.6.1). The Cope rearrangement of this intermediate proceeds through a boat-like transition state to generate **286** as a single diastereomer.



Scheme 29

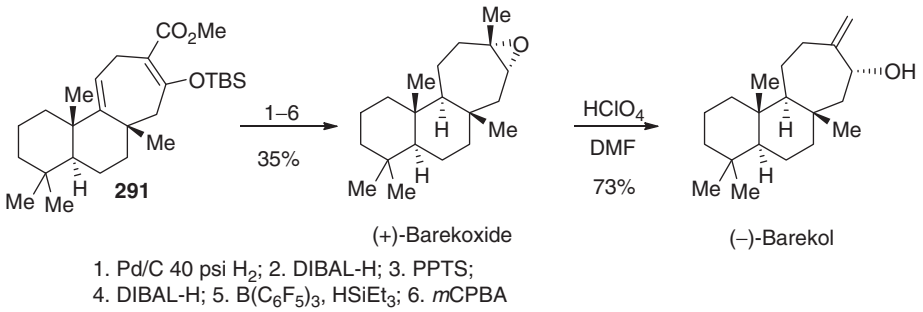
The *cis*-olefin in cycloheptadiene **286** was selectively hydrogenated by Wilkinson's catalyst to form cycloheptene **287** in 90% yield. Hydrolysis of the acetyl group with aqueous potassium carbonate followed by *in situ* lactonization completes the synthesis of (±)-tremulenolide A. Alternatively, DIBAL-H reduction of the two ester groups in cycloheptene **287** resulted in the synthesis of (±)-tremulenediol A (Scheme 29).[137]



An enantioselective (4 + 3) cycloaddition was a crucial step for the first total synthesis of a single enantiomer of the diterpene 5-*epi*-vibsanin E (Scheme 30).[121] In this case the authors demonstrated that vinyldiazoacetate **245b** reacts with triene **288** in the presence of 0.5 mol% of chiral catalyst Rh_2(*R*-PTAD)$_4$ to produce the cycloheptadiene **289** in 65% yield and 90% *ee*. Therefore, this cycloaddition, which can be carried out on a 10-g scale, allows the quaternary center of the natural product to be established. Transformation of this intermediate into the product involves a 10-step process, with key steps being an intramolecular hetero-Diels–Alder reaction to establish the oxacyclic ring of 5-*epi*-vibsanin E and a conjugated addition/alkylation process.

In collaboration with the Sarpong group, Davies et al. have further demonstrated the great synthetic potential of the cycloaddition technology by developing several total syntheses of complex diterpenes of the cyanthane and barekol family. During

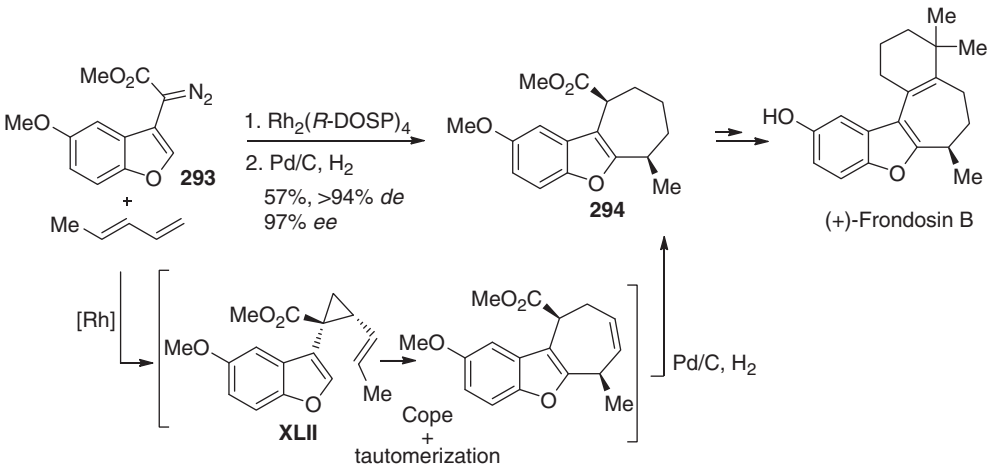
Scheme 30



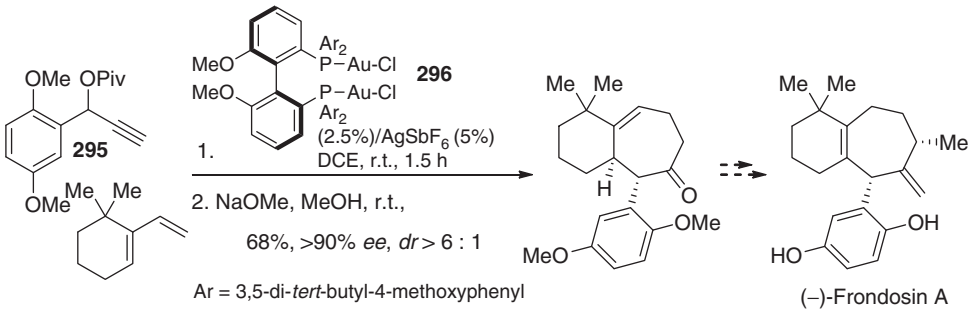
this research, the authors found that the use of chiral catalysis in the (4 + 3) cycloaddition can overwhelm the inherent directing nature of a chiral substrate. Therefore, although the reaction of diene **290** with diazoester **245b** in presence of the Rh_2(*R*-PTAD)$_4$ gave **291** as the major diastereoisomer, the use of the enantiomeric catalyst Rh_2 (*S*-PTAD)$_4$) led to the diasterosimer **292** as the major product (Scheme 31). Tricycle **291** could be readily converted to (+)-barekoxide and (–)-barekol following the sequence of steps indicated in Scheme 32.[138]

Catalyst	**245b** (equivalents)	**291** : **292**	Yield (%)[a]
Rh_2(*R*-PTAD)$_4$	5	6 : 1	65
Rh_2(*S*-PTAD)$_4$	3	1 : 9	63

