BOB JONES *University*

LIBRARY

Greenville, South Carolina

The fact that this volume is included in the Bob Jones University Library does not mean that the University endorses its contents from the standpoint of morals, philosophy, theology, or scientific hypotheses. The position of Bob Jones University on these subjects is well known.

In order to standardize the work and validate the credits of Bob Jones University it is sometimes necessary to include in this library books whose contents the University cannot wholly endorse.

Preface

The vast growth in our knowledge of organic reactions, mechanisms, and structure since the completion of the first edition of this book has prompted this second edition. Every topic retained from the first edition has been brought up to date. Changes, ranging from minor to extensive, have been made on virtually every page of the first edition. Furthermore, a number of significant new topics have come to the fore in recent years, and these have also been included. Among the changes and additions are the following: (1) more than 100 new reactions including, among others, sigmatropic rearrangements, olefin metathesis, extrusion reactions, new 2 + 2 and other cycloadditions, many new reactions involving organoboranes, lithium dialkylcopper reagents, and metal carbonyl and other metallic coordination compounds, the Meyers and Story syntheses, the di-π-methane rearrangement, $AlCl_3$-catalyzed rearrangements, the synthetic use of organoselenium and arylthallium compounds, and a number of new oxidation and reduction reactions; (2) major advances in our understanding of many mechanisms, among them elimination, electrophilic addition to C=C bonds, both nucleophilic and electrophilic substitution at saturated carbon, amide hydrolysis, aromatic sulfonation, the Stevens and Wittig rearrangements, ozonolysis, and the addition of Grignard reagents to ketones; (3) other newly-included topics, including crown ethers, phase-transfer catalysts, memory effects, antiaromaticity, the syn-anti dichotomy, heterogeneous hydrogenation catalysts, correlation diagrams, Hückel and Möbius transition states, hard and soft acids and bases, CIDNP, photoelectron spectroscopy, enantiotopic and diastereotopic atoms, groups, and faces, introduction of functionality at remote positions, and $(CH)_n$ compounds.

Two chapters from the first edition have been dropped. One of these, on instrumental methods of structure determination, is no longer pertinent for an advanced organic chemistry course (though some of the material from this chapter has been used elsewhere in the book). This chapter has been replaced by a new one on photochemistry. In addition, the coverage of photochemical reactions and mechanisms in Part 2 of this book has been expanded. The other deleted chapter is the former appendix chapter on nomenclature, which was dropped with great reluctance, but the large size of the manuscript made its deletion necessary. Apart from these changes the structure of the second edition is essentially the same as that of the first.

The second edition, like the first, is intended to be a textbook for a course in advanced organic chemistry taken by students who have had the standard undergraduate organic and physical chemistry courses. I have attempted to give equal weight to the three fundamental aspects of the study of organic chemistry: reactions, mechanisms, and structure. A student who has completed a course based on this book should be able to approach the literature directly, with a sound knowledge of modern basic organic chemistry. I have treated lightly, or not at all, the major special areas of organic chemistry: terpenes, carbohydrates, proteins, polymerization and electrochemical reactions, steroids, and the like. It is my opinion that these topics are best approached after the first year of graduate study, when the fundamentals have been mastered, either in advanced courses, or directly, by consulting the many excellent books and review articles available on these subjects.

The organization is based on reaction types, so that the student can be shown that despite the large number of organic reactions, a relatively few principles suffice to explain nearly all of them. Accordingly, the reactions-mechanisms section of this book (Part 2) is divided into 10 chapters, each concerned with a different type of reaction. In the first part of each chapter the appropriate basic mechanisms are discussed along with considerations of reactivity and orientation, while the second part consists of numbered sections devoted to individual reactions, where the scope and the mechanism of each reaction are discussed. I have used numbered sections for the reactions, because I have found that students learn better when they are presented with clear outlines (for a further discussion of the arrangement of Part 2, see pp. 261–263). Since the methods for the preparation of individual classes of compounds, (e.g., ketones, nitriles, etc.) are not treated all in one place, an index has been provided (Appendix B) by use of which all methods for the preparation of a given type of compound will be found. For each reaction, a list of *Organic Synthesis* references is given. Thus for most reactions the student can consult actual examples in *Organic Syntheses.*

The structure of organic compounds is discussed in the first five chapters of Part 1. This section provides a necessary background for understanding mechanisms and is also important in its own right. The discussion begins with chemical bonding and ends with a chapter on stereochemistry. There follow two chapters on reaction mechanisms in general, one for ordinary reactions and the other for photochemical reactions. Part 1 concludes with two more chapters which give further background to the study of mechanisms.

In addition to reactions, mechanisms, and structure, the student should have some familiarity with the literature of organic chemistry. A chapter devoted to this topic has been placed in Appendix A, though many teachers may wish to cover this material at the beginning of the course.

In treating a subject as broad as the basic structures, reactions, and mechanisms of organic chemistry, it is obviously not possible to cover each topic in great depth. Nor would this be desirable even if possible. Nevertheless, students will often wish to pursue individual topics further. An effort has therefore been made to guide the reader to pertinent review articles and books published since about 1950. In this respect, this book is intended to be a guide to the secondary literature (since about 1950) of the field it covers. Furthermore, in a graduate course, students should be encouraged to consult primary sources. To this end I have included more than 6000 references to original papers.

Although basically designed for a one-year course on the graduate level, this book can also be used in advanced undergraduate courses as long as they are preceded by one-year courses in organic and physical chemistry. It can also be adapted, by the omission of a large part of its contents, to a one-semester course. Indeed, even for a one-year course, more is included than can be conveniently covered. Many individual sections can be easily omitted without disturbing continuity.

The reader will observe that this text contains much material which is included in first-year organic and physical chemistry courses, though in most cases it goes more deeply into each subject and, of course, provides references, which first-year texts do not. It has been my experience that students who have completed the first-year courses often have a hazy recollection of the material, and greatly profit from a re-presentation of the material if it is organized in a different way. It is hoped that the organization of the material on reactions and mechanisms will greatly aid the memory and the understanding. In any given course the teacher may want to omit some chapters because his students already have an adequate knowledge of the material, or because there are other graduate courses which cover the areas more thoroughly. Chapters 1, 4, and 7 especially may fall into one of these categories.

Although this is a textbook, it has been designed to have reference value also. Students who are preparing for qualifying examinations and practicing organic chemists will find that Part 2 contains a survey of what is known about the mechanism and scope of about 610 reactions, arranged in an orderly manner based on reaction type and on which bonds are broken and formed. Also valuable for reference purposes are the previously mentioned lists of reactions classified by type of compound prepared (Appendix B) and of all of the *Organic Syntheses* references to each reaction.

Once again, it is a pleasure to acknowledge the assistance of a number of chemists who have been kind enough to read portions of the manuscript and to send me their comments, which were exceedingly helpful. I wish to thank Professors J. F. Bunnett, A. W. Burgstahler, D. J. Cram, P. de Mayo, E. L. Eliel, R. W. Griffin, Jr., G. S. Hammond, M. Kreevoy, J. Landesberg, S. Moon, G. A. Olah, G. C. Pimentel, W. H. Saunders, Jr., C. G. Swain, R. W. Taft, Jr., W. S. Trahanovsky, N. J. Turro, C. Walling, and R. Wistar, each of whom read one or more chapters of either the first or second editions, and Professor B. B. Jarvis, who read the entire manuscript of the second edition. Special thanks are due to Professor C. A. Bunton, who read the entire manuscript of both the first and second editions. In addition, I wish to thank many of my colleagues at Adelphi University who have rendered assistance in various ways, among them F. Bettelheim, W. P. Gallagher, M. Hall, R. Halliday, J. Landesberg, S. Milstein, S. Moon, D. Purins, R. Rudman, A. J. Sisti, and S. Windwer. I am also grateful to those readers who wrote to tell me about errors they discovered in the first edition or to make other comments. Such letters are always welcome.

Jerry March

Bibliographical Note

In this book the practices used in citing references are slightly different from those prevailing elsewhere. The reader should note:

1 For review articles, both the first and last page numbers are given, so that the reader may form an idea of the length of the article. If reference is made to only a portion of the article, these page numbers are also given.
2 Author's initials are omitted in references. They will be found, however, in the author index.
3 When a journal is available both in Russian and in English, the page numbers of each article are, of course, different. The language of the journal title indicates whether the page number cited is to be found in the Russian or in the English version. For articles which have appeared in *Angewandte Chemie, International Edition in English*, both the English and German page numbers are given.
4 Certain hardbound serial publications (see p. 1156) are here cited as journals rather than as books.

PART ONE

This book contains 19 chapters. Chapters 10 through 19, which make up Part 2, are directly concerned with organic reactions and their mechanisms. Chapters 1 through 9 may be thought of as an introduction to Part 2. The first five chapters constitute a unit dealing with the structure of organic compounds. In this unit we shall discuss the kinds of bonding important in organic chemistry, the three-dimensional structure of organic molecules, and the structure of species in which the valence of carbon is less than 4. Chapters 6 to 9 are concerned with other topics which help to form a background to Part 2: acids and bases, photochemistry, the relationship between structure and reactivity, and a general discussion of mechanisms and of the means by which they are determined.

One

Localized Chemical Bonding

Localized chemical bonding, which is treated in this chapter, may be defined as bonding in which the electrons are shared by two and only two nuclei. In Chapter 2 we shall consider *delocalized bonding*, in which electrons are shared by more than two nuclei. But before we can intelligently discuss bonding at all, we must consider the electronic structure of atoms, in which the electrons surround only one nucleus.

Atomic Orbitals[1]

The fundamental principle upon which wave mechanics is based is that electrons behave as waves (e.g., they can be diffracted) and that consequently a wave equation can be written for them, in the same sense that light waves, sound waves, etc., can be described by wave equations. The equation which serves as a mathematical model for electrons is known as the *Schrödinger equation*, and for a one-electron system is

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E - V)\psi = 0 \qquad (1)$$

where m is the mass of the electron, E is its total energy, V is its potential energy, and h is Planck's constant. In physical terms, the function ψ expresses the square root of the probability of finding the electron at any position defined by the coordinates x, y, and z, where the origin is at the nucleus. For systems containing more than one electron the equation is similar but more complicated.

The solutions to the Schrödinger equation are themselves equations. Solutions exist only for certain values of E. These are called *eigenvalues*, and the solutions are called *eigenfunctions*. This is another way of saying that the energy possessed by electrons is quantized. For the hydrogen atom, which is spherically symmetrical, the natural coordinate system is the system of spherical polar coordinates (r, θ, and ϕ), and solutions to (1) for the hydrogen atom are generally expressed in these coordinates. The spherical coordinates are related to the rectangular coordinates as follows (see Figure 1):

$$x = r \sin\theta \cos\phi \qquad (2)$$

$$y = r \sin\theta \sin\phi \qquad (3)$$

$$z = r \cos\theta \qquad (4)$$

$$r = (x^2 + y^2 + z^2)^{1/2} \qquad (5)$$

---

[1] The treatment of atomic and molecular orbitals given here is necessarily simplified. For much fuller treatments of orbital theory as applied to organic chemistry, see Dewar, "The Molecular Orbital Theory of Organic Chemistry," McGraw-Hill Book Company, New York, 1969; Liberles, "Introduction to Molecular-Orbital Theory," Holt, Rinehart, and Winston, New York, 1966; Streitwieser, "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, Inc., New York, 1961; Coulson, "Valence," 2d ed., Oxford University Press, New York, 1961; Coulson and Stewart, in Patai, "The Chemistry of Alkenes," pp. 1–147, Interscience Publishers, Inc., New York, 1964; and Higasi, Baba, and Rembaum, "Quantum Organic Chemistry," Interscience Publishers, Inc., New York, 1965.

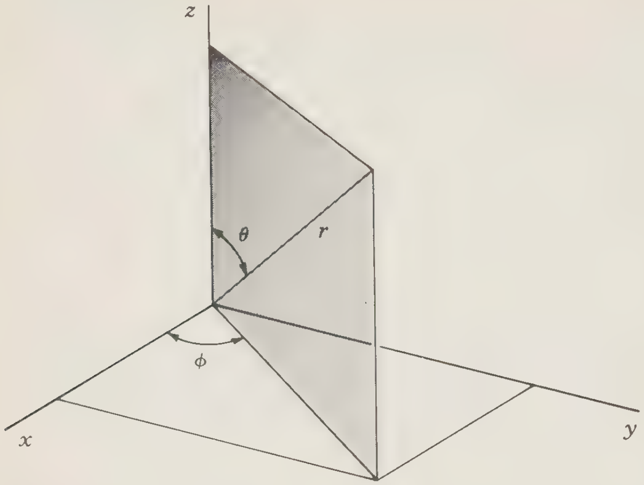

Figure 1 The spherical coordinates.

For a given point *P*, the coordinate r is the distance between the origin O and the point, while θ represents the angle between the line OP and the z axis and ϕ is the angle between the xz plane and the plane containing OP and the z axis.

For the hydrogen atom, the potential energy is

$$V = -\frac{Ze^2}{r} \tag{6}$$

where r is the distance between the nucleus and the electron, e the charge on the electron, and Z the nuclear charge (in this case, 1). The solution of the Schrödinger equation which corresponds to the lowest possible energy for the electron is

$$\psi = \frac{1}{\sqrt{\pi}}\left(\frac{Z}{a_0}\right)^{3/2} e^{-Zr/a_0} \tag{7}$$

where

$$a_0 = \frac{h^2}{4\pi^2 me^2} \tag{8}$$

The energy corresponding to this solution is

$$E = \frac{-2\pi^2 mZ^2e^4}{h^2} \tag{9}$$

which turns out to be -13.60 eV. The distance a_0, which is equal to 0.529Å, is called the *Bohr radius.*

Three of the higher solutions are

$$\psi = \frac{1}{\sqrt{32\pi}}\left(\frac{Z}{a_0}\right)^{5/2} re^{-Zr/2a_0}\cos\theta \tag{10}$$

$$\psi = \frac{1}{\sqrt{64\pi}}\left(\frac{Z}{a_0}\right)^{5/2} re^{-Zr/2a_0} \sin\theta \cos\phi \tag{11}$$

$$\psi = \frac{1}{\sqrt{64\pi}}\left(\frac{Z}{a_0}\right)^{5/2} re^{-Zr/2a_0} \sin\theta \sin\phi \tag{12}$$

Since the energies corresponding to these three eigenfunctions are equal, the energy levels are said to be *degenerate*. There are an infinite number of other solutions, each with its corresponding energy, but there are no solutions with an energy between those of any two successive solutions.

Since these eigenfunctions are equations, we can graph them. The graphs are three-dimensional pictures of the density of the electron. The graph corresponding to Eq. (7) shows that the electron density is distributed symmetrically about the nucleus. The density increases along a line beginning at the nucleus and proceeding in any direction until a maximum is reached, after which it rapidly drops off. This maximum is at $r = 0.529$ Å; i.e., it is at the Bohr radius. Although in theory there is still some density at an infinite distance from the nucleus, it is possible to draw a sphere with a radius of about 4 or 5 times that of the Bohr radius and enclose nearly all the electron density in it. Such a sphere is shown in Figure 2.

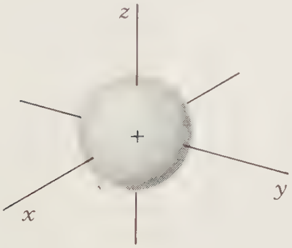
A wave function like that depicted in Figure 2 is called an *orbital* or an electron cloud. Some have spherical symmetry, like that in Figure 2. These are called s orbitals. The orbital corresponding to Eq. (10), shown in Figure 3, is called a p orbital. Unlike s orbitals, p orbitals are not spherically symmetrical but are directed along one of the axes. A p orbital consists of two lobes, separated by a *node*, which is a region in space where the probability of finding the electron is very small, almost zero.[2] In this case the node is the entire xy plane. In Figure 3 one lobe of the orbital is labeled + and the other −. These signs do not refer to positive or negative *charges*, since both lobes of an electron cloud must be negatively charged. They are the signs of the function ψ. When two parts of any orbital are separated by a node, ψ always has opposite signs on the two sides of the node. Other things being equal, the more nodes an orbital has, the higher its energy.

The orbitals corresponding to Eqs. (11) and (12) have the same shape as the one in Figure 3, but they are directed along the other axes. The three p orbitals are often called p_x, p_y, and p_z, to distinguish among them. There are also orbitals of higher energy, called d and f orbitals, but

---

[2] When wave-mechanical calculations are made according to the Schrödinger equation, the probability of finding the electron in a node is zero, but this treatment ignores relativistic considerations, and when such considerations are applied, Dirac has shown that nodes do have a very small electron density: Powell, *J. Chem. Educ.* **45**, 558 (1968).

Figure 2 The wave function for the lowest energy level (ground state) of the hydrogen atom.