[a]Combined isolated yield of **291** and **292.**



Scheme 31

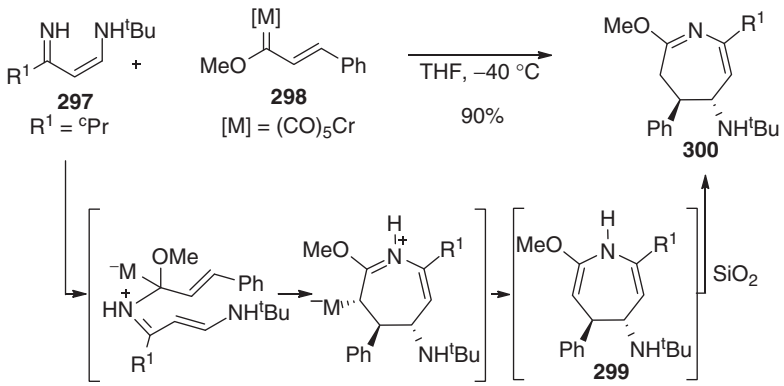


Scheme 32

The (4 + 3) cycloaddition strategy can also be accomplished with heteroaryldiazoacetates as illustrated by the formal synthesis of (+)-frondosin B (Scheme 33).[139] Reaction of heteroaryldiazoacetate **293** with *trans*-piperylene in the presence of Rh_2(*R*-DOSP)$_4$ followed by immediate hydrogenation of the product generated the reduced (4 + 3) cycloadduct **294** in 57% yield over the two steps, with excellent diastereoselectivity and enantioselectivity (97% *ee*). In this case the *cis*-divinylcyclopropane **XLII** undergoes the Cope rearrangement followed by a tautomerization to generate the aromatic benzofuran ring. Tricycle **294** was then further advanced to an intermediate used in Danishefsky's synthesis of (+)-frondosin B.[140]

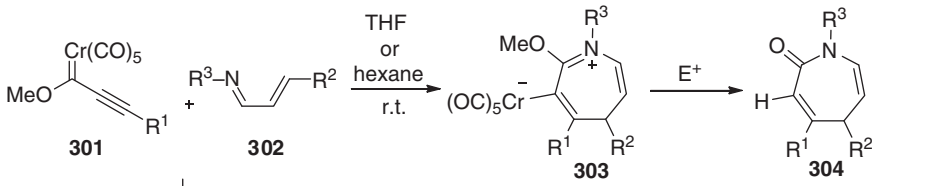
Nevado and coworkers have recently described an alternative and straightforward synthetic route to (+)-frondosin A relying on a gold-catalyzed (4 + 3) annulation between propargylic acetates and dienes (see above).[131a] The authors demonstrated that treatment of pivaloate **295** with 6,6-dimethyl-1-vinyl cyclohexene in the presence of (*S*)-OMe-DTBM-BIPHEP–gold(I) complex (**296**), followed by *in situ* hydrolysis, allows the basic bicarbocycle of frondosin to be installed in an enantioselective manner. Since this bicyclic enone was recently elaborated into frondosins A and B, the approach represented a streamlined formal enantioselective synthesis of both molecules (Scheme 34).[141]

Scheme 33



Scheme 34

5.13.7 Miscellaneous

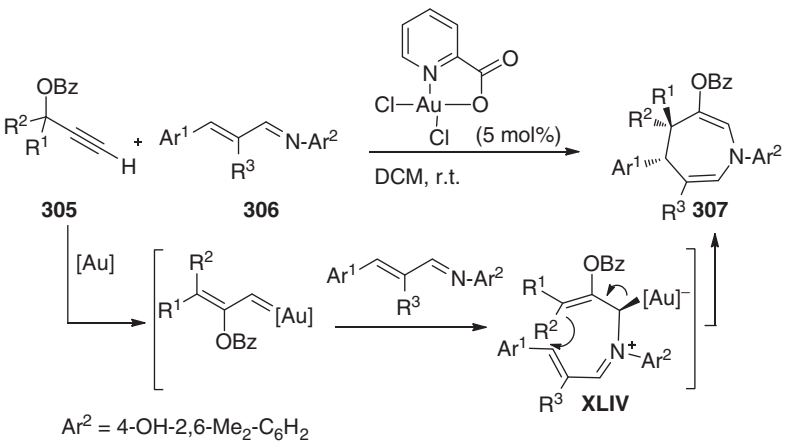


In the previous sections, the authors have discussed the most common (4 + 3) assembly strategies to make seven-membered rings organized according to mechanistic scenarios. However, there are isolated examples of other (4 + 3) annulations that take place by alternative, less common mechanisms.

As previously shown, vinylcarbenes are powerful three-carbon components in cycloaddition reaction with a broad range of dienes. In 1994, Barluenga et al. found that 4-amino-1-azadienes **297** react with alkenylcarbene complexes **298** under unusually mild conditions to give 4,5-dihydroazepines **299**.[142] Although the reaction was initially considered to proceed through a cyclopropanation/rearrangement sequence, later NMR identification of several intermediates in the reaction with tungsten vinylcarbenes[142b] led the authors propose an alternative mechanistic pathway. This route consists of an initial attack of the imine nitrogen to the carbene carbon, followed by cyclization induced by the [1,2] migration of the metal fragment, and a final thermal demetalation and decomplexation to give the observed azepines **299**. Treatment of the resulting mixture with SiO_2 allows the azepines of type **300** to be isolated in excellent yields (equation 65).

(65)

The same group also reported that simple 1-azadienes add to alkynyl carbene complexes in a similar way as shown in equation 66.[143] The reaction again must involve the initial formation of an intermediate such as **XLIII**, which evolves to the σ-complex azepine **303** by [1,2]-metallotrophic shift and cyclization. Although these complexes are air-stable, the carbon–metal σ-bond is sufficiently labile to provide, under thermal, hydrolytic, or electrophilic conditions, azepinones of type **304**. The authors were able to obtain an X-ray crystal structure of a complex **303** with R^1 = Ph, R^2 = Pr, and R^3 = Ph, which reinforced the mechanistic hypothesis.



R^1	R^2	R^3	Yield **303**, **304**[a] (%)

Ph	Bn	Ph	80, 87
Me	^{n}Pr	TMS	60, 85

[a]**304** obtained after heating **303** at 50 °C.

(66)

In the context of this chemistry, Toste and coworkers have recently reported a related approach to azepines such as **307** based on a gold-catalyzed reaction between propargylic esters **305** and α,β-unsaturated arylimines **306** (Table 28).[144] According to the authors, the reaction must involve the initial generation of a vinylgold carbene from the rearrangement of the propargylic ester. Subsequent addition of the imine nitrogen to the carbene, as in the case of the previous reactions of Barluenga, generates the allylgold intermediate **XLIV**, which undergoes an intramolecular nucleophilic addition onto the pendant α,β-unsaturated imine electrophile. The mechanism is supported by different observations, such as a rate enhancement when the Ar group in the nitrogen is more electron rich.