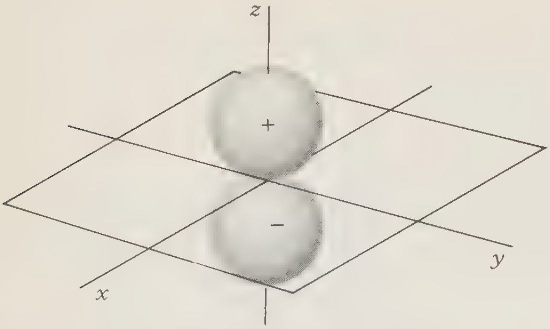


Figure 3 The orbital corresponding to Eq. (10).

we shall not consider their shapes here since they are less important to organic chemists than the *s* and *p* orbitals.[3]

The orbital shown in Figure 2 corresponds to the lowest possible energy for the electron of the hydrogen atom. It is called the 1*s* orbital. If we examine the eigenfunctions corresponding to the next energy value, we find four additional orbitals. One of these, called the 2*s* orbital, is spherical and contains a node (Figure 4). The others are the three *p* orbitals mentioned before, which are called 2*p* orbitals. Orbitals of higher energy are 3*s*, 3*p*, 3*d*, 4*s*, etc. In any given hydrogen atom, the electron at any instant is in only one of these orbitals. The others exist only as potential states. However, it is possible (and often happens) that an electron may pass from one orbital to another. When this occurs, the orbital previously occupied becomes a potential state and the new one is occupied. In order for an electron to go from a lower-energy orbital to a higher one, it must get energy from somewhere; and when it goes from a higher to a lower state, it must give up the necessary energy. Not all transitions are allowed; selection rules determine the ones which can occur. When the electron is in the 1*s* orbital, the hydrogen atom is said to be in the *ground state*. All levels above the ground state are called *electronically excited states.*

Unfortunately, the Schrödinger equation can be solved exactly only for one-electron atomic systems, such as the hydrogen atom or He^+. For all systems more complicated than this, approximations are required. For a number of simple cases, such as the hydrogen molecule and the helium atom, these approximate solutions are so accurate that for practical purposes they are as good as exact solutions.[4] Even for atoms much larger than helium, a good qualitative picture is at hand. By the use of the following principles, electronic structures can be determined for atoms up to about calcium:

1. In any atom the orbitals available for electron occupancy are similar in shape to those of the hydrogen atom, though the energies are different. The designations 1*s*, 2*s*, 2*p*, etc., are the same.

2. In the ground state of any atom the electrons occupy the lowest possible energy levels. If even one electron is in an orbital of energy higher than a vacant orbital, the atom is in an excited state.

---

[3] The shapes of many atomic and molecular orbitals can be found in Streitwieser and Owens, "Orbital and Electron Density Diagrams," The Macmillan Company, New York, 1973. For the shapes of all the molecular orbitals in 104 typical molecules, see Jorgensen and Salem, "The Organic Chemist's Book of Orbitals," Academic Press, Inc., New York, 1973.

[4] See, for example, Roothaan and Weiss, *Rev. Mod. Phys.* **32,** 194 (1960); Kolos and Roothaan, *Rev. Mod. Phys.* **32,** 219 (1960). For a review, see Clark and Stewart, *Q. Rev., Chem. Soc.* **24,** 95–118 (1970).

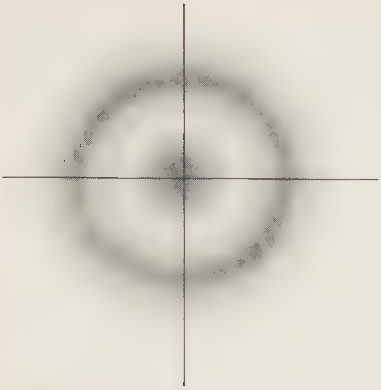

Figure 4 Cross section of a $2s$ orbital.

3. No more than two electrons may be present in an orbital, and they must have opposite spins.[5] This is the *Pauli exclusion principle*.

4. When a number of degenerate orbitals are available and there are not enough electrons to fill them all, then all the orbitals will be half-filled before any of them are filled. This is called *Hund's rule*. For example, the nitrogen atom has seven electrons. Four of these are accommodated in the two orbitals of lowest energy, the $1s$ and $2s$ orbitals. Above these are the three p orbitals, which can hold a maximum of six electrons. Hund's rule tells us that each of the three remaining electrons will go into a different $2p$ orbital; i.e., the configuration of the ground state of the nitrogen atom is $1s^2 2s^2 2p_x{}^1 2p_y{}^1 2p_z{}^1$ and not $1s^2 2s^2 2p_x{}^2 2p_y{}^1$. Hund's rule is valid because a situation in which two electrons have parallel spins is of lower energy than that in which the spins are opposite, owing to the greater mutual repulsion of electrons with opposite spins. In the case of a $2p_x{}^2 2p_y{}^1$ configuration, two of the electrons must have opposite spins (or they could not be in the same orbital), while for $2p_x{}^1 2p_y{}^1 2p_z{}^1$ all the spins may be and generally are parallel.

For atoms higher than hydrogen, the energy of the orbitals is in the order $1s < 2s < 2p < 3s < 3p < 4s$. From this, and the above rules, the electronic structures for the ground states of the first 20 atoms are

H	$1s^1$	**Na**	Ne core $3s^1$
He	$1s^2$	**Mg**	Ne core $3s^2$
Li	$1s^2 2s^1$	**Al**	Ne core $3s^2 3p_x{}^1$
Be	$1s^2 2s^2$	**Si**	Ne core $3s^2 3p_x{}^1 3p_y{}^1$
B	$1s^2 2s^2 2p_x{}^1$	**P**	Ne core $3s^2 3p_x{}^1 3p_y{}^1 3p_z{}^1$
C	$1s^2 2s^2 2p_x{}^1 2p_y{}^1$	**S**	Ne core $3s^2 3p_x{}^2 3p_y{}^1 3p_z{}^1$
N	$1s^2 2s^2 2p_x{}^1 2p_y{}^1 2p_z{}^1$	**Cl**	Ne core $3s^2 3p_x{}^2 3p_y{}^2 3p_z{}^1$
O	$1s^2 2s^2 2p_x{}^2 2p_y{}^1 2p_z{}^1$	**Ar**	Ne core $3s^2 3p_x{}^2 3p_y{}^2 3p_z{}^2$
F	$1s^2 2s^2 2p_x{}^2 2p_y{}^2 2p_z{}^1$	**K**	Ar core $4s^1$
Ne	$1s^2 2s^2 2p_x{}^2 2p_y{}^2 2p_z{}^2$	**Ca**	Ar core $4s^2$

It is the custom to designate the first occupied orbital of a set of p orbitals as the p_x orbital. Of course, this is purely arbitrary, since the three p orbitals differ only in direction. For example, it would be just as correct to show the electronic structure of boron as $1s^2 2s^2 2p_y{}^1$ or $1s^2 2s^2 2p_z{}^1$.

---

[5] In this book we shall not define electron spin but merely state that it is a property of an electron for which two and only two possible states exist.

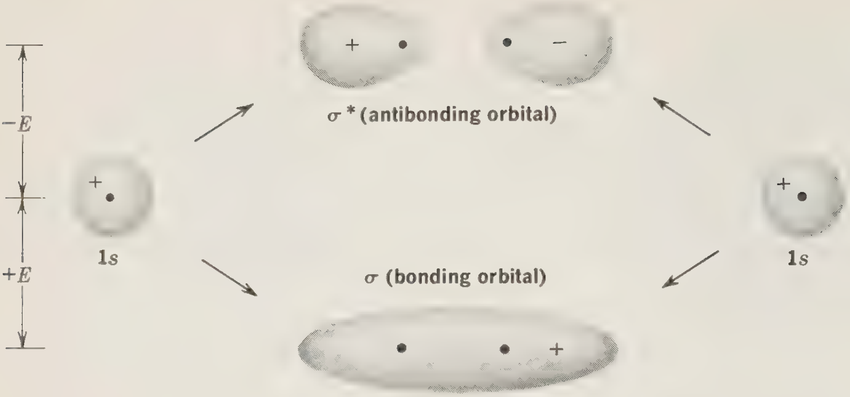

Figure 5 Overlap of two 1*s* orbitals gives rise to a σ and a σ^* orbital.

Covalent Bonding

If the Schrödinger equation could be exactly solved for molecules, we would have a complete picture which would show for each electron precisely the shape of the orbitals available to it (especially for the important ground state) and the energy for each orbital. Since exact solutions are not available, drastic approximations must be made. There are two chief general methods of approximation, called the *molecular-orbital* method and the *valence-bond* method.

In the molecular-orbital method bonding is considered to arise from the overlap of atomic orbitals. When any number of atomic orbitals overlap, they disappear and are replaced by the same number of new orbitals, called *molecular orbitals*. Molecular orbitals differ from atomic orbitals in that they are clouds which surround the nuclei of two or more atoms, rather than just one. In localized bonding the number of atomic orbitals which overlap is two (each containing one electron), so that two molecular orbitals are generated. One of these, called a *bonding orbital*, has a lower energy than the original atomic orbitals (otherwise a bond would not form), and the other, called an *antibonding orbital*, has a higher energy. Whereas the two original atomic orbitals each held one electron, both of these electrons may now go into the new molecular *bonding* orbital, since any orbital can hold two electrons. The antibonding orbital remains empty in the ground state. The greater the overlap, the stronger the bond, although total overlap is prevented by repulsion between the nuclei. Figure 5 shows the bonding and antibonding orbitals which arise by overlap of two 1*s* electrons.[3] Note that since the antibonding orbital has a node between the nuclei, there is practically no electron density in that area, so that this orbital cannot be expected to bond very well. Molecular orbitals formed by overlap of two atomic orbitals when the centers of electron density are on the axis common to the two nuclei are called σ orbitals, and the bonds so formed are called σ bonds. Corresponding antibonding orbitals are designated σ^*. Because total energy is conserved when molecular orbitals are formed from atomic orbitals, the total energy of the σ and σ^* orbitals must equal the total energy of the two atomic orbitals, so that the σ^* orbital is destabilized by the same amount of energy by which the σ orbital is stabilized (this is called the *bond energy D*, see p. 26). σ orbitals are formed not only by overlap of two *s* orbitals but also by overlap of any of the kinds of atomic orbital mentioned earlier (*s*, *p*, *d*, or *f*) whether they are the same or different, but the two lobes which overlap must have the same sign: a positive *s* orbital can form a bond only by overlapping with another positive *s* orbital or with a positive lobe of a *p*, *d*, or *f* orbital. Any σ orbital, no matter what kind of atomic orbitals it has arisen from, may be represented as approximately ellipsoidal in shape.

Orbitals are frequently designated by their symmetry properties. The σ orbital of hydrogen is often written Ψ_g. The g stands for *gerade*. A gerade orbital is one in which the sign of the orbital does not change when it is reflected through its center of symmetry. The σ^* orbital is *ungerade* (designated Ψ_u). An ungerade orbital changes sign when reflected through its center of symmetry.

In molecular-orbital calculations, a wave function is formulated which is a linear combination of the atomic orbitals which have overlapped (this method is often called the *linear combination of atomic orbitals*, or LCAO):

$$\Psi = c_\mathrm{A}\psi_\mathrm{A} + c_\mathrm{B}\psi_\mathrm{B} \tag{13}$$

The functions ψ_A and ψ_B are the functions for the atomic orbitals of atoms A and B, respectively, and c_A and c_B represent weighting factors.

In the valence-bond method, a wave equation is written for each of various possible electronic structures which a molecule may have (each of these is called a *canonical form*), and the total Ψ is obtained by summation of as many of these as seem plausible, each with its weighting factor:

$$\Psi = c_\mathrm{A}\psi_\mathrm{A} + c_\mathrm{B}\psi_\mathrm{B} + \cdots \tag{14}$$

This resembles Eq. (13), but here each ψ represents a wave equation for an imaginary canonical form and each c is the amount contributed to the total picture by that form. For example, a wave function can be written for each of the following canonical forms of the hydrogen molecule:[6]

$$\mathrm{H{-}H} \qquad {}^{\ominus}\overline{\mathrm{H}}\quad \mathrm{H}^{\oplus} \qquad {}^{\oplus}\mathrm{H}\quad \overline{\mathrm{H}}^{\ominus}$$

Values for c in each method are obtained by solving the equation for various values of each c and choosing the solution of lowest energy. In practice, both methods give similar solutions for molecules which contain only localized electrons, and these are in agreement with the Lewis structures long familiar to the organic chemist. Delocalized systems are considered in Chapter 2.

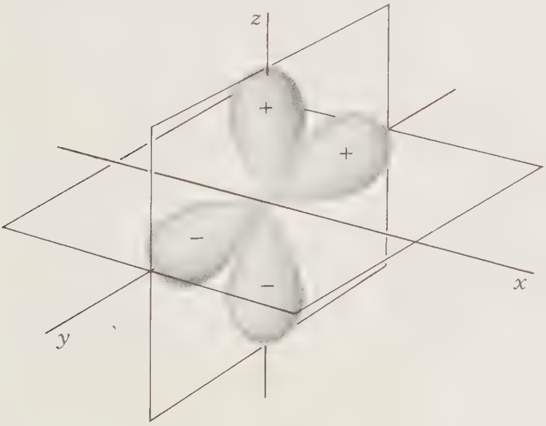
Multiple Valence

A univalent atom has only one orbital available for bonding. But atoms with a valence of 2 or more must form bonds by using at least two orbitals. From our previous discussion of atomic orbitals, we have seen that the oxygen atom has two half-filled orbitals, thus giving it a valence of

---

[6] In this book a pair of electrons, whether in a bond or unshared, is represented by a straight line.

Figure 6 The p orbitals of oxygen which are available for bonding.



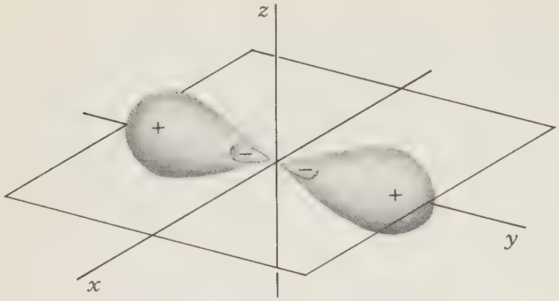


Figure 7 The two *sp* orbitals formed by mercury.

2. It forms single bonds by overlap of these with the orbitals of two other atoms. According to the principle of maximum overlap, the other two nuclei should form an angle of 90° with the oxygen nucleus, since the two available orbitals on oxygen are *p* orbitals, which are perpendicular (Figure 6). Similarly, we should expect that nitrogen, which has three mutually perpendicular *p* orbitals, would have bond angles of 90° when it forms three single bonds. However, these are not the observed bond angles. The bond angles are,[7] in water, 104°27′, and in ammonia, 106°46′. For alcohols and ethers the angles are even larger (see p. 25). A discussion of this will be deferred to p. 25, but it is important to note that covalent compounds do have definite bond angles. Although the atoms are continuously vibrating, the mean position is the same for each molecule of a given compound.

Hybridization

Consider the case of mercury. Its electronic structure is

$$\text{Xe core } 4f^{14}5d^{10}6s^2$$

Although it has no half-filled orbitals, it has a valence of 2 and forms two covalent bonds. We can explain this by imagining that one of the 6*s* electrons is promoted to a vacant 6*p* orbital to give the configuration

$$\text{Xe core } 4f^{14}5d^{10}6s^1 6p^1$$

In this state the atom has two half-filled orbitals, but they are not equivalent. If bonding were to occur by overlap of these orbitals with the orbitals of external atoms, the two bonds would not be equivalent and the bond formed from the 6*p* orbital would be more stable than the one formed from the 6*s* orbital, since a larger amount of overlap is possible with the former. A more stable situation is achieved when, in the course of bond formation, the 6*s* and 6*p* orbitals combine to form two new orbitals which *are* equivalent; these are shown in Figure 7.

Since these new orbitals are a mixture of the two original orbitals, they are called *hybrid orbitals*. Each is called an *sp* orbital, since a merger of an *s* and a *p* orbital was required to form it. The *sp* orbitals, each of which consists of a large lobe and a very small one, are atomic orbitals, although they can arise only in the bonding process and do not represent a possible structure for the free atom. A mercury atom forms its two bonds by overlapping each of the large lobes shown in Figure 7 with an orbital from an external atom. This external orbital may be any of the atomic orbitals previously considered (*s*, *p*, *d*, or *f*), or it may be another hybrid orbital, though of course

---

[7] Bent, *Chem. Rev.* **61**, 275–311 (1961), p. 277.

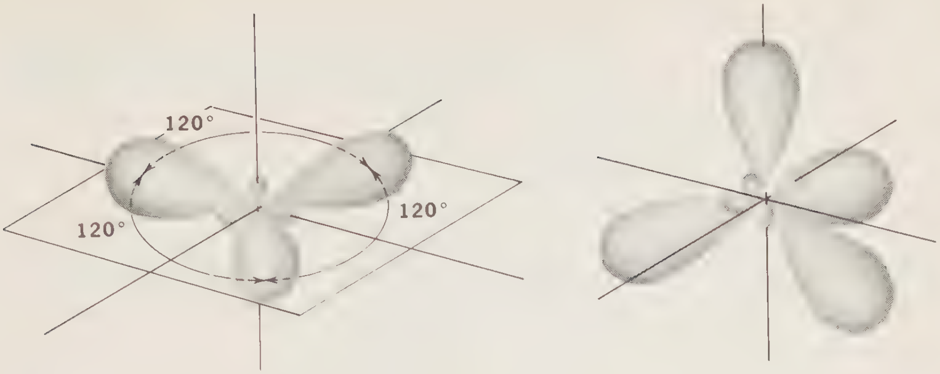

Figure 8 The three sp^2 and the four sp^3 orbitals.

only lobes of the same sign can overlap. In any of these cases the molecular orbital which arises is called a σ orbital since it fits our previous definition of a σ orbital (p. 8).

In general, because of mutual repulsion, equivalent orbitals lie as far away from each other as possible, and so the two *sp* orbitals form an angle of 180°. This means that $HgCl_2$, for example, should be a linear molecule (in contrast to H_2O), and it is. This kind of hybridization is called *digonal hybridization*. An *sp* hybrid orbital forms a stronger covalent bond than either an *s* or a *p* orbital because it extends out in space in the direction of the other atom's orbital farther than the *s* or the *p* and so permits greater overlap. Although it would require energy to promote a 6*s* electron to the 6*p* state, the extra bond energy more than makes up the difference.

Many other kinds of hybridization are possible, of which we shall discuss two. Consider boron, which has the electronic configuration

$$1s^2 2s^2 2p^1$$

yet has a valence of 3. Once again we may imagine promotion and hybridization:

$$1s^2 2s^2 2p^1 \longrightarrow 1s^2 2s^1 2p_x{}^1 2p_y{}^1 \longrightarrow 1s^2 (sp^2)^3$$

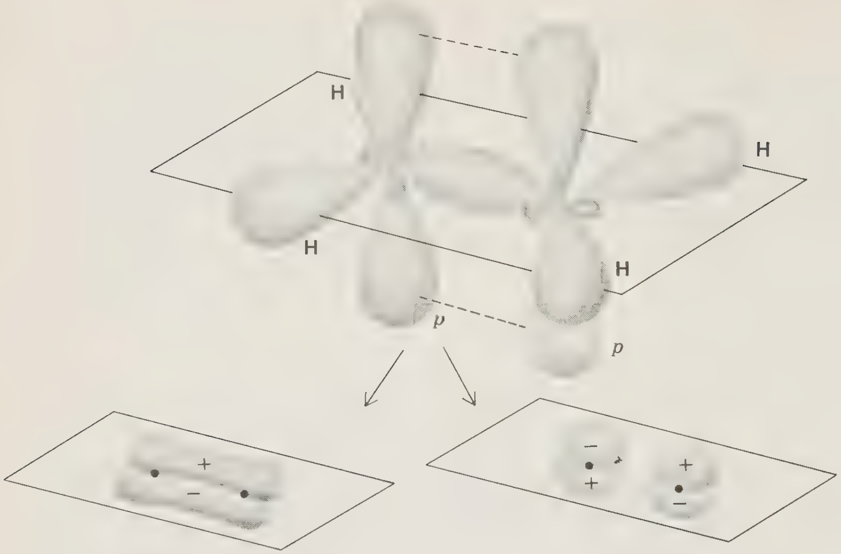
In this case there are three equivalent hybrid orbitals, each called sp^2 (*trigonal hybridization*). This method of designating hybrid orbitals is perhaps unfortunate since nonhybrid orbitals are designated by single letters, but it must be kept in mind that *each* of the three orbitals is called sp^2. These orbitals are shown in Figure 8. The three axes are all in one plane and point to the corners of an equilateral triangle. This is in accord with the known structure of BF_3, a planar molecule with angles of 120°.

The case of carbon (in forming four single bonds) may be represented as follows:

$$1s^2 2s^2 2p_x{}^1 2p_y{}^1 \longrightarrow 1s^2 2s^1 2p_x{}^1 2p_y{}^1 2p_z{}^1 \longrightarrow 1s^2 (sp^3)^4$$

Here there are four equivalent orbitals, each called sp^3, which point to the corners of a regular tetrahedron (Figure 8). The bond angles of methane would thus be expected to be 109°28′, which is the angle for a regular tetrahedron.

Although the hybrid orbitals discussed in this section satisfactorily account for most of the physical and chemical properties of the molecules involved, it is necessary to point out that the sp^3 orbitals, for example, stem from only one possible approximate solution of the Schrödinger equation. The *s* and the three *p* atomic orbitals can also be combined in many other equally valid ways. As we shall see on p. 15, the four C—H bonds of methane do not always behave as if they are equivalent.



π orbital (bonding)

π* orbital (antibonding)

Figure 9 Overlapping *p* orbitals form a π and a π* orbital. The σ orbitals are shown in the upper figure. They are still there in the diagrams below but have been removed from the picture for clarity.

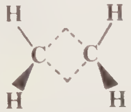
Multiple Bonds

If we consider the ethylene molecule in terms of the molecular-orbital concepts so far discussed, we have each carbon using sp^2 orbitals to form bonds with the three atoms to which it is connected. These sp^2 orbitals arise from hybridization of the $2s^1$, $2p_x{}^1$, and $2p_y{}^1$ electrons of the promoted state shown on p. 11. We may consider that any carbon atom which is bonded to only three different atoms uses sp^2 orbitals for this bonding. Each carbon of ethylene is thus bonded by three σ bonds: one to each hydrogen and one to the other carbon. Each carbon therefore has another electron in the $2p_z$ orbital, which, by the principle of maximum repulsion, is perpendicular to the plane of the sp^2 orbitals. The two parallel $2p_z$ orbitals can overlap sideways to generate two new orbitals, a bonding and an antibonding orbital (Figure 9). Of course, in the ground state both electrons go into the bonding orbital, and the antibonding orbital remains vacant. Molecular orbitals which are formed by overlap of atomic orbitals whose axes are parallel are called π orbitals if they are bonding and π* if they are antibonding.

In this picture of ethylene, the two orbitals which make up the double bond are not equivalent. The σ orbital is ellipsoidal and symmetrical about the C—C axis. The π orbital is in the shape of two ellipsoids, one above the plane and one below. The plane itself represents a node for the π orbital. In order for the *p* orbitals to maintain maximum overlap, they must be parallel. This means that free rotation is not possible about the double bond, since the two *p* orbitals would have to reduce their overlap to allow one H—C—H plane to rotate with respect to the other. The six atoms of a double bond are therefore in a plane with angles which should be about 120°. Double bonds are shorter than the corresponding single bonds because maximum stability is obtained when the *p* orbitals overlap as much as possible.

Figure 10 The σ electrons of acetylene

The lack of free rotation about double bonds can also be explained by the *bent-bond* picture,[8] in which the two bonds in the double bond of the ethylene molecule are equivalent. The centers of electron density are pointed *away* from the C—C axis:



That is, all four of the bonds of each carbon point to the corners of a tetrahedron. This is essentially the old picture of formation of a double bond by joining two tetrahedra together along one edge. Although there are some reasons to support this picture,[9] rather than the σ-π concept, in this book we shall use the latter because most of the recent literature is written in these terms. Similar pictures of both kinds can be drawn for double bonds between carbon and oxygen or nitrogen.

In triple-bond compounds, carbon is connected to only two other atoms and hence uses *sp* hybridization, which means that the four atoms involved are in a straight line (Figure 10).[10] Each carbon has two *p* orbitals remaining, with one electron in each. These orbitals are perpendicular to each other and to the C—C axis. They overlap in the manner shown in Figure 11 to form two π orbitals. A triple bond is thus composed of one σ and two π orbitals. (In the bent-bond

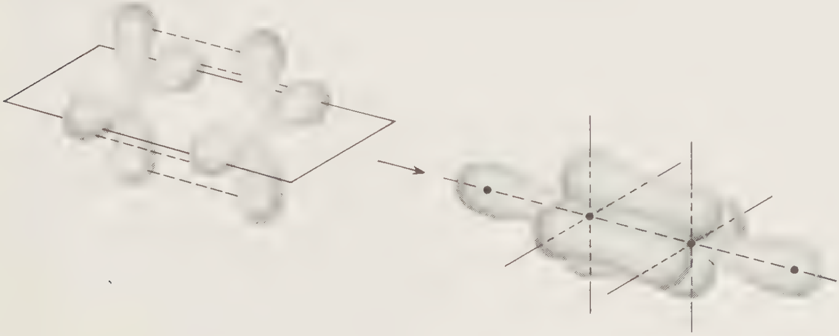
[8] Pauling, in "Theoretical Organic Chemistry, The Kekulé Symposium," pp. 2-5, Butterworth Scientific Publications, London, 1959. Bent bonds are also called "banana bonds." See also Walters, *J. Chem. Educ.* **43**, 134 (1967).

[9] For example, the σ-π picture predicts an H—C—C angle of 120°, while this angle in the bent-bond picture would be 125°16′. Although the H—C—C angle in ethylene is about 121 to 122°, the corresponding angle is larger for other olefins: 124.8° for propylene, 124° for isobutylene, etc. (see Ref. 8). Also, charge-density calculations show that in ethylene the electrons associated with the C—C bond tend to accumulate above and below the molecular plane [Roux, Cornille, and Burnelle, *J. Chem. Phys.* **37**, 933 (1962)].

[10] For a review of triple bonds, see Dale, in Viehe, "Acetylenes," pp. 3–96, Marcel Dekker, Inc., New York, 1969.

Figure 11 Overlap of *p* orbitals in a triple bond. For clarity, the σ orbitals have been removed from the drawing on the left, though they are shown on the right.



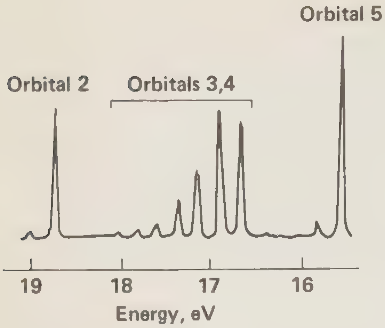


Figure 12 Photoelectron spectrum of N_2.[14]

picture, a triple bond is made up of two tetrahedra with a common face.) Triple bonds between carbon and nitrogen can be represented in a similar manner.

Double and triple bonds are important only for the first-row elements carbon, nitrogen, and oxygen. For second-row elements multiple bonds are rare and compounds containing them are unstable[10a] because the *p* orbitals necessary to form them are farther apart and hence overlap less. The only ones of any importance at all are C═S bonds, and C═S compounds are generally much less stable than the corresponding C═O compounds (however, see p. 39).

Photoelectron Spectroscopy

Although the four bonds of methane are equivalent according to most physical and chemical methods of detection (for example, neither the nmr nor the ir spectrum of methane contains peaks which can be attributed to different kinds of C—H bonds), there is one physical technique which shows that the eight valence electrons of methane can be differentiated. In this technique, called *photoelectron spectroscopy*,[11] a molecule or free atom is bombarded with vacuum ultraviolet radiation,[12] causing an electron to be ejected. The energy of the ejected electron can be measured, and the difference between the energy of the radiation used and that of the ejected electron is the *ionization potential* of that electron. A molecule which contains several electrons of differing energies can lose any one of them, as long as its ionization potential is less than the energy of the radiation used (a single molecule loses only one electron; loss of two electrons by any individual molecule almost never occurs). A photoelectron spectrum therefore consists of a series of bands, each of which corresponds to an orbital of a different energy. The spectrum gives a direct experimental picture of all of the orbitals present, in order of their energies, provided that radiation of sufficiently high energy is used.[13] Broad bands usually correspond to strongly bonding electrons

[12] Other kinds of radiation, of higher energy, can also be used.

[13] The correlation is not perfect, but the limitations do not seriously detract from the usefulness of the method.

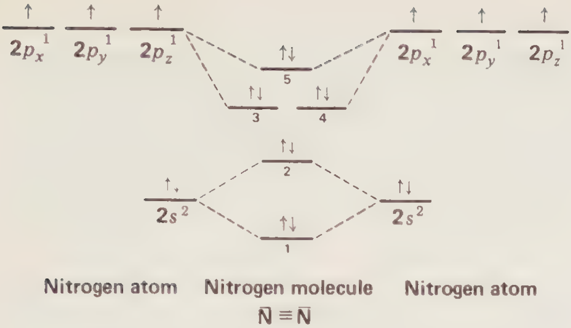

Figure 13 Electronic structure of N_2 (inner-shell electrons omitted).[14]

and narrow bands to weakly bonding or nonbonding electrons. A typical spectrum is that of N_2, shown in Figure 12.[14] The N_2 molecule has the electronic structure shown in Figure 13. The two 2*s* orbitals of the nitrogen atoms combine to give the two orbitals marked 1 (bonding) and 2 (antibonding), while the six 2*p* orbitals combine to give six orbitals, three of which (marked 3, 4, and 5) are bonding. The three antibonding orbitals (not indicated in Figure 13) are unoccupied. Electrons ejected from orbital 1 are not found in Figure 12 because the ionization potential of these electrons is greater than the energy of the light used (they can be seen when higher-energy light is used). The broad band in Figure 12 (the individual peaks within this band are caused by different vibrational levels; see Chapter 7) corresponds to the four electrons in the degenerate orbitals 3 and 4. The triple bond of N_2 is therefore composed of these two orbitals and of orbital 1. The bands corresponding to orbitals 2 and 5 are narrow; hence these orbitals contribute little to the bonding and may be regarded as the two unshared pairs of $\bar{N}\equiv\bar{N}$. Note that this result is contrary to that expected from a naïve consideration of orbital overlaps, where it would be expected that the two unshared pairs would be those of orbitals 1 and 2, which result from overlap of the filled 2*s* orbitals, and that the triple bond would be composed of orbitals 3, 4, and 5, resulting from overlap of the *p* orbitals. This example is one illustration of the value of photoelectron spectroscopy.

The photoelectron spectrum of methane[15] shows *two* bands,[16] at about 23 and 14 eV, and not the single band we would expect from the equivalency of the four C—H bonds. The reason is that ordinary sp^3 hybridization is not adequate to explain phenomena involving ionized molecules (such as the $CH_4{\cdot}^+$ radical ion, which is left behind when an electron is ejected from methane). For these phenomena it is necessary to use other combinations of atomic orbitals (see p. 11). The band at 23 eV comes from two electrons in a low energy level (called the a_1 level), which can be regarded as arising from a combination of the 2*s* orbital of carbon with an appropriate combination of hydrogen 1*s* orbitals. The band at 14 eV, which is more bonding than the other, comes from six electrons in a triply degenerate level (the (t_2 level) arising from a combination of the three 2*p* orbitals of carbon with other combinations of 1*s* hydrogen orbitals. As mentioned above, most physical and chemical processes cannot distinguish these levels, but photoelectron spectroscopy is one technique which can.

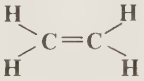
[16] A third band, at 290 eV, caused by the 1*s* electrons of carbon, can also be found if radiation of sufficiently high energy is used.

Electronic Structures of Molecules

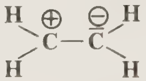
For each molecule, ion, or free radical which has only localized electrons, it is possible to draw an electronic formula, called a *Lewis structure*, which shows the location of these electrons. In practice only the valence electrons are shown. These may be found in covalent bonds connecting two atoms, or they may be unshared. It is important that the student be able to draw these structures correctly, since the position of electrons changes in the course of a reaction, and it is necessary to know which orbitals the electrons are in initially before one can follow where they are going. To this end, the following rules operate:

1. The total number of valence electrons in the molecule (or ion or free radical) must be the sum of all outer-shell electrons "contributed" to the molecule by each atom plus the negative charge or minus the positive charge, for the case of ions. Thus, for H_2SO_4, there are 2 (one for each hydrogen) + 6 (for the sulfur) + 24 (6 for each oxygen) = 32; while for SO_4^{2-}, the number is also 32, since each atom "contributes" 6, plus 2 for the negative charge.

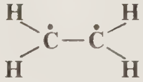
2. Once the number of valence electrons has been ascertained, it is necessary to determine which of them are found in covalent bonds and which are unshared. Unshared electrons (either a single electron or a pair) form part of the outer shell of just one atom, but electrons in a covalent bond are part of the outer shell of both atoms of the bond. *First-row atoms* (B, C, N, O, F) *can have a maximum of eight valence electrons*, and usually have this number, although some cases are known where a first-row atom has only six or seven. Where there is a choice between a structure which has six or seven electrons around a first-row atom and one in which all such atoms have an octet, it is the latter which generally has the lower energy and which consequently exists. For example, ethylene is



and not



or



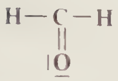
There are a few exceptions. In the case of the molecule O_2, the structure $|\dot{\underline{O}}-\dot{\underline{O}}|$ has a lower energy than $|\underline{O}=\underline{O}|$. Although first-row atoms are limited to 8 valence electrons, this is not so for second-row atoms, which can accommodate 10 or even 12 because they can use their empty d orbitals for this purpose.[17] For example, PCl_5 and SF_6 are stable compounds. In SF_6 one s and one p_x electron from the ground state $3s^2 3p_x^2 3p_y^1 3p_z^1$ are promoted to empty d orbitals, and the six orbitals hybridize to give six sp^3d^2 orbitals, which point to the corners of a regular octahedron.

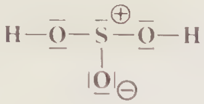
3. It is customary to show the formal charge on each atom. For this purpose an atom is considered to "own" all unshared electrons but only *one-half of the electrons in covalent bonds.* The sum of electrons which thus "belong" to an atom is compared with the number "contributed" by the atom. An excess belonging to the atom results in a negative charge, and a deficiency results in a positive charge. The total of the formal charges on all atoms equals the charge on the whole molecule or ion. It should be noted that the counting procedure is not the same for determining formal charge as it is for determining the number of valence electrons. For both purposes an atom "owns" all unshared electrons, but for outer-shell purposes it "owns" both of the electrons of the covalent bond, while for formal-charge purposes, it "owns" only one-half of these electrons.