[a]Propargyl ester (1.3 equivalents), catalyst (5%), DCM, r.t.
[b]Relative stereochemistry of the diastereoisomers not determined.

Finally, it should also be mentioned that Molander et al. have developed different types of annulative strategies to construct medium-sized rings which involve the condensation of a three-carbon 1,3-dinucleophile and a dicarbonyl electrophile. When the

carbonyls are in a 1,4-disposition, the strategy can be considered as a formal (4 + 3) cycloaddition, and allows interesting oxabicyclic products to be made in a rapid and practical manner.[145] Key aspects of the strategy are the use of bis(trimethylsilyl) enol ethers **308** as synthetic equivalents of β-dicarbonyl dianions and TMSOTf as Lewis acid promoter. This Lewis acid activates the less hindered carbonyl group of a 1,4-dicarbonyl compound, which then undergoes an intramolecular addition of the other carbonyl oxygen to give an oxocarbenium intermediate. Nucleophilic attack of the terminal carbon of the dinucleophilic synthon at this electrophilic center followed by cyclization generates the observed product. The reaction is quite efficient with keto-aldehydes, although a number of good yielding annulations of diketo-substrates has also been described. An example is shown in equation 67.

(67)

5.13.8 Conclusion

The (4 + 3) cycloaddition of dienes and oxyallyl cations is a classical and powerful method to assemble seven-membered rings. The past century has witnessed many developments in the area, particularly in the implementation of different types of oxyallyl cation precursors. However, in more recent years, there have been many other developments that greatly expanded the potential of the methodology from many points of view, namely, the availability of the precursors, the scope and efficiency, the implementation of substoichiometric variants, and the development of asymmetric processes. Furthermore, other alternatives to generate cycloaddition-active allyl cations have been developed, with special emphasis on metal-catalyzed processes. However, there have also been substantial advances in the discovery of different classes of (4 + 3) annulations that are not necessarily mediated by allyl cations.

Despite all these advances, truly catalytic versions of inter- and intramolecular versions of (4 + 3) annulations relying on readily accessible starting materials are still very scarce. Even rarer are the enantioselective versions of these transformations. However, the versatility of many of the processes, in particular with regard to the diene component, is not as good as one might wish. Therefore, there are still many challenges in this area, and new, and important advances are expected in the coming years. Glossary

Cycloaddition A reaction in which two or more unsaturated molecules (or parts of the same molecule) combine with the formation of a cyclic adduct in which there is a net reduction of the bond multiplicity. Cycloadditions may be pericyclic reactions or (nonconcerted) stepwise reactions.

Dynamic kinetic resolution A reaction in which one enantiomer of a racemic compound reacts selectively, with the unreacted enantiomer undergoing facile epimerization.

Exo*/*Endo These terms refer to the location of a specific motif. *Exo* (outside) and *endo* (inside) originate from the Greek language.

Kinetic resolution A reaction in which only one enantiomer of a racemic compound reacts selectively.

Structure–activity relationship The relationship between the chemical properties of a molecule and its biological activity. Comparison of chemical and biological properties can provide information on the mechanism of a particular molecule/functional group.

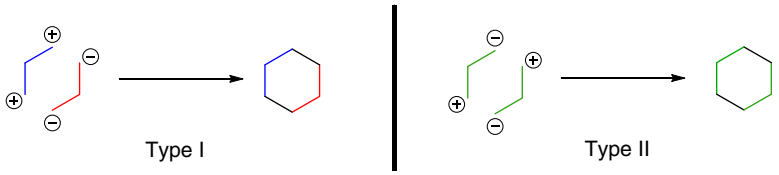
Synthon A motif that represents a synthetic equivalent. A synthon can either be described as an actual compound or as cation/anion equivalents. This terminology is often utilized when describing retrosynthesis.

5.14.1 Introduction

Over the past 60 years, higher-order cycloadditions have become extremely useful tools in organic chemistry because these reactions generate complex molecular architectures from readily accessible building blocks with predictable regio-, diastereo- and enantioselectivity.[1] Additionally, the combination of simple precursors in multicomponent transformations has the potential for broad substrate scope and high atom efficiency. Hence, it is unsurprising that there are many applications in medicinal, agrochemical and materials chemistry, which attests to their continued importance in the construction of complex cyclic systems. This chapter focuses on seminal examples of higher-order cycloadditions within the past 20 years and provides a comprehensive overview of a variety of approaches to small- and medium-sized carbo- and heterocycles.

 doi:10.1016/B978-0-08-097742-3.00515-2

The chapter commences with [‘$m+n$’] cycloadditions using the size of the synthon to categorize the various reactions. For example, [‘$3+n$’] will be followed by [‘$4+n$’], which will precede [‘$5+n$’], and so on. The sections on [‘$m+n+o$’] and [‘$m+n+o+p$’] are also categorized in an analogous manner.



5.14.2 [‘$m+n$’] Cycloadditions

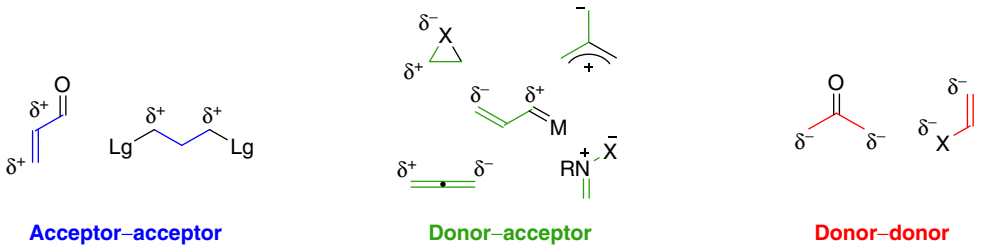
The first section of the chapter outlines various [‘$m+n$’] cycloaddition reactions ($m=3$–8, $n=2$–8), however, [‘$m+1$’] (*see* Chapter 5.24), [‘$2+2$’] (*see* Chapters 5.04 and 5.07), [‘$3+2$’] (*see* Chapters 4.21, 4.22, and 5.08), [‘$4+2$’] (*see* Chapters 5.09, 5.10, and 5.11) and [‘$4+3$’] cycloadditions (*see* Chapter 5.13) are not described, in addition to all photochemical cycloadditions, including arene–ene [‘$5+2$’] reactions (*see* Chapter 5.04). The nomenclature used to describe intra- and intermolecular reactions follows the recently described nomenclature for categorizing these types of reactions.[1q,2] For example, intermolecular reactions are denoted by $[m+n+o]$, whereas intramolecular are represented by $[(m+n+o)]$. Finally, the three-component semi-intermolecular cycloadditions are represented by $[(m+n)+o]$ and generic cycloadditions by [‘$m+n+o$’].