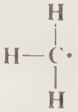
---

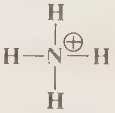
[17] For reviews concerning sulfur compounds with a valence shell larger than eight, see Cilento, *Chem. Rev.* **60,** 147-167 (1960), and Salmond, *Q. Rev., Chem. Soc.* **22,** 253-275 (1968).

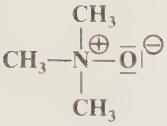
Examples of electronic structures are (as mentioned in footnote 6, in this book an electron pair, whether unshared or in a bond, is represented by a straight line):

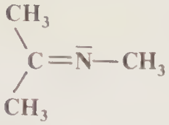


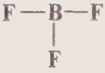


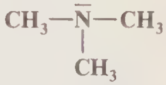




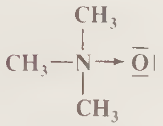








A coordinate-covalent bond, represented by an arrow, is one in which both electrons come from the same atom; i.e., the bond can be regarded as being formed by overlap of an orbital containing two electrons with an empty one. Thus trimethylamine oxide would be represented



For a coordinate-covalent bond the rule concerning formal charge is amended, so that both electrons count for the donor and neither for the recipient. Thus, as written here, the nitrogen and oxygen atoms of trimethylamine oxide bear no formal charges. However, it is apparent that the electronic picture is exactly the same as the picture of trimethylamine oxide given just above, and we have our choice of drawing an arrowhead or a charge separation. Some compounds, e.g., amine oxides, must be drawn one way or the other. It seems simpler to use charge separation, since this spares us from having to consider as a "different" method of bonding a way that is really the same as ordinary covalent bonding once the bond has formed.[18]

Electronegativity[19]

The electron cloud which bonds two atoms is not symmetrical (with respect to the plane which is the perpendicular bisector of the bond) except when the two atoms are the same and have the same substituents. The cloud is necessarily distorted toward one side of the bond or the other, depending on which atom (nucleus plus electrons) maintains the greater attraction for the cloud. This attraction is called *electronegativity*; it is greatest for atoms in the upper right corner of the periodic table and lowest for atoms in the lower left corner. Thus a bond between fluorine and chlorine will be distorted so that there is a higher probability of finding the electrons near the fluorine than near the chlorine. This gives the fluorine a partial negative charge and the chlorine a partial positive charge.

A number of attempts have been made to set up quantitative tables of electronegativity which indicate the direction and extent of electron-cloud distortion for a bond between any pair of

---

[18] It has been suggested that the valence octet around atoms can better be understood as being made up of two quartets rather than four pairs. For this argument see Linnett, "The Electronic Structure of Molecules," John Wiley & Sons, Inc., New York, 1964.

[19] For reviews of this topic, see Batsanov, *Russ. Chem. Rev.* **37**, 332–351 (1968); Syrkin, *Russ. Chem. Rev.* **31**, 197–206 (1962); Pritchard and Skinner, *Chem. Rev.* **55**, 745–786 (1955); and Pauling, "The Nature of the Chemical Bond," 3d ed., Cornell University Press, Ithaca, N.Y., 1960.

TABLE 1 Electronegativities of some atoms[20]

F	4.0	S	2.5	B	2.0
O	3.5	C	2.5	Si	1.8
N	3.0	I	2.5	Mg	1.2

Br	2.8	H	2.1	Cs	0.7

atoms. The most popular of these scales, devised by Pauling, is based on bond energies (see p. 26) of diatomic molecules. The reasoning here is that if in a molecule A—B the electron distribution were symmetrical, the bond energy would be the mean of the energies of A—A and B—B, since in these cases the cloud must be undistorted. If the actual bond energy of A—B is higher than this (and it usually is), it is the result of the partial charges, since the charges attract each other and make a stronger bond, which requires more energy to break. It is necessary to assign a value to one element arbitrarily (F = 4.0 is the one used); then the electronegativity of another is obtained from the difference between the actual energy of A—B and the mean of A—A and B—B (this difference is called Δ) by the formula

$$x_A - x_B = \sqrt{\frac{\Delta}{23.06}} \qquad (15)$$

where x_A and x_B are the electronegativities of the known and unknown atoms and 23.06 is an arbitrary constant. Part of the scale derived from this treatment is shown in Table 1.[20]

Other treatments have led to scales which are based on different principles, e.g., the sum of the ionization potential and the electron affinity,[21] or on the same principle with corrections.[22] In some of these treatments electronegativities can be calculated for different valence states, for different hybridizations (e.g., *sp* carbon atoms are more electronegative than sp^2, which are still more electronegative than sp^3)[23] and even differently for primary, secondary, and tertiary carbon atoms. Also, electronegativities can be calculated for groups rather than atoms (Table 2).[24]

Electronegativity information can be obtained from nmr spectra. In the absence of a magnetically anisotropic group[25] the chemical shift of a proton is approximately proportional to the electron density around it and hence to the electronegativity of the atom or group to which it is attached. The greater the electronegativity of the atom or group the lower the electron density around the proton and the further downfield the chemical shift. An example of the use of this correlation is found in the variation of chemical shift of the *ring* protons in the series toluene, ethylbenzene, isopropylbenzene, *t*-butylbenzene (there is a magnetically anisotropic group here, but its effect should be constant throughout the series). It is found that the electron density surrounding the ring protons decreases[26] in the order given.[27] However, this type of correlation

TABLE 2 Some group electronegativities[24]

CH_3	2.30	$CHCl_2$	2.63
CH_2Cl	2.47	CCl_3	2.79
CI_3	2.50	CF_3	3.29
CBr_3	2.57		

is by no means perfect, since all the measurements are being made in a powerful field, which itself may affect the electron-density distribution. Coupling constants between the two protons of a system $-\underset{|}{C}H-\underset{|}{C}H-X$ have also been found to depend on the electronegativity of X.[28] For carbons involved in π bonding, ^{13}C chemical shifts correlate with the π-electron density on the carbon.[29] For example, ^{13}C nmr spectra for a series of carbonyl compounds ($R^{13}COR'$) in a variety of solvents showed that the ^{13}C chemical shift was approximately proportional to the polarity of the $C{=}O$ bond.[30] It has also been found that ^{14}N chemical shifts of nonaromatic nitro compounds are dependent on the electronegativity of the rest of the molecule.[31]

When the difference in electronegativities is great, the orbital may be so far over to one side that it barely covers the other nucleus. This is an *ionic bond*, which is seen to arise naturally out of the previous discussion, leaving us with basically only one type of bond in organic molecules. Most bonds can be considered as intermediate between ionic and covalent. We may speak of percent ionic character of a bond, which indicates the extent of electron-cloud distortion. There is a continuous graduation from ionic to covalent bonds.

The *dipole moment* is a property of the molecule which results from charge separations like those discussed above. However, it is not possible to measure the dipole moment of an individual bond within a molecule; we can measure only the total moment of the molecule, which is the vectorial sum of the individual bond moments.[32] These individual moments are roughly the same from molecule to molecule, but this constancy is by no means universal. Thus, from the dipole moments of toluene and nitrobenzene (Figure 14) we should expect the moment of *p*-nitrotoluene to be about 4.36 D. The actual value 4.39 D is quite reasonable. However, the moment of *p*-cresol (1.57 D) is quite far from the predicted value of 1.11 D. In some cases, molecules may have substantial individual bond moments but no total moments at all because the individual moments are canceled out by the overall symmetry of the molecule. Some examples are CCl_4, *trans*-1, 2-dibromoethene, and *p*-dinitrobenzene.

Because of the small difference between the electronegativities of carbon and hydrogen, alkanes have very small dipole moments, so small that they are difficult to measure. For example, the dipole moment of isobutane is 0.132 D[33] and that of propane is 0.083 D[34]. Of course, methane

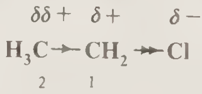
and ethane, because of their symmetry, have no dipole moments.[36] Few organic molecules have dipole moments greater than 7 D.

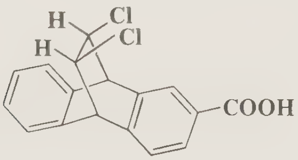
Inductive and Field Effects

The C—C bond in ethane is completely nonpolar because it connects two equivalent atoms. However, the C—C bond in chloroethane is polarized by the presence of the electronegative chlorine atom. This polarization is actually the sum of two effects. In the first of these, the C-1 atom, having been deprived of some of its electron density by the greater electronegativity

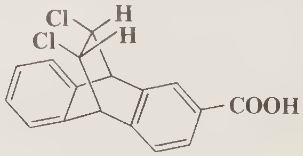


$$\overset{\delta\delta+}{\underset{2}{H_3C}}\rightarrow\overset{\delta+}{\underset{1}{CH_2}}\twoheadrightarrow\overset{\delta-}{Cl}$$

of Cl, is partially compensated by drawing the C—C electrons closer to itself, resulting in a polarization of this bond and a slightly positive charge on the C-2 atom. This polarization of one bond caused by the polarization of an adjacent bond is called the *inductive effect*. The effect is greatest for adjacent bonds but may also be felt farther away; thus the polarization of the C—C bond causes a (slight) polarization of the three methyl C—H bonds. The other effect operates directly through space or through solvent molecules, and is called the *field effect*.[37] It is often very difficult to separate the two kinds of effect, but it has been done in a number of cases, generally by taking advantage of the fact that the field effect depends on the geometry of the molecule but the inductive effect depends only on the nature of the bonds. For example, in isomers **1** and **2**[38] the inductive effect of the chlorine atoms on the position of the electrons



1



2

---

[35] The values for toluene, nitrobenzene, and *p*-nitrotoluene are from McClellan, Ref. 32. The values for phenol and *p*-cresol were determined by Goode and Ibbitson, *J. Chem. Soc.* 4265 (1960).

[36] Actually, symmetrical tetrahedral molecules like methane do have extremely small dipole moments, caused by centrifugal distortion effects; these moments are so small that they can be ignored for all practical purposes. For CH_4 μ is about 5.4×10^{-6} D: Ozier, *Phys. Rev. Lett.* **27**, 1329 (1971); Rosenberg, Ozier, and Kudian, *J. Chem. Phys.* **57**, 568 (1972).

[37] Roberts and Moreland, *J. Am. Chem. Soc.* **75**, 2167 (1953).

[38] This example is from Grubbs, Fitzgerald, Phillips, and Petty, *Tetrahedron* **27**, 935 (1971).

TABLE 3 Field effects of various groups relative to hydrogen

The groups are listed approximately in order of decreasing strength for both $-I$ and $+I$ groups

$+I$	$-I$		
O^-	NR_3^+	COOH	OR
COO^-	SR_2^+	F	COR
CR_3	NH_3^+	Cl	SH
CHR_2	NO_2	Br	SR
CH_2R	SO_2R	I	OH
CH_3	CN	OAr	$C{\equiv}CR$
D	SO_2Ar	COOR	Ar
			$CH{=}CR_2$

in the COOH group (and hence on the acidity, see Chapter 8) should be the same since the same bonds intervene; but the field effect is different because the chlorines are closer in space to the COOH in **1** than they are in **2**. Thus a comparison of the acidity of **1** and **2** should reveal whether a field effect is truly operating. The evidence obtained from experiments of this kind is overwhelming that field effects are much more important than inductive effects.[39] In most cases the two types of effect are considered together, and in this book we shall not attempt to separate them but shall use the name *field effect* to refer to their combined action.

Functional groups can be classified as electron-withdrawing $(-I)$ or electron-donating $(+I)$ groups relative to hydrogen. This means, for example, that NO_2, a $-I$ group, will draw electrons to itself more than a hydrogen atom would if it occupied the same position in the molecule.

$$O_2N \twoheadleftarrow CH_2 \leftarrow Ph$$
$$H{-}CH_2{-}Ph$$

Thus, in α-nitrotoluene, the electrons in the N—C bond are farther away from the carbon atom than the electrons in the H—C bond of toluene. Similarly, the electrons of the C—Ph bond are farther away from the ring in α-nitrotoluene than they are in toluene. Field effects are always comparison effects. We compare the $-I$ or $+I$ effect of one group with another (usually hydrogen). It is commonly said that, compared with hydrogen, the NO_2 group is electron-withdrawing and the O^- group electron-donating or electron-releasing. However, there is no actual donation or withdrawal of electrons, though these terms are convenient to use; there is merely a difference in position of electrons due to the difference in electronegativity between H and NO_2 or between H and O^-.

Table 3 lists a number of the most common $-I$ and $+I$ groups.[40] It can be seen that compared with hydrogen, most groups are electron-withdrawing. The only electron-donating groups are groups with a formal negative charge (but not even all these), atoms of low electronegativity, such as Si, Mg, etc., and perhaps alkyl groups. Alkyl groups have usually been regarded as electron-donating, but in recent years many examples of behavior have been found which can be interpreted only by the conclusion that alkyl groups are electron-withdrawing compared with hydrogen.[41] In accord with this is the value of 2.30 for the group electronegativity of CH_3 (Table 2) compared with 2.1 for H (Table 1). We shall see that when an alkyl group is attached to an unsaturated or trivalent carbon (or other atom), its behavior is best explained by assuming it is $+I$ (see, for example, pp. 153, 161, 243, 463), but when it is connected to a saturated atom, the results are not as clear and alkyl groups seem to be $+I$ in some cases and $-I$ in others[42] (see also p. 244). Similarly, it is clear that the field-effect order of alkyl groups attached to unsaturated systems is tertiary > secondary > primary > CH_3, but this order is not always maintained when the groups are attached to saturated systems. Deuterium is electron-donating with respect to hydrogen.[43] Other things being equal, atoms with *sp* bonding generally have a greater electron-withdrawing power than those with sp^2 bonding, which in turn have more electron-withdrawing power than those with sp^3 bonding.[44] This accounts for the fact that aryl, vinyl, and ethynyl groups are $-I$. Field effects always decrease with increasing distance, and in most cases (except when a very powerful $+I$ or $-I$ group is involved) cause very little difference in a bond four bonds away or more.

Bond Distances[45]

The distances between atoms in a molecule are characteristic properties of the molecule and can give us information if we compare the same bond in different molecules. The chief methods of determining bond distances and angles are x-ray diffraction (only for solids), electron diffraction (only for gases), and spectroscopic methods.[46] The distance between the atoms of a bond is not constant, since the molecule is always vibrating; the measurements obtained are therefore average values, so that different methods give different results.[47] However, this must be taken into account only when fine distinctions are made.

Measurements vary in accuracy, but indications are that similar bonds have fairly constant lengths from one molecule to the next. The variation is generally less than 1%. Thus for a bond between two sp^3 carbons the following results have been found:

C—C bond in	Bond length, Å
Diamond	1.544[53]
C_2H_6	1.5324 ± 0.0011[48]
C_2H_5OH	1.55 ± 0.02[49]
C_2H_5Cl	1.5495 ± 0.0005[50]
C_3H_8	1.532 ± 0.003[54]
Cyclohexane	1.540 ± 0.015[49]
t-Butyl chloride	1.532[51]
n-Butane to *n*-heptane	1.531–1.534[52]
Isobutane	1.535 ± 0.001[55]

Bond distances for some important bond types are given in Table 4. As can be seen in this table, carbon bonds are shortened by increasing *s* character. This is most often explained by the fact that, as the percentage of *s* character in a hybrid orbital increases, the orbital becomes more like an *s* orbital and hence is held more tightly by the nucleus than an orbital with less *s* character. However, other explanations have also been offered (see p. 33), and the matter is not completely settled.

Indications are that a C—D bond is slightly shorter than a corresponding C—H bond. Thus, electron-diffraction measurements of C_2H_6 and C_2D_6 showed a C—H bond distance of 1.1122 ± 0.0012 Å and a C—D distance of 1.1071 ± 0.0012 Å.[48]

Bond Angles

It might be expected that the bond angles of sp^3 carbon would always be the tetrahedral angle 109°28′, but this is so only where the four groups are identical, as in methane, neopentane, or carbon tetrachloride. In most cases the angles deviate a little from the pure tetrahedral value. For

sp—halogen	1.27	1.63	1.79	1.99

TABLE 5 Oxygen, sulfur, and nitrogen bond angles in some compounds

Angle	Value	Compound	Ref.
H—O—H	104°27′	Water	7
C—O—H	107–109°	Methanol	49
C—O—C	111°43′	Dimethyl ether	59
C—O—C	124 ± 5°	Diphenyl ether	63
H—S—H	92.1°	H_2S	63
C—S—H	99.4°	Methyl mercaptan	63
C—S—C	109°	*p*-Tolyl sulfide	63
H—N—H	106°46′	Ammonia	7
H—N—H	106°	Methylamine	72
C—N—H	112°	Methylamine	72
C—N—C	108.7°	Trimethylamine	73

example, the C—C—Br angle in 2-bromopropane is 114.2°.[69] Similarly, slight variations are generally found from the ideal values of 120 and 180° for sp^2 and *sp* carbon, respectively.[9] These deviations occur because of slightly different hybridizations; i.e., a carbon bonded to four other atoms hybridizes one *s* and three *p* orbitals, but the four hybrid orbitals thus formed are generally not equivalent, nor does each contain exactly 25% *s* and 75% *p* character. Because the four atoms have (in the most general case) different electronegativities, each makes its own demand for electrons from the carbon atom. The carbon atom supplies more *p* character when it is bonded to more electronegative atoms, so that in chloromethane, for example, the bond to chlorine has somewhat more than 75% *p* character, which of course requires that the other three bonds have somewhat less, since there are only three *p* orbitals (and one *s*) to be divided among the four hybrid orbitals.[69a] The nmr coupling constant between ^{13}C and a hydrogen directly attached to it has been reported to be a linear function of the amount of *s* character of the orbitals of that carbon atom.[70] However, this relationship is not completely general, because other factors, e.g., the geometry of the molecule and electronegativity effects, also affect the coupling constants.[71] Of course, in strained molecules, the bond angles may be greatly distorted from the ideal values (see p. 140).