5.14.2.1 [‘3 + 3’] Cycloadditions

The [‘$3+3$’] cycloaddition represents one of the most studied reaction of this class and has provided an attractive alternative to the classical [‘$4+2$’] cycloaddition. Pioneering work by Link, Prelog, Stork and Seebach provided the basis for the development of this field over the past 20 years, with the introduction of a plethora of three-atom synthons.[3] These synthons can generally be classified on the basis of an anion/cation equivalent, which can have a profound effect on the outcome of a given [‘$3+3$’] cycloaddition reaction. Type I describes the coupling of donor–donor and acceptor–acceptor synthons, which afford six-membered adducts. The alternative reaction (Type II) relies on the implementation of two 1,3-dipoles, which combine to generate six-membered rings.

The following section focuses on various three-atom synthons that are capable of promoting [‘$3+3$’] cycloaddition reactions. As depicted in Scheme 1, acceptor–acceptor synthons are only permitted to react with donor–donor synthons, whereas donor–acceptors combine with an additional donor–acceptor to generate the cycloadduct. Several advantages and disadvantages exist for each type of system, for example, Type I dianions and dications are relatively unstable compared to the corresponding Type II processes involving 1,3-dipoles, however, the latter have to rely on orthogonal reactivity of each component to minimize homodimerization and polymerization. Figure 1 highlights various synthons that participate in Type I and II [‘$3+3$’] cycloadditions and the following sections focus on reactions using these types of reactive intermediates. Furthermore, because there are a significant number of combinations, some examples will be covered in other sections of the chapter.

Scheme 1 Potential classes of [3 + 3] cycloadditions.



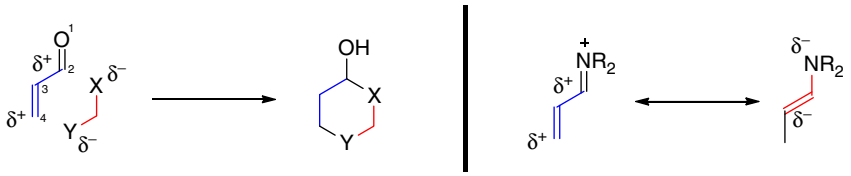


Figure 1 Various three-atom synthons utilized in [‘$3+3$’] cycloadditions.

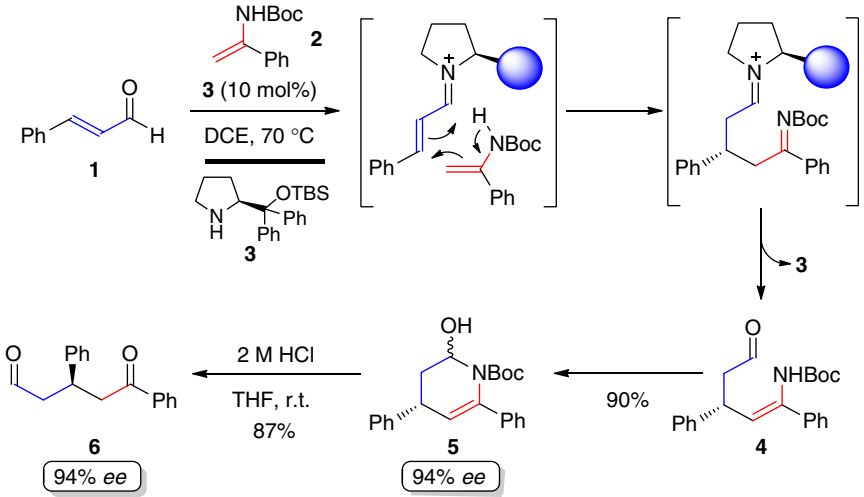
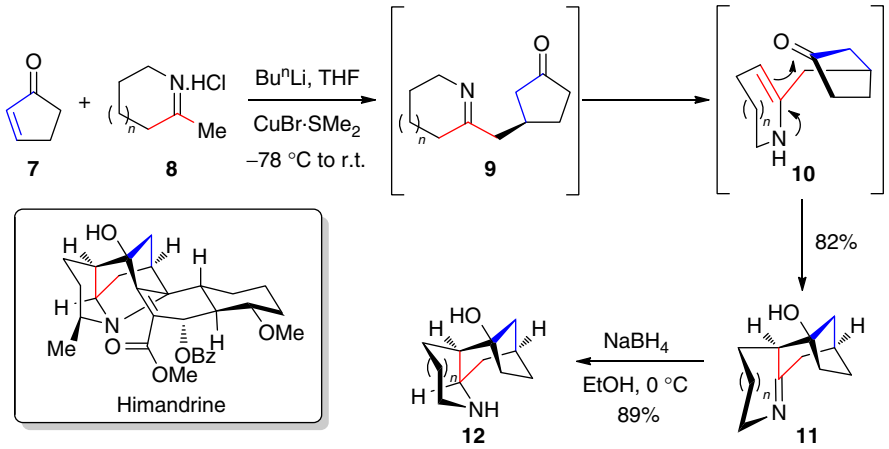


5.14.2.1.1 Michael addition-promoted reactions

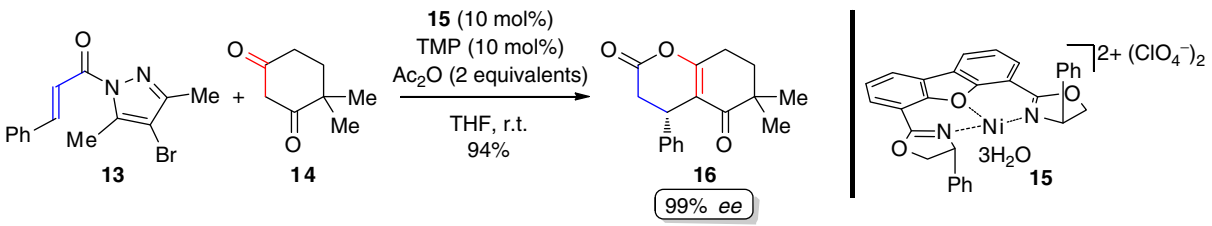
Many cycloadditions take advantage of the inherent electron deficiency at the 2- and 4-positions of α,β-unsaturated carbonyl compounds. Hence, the ability for these intermediates to react with 1,3-dianions provides an opportunity for a Type I [‘$3+3$’] cycloaddition, in which the enantioselective variants utilize iminium ion catalysis. A key component with this approach is that imines, derived from α,β-unsaturated carbonyl compounds, display antipodean behavior through their ability to tautomerize to the corresponding enamines (Scheme 2).