For oxygen and nitrogen, angles of 90° would be predicted from p^2 bonding. However, as we have seen (p. 10), the angles of water and ammonia are much larger than this, as are the angles of other oxygen and nitrogen compounds (Table 5); in fact they are much closer to the tetrahedral angle of 109°28′ than to 90°. These facts have led to the suggestion that in these compounds oxygen and nitrogen use sp^3 bonding; i.e., instead of forming bonds by the overlap of two (or three) *p* orbitals with 1*s* orbitals of the hydrogen atoms, they hybridize their 2*s* and 2*p* orbitals to form four sp^3 orbitals and then use only two (or three) of these for bonding with hydrogen, the others remaining occupied by unshared pairs (also called *lone pairs*). If this description is valid, and it is generally accepted by most chemists today, it becomes necessary to explain why the angles of these two compounds are in fact not 109°28′ but a few degrees smaller. One explanation which has been offered is that the unshared pair actually has a greater steric requirement than a pair in a bond, since there is no second nucleus to draw away some of the electron density and the bonds are thus crowded together. However, most evidence is that unshared pairs have smaller steric requirements than bonds[74] and the explanation most commonly accepted is that the hybridization is not pure sp^3. As we have seen above, an atom supplies more *p* character when it is bonded to more electronegative atoms. An unshared pair may be considered to be an "atom" of the lowest possible electronegativity, since there is no attracting power at all. Consequently, the unshared pairs have more *s* and the bonds more *p* character than pure sp^3 orbitals would have, making the bonds somewhat more like p^2 bonds and reducing the angle. As seen in Table 5, oxygen, nitrogen, and sulfur angles generally increase with decreasing electronegativity of the substituents. Note that the explanation given above cannot explain why some of these angles are *greater* than the tetrahedral angle.[75]

Bond Energies[76]

There are two kinds of bond energy. The energy necessary to cleave a bond to give the constituent radicals is called the *dissociation energy D*. For example, *D* for $H_2O \rightarrow HO + H$ is 118 kcal/mol. However, this is not taken as the energy of the O—H bond in water, since *D* for $H—O \rightarrow H + O$ is 100 kcal/mol. The average of these two values, 109 kcal/mol, is taken as the *bond energy E*. In diatomic molecules, of course, $D = E$.

D values may be easy or difficult to measure, but there is no question what they mean. With *E* values the matter is not so simple. For methane, the total energy of conversion from CH_4 to $C + 4H$ (at 0 K) is 393 kcal/mol.[77] Consequently, *E* for the C—H bond in methane is 98 kcal/mol at 0 K. The more usual practice, though, is not to measure the heat of atomization (i.e., the energy necessary to convert a compound to its atoms) directly but to calculate it from the heat of combustion. Such a calculation is shown in Figure 15.

Heats of combustion are very accurately known for hydrocarbons.[78] For methane the value is 212.8 kcal/mol (at 25°C), which leads to a heat of atomization of 398.0 kcal/mol (at 25°C), or a

Figure 15 Calculation of the heat of atomization of ethane at 25°C.

value of E for the C—H bond of 99.5 kcal/mol at 25°C. This method is fine for molecules like methane in which all the bonds are equivalent, but for more complicated molecules assumptions must be made. Thus for ethane, the heat of atomization of 25°C is 676.1 kcal/mol (Figure 15), and we must decide how much of this energy is due to the C—C bond and how much to the six C—H bonds. Any assumption must be artificial, since there is no way of actually obtaining this information, and indeed the question has no real meaning. If we make the assumption that E for each of the C—H bonds is the same as E for the C—H bond in methane (99.5 kcal/mol), then $6 \times 99.5 = 597.0$, leaving 79.1 kcal/mol for the C—C bond. However, a similar calculation for propane gives a value of 80.3 for the C—C bond, and for isobutane, the value is 81.6. A consideration of heats of atomization of isomers also illustrates the difficulty. E values for the C—C bonds in pentane, isopentane, and neopentane, calculated from heats of atomization in the same way, are (at 25°C) 81.1, 81.8, and 82.4 kcal/mol, respectively, even though all of them have twelve C—H bonds and four C—C bonds.

These differences have been attributed to various factors caused by the introduction of new structural features. Thus isopentane has a tertiary carbon whose C—H bond does not have exactly the same amount of *s* character as the C—H bond in pentane, which for that matter contains secondary carbons not possessed by methane. It is known that D values, which *can* be measured, are not the same for primary, secondary, and tertiary C—H bonds (see Table 2 in Chapter 5). There is also the steric factor. Hence it is certainly not correct to use the value of 99.5 from methane as the E value for all C—H bonds. Several empirical equations have been devised which account for these factors; from these the total energy can be computed[79] if the proper set of parameters (one for each structural feature) is inserted. Of course these parameters are originally calculated from the known total energies of some molecules which contain the structural feature.

Table 6 gives E values for various bonds. The mean values given are those averaged over a large series of compounds. The other values are calculated for just one compound, using values for the other bonds from earlier values in the table. The literature contains charts which take account of hybridization (thus an sp^3 C—H bond does not have the same energy as an sp^2 C—H bond).[80]

Certain generalizations can be derived from the data in Table 6.

1. There is a correlation of bond strengths with bond distances. A comparison of Tables 4 and 6 shows that, in general, *shorter bonds are stronger bonds.* Since we have already seen that increasing *s* character shortens bonds (p. 23), it follows that bond strengths increase with increasing *s* character.

C=O	173–81	164 192	HCHO CO_2
C=N	143[82]		
C=S	. . .	132	CS_2

2. Bonds become weaker as we move down the periodic table. Compare C—O and C—S or the four carbon-halogen bonds. This is a consequence of the first generalization, since bond distances must increase as we go down the periodic table because the number of inner electrons increases.

3. Double bonds are both shorter and stronger than the corresponding single bonds, but not twice as strong, because π overlap is less than σ overlap. The difference in energy between a single bond, say C—C, and the corresponding double bond is the amount of energy necessary to cause rotation around the double bond.

Two

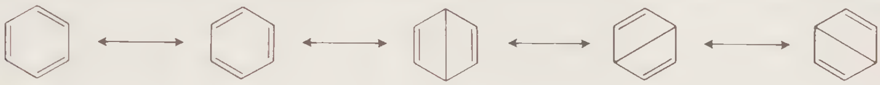
Delocalized Chemical Bonding

Although the bonding of many compounds can be adequately described by a single Lewis structure (page 16), this is not sufficient for many other compounds. These compounds contain one or more bonding orbitals which are not restricted to two atoms, but which are spread out over three or more. Such bonding is said to be *delocalized*.[1] In this chapter we shall see which types of compounds must be represented in this way.

The two chief general methods of approximately solving the wave equation, discussed in Chapter 1, are also used for compounds containing delocalized bonds.[2] In the valence-bond method several possible Lewis structures, called *canonical forms*, are drawn, and the molecule is taken to be a weighted average of them. Each ψ in Eq. (14), Chapter 1,

$$\Psi = c_A \psi_A + c_B \psi_B + \cdots$$

represents one of these structures. This representation of a real structure as a weighted average of two or more canonical forms is called *resonance*. For benzene the canonical forms are **1** and **2**.



1 **2** **3** **4** **5**

Double-headed arrows are used to indicate resonance. When the wave equation is solved, it is found that the energy value obtained by considering that **1** and **2** participate equally is lower than that for **1** or **2** alone, and if **3**, **4**, and **5** (called *Dewar structures*) are also considered, the value is lower still. According to this method, **1** and **2** each contribute 39% to the actual molecule, and the others 7.3% each.[3] The carbon-carbon bond order is 1.463 (not 1.5, which would be the case if only **1** and **2** contributed). In the valence-bond method the *bond order* of a particular bond is the sum of the weights of those canonical forms in which the bond is double plus 1 for the single bond which is present in all of them.[4] Thus, according to this picture, each C—C bond is not halfway between a single and a double bond but somewhat less. The energy of the actual molecule is obviously less than that of any one Lewis structure, since otherwise it would have one of those structures. The difference in energy between the actual molecule and the Lewis structure of lowest energy[5] is called the *resonance energy*.

---

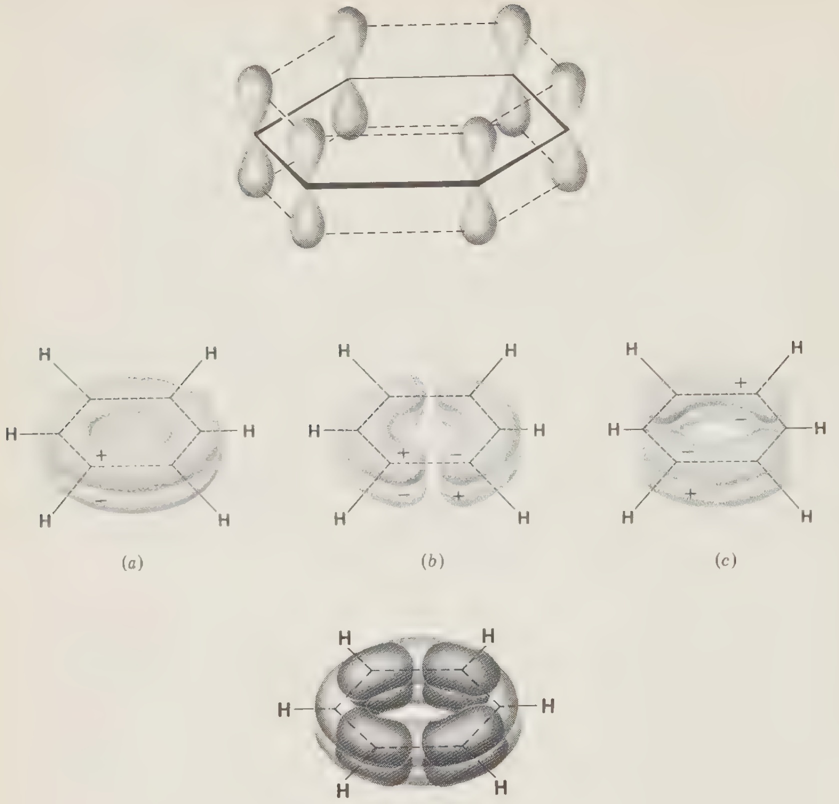
[1] For a definitive treatment of delocalization, see Wheland, "Resonance in Organic Chemistry," John Wiley & Sons, Inc., New York, 1955.

[2] There are other methods. For a discussion of the free-electron method, see Streitwieser, "Molecular Orbital Theory for Organic Chemists," pp. 27–29, John Wiley & Sons, Inc., New York, 1961. For the nonpairing method, in which benzene is represented as having three electrons between adjacent carbons, see Hirst and Linnett, *J. Chem. Soc.* 1035 (1962); and Firestone, *J. Org. Chem.* **34**, 2621 (1969).

[3] Pullman and Pullman, *Prog. Org. Chem.* **4**, 31–71 (1958), p. 33.

[4] For a more precise method of calculating valence-bond bond orders, see Clarkson, Coulson, and Goodwin, *Tetrahedron* **19**, 2153 (1963). See also Herndon, *J. Am. Chem. Soc.* **96**, 7605 (1974).

[5] Of course, the Lewis structures are not real, and their energies can only be estimated.



(a) (b) (c)

Superposition of (a), (b), and (c).

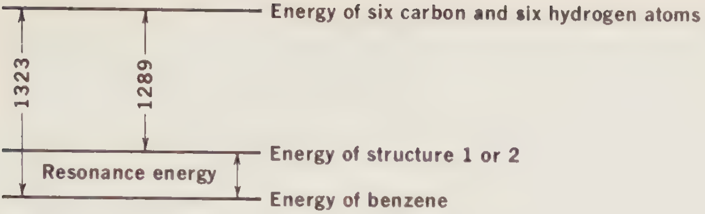
(d)

Figure 1 The six *p* orbitals of benzene overlap to form three bonding orbitals, (*a*), (*b*), and (*c*). The three orbitals superimposed are shown in (*d*).

Qualitatively, the resonance picture is often used to describe the structure of molecules, but quantitative valence-bond calculations become much more difficult as the structures become more complicated (e.g., naphthalene, pyridine, etc.). Therefore the molecular-orbital method is much more often used for the solution of wave equations. If we look at benzene by this method (qualitatively), we see that each carbon atom, being connected to three other atoms, uses sp^2 orbitals to form σ bonds, so that all 12 atoms are in one plane. Each carbon has a *p* orbital (containing one electron) remaining, and each of these can overlap equally with the two adjacent *p* orbitals. This overlap of six orbitals (see Figure 1) produces six new orbitals, of which three (shown) are bonding. These three (called π orbitals) all occupy approximately the same space. One of the three is of lower energy than the other two, which are degenerate. They each have the plane of the ring as a node, and so are in two parts, one above and one below the plane. The two orbitals of higher energy (Figure 1*b* and *c*) also have another node. The six electrons which occupy this torus-shaped cloud are called the *aromatic sextet*. The carbon-carbon bond order for benzene, calculated by the molecular-orbital method, is 1.667.[6]

---

[6] The molecular-orbital method of calculating bond order is more complicated than the valence-bond method. See Ref. 3, p. 36, and Clarkson, Coulson, and Goodwin, Ref. 4.



Energy of six carbon and six hydrogen atoms

1289
Energy of structure 1 or 2
Resonance energy
Energy of benzene

Figure 2 Resonance energy in benzene (in kilocalories per mole).

For planar unsaturated and aromatic molecules, many molecular-orbital calculations have been made by treating the σ and π electrons separately. It is assumed that the σ orbitals can be treated as localized bonds and the calculations involve only the π electrons. The first such calculations were made by Hückel, and such calculations are often called *Hückel molecular-orbital* (HMO) *calculations.*[7] Because electron-electron repulsions are either neglected or averaged out in the HMO method, another approach, the *self-consistent field* (SCF), or *Hartree-Fock*, method, was devised.[8] Although these methods have given many useful results for planar unsaturated and aromatic molecules, they are often unsuccessful for other molecules, and it would obviously be better if all electrons, both σ and π, could be included in the calculations. The development of modern computers has now made this possible,[9] and many such calculations have now been made[10] using a number of methods, among them an extension of the Hückel method (EHMO)[11] and the application of the SCF method to all valence electrons.[12]

Although the valence-bond and molecular-orbital methods give slightly different results, both show that there is delocalization in benzene. For example, each predicts that the six carbon-carbon bonds should have equal lengths, which is true. Since each method is useful for certain purposes, we shall use one or the other, as appropriate.

Bond Distances and Energies in Compounds Containing Delocalized Bonds

If we add the energies of all the bonds in benzene, taking the values from a table like Table 6 in Chapter 1, the value for the heat of atomization turns out to be less than that actually found in benzene (Figure 2). The actual value is 1323 kcal/mol. If we use E values for a C=C double bond obtained from cyclohexene (148.8), for a C—C single bond from cyclohexane (81.8), and for C—H bonds from methane (99.5), we get a total of 1289 kcal/mol for structure **1** or **2**. The resonance energy by this calculation is therefore 34 kcal/mol. Of course, this is an arbitrary calculation since, in addition to the fact that we are calculating a heat of atomization for a nonexistent structure (**1**), we are forced to use E values, which themselves do not have a firm basis in reality. The resonance energy can never be measured, only estimated, since we can

[12] Dewar, "The Molecular Orbital Theory of Chemistry," Ref. 8; Jaffé, *Acc. Chem. Res.* **2,** 136–143 (1969); Kutzelnigg, Del Re, and Berthier, *Fortschr. Chem. Forsch.* **22,** 1–222 (1971).

measure the heat of atomization of the real molecule but can only make an intelligent guess at that of the Lewis structure of lowest energy. Another method frequently used for estimation of resonance energy involves measurements of heats of hydrogenation. Thus, the heat of hydrogenation of cyclohexene is 28.6 kcal/mol, so that we might expect a hypothetical **1** or **2** with three double bonds to have a heat of hydrogenation of about 85.8 kcal/mol. The real benzene has a heat of hydrogenation of 49.8 kcal/mol, giving a resonance energy by this calculation of 36 kcal/mol. The generally accepted value for the resonance energy of benzene is 36 kcal/mol, and by any calculation the real molecule is more stable than a hypothetical **1** or **2.**

The energies of the six benzene orbitals can be calculated from HMO theory in terms of two quantities, α and β. The quantity α is the amount of energy possessed by an isolated $2p$ orbital before overlap, while β (called the *resonance integral*) is an energy unit expressing the degree of stabilization resulting from π-orbital overlap. A negative value of β corresponds to stabilization, and the energies of the six orbitals are (lowest to highest): $\alpha + 2\beta$, $\alpha + \beta$, $\alpha + \beta$, $\alpha - \beta$, $\alpha - \beta$, and $\alpha - 2\beta$.[13] The total energy of the three occupied orbitals is $6\alpha + 8\beta$, since there are two electrons in each orbital. The energy of an ordinary double bond is $\alpha + \beta$, so that structure **1** or **2** would have an energy of $6\alpha + 6\beta$. The resonance energy of benzene is therefore 2β. Unfortunately, there is no convenient way to calculate the value of β from molecular-orbital theory, and it is often given (for benzene) as about 18 kcal/mol, this number being half of the resonance energy calculated from heats of combustion or hydrogenation.

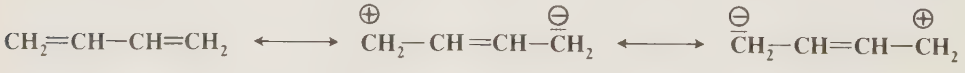
We might expect that bond distances in compounds exhibiting delocalization would lie between the values given in Table 4 in Chapter 1. For benzene this is certainly the case, since the carbon-carbon bond distance is 1.40 Å,[13a] which is between the 1.48 Å for an sp^2-sp^2 C—C single bond and the 1.34 Å of the sp^2-sp^2 C═C double bond.

Kinds of Molecules Which Have Delocalized Bonds

There are three main types of structure that exhibit delocalization:

1. *Double (or triple) bonds in conjugation.*[14] Benzene is, of course, an example, but the simplest is butadiene. In the molecular-orbital picture (Figure 3) the overlap of four orbitals gives two bonding orbitals, which contain the four electrons, and two vacant antibonding orbitals. It can be seen that each orbital has one more node than the one of next lower energy. The energies of the four orbitals are (lowest to highest): $\alpha + 1.618\beta$, $\alpha + 0.618\beta$, $\alpha - 0.618\beta$, and $\alpha - 1.618\beta$; hence the total energy of the two occupied orbitals is $4\alpha + 4.472\beta$. Since the energy of two isolated double bonds is $4\alpha + 4\beta$, the resonance energy by this calculation is 0.472β.

In the resonance picture, these structures are considered to contribute:



$$\mathrm{CH_2{=}CH{-}CH{=}CH_2} \longleftrightarrow \overset{\oplus}{\mathrm{C}}\mathrm{H_2{-}CH{=}CH{-}}\overset{\ominus}{\bar{\mathrm{C}}}\mathrm{H_2} \longleftrightarrow \overset{\ominus}{\bar{\mathrm{C}}}\mathrm{H_2{-}CH{=}CH{-}}\overset{\oplus}{\mathrm{C}}\mathrm{H_2}$$

[14] For reviews of conjugation in open-chain hydrocarbons, see Simmons, *Prog. Phys. Org. Chem.* **7,** 1–50 (1970); and Popov and Kogan, *Russ. Chem. Rev.* **37,** 119–141 (1968).

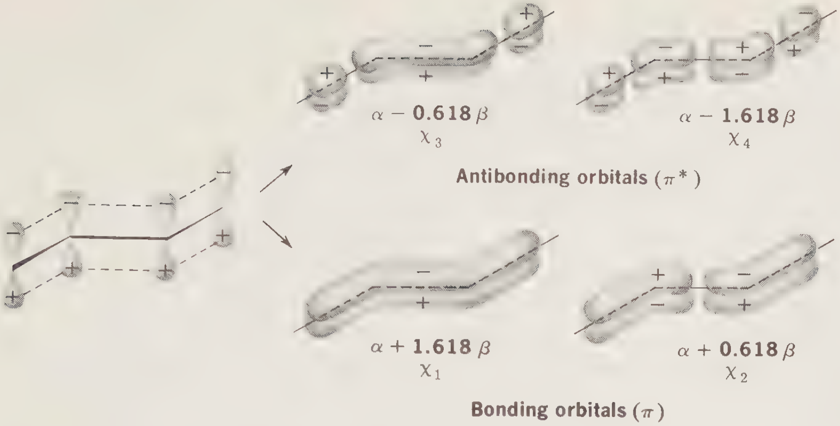

Figure 3 The four π orbitals of butadiene, formed by overlap of four *p* orbitals.

By either picture the bond order of the central bond should be higher than 1 and that of the other carbon-carbon bonds less than 2, although neither predicts that the three bonds have equal electron density. Molecular-orbital bond orders of 1.894 and 1.447 have been calculated.[15]

In recent years doubt has been cast on the reality of delocalization in butadiene and similar molecules. Thus, the bond lengths in butadiene are 1.34 Å for the double bonds and 1.48 Å for the single bond.[16] Since the typical single-bond distance of a bond which is not adjacent to an unsaturated group is 1.54 Å (p. 23), it has been argued that the shorter single bond in butadiene provides evidence for resonance. However, this shortening can also be explained as being caused by hybridization changes (see p. 23), and other explanations have also been offered.[17] Also, resonance energies for butadienes, calculated from heats of combustion or hydrogenation, are only about 4 kcal/mol, and these values may not be entirely attributable to resonance. Thus, a calculation from heats-of-atomization data gives a resonance energy of 4.6 kcal/mol for *cis*-1,3-pentadiene, and −0.2 kcal/mol for 1,4-pentadiene. These two compounds, each of which possesses two double bonds, two C—C single bonds, and eight C—H bonds, would seem to offer as similar comparison as we could make of a conjugated with a nonconjugated compound, but they are nevertheless not strictly comparable. The former has three sp^3 C—H and five sp^2 C—H bonds, while the latter has two and six, respectively. Also, the two single C—C bonds of the 1,4-diene are both sp^2-sp^3 bonds, while in the 1,3-diene, one is sp^2-sp^3, and the other is sp^2-sp^2. Therefore, it may be that some of the already small value of 4 kcal/mol is not resonance energy but arises from differing energies of bonds of different hybridization.[18]

Educ.* **45,** 754–767 (1968); Wilson, *Tetrahedron* **17,** 191 (1962); Hughes, *Tetrahedron* **24,** 6423 (1968); Politzer and Harris, *Tetrahedron* **27,** 1567 (1971).

[18] For negative views on delocalization in butadiene and similar molecules, see Dewar and Gleicher, *J. Am. Chem. Soc.* **87,** 692 (1965); Dewar and Schmeising, *Tetrahedron* **5,** 166 (1959), **11,** 96 (1960); Dewar, *Tetrahedron* **19,** suppl. 2, 89 (1963); Brown, *Trans. Faraday Soc.* **55,** 694 (1959); Somayajulu, *J. Chem. Phys.* **31,** 919 (1959); Mikhailov, *Bull. Acad. Sci. USSR, Div. Chem. Sci.* 1284 (1960), *J. Gen. Chem. USSR* **36,** 379 (1966). For positive views, see Miyazaki, Shigetani, and Shinoda, *Bull. Chem. Soc. Jpn.* **44,** 1491 (1971); Miyazaki and Ohbayashi, *Bull. Chem. Soc. Jpn.* **42,** 2767 (1969); Miyazaki, *Tetrahedron Lett.* 1363 (1970); Berry, *J. Chem. Phys.* **30,** 936 (1962); and Kogan and Popov, *Bull. Acad. Sci. USSR, Div. Chem. Sci.* 1306 (1964). In general, the negative argument is that resonance involving excited structures, such as **7** and **8,** is unimportant. See rule 6 on p. 37. An excellent discussion of the controversy is found in Popov and Kogan, Ref. 14, pp. 119–124.

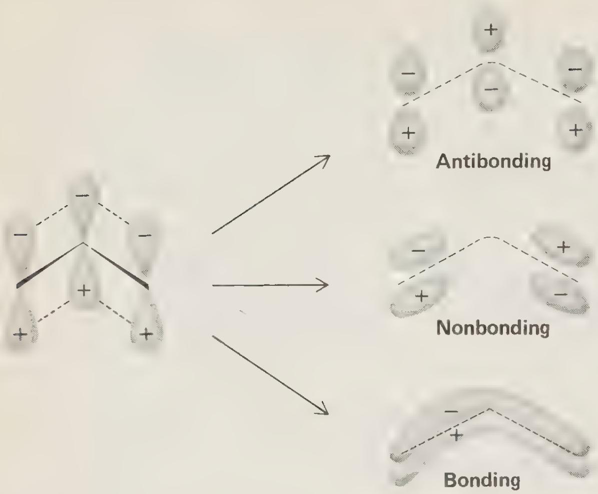

Figure 4 The three orbitals of an allylic system, formed by overlap of three *p* orbitals.

Although bond distances fail to show it and although the resonance energy is low, the fact that butadiene is planar[19] shows that there is some delocalization, even if not so much as previously thought.

Similar delocalization is found in other conjugated systems, e.g., C=C—C=O and C≡C—C=N, in longer systems, with three or more multiple bonds in conjunction, and where double or triple bonds are conjugated with aromatic rings.

2. *Double (or triple) bonds in conjugation with a p orbital on an adjacent atom.* Where a *p* orbital is on an atom adjacent to a double bond, there are three parallel *p* orbitals which overlap. As we have previously noted, it is a general rule that when *n* atomic orbitals overlap, *n* molecular orbitals are created, so that in this case overlap of a *p* orbital with an adjacent double bond gives rise to three new orbitals, shown in Figure 4. The middle orbital is a *nonbonding orbital* of zero bonding energy. The central carbon atom does not participate in the nonbonding orbital.

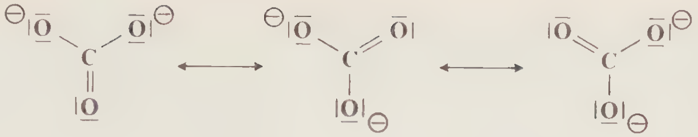
There are three cases: the original *p* orbital may have contained two, one, or no electrons. Since the original double bond contributes two electrons, the total number of electrons to be accommodated by the new orbitals is four, three, or two. A typical example of the first situation is vinyl chloride $\mathrm{CH_2{=}CH{-}Cl}$. In this case, although the *p* orbital of the chlorine atom is filled, it still overlaps with the double bond. The four electrons occupy the two molecular orbitals of lowest energies. This is our first example of resonance involving overlap between unfilled orbitals and a *filled* orbital. Canonical forms for vinyl chloride are

$$\mathrm{CH_2{=}CH{-}\overline{\underline{Cl}}|} \longleftrightarrow \mathrm{\overset{\ominus}{\overline{C}}H_2{-}CH{=}\overset{\oplus}{\underline{Cl}}|}$$

Any system containing an atom which has an unshared pair and which is directly attached to a multiple-bond atom can show this type of delocalization. Another example is the carbonate ion:

---

[19] See Ref. 16. See discussion of this in Bastiansen and Traetteberg, *Tetrahedron* **17**, 147 (1962); Fischer-Hjalmars, *Tetrahedron* **17**, 235 (1962), **19**, 1805 (1963); and Coulson, *Tetrahedron* **17**, 258 (1962).



The bonding in allylic carbanions, e.g., $CH_2{=}CH{-}\overline{C}H_2^{\ominus}$, is similar.

The other two cases, where the original p orbital contains only one or no electron, are generally found only in free radicals and cations, respectively. Allylic free radicals have one electron in the nonbonding orbital. In allylic cations this orbital is vacant, and only the bonding orbital is occupied. The orbital structures of the allylic carbanion, free radical, and cation differ from each other, therefore, only in that the nonbonding orbital is filled, half-filled, or empty. Since this is an orbital of zero bonding energy, it follows that the bonding π energies of the three species, relative to electrons in the $2p$ orbitals of free atoms, are the same. The electrons in the nonbonding orbital do not contribute to the bonding energy, positively or negatively.

By the resonance picture, the three species may be described as having double bonds in conjugation with, respectively, an unshared pair, an unpaired electron, and an empty orbital (see Chapter 5):

$$CH_2{=}CH{-}\overset{\ominus}{\overline{C}}H_2 \longleftrightarrow \overset{\ominus}{\overline{C}}H_2{-}CH{=}CH_2$$

$$CH_2{=}CH{-}\dot{C}H_2 \longleftrightarrow \dot{C}H_2{-}CH{=}CH_2$$

$$CH_2{=}CH{-}\overset{\oplus}{C}H_2 \longleftrightarrow \overset{\oplus}{C}H_2{-}CH{=}CH_2$$

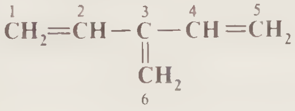
3. *Hyperconjugation.* The third type of delocalization, called *hyperconjugation*, is discussed on p. 69.

We shall find examples of delocalization which cannot be strictly classified as belonging to any of these types.

Cross Conjugation[20]

In a cross-conjugated compound, three groups are present, two of which are not conjugated with each other, though each is conjugated with the third. Some examples are

$$Ph{-}\underset{\underset{O}{\|}}{C}{-}Ph$$



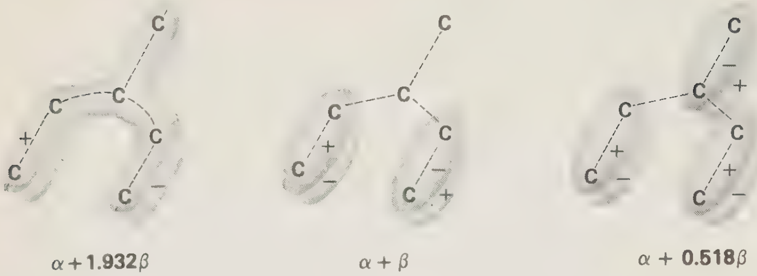
$$\overset{1}{C}H_2{=}\overset{2}{C}H{-}\underset{\underset{\underset{6}{CH_2}}{\|}}{\overset{3}{C}}{-}\overset{4}{C}H{=}\overset{5}{C}H_2$$

9

$CH_2{=}CH{-}O{-}CH{=}CH_2$

If we look at **9** by the molecular-orbital method, we find that overlap of six p orbitals gives six molecular orbitals, of which the three bonding orbitals are shown in Figure 5, along with their energies. Note that two of the carbon atoms do not participate in the $\alpha + \beta$ orbital. The total energy of the three occupied orbitals is $6\alpha + 6.900\beta$, so that the resonance energy is 0.900β.

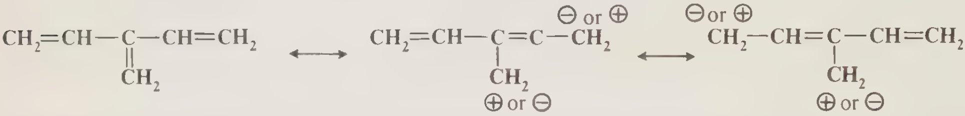
[20] For a discussion, see Phelan and Orchin, *J. Chem. Educ.* **45**, 633–637 (1968).



$\alpha + 1.932\beta$ $\alpha + \beta$ $\alpha + 0.518\beta$

Figure 5 The three bonding orbitals of 3-methylene-1,4-pentadiene (**9**).

Molecular-orbital bond orders are 1.930 for the C-1,C-2 bond, 1.859 for the C-3,C-6 bond, and 1.363 for the C-2,C-3 bond.[20] Comparing these values with those for butadiene (p. 33), we see that the C-1,C-2 bond contains more, and the C-3,C-6 bond less, double-bond character than the double bonds in butadiene. The resonance picture supports this conclusion, since each C-1,C-2 bond is double in three of the five canonical forms, while the C-3,C-6 bond is double in only one. In most cases it is easier to treat cross-conjugated molecules by the molecular-orbital method than by the valence-bond method.



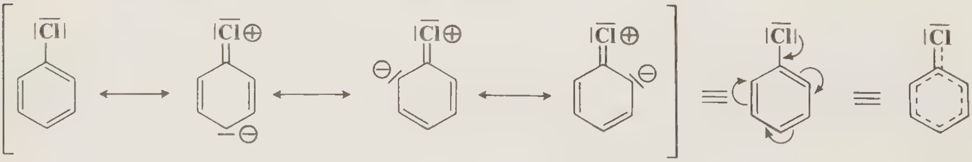
$$CH_2{=}CH{-}\underset{\overset{\|}{CH_2}}{C}{-}CH{=}CH_2 \longleftrightarrow CH_2{=}CH{-}\underset{\underset{\oplus \text{ or } \ominus}{\overset{|}{CH_2}}}{C}{=}\overset{\ominus \text{ or } \oplus}{C{-}CH_2} \longleftrightarrow \overset{\ominus \text{or} \oplus}{CH_2}{-}CH{=}\underset{\underset{\oplus \text{ or } \ominus}{\overset{|}{CH_2}}}{C}{-}CH{=}CH_2$$

The Rules of Resonance

We have seen that one way of expressing the actual structure of a molecule containing delocalized bonds is to draw several possible structures and to assume that the actual molecule is a hybrid of them. These canonical forms have no existence except in our imagination. The molecule does *not* rapidly shift between them. It is *not* the case that some molecules have one canonical form and some another. All the molecules of the substance have the same structure. That structure is always the same all the time and is a weighted average of all the canonical forms. In drawing canonical forms and in deriving the true structures from them, we are guided by certain rules, among them the following:

1. All the canonical forms must be bona fide Lewis structures (see p. 16). For instance, in none of them may carbon have five bonds.

2. The positions of the nuclei must be the same in all the structures. This means that all we are doing when we draw the various canonical forms is putting the *electrons* in in different ways. For this reason, shorthand ways of representing resonance are easy to devise:



10 11

The resonance interaction of chlorine with the benzene ring may be represented as shown in **10** or **11**, and either of these representations is often used to save space. However, we shall not use the curved-arrow method of **10** since in this book arrows will be used to express actual movement of electrons in reactions. We shall use representations like **11**, or else write out the canonical forms. The convention used in dashed-line formulas like **11** is that bonds which are present in all canonical forms are drawn as solid lines while bonds which are not present in all forms are drawn as dashed lines. In most resonance, σ bonds are not involved, and only the π or unshared electrons are put in in different ways. This means that if we write one canonical form for a molecule, we can then write the others by merely moving π and unshared electrons.