Scheme 2 General mechanism of the Michael addition-promoted ['3 + 3'] cycloaddition.

Hayashi and Wang independently reported the catalytic enantioselective aza-[3 + 3] cycloadditions in 2008.[4] Hayashi and coworkers serendipitously discovered this process while investigating the use of enamines as enolate equivalents in the conjugate addition reaction with enals (Scheme 3). The unexpected cyclization occurred via the rapid ring closure of **4** to generate piperidine **5**, rather than the expected hydrolysis of the enamine in **4** to provide *δ*-keto aldehyde **6**. Iminium ion activation of the *α*,*β*-unsaturated aldehyde **1** by the secondary amine catalyst **3** results in a lowering of the lowest unoccupied molecular orbital (LUMO) coefficient of the *π*-system and initiates nucleophilic attack at the 4-position to provide the iminium ion. Hydrolysis of the iminium ion with the water generated in the iminium ion activation step provided **4**, which spontaneously cyclized to afford **5**, albeit as an inconsequential 1:2 mixture of *α*/*β*-anomers, in 90% yield and with 94% enantiomeric excess. The expected hydrolysis product **6** could, however, be obtained via the addition of either a Brønsted or Lewis acid.



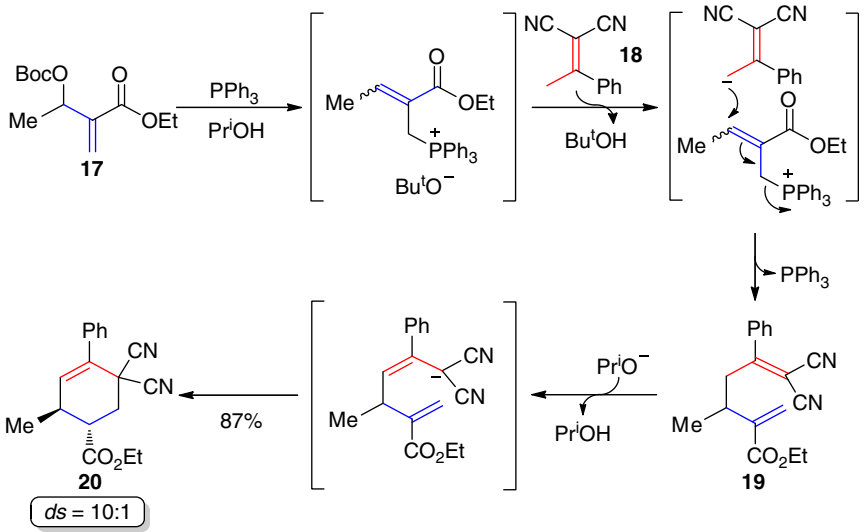
Scheme 3 Iminium ion-activated Michael addition.



In a related transformation, the dimerization of crotonaldehyde proved successful through the ability of *α*,*β*-unsaturated carbonyls to provide 1,3-dication and dianion equivalents, respectively, in the presence of organocatalysts (Scheme 2).[5] Moreover, the high enantioselectivity, which is governed by chiral proline derivatives, afforded functionalized cyclohexene products that provide important intermediates for the expeditious construction of a number of monoterpene natural products. Despite the growing number of organocatalyzed cycloaddition reactions, this represents the first example of dual enamine/iminium activation in a [3 + 3] cycloaddition.

In this context, the potential of enamines as three-atom synthons was highlighted in an elegant approach to the densely functionalized core of himandrine (Scheme 4).[6] Initial conditions probed the addition of the *in situ*-generated cuprate, derived from **8** ($n = 1$), to the cyclopentenone **7** to afford the imine **9**. Tautomerization of the imine to the enamine **10**, followed by the intramolecular addition to the carbonyl and concomitant reduction of the imine afforded tricycle **12** ($n = 1$). Although the first step in the synthesis relies on the 1,4-addition of an organocuprate to generate imine **9**, the process is also amenable to iminium ion catalysis with a chiral organocatalyst. For example, L-proline catalyzed the initial reaction between **7** and **8** ($n = 0$) to afford the cyclopentanone **9**; however, it did not undergo spontaneous tautomerization/ketone addition in a similar manner to the analogous cuprate conditions and the enantioselectivity was modest (52% *ee*).

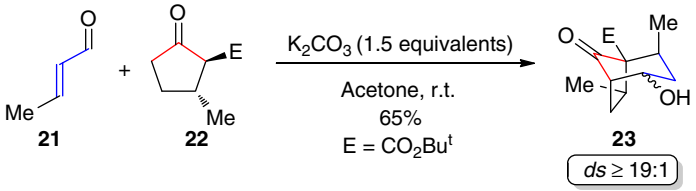
Enamines, in the form of vinylogous amides, have also been used in conjunction with the 1,2-/1,4-acceptor, acryloyl chloride, for the construction of six-membered lactams.[7a] The formation of nonracemic lactams was successful by employing chiral directing groups in a diastereoselective reaction. Vinylogous esters can also be used to generate lactones, and vinylogous ester equivalents, namely **14**, can provide enol lactones via a nickel-catalyzed process (equation 1).[7b] The chiral nickel(II) catalyst acts as a Lewis acid by activating both the carbonyl of **13** and enol form of **14**.



Scheme 4 Total synthesis of himandrine via [3 + 3] cycloaddition.