3. All atoms taking part in the resonance, i.e., covered by delocalized electrons, must lie in a plane, or nearly so (see p. 38). This, of course, does not apply to atoms which have the same bonding in all the canonical forms. The reason for planarity is maximum overlap of the p orbitals.

4. All canonical forms must have the same number of unpaired electrons. Thus $\dot{C}H_2-CH=CH-\dot{C}H_2$ is not a valid canonical form for butadiene.

5. The energy of the actual molecule is lower than that of any form, obviously. Therefore, delocalization is a stabilizing phenomenon. Many species which would not be expected to be stable solely on the basis of the Lewis structure of lowest energy turn out to be stable because of the resonance.

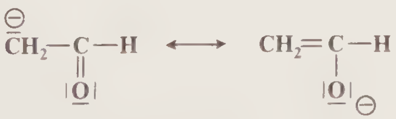
6. All canonical forms do not contribute equally to the true molecule. Each form contributes in proportion to its stability, the most stable form contributing most. Thus, for ethylene, the form $\overset{-}{C}H_2-\overset{+}{C}H_2$ has such a high energy compared with $CH_2=CH_2$ that it essentially does not contribute at all. We have seen the argument that such structures do not contribute even in such cases as butadiene.[18] Equivalent canonical forms, such as **1** and **2**, contribute equally. The greater the number of significant structures that can be written and the more nearly equal they are, the greater the resonance energy, other things being equal.

It is not always easy to decide relative stabilities of imaginary structures, and the chemist is often guided by intuition. However, the following rules may be helpful:

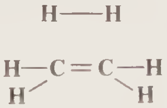
1. Structures with more covalent bonds are ordinarily more stable than those with fewer (compare **6** and **7**).

2. Stability is decreased by an increase in charge separation. Structures with formal charges are less stable than uncharged structures, and structures with more than two formal charges usually contribute very little. An especially unfavorable type of structure is one with two like charges on adjacent atoms. However, when a compound is dissolved in different solvents, ionic structures make a greater contribution in the more polar solvent.[21]

3. Structures which carry a negative charge on a more electronegative atom are more stable than those in which the charge is on a less electronegative atom. Thus, **13** is more stable than **12**. Similarly, positive charges are best carried on atoms of low electronegativity.



12 **13**



14

4. Structures with distorted bond angles or lengths are unstable, e.g., the structure **14** for ethane.

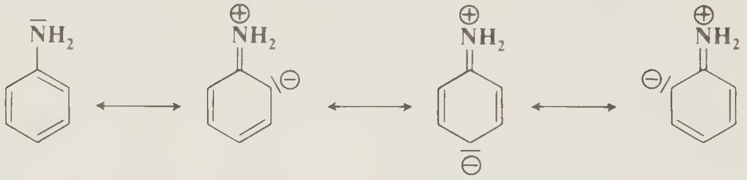
The Resonance Effect

Resonance always results in a different distribution of electron density than would be the case if there were no resonance. For example, if **15** were the actual structure of aniline, the two unshared electrons of the nitrogen would reside entirely on that atom. Since the real structure is not **15** but a hybrid which includes contributions from the other canonical forms shown, the electron density of the unshared pair does not reside entirely on the nitrogen, but is spread over the ring. This decrease in electron density at one position (and corresponding increase elsewhere) is called the *resonance*, or *mesomeric*, *effect*. We loosely say that the NH_2 contributes or donates electrons to the ring by a resonance effect, although no actual contribution has taken place. The "effect" is caused by the fact that the electrons are in a different place from that we should expect if there were no resonance. In ammonia, where resonance is absent, the unshared pair *is* located on the nitrogen atom. As with the field effect (p. 20), we may think of a certain molecule (in this case ammonia) as a substrate and then see what happens to the electron density when we make a substitution. When one of the hydrogen atoms of the ammonia molecule is replaced by a benzene ring, the electrons are "withdrawn" by the resonance effect, just as when a methyl group replaces a hydrogen of benzene, electrons are "donated" by the field effect of the methyl. The idea of donation or withdrawal merely arises from the comparison of a compound with a closely related one or of a real compound with a canonical form.

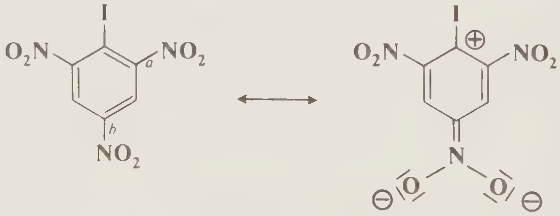


15

Steric Hindrance to Resonance

In rule 3 (p. 37), it was stated that all the atoms covered by delocalized electrons must lie in a plane, or nearly so. Many examples are known where resonance is reduced or prevented because the atoms are sterically forced out of planarity.

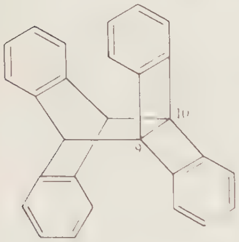
Bond lengths for the *o*- and *p*-nitro groups in picryl iodide are quite different.[22] Distance *a* is 1.45 Å, whereas *b* is 1.35 Å. The obvious explanation is that the oxygens of the *p*-nitro group are in the plane of the ring and thus in resonance with it, so that *b* has partial double-bond character, while the oxygens of the *o*-nitro groups are forced out of the plane by the large iodine atom.



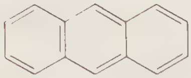
[22] Wepster, *Prog. Stereochem.* **2**, 99–156 (1958), p. 125.

Another example is 2,3-di-*t*-butylbutadiene, which is a stable, *nonconjugated* diene.[23] The double bonds are not in the same plane but are forced out by the large *t*-butyl groups.

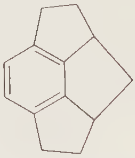
The Dewar-type structure for the central ring of the anthracene system in **16** is possible only because the 9,10 substituents prevent the system from being planar.[24] **16** is the actual structure of the molecule, and it is not in resonance with forms like **17**, though in anthracene itself, Dewar structures and structures like **17** both contribute. This is a consequence of rule 2 (p. 36). In order for a **17**-like structure to contribute to resonance in **16** the nuclei would have to be in the same positions in both forms.



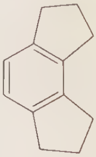
16



17

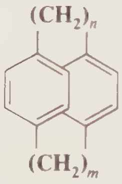


18

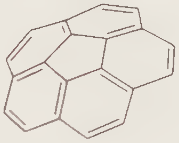


19

Even the benzene ring may be forced out of planarity.[25] Thus, **18** absorbs oxygen on standing and is easily hydrogenated, although **19** is almost completely unreactive.[26] Similarly, [*n.m*]paracyclophanes (**20**), where *n* and *m* are both 3 or less (the smallest yet prepared is [2.2]paracyclophane), have bent benzene rings and properties which depart significantly from those of ordinary benzene compounds.[27] Another molecule in which benzene rings are forced out of planarity is corannulene (**21**).[28]



20



21

$p\pi$-$d\pi$ Bonding. Ylides

We have mentioned (p. 14) that, in general, atoms of the second row of the periodic table do not form stable double bonds because the parallel *p* orbitals are too far for a reasonable amount of overlap. However, there is another type of double bond which is particularly common for the second-row atoms sulfur and phosphorus. For example, such a double bond is found in the compound H_2SO_3, as written on the left. Like an ordinary double bond, this double bond contains one σ orbital,

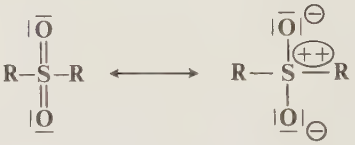
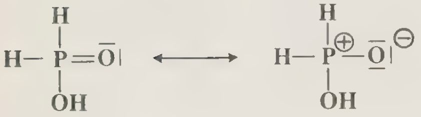
but the second orbital is not a π orbital formed by overlap of half-filled p orbitals; instead it is formed by overlap of a filled p orbital from the oxygen with an empty d orbital from the sulfur. It is called a *pπ-dπ orbital.* Note that we can represent this molecule by two canonical forms but that, despite the resonance, the bond is nevertheless localized. Some other examples of *pπ-dπ* bonding are

$R_3P{=}\overline{O}| \longleftrightarrow R_3\overset{\oplus}{P}-\overset{\ominus}{\underline{\overline{O}}}|$

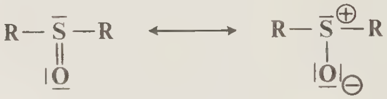
Phosphine oxides



Sulfones



Hypophosphorous acid



Sulfoxides

For some of these phosphorus compounds, nitrogen analogs are known, but they are less stable because the resonance is lacking. For example, amine oxides, analogs of phosphine oxides, can only be written $R_3\overset{\oplus}{N}-\overset{\ominus}{O}$. The *pπ-dπ* canonical form is impossible in this case, since nitrogen is limited to eight outer-shell electrons.

In all the examples given above the atom which donates the electron pair is oxygen, and indeed, oxygen is the most common such atom. But in another important class of compounds, called *ylides*, this atom is carbon.[29] There are three main types, phosphorus,[30] nitrogen,[31] and sulfur ylides,[32] although arsenic, selenium, etc., ylides are also known. Ylides may be defined as com-

$R_3P{=}CR_2 \longleftrightarrow R_3\overset{\oplus}{P}-\overset{\ominus}{\overline{C}}R_2$

Phosphorus ylides

$R_2S{=}CR_2 \longleftrightarrow R_2\overset{\oplus}{S}-\overset{\ominus}{\overline{C}}R_2$

Sulfur ylides

$R_3\overset{\oplus}{N}-\overset{\ominus}{\overline{C}}R_2$

Nitrogen ylides

---

[29] For a monograph, see Johnson, "Ylid Chemistry," Academic Press, Inc., New York, 1966. For reviews, see Hudson, *Chem. Br.* 7, 287–294 (1971); and Lowe, *Chem. Ind.* (*London*) 1070–1079 (1970).

[30] Although the phosphorus ylide shown has three R groups on the phosphorus atom, other phosphorus ylides are known where other atoms, e.g., oxygen, replace one or more of these R groups. When the three groups are all alkyl or aryl, the phosphorus ylide is also called a *phosphorane.*

[31] For a review of nitrogen ylides, see Musker, *Fortschr. Chem. Forsch.* **14**, 295–365 (1970).

[32] For a review of sulfur ylides, see König, *Fortschr. Chem. Forsch.* **9**, 487–533 (1968).

pounds in which an atom from group V or VI of the periodic table, bearing a positive charge, is connected to a carbon atom carrying an unshared pair of electrons. Because of $p\pi$-$d\pi$ bonding, two canonical forms can be written for phosphorus and sulfur ylides, but for nitrogen ylides there is only one. Once again, because of the resonance, phosphorus ylides are much more stable than nitrogen ylides (see also p. 865). In spite of their resonance, sulfur ylides also have a low stability.

In almost all compounds which have $p\pi$-$d\pi$ bonds, the central atom is connected to four atoms or to three atoms and an unshared pair, and the bonding is tetrahedral. The $p\pi$-$d\pi$ bond, therefore, does not change the geometry of the molecule, in contrast to the normal π bond, which changes an atom from tetrahedral to trigonal.

AROMATICITY

It was recognized in the nineteenth century that aromatic compounds[33] differed greatly from unsaturated aliphatic compounds,[34] but for many years chemists were hard pressed to arrive at a mutually satisfactory definition of aromatic character.[35] Qualitatively, there has never been real disagreement. Definitions have taken the form that aromatic compounds are characterized by a special stability and that they undergo substitution reactions more easily than addition reactions. The difficulty arises because these definitions are vague and not easy to apply in borderline cases.[36] In 1925 Armit and Robinson[37] recognized that the aromatic properties of the benzene ring are related to the presence of a closed loop of electrons, the *aromatic sextet* (aromatic compounds are thus the arch examples of delocalized bonding), but it still was not easy to determine whether rings other than the benzene ring possessed such a loop. With the advent of magnetic techniques, most notably nmr, it is now possible to determine experimentally whether or not a compound has a closed ring of electrons; and aromaticity can now be defined as the *ability to sustain an induced ring current*. A compound which has this ability is called *diatropic*. Although this definition also has its flaws,[38] it is the one most commonly accepted today. There are several methods of determining whether a compound can sustain a ring current, but the most important one is based on nmr chemical shifts.[39] In order to understand this, it is necessary to remember that, as a general rule, the value of the chemical shift of a proton in an nmr spectrum depends upon the electron density of its bond: the greater the density of the electron cloud surrounding or partially surrounding a proton, the more upfield its chemical shift (a higher value of τ). However, this rule has several exceptions, one being for protons in the vicinity of an aromatic ring. When an external

[33] For books on aromaticity, see Badger, "Aromatic Character and Aromaticity," Cambridge University Press, London, 1969; Snyder, "Nonbenzenoid Aromatics," 2 vols., Academic Press, Inc., New York, 1969–1971; Lloyd, "Carbocyclic Non-Benzenoid Aromatic Compounds," American Elsevier Publishing Company, New York, 1966; Ginsburg, "Non-Benzenoid Aromatic Compounds," Interscience Publishers, Inc., New York, 1959; Bergmann and Pullman, "Aromaticity, Pseudo-Aromaticity, and Anti-Aromaticity," Israel Academy of Sciences and Humanities, Jerusalem, 1971; and "Aromaticity," *Chem. Soc. Spec. Pub.* no. 21, 1967. For reviews, see Sondheimer, *Chimia* **28,** 163–172 (1974); Cresp and Sargent, *Essays Chem.* **4,** 91–114 (1972); Figeys, *Top. Carbocyclic Chem.* **1,** 269–359 (1969); Garratt and Sargent, *Adv. Org. Chem.* **6,** 1–108 (1969); Vol'pin, *Russ. Chem. Rev.* **29,** 129–160 (1960); Hafner, *Angew. Chem. Int. Ed. Engl.* **3,** 165–173 (1964) [*Angew. Chem.* **75,** 1041–1050 (1963)]; and Agranat, *MTP Int. Rev. Sci.: Org. Chem. Ser. One,* **3,** 139–178 (1973).

[34] For an account of the early history of aromaticity, see Snyder, in Snyder, Ref. 33, vol. 1, pp. 1–31.

[35] For a review of the criteria used to define aromatic character, see Jones, *Rev. Pure Appl. Chem.* **18,** 253–280 (1968). For a method of assigning aromaticity on the basis of Hückel theory, see Schaad and Hess, *J. Am. Chem. Soc.* **94,** 3068 (1972), *J. Chem. Educ.* **51,** 640 (1974).

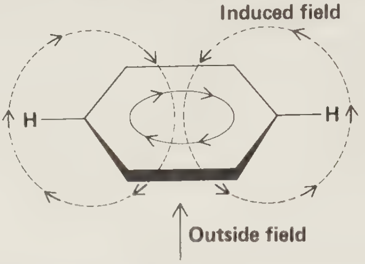
[36] It has been proposed that use of the word *aromatic* be discontinued altogether: see Lloyd and Marshall, *Angew. Chem. Int. Ed. Engl.* **11,** 404 (1972) [*Angew. Chem.* **84,** 477]; Labarre, in Bergmann and Pullman, Ref. 33, p. 55.

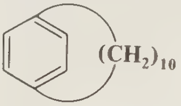
[37] Armit and Robinson, *J. Chem. Soc.* **127,** 1604 (1925).

[38] Jones, Ref. 35, pp. 266–274.

[39] For a review of nmr and other magnetic properties with respect to aromaticity, see Haddon, Haddon, and Jackman, *Fortschr. Chem. Forsch.* **16,** 103–220 (1971). For an example of a magnetic method other than nmr, see Dauben, Wilson, and Laity, in Snyder, Ref. 33, vol. 2, pp. 167–206.

magnetic field is imposed upon an aromatic ring (as in an nmr instrument), the closed loop of aromatic electrons circulates in a diamagnetic ring current, which sends out a field of its own. As can be seen in the diagram, this induced field curves around and in the area of the proton is parallel to the external field, so that the field "seen" by the aromatic protons is greater than it would have been in the absence of the diamagnetic ring current and the protons are moved downfield (to lower τ) compared with where they would be if electron density were the only factor. Thus ordinary olefinic hydrogens are found at approximately 3.5 to 5 τ, while the hydrogens of benzene rings are located at about 2 to 3 τ. However, if there were protons located above or within the ring, they would be subjected to a *decreased* field and should appear at higher τ values than normal CH_2 groups (normal τ for CH_2 is approximately 8 to 9). The nmr spectrum of [10]paracyclophane (**22**) showed that this was indeed the case[40] and that the CH_2 peaks were shifted to higher τ the closer they were to the middle of the chain.