(1)

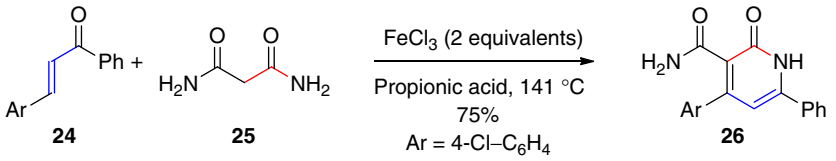
Phosphines have recently attracted significant interest as nucleophilic catalysts for the synthesis of functionalized cycloadducts. The aptitude of the Lewis basic phosphine to act as a good nucleophile, while also enabling facile elimination, provided the basis for these interesting developments. For example, the triphenylphosphine-catalyzed reaction of allylic carbonate **17** with alkylidenemalonitriles provides the requisite cyclohexene **20** (Scheme 5).[8] The reaction is thought to proceed via a series of 1,4-additions, with the leaving group in **17** being vital to the success of the reaction, since the resultant alkoxide must be sufficiently basic to deprotonate **18**.



Scheme 5 Phosphine-catalyzed [3 + 3] cycloaddition.

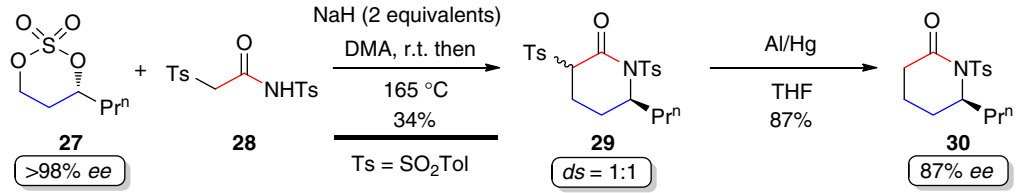
5.14.2.1.2 α,α′-Carbonyl 1,3-dianions

Dianion equivalents, derived from sequential deprotonation of the α- and α′-positions of carbonyl compounds have long been used as three-carbon synthons in organic chemistry. The combination of these systems with additional three-atom synthons has emerged as a convenient protocol to prepare densely functionalized six-membered polycycles. In 1995, Rodriguez and coworkers



described the sequential base-promoted Michael addition/aldolization for the synthesis of optically active bicyclo[3.2.1]octane systems.[9] The thermodynamic enolate reacts selectively at the 4-position of the enal followed by reenolization and intramolecular aldol cyclization with the pendant aldehyde (equation 2). The reaction displays good to excellent diastereoselectivity for a variety of examples, because the enal is attacked from the least hindered face of the cyclic enolate, albeit the secondary alcohol is generated as a 2.8:1 mixture of equatorial and axial epimers, respectively.

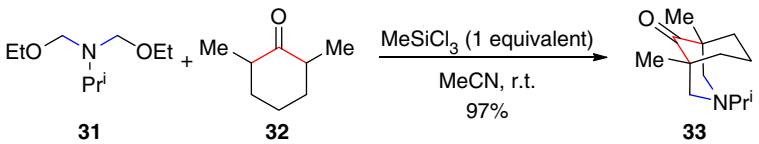
(2)



This principle has been extended to α,β-unsaturated ketones as dication equivalents in an organocatalyzed [3 + 3] annulation for the formation of [3.3.1] cycloadducts under mild conditions. The reaction is quite general with broad substrate scope affording excellent yields and enantioselectivities.[10]

Pyridones are of considerable synthetic interest, largely due to the plethora of pharmaceuticals that contain substituted 2-pyridones. The formation of these systems via a formal [3 + 3] cycloaddition is desirable from a structure–activity relationship (SAR) standpoint because it provides the desired motif at a late stage, which permits analogs to be readily prepared. Recently, the iron-mediated synthesis of trisubstituted 2-pyridones was reported by Wang (equation 3).[11] In this context, the metal-mediated combination of **24** and **25** affords 2-pyridone **26** via a Michael addition and dehydration, followed by aromatization of the 3,4-dihydro-2-pyridone intermediate, which occurs in the absence of additional oxidants or leaving groups.

(3)

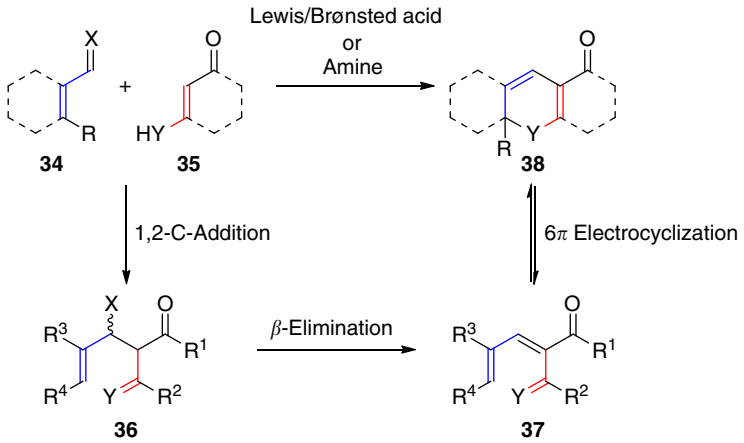


Stabilized dianions have also found application in the formation of enantiomerically enriched lactams. In 2000, Gallagher and Eskici reported the alkylation of such anions with C(sp^3) 1,3-electrophiles, which provided an opportunity to develop a stereospecific protocol using chiral C(sp^3) stereogenic centers (**Scheme 6**).[12]

Scheme 6 Cyclic lactams from [3 + 3] cycloaddition.

The reaction spontaneously occurs between the more electrophilic primary C(sp^3) and the nucleophilic carbanion at room temperature in the presence of sodium hydride. The second S_N2 reaction is considerably more challenging and requires extensive heating to provide the [3 + 3] adduct. Although the lactam was isolated as a mixture of diastereoisomers, removal of the sulfone provided **30** in 87% yield and with 87% enantiomeric excess, which indicates some stereochemical leakage in the alkylation. Hence, this strategy provides enantiomerically enriched lactams in a facile manner and has the capacity for extension to more complex [3 + *n*] cycloaddition reactions because the two electrophilic sites are independent of each other and do not form part of a larger motif, as is the case with α,β-unsaturated carbonyl derivatives.

In an effort to generate bicyclo[3.3.1]octane derivatives via a [3 + 3] cycloaddition, several groups have probed the double Mannich annulation of cyclic ketones.[13] The products of this transformation have great synthetic utility because they represent a pharmacophore present in biologically important molecules and have demonstrated important biological activity as antagonists for nicotinic receptors. For instance, the Lewis acid-mediated double Mannich condensation of the ketone **32** with the bis-imine equivalent **31** affords the cycloadduct **33** in excellent yield (equation 4). Additionally, replacing the isopropyl group on the amine with a chiral α-methylbenzyl functional group provided enantiomerically enriched intermediates, albeit as a mixture of diastereoisomers.

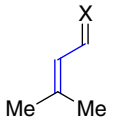


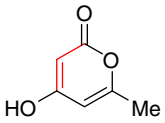
(4)

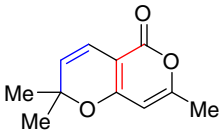
A major disadvantage with 1,3-dianions as three-carbon synthons is their propensity to undergo polymerization, which has led to the preparation of 1,3-dianion equivalents that provide a slow release of the desired nucleophile. This approach was initially developed by Chan et al. for the synthesis of methyl salicylates and has recently found favor in a number of α,α′-carbonyl dianion [3 + 3] cycloadditions.[14a] Later developments by Langer and coworkers, who have dominated this particular area of [3 + 3] cycloadditions, provided a new approach to spiroannulated hydroxycyclohexenones using 1,3-bis(silyl enol ethers) as mild three-carbon synthons,[14b] which is the subject of a recent comprehensive review.[1n]

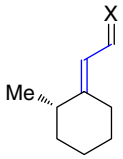
5.14.2.1.3 Sequential Knoevenagel/6π electrocyclization reactions

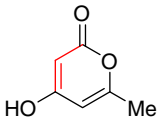
Similarly to the Michael addition-mediated [3 + 3] cycloaddition reaction of α,β-unsaturated carbonyls with 1,3-diketo equivalents, which each provide three-atom synthons, there is an alternative reaction pathway for this cycloaddition. In this context, the sequential Knoevenagel condensation/6π electrocyclization reaction has become a well-studied class of [3 + 3] cycloaddition reactions. A general scheme for this reaction is highlighted in Scheme 7, which proceeds via the initial 1,2-C-addition of **35** to α,β-unsaturated **34**. Subsequent β-elimination of **36** provides the Knoevenagel condensation product **37**, which undergoes rapid 6π electrocyclization to afford the formal [3 + 3] cycloadduct **38**. It is noteworthy that the stereochemically defining step for the formation of the stereocenter adjacent to the heteroatom occurs during the 6π electrocyclization, and as such has proven challenging for the development of asymmetric versions of this transformation.

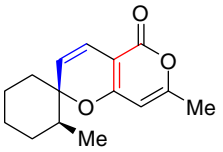


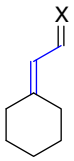


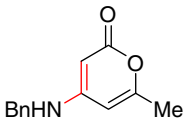


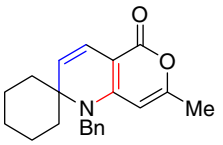


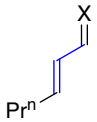


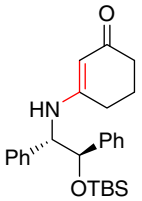


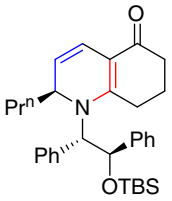


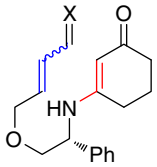


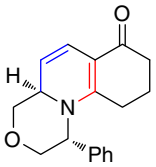




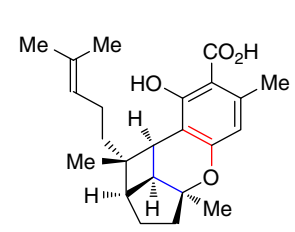




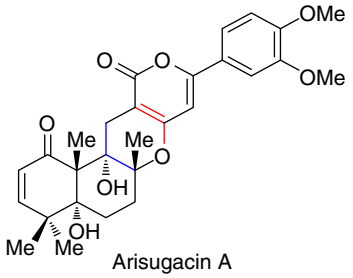




Scheme 7 Mechanism of the Knoevenagel condensation/6π electrocyclization reaction.



The reaction was first reported in 1944 by Link, and then further developed by Moreno–Mañas. However, its synthetic utility remained problematic because of the formation of several isomers from competing reaction pathways. The side reactions primarily result from initial 1,4-C- and Y-addition (X/Y = O), with the desired [3 + 3] adduct constituting less than 10% of the reaction mixture. In an effort to overcome this limitation, Jonassohn and Hua independently reported the use of cyclic enals, which favor the 1,2-C-addition. More recently, Hsung has expanded the scope of this transformation by employing iminium salts (X = piperidine acetate) for the construction of six-membered heterocycles using both cyclic and acyclic systems.[15] Table 1 outlines several examples that highlight this process. A key and striking feature with the substrate scope is that oxygen and nitrogen substitution can be tolerated at the vinylogous position and that quaternary stereogenic centers can be readily prepared adjacent to this heteroatom, which includes spirocyclic centers (entries 2–3). Although high diastereocontrol was not achieved when **34b** was employed, **38d** and **38e** were formed with excellent stereocontrol using chiral *N*-directing groups. The mechanism of this transformation has been the subject of extensive investigation[16] and supported by the isolation of the triene intermediate **37**. For example, the 1-azatriene derived from **34c** and **35c** was isolated and found to undergo thermal 6π electrocyclization at 150 °C, affording the corresponding [3 + 3] adduct **38c** in quantitative yield. Additional experiments provided evidence for a reversible cyclization process between **37** and **38**, which results in thermodynamic control in the formation of **38**. For example, subjecting the minor diastereoisomer of **38d** to thermal conditions at 150 °C provided the major isomer **38d** with ≥19:1 selectivity. More recently, catalytic Lewis and Brønsted acids have been demonstrated to promote these cycloadditions under mild conditions with excellent efficiency without the requirement of iminium ion activation.[17]



Interestingly, although the intramolecular version of this reaction also provides the corresponding [(3 + 3)] cycloadduct **38e** in modest yield as a single diastereoisomer, it was proposed to occur via an alternative pathway. The isolation of a reactive intermediate again provided additional support for this hypothesis, which suggested that initial 1,4-N-addition followed by 1,2-C-addition prevails. The low yield for the intramolecular reaction is presumably a result of a challenging β-elimination of the amine, albeit there are advantages for this transformation compared to the intermolecular version. The stereochemically defining step in this process is the initial 1,4-N-addition and chiral iminium ion catalysis activation provides some asymmetric induction, although the enantioselectivities are generally modest (≤50% *ee*). The major highlight of this type of cycloaddition has been the successful implementation in complex total syntheses, which have been extensively reviewed by Hsung and coworkers (Figure 2).[1k]

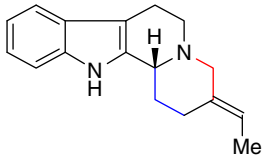


Table 1 Knoevenagel condensation/6π electrocyclization of α,β-unsaturated imines

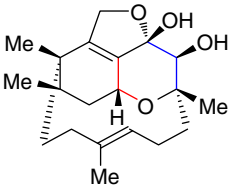

Entry	34[a]	35	38		ds	Yield (%)	References

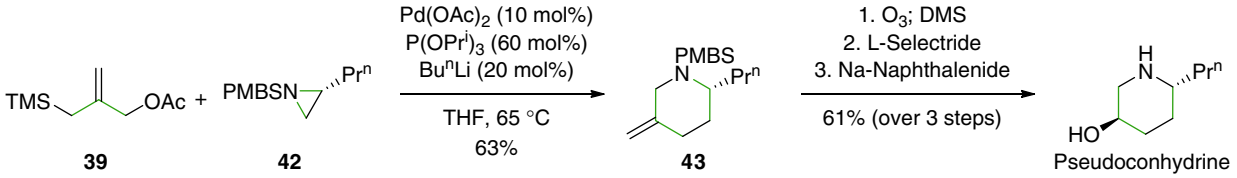
5.14.2.1.4 Trimethylenemethane-promoted reactions

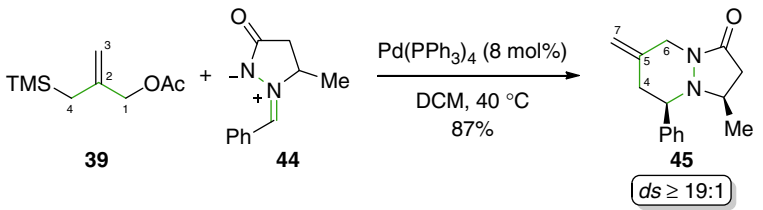
Cyclopropanes provide important three-carbon synthons because of their ability to release ring strain and provide important reactive intermediates that facilitate useful synthetic transformations, particularly in the presence of transition metals. For



example, the cyclopropane ring has a calculated strain energy of 27.5 kcal mol^{-1} higher than the acyclic counterpart. Moreover, when one of the carbon atoms contained within the cyclopropane ring becomes sp^2-hybridized, as in the methylenecyclopropane (MCP) **41**, the strain energy increases further to 40.9 kcal mol^{-1}. Hence, it is unsurprising that cyclopropanes bearing a C(sp^2) have become extremely popular in synthetic organic chemistry.

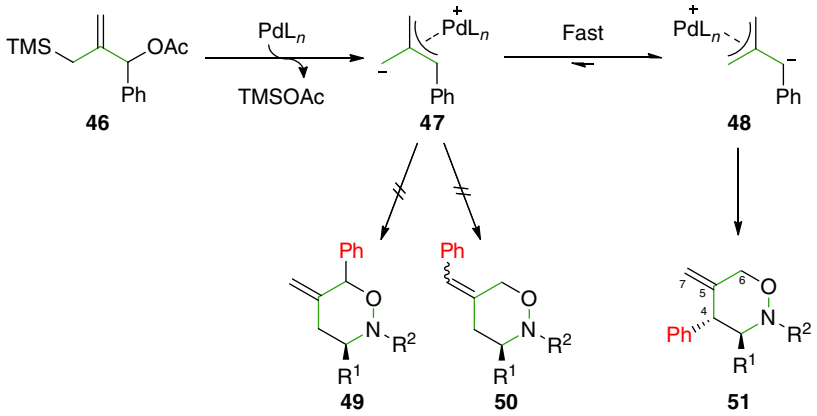
Noyori, Binger, and Trost pioneered the studies on cycloadditions of trimethylenemethane (TMM) complexes (**40**) in the 1970s and 1980s, in which they demonstrated their propensity to provide novel 1,3-dipoles for cycloaddition reactions.[18] Although the reactive intermediate can be derived either from the MCP (**41**) or from the 2-[(acetoxymethyl)-3-allyl]trimethyl silane (**39**) with a nickel or palladium complex, the two systems have contrasting modes of reactivity despite their similarities. In this context, countless examples of [3 + 2] cycloadditions involving **40** have been reported, whereas only a few [3 + 3] cycloadditions have proven successful, all of which have been promoted using **39** with a palladium catalyst (Scheme 8). The following examples will highlight the potential of Type II cycloadditions utilizing palladium-bound TMM complexes.

Scheme 8 Formation of palladium–TMM complexes.



The most studied [3 + 3] cycloaddition involving TMM complexes involves the ring-opening of aziridines. The reaction is highly regioselective for the nucleophilic addition to the aziridine at the less substituted carbon, and as a result permits the formation of piperidines with α-nitrogen stereogenic centers. Although the early reports did not probe the effect of enantiomerically enriched aziridines, Harrity and coworkers have developed the enantiospecific reaction, which proceeds without appreciable loss in enantiomeric purity (Scheme 9). The facile preparation of enantiomerically enriched aziridines, coupled with their reactivity toward TMM complexes, provides a very convenient approach to optically active piperidine alkaloids such as pseudoconhydrine.[19]

Scheme 9 [3 + 3] Cycloaddition of TMM complexes and aziridines.



The most plausible reaction pathway invokes the initial formation of a TMM complex followed by nucleophilic attack of the strained methylene of **42**. The catalytic cycle culminates with *N*-nucleophilic attack of the π-allyl-palladium intermediate to generate the six-membered heterocycle. Interestingly, only electron-rich sulfonamides on nitrogen are tolerated and byproducts resulting from nucleophilic addition of acetate to the methylene of the aziridine are often detected in more complex systems.

Despite the plethora of asymmetric palladium-catalyzed [3 + 2] cycloadditions of TMM complexes, the corresponding asymmetric [3 + 3] cycloaddition is limited to a single example. In 2006, Hayashi and Shintani provided the basis for the asymmetric approach with the development of a novel [3 + 3] cycloaddition of TMM complexes with azomethine imines.[20] Azomethine imines were reported in 1968 to be stable 1,3-dipoles, however, they had not previously been coupled with three-atom synthons in the context of a [3 + 3] cycloaddition. Nevertheless, the palladium-catalyzed reaction of the ylide **44** with **39** furnished the aza-bicycle **45** in excellent yield and diastereoselectivity (equation 5).