22

It follows, then, that aromaticity can be determined from an nmr spectrum. If the protons attached to the ring are shifted downfield from the normal olefinic region, we can conclude that the molecule is diatropic and hence aromatic. If, in addition, the compound has protons above or within the ring (we shall see an example of the latter on p. 61), then if the compound is diatropic, these will be shifted upfield. One drawback to this method is that it cannot be applied to compounds which have no protons in either category, e.g., the dianion of squaric acid (p. 67). Unfortunately, ^{13}C nmr is of no help here, since these spectra do not show ring currents.[40a]

It should be emphasized that the old and new definitions of aromaticity are not necessarily parallel. If a compound is diatropic (and is therefore aromatic under the new definition), it is more stable than the canonical form of lowest energy, but this does not mean that it will be in fact stable to air, light, or common reagents, since *this* stability is determined not by the resonance energy but by the difference in free energy between the actual molecule and the transition states for the reactions involved; and these differences may be quite small, even if the resonance energy is large.

The vast majority of aromatic compounds have a closed loop of six electrons in a ring (the aromatic sextet), and these compounds will be considered first.[41]

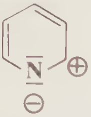
[40a] For a review of ^{13}C spectra of aromatic compounds, see Günther and Schmickler, *Pure Appl. Chem.* **44,** 807–828 (1975).

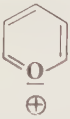
[41] Values of molecular-orbital energies for many aromatic systems, calculated by the HMO method, are given in Coulson and Streitwieser, Ref. 13. Values calculated by a variation of the SCF method are given by Dewar and Trinajstić, *Collect. Czech. Chem. Commun.* **35,** 3136, 3484 (1970).

Six-membered Rings

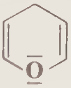
Not only is the benzene ring aromatic, but so are many heterocyclic analogs in which one or more hetero atoms replace carbon in the ring.[41a] When nitrogen is the hetero atom, little difference is made in the sextet and the unshared pair of the nitrogen does not participate in the aromaticity. Therefore, derivatives such as N-oxides or pyridinium ions are still aromatic. However, for nitrogen heterocycles there are more significant canonical forms (e.g., **23**) than for benzene. Where oxygen or sulfur is the hetero atom, it must be present in its ionic form (**24**) in order to possess the valence of 3 that participation in such a system demands. Thus, pyran (**25**) is not aromatic, but the pyrylium ion (**24**) is.[42]



23

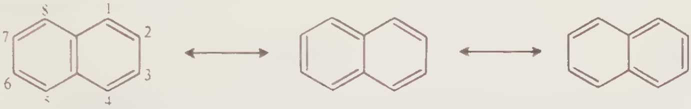


24



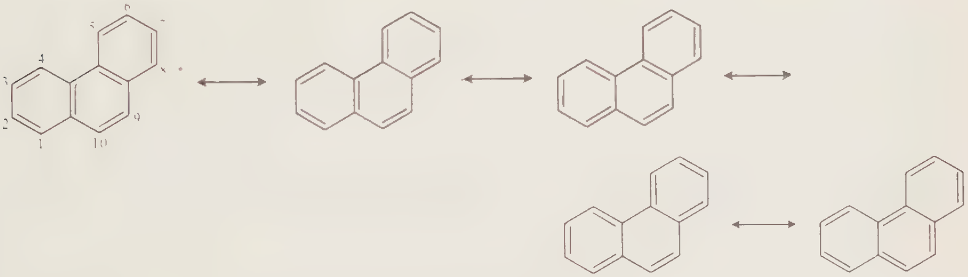
25

In systems of fused six-membered aromatic rings,[43] the principal canonical forms are usually not all equivalent. **26** has a central double bond and is thus different from the other two canonical forms of naphthalene, which are equivalent to each other:



26

For naphthalene, these are the only forms that can be drawn without consideration of Dewar forms or those with charge separation.[44] If we assume that the three forms contribute equally, the 1,2 bond has more double-bond character than the 2,3 bond. Molecular orbital calculations show bond orders of 1.724 and 1.603, respectively (compare benzene, 1.667). In agreement with these predictions, the 1,2 and 2,3 bond distances are 1.36 and 1.415 Å, respectively,[45] and ozone preferentially attacks the 1,2 bond.[46] This nonequivalency of bonds, called *partial bond fixation*,[47] is found in nearly all fused aromatic systems. In phenanthrene, where the 9,10 bond is a single bond in only one of five forms, bond fixation becomes extreme, and this bond is readily attacked by many reagents:



[41a] For a review of aromaticity of heterocycles, see Cook, Katritzky, and Linda, *Adv. Heterocycl. Chem.* **17,** 255–356 (1974).

[42] For a review of pyrylium salts, see Balaban, Schroth, and Fischer, *Adv. Heterocycl. Chem.* **10,** 241–326 (1969).

[43] For a treatise, see Clar, "Polycyclic Hydrocarbons," 2 vols., Academic Press, Inc., New York, 1964.

[44] As the size of a given fused ring system increases, it becomes more difficult to draw all the canonical forms. For a discussion of methods for doing this, see Herndon, *J. Chem. Educ.* **51,** 10–15 (1974).

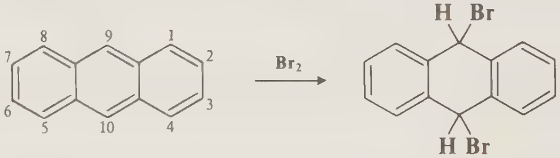
[45] Cruickshank, *Tetrahedron* **17,** 155 (1962).

[46] Kooyman, *Recl. Trav. Chim. Pays-Bas* **66,** 201 (1947).

[47] For reviews see Efros, *Russ. Chem. Rev.* **29,** 66–78 (1960); and Badger, *Q. Rev., Chem. Soc.* **5,** 147–170 (1951).

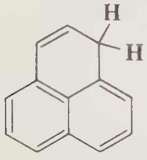
In general there is a good correlation between bond distances in fused aromatic compounds and bond orders, whether these are calculated by the valence-bond or molecular-orbital method. Another experimental quantity which correlates well with the bond order of a given bond in an aromatic system is the nmr coupling constant for coupling between the hydrogens on the two carbons of the bond.[48]

The resonance energies of fused systems increase as the number of principal canonical forms increases, as predicted by rule 6 (p. 37).[49] Thus, for benzene, naphthalene, anthracene, and phenanthrene, for which we can draw, respectively, two, three, four, and five principal canonical forms, the resonance energies are, respectively, 36, 61, 84, and 92 kcal/mol, calculated from heat-of-combustion data.[50] Note that when phenanthrene, which has a total resonance energy of 92 kcal/mol, loses the 9,10 bond by attack of a reagent such as ozone or bromine, two complete benzene rings remain, each with 36 kcal/mol of resonance energy, so that the molecule has lost only 20 kcal/mol, which is much less than the 36 kcal/mol which would be lost if benzene were similarly attacked. The fact that anthracene undergoes many reactions across the 9,10 positions can be explained in a similar manner. These reactions leave intact the outside aromatic rings, so that of the original resonance energy of 84 kcal/mol, 72 kcal/mol remains and only 12 kcal/mol is lost.

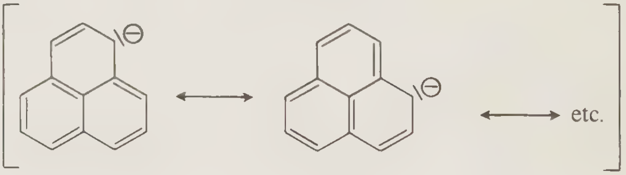


Anthracene

Not all fused systems can be fully aromatic. Thus for phenalene (**27**) there is no way double bonds can be distributed so that each carbon has one single and one double bond.[51] However, phenalene is acidic and reacts with potassium methoxide to give the corresponding anion (**28**), which is completely aromatic. So also are the corresponding free radical and cation, in which the resonance energies are the same (see p. 52).[52]



27



28

In a fused system there are not six electrons for each ring. In naphthalene, if one ring is to have six, the other must only have four. One way to explain the greater reactivity of the ring system of naphthalene compared with benzene is to regard one of the naphthalene rings as aromatic and the other as a butadiene system.[53] This effect may become extreme, as in the case of triphenylene.[54] For this compound, there are eight canonical forms like **29**, in which none of the three bonds marked *a* is a double bond, and only one form (**30**) in which at least one of them is double. Thus the molecule behaves as if the 18 electrons were distributed so as to give each of the outer rings a sextet, while the middle ring is "empty." Since none of the outer rings need share any electrons with an adjacent ring, they are as stable as benzene; and triphenylene, unlike most fused aromatic hydrocarbons, does not dissolve in concentrated sulfuric acid and has a low reactivity.[55] This phenomenon, whereby in fused systems some rings give up part of their aromaticity to adjacent rings, is called *annellation* and can be demonstrated by uv spectra[43] as well as by reactivities.

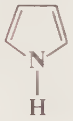
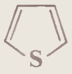
29 **30**

Five-membered Rings

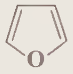
Five-membered rings containing two double bonds can also have an aromatic sextet if the fifth atom has an unshared pair of electrons. Such is the case in pyrrole, thiophene, and furan, though the latter has a lower degree of aromaticity than the other two.[56] Resonance energies for these compounds are, respectively, 21, 29, and 16 kcal/mol.[57] The filled orbital containing the unshared pair overlaps with the adjacent *p* orbitals to create five new orbitals, three of which are bonding and two antibonding. The three bonding orbitals contain the aromatic sextet. The aromaticity can also be shown by canonical forms; e.g., for pyrrole



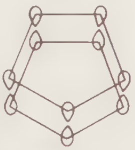
Pyrrole

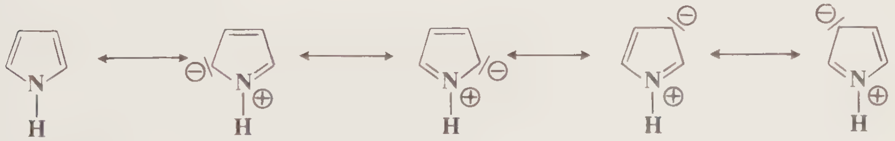


Thiophene



Furan





---

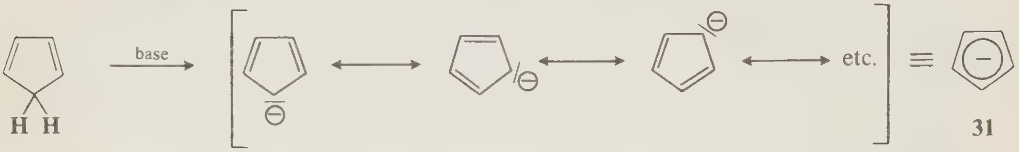
[55] Clar and Zander, *J. Chem. Soc.* 1861 (1958).

[56] The order of aromaticity in some of these compounds is benzene > thiophene > selenophene > tellurophene > furan: Fringuelli, Marino, Taticchi, and Grandolini, *J. Chem. Soc., Perkin Trans. 2* 332 (1974).

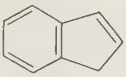
[57] Ref. 1, p. 99.

In contrast to the case of pyridine, the unshared pair in pyrrole is needed for the aromatic sextet. This is the reason pyrrole is so much weaker a base than pyridine.[58]

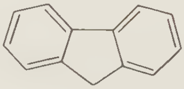
The fifth atom may be carbon if it has an unshared pair. Cyclopentadiene has unexpected acidic properties, since on loss of a proton, the resulting carbanion is greatly stabilized by resonance although it is quite reactive. The cyclopentadienide ion is usually represented as in **31**. Resonance in this ion is greater than in pyrrole, thiophene, and furan, since all five forms are equivalent. The calculated resonance energy for **31** is 42 kcal/mol.[59] That all five carbons are equivalent has been demonstrated by labeling the starting compound with ^{14}C and finding all positions equally labeled when cyclopentadiene was regenerated.[60] As expected for an aromatic system, the cyclopentadienide ion has been shown to be diatropic,[61] and aromatic substitutions on it have been successfully carried out.[62] Indene (**32**) and fluorene (**33**) are also acidic but less so than cyclopentadiene, since annellation causes the electrons to be less available to the five-membered ring.



31

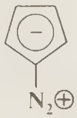


32

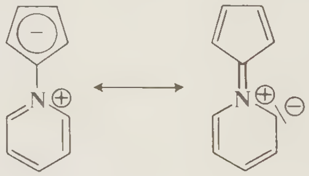


33

Cyclopentadienylides are a special type of cyclopentadienide (see ylides, p. 40) in which the five-membered ring is connected to a positively charged nitrogen atom. A number of these have been prepared, of which **34** and **35** are examples. **35** is further stabilized by the resonance shown. In these compounds, the cyclopentadiene ring has only four hydrogens, the nitrogen replacing the fifth. The electrons of the C—N bond may be regarded as having come from the nitrogen. Aromatic substitutions have been successfully carried out on **34**.[63]



34



35

Five-membered aromatic or aromatic-like rings are also found in other types of compounds: fulvenes and metallocenes. In *fulvenes*[64] (**36**) the exocyclic double bond is greatly polarized in

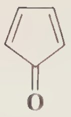
36



37

the direction of the ring. These compounds have dipole moments and react with $LiAlH_4$, which ordinarily does not reduce carbon-carbon double bonds but does so here because of the polarity. Also, cis-trans isomerism is not found in most fulvenes, since the exocyclic bond has a high degree of single-bond character. The ring attracts the electrons so as to have a sextet. Nevertheless, since fulvenes show no evidence of ring currents, the chemical shifts of the protons being found in the normal olefinic region,[65] they must therefore be regarded as nonaromatic compounds which show some aromatic properties. In cyclopentadienone (**37**) the oxygen, because of its electronegativity, attracts the electron pair away from the ring, and this compound is unknown, though some of its derivatives have been prepared.[66]

Metallocenes (also called *sandwich compounds*) are compounds in which two cyclopentadienylide rings form a sandwich around a metallic ion. The best known of these is ferrocene (**38**), although others have been prepared with Co, Ni, Cr, Ti, V, and many other metals.[67] Ferrocene is quite stable, subliming above 100 C and unchanged at 400 C. The two rings rotate freely, though the most stable position is a staggered one, in which the rings are not flush. Many aromatic substitutions have been carried out on metallocenes.[68] The compound **39**, prepared by Salzer and Werner, contains three cyclopentadienyl rings and two metal atoms.[69] Such compounds are called *triple-decker sandwiches.*[70]

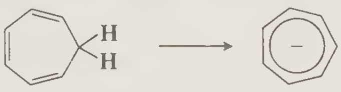
39

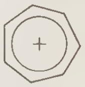
The bonding in ferrocene may be looked upon in simplified molecular-orbital terms as follows.[71] Each of the cyclopentadienide rings has five molecular orbitals: three filled bonding and two empty antibonding orbitals (p. 45). The outer shell of the Fe atom possesses nine atomic orbitals, i.e., one 4*s*, three 4*p*, and five 3*d* orbitals. The six filled orbitals of the two cyclopentadienide rings overlap with the *s*, three *p*, and two of the *d* orbitals of the Fe to form twelve new orbitals, six of which are bonding. These six orbitals make up two ring-to-metal triple bonds. In addition further bonding results from overlap of the empty antibonding orbitals of the rings with additional filled *d* orbitals of the iron. All told, there are eighteen electrons (ten of which may be considered to come from the rings and eight from iron in the zero oxidation state) in nine orbitals; six of these are strongly bonding and three weakly bonding or nonbonding.

Seven- and Eight-membered Rings[72]

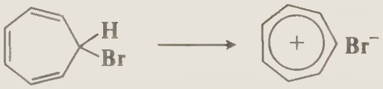
Cycloheptatriene (**40**) is much less acidic than cyclopentadiene. This would be hard to explain without the aromatic-sextet theory, since, on the basis of resonance forms or a simple consideration of orbital overlaps, **41** should be as stable as the cyclopentadienyl anion (**31**). While **41** has been prepared in solution,[73] it is apparently less stable than **31** and far less stable than **42**, in which **40** has lost not a proton but a hydride ion. The six double-bond electrons of **42** overlap with the empty orbital on the seventh carbon, and there is a sextet of electrons covering seven carbon atoms. **42**, known as the *tropylium ion*, is quite stable. Tropylium bromide, which could be completely covalent if the electrons of the bromine were sufficiently attracted to the ring, is actually an ionic compound[74]



40 **41**



42



Just as with **31**, the equivalence of the carbons in **42** has been demonstrated by isotopic labeling.[75]

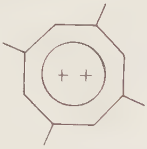
The tropylium ion has an aromatic sextet spread over seven carbon atoms. An analogous ion, with the sextet spread over eight carbon atoms, is 1,3,5,7-tetramethylcyclooctatetraene dianion (**43**).[75a] This ion, which is stable in solution at −50°C, is diatropic and approximately planar. **43** is not stable above about −30°C.



43

The search for aromaticity in seven-membered compounds has been extended to other types of systems, analogous to the five-membered ring compounds previously discussed. *Heptafulvenes* (**44**) would be expected to have the exocyclic double-bond electrons polarized *away* from the ring. The simplest heptafulvene (R = H) has been prepared[76] but is stable only at low temperatures or in dilute solutions. However, electron-withdrawing groups such as CN would stabilize the negative charge, and **45** is a more stable compound[77] with a very large dipole moment (7.49 D). In contrast to cyclopentadienone (**37**), cycloheptatrienone, called *tropone* (**46**), is predicted by the sextet theory to be stable, since the seven-membered ring *donates* electrons to the electronegative oxygen, while the five-membered ring requires them. In fact, in great contrast to cyclopentadienones, tropones are quite stable, and indeed tropolones (**47**) are found in nature.[78] However, analyses of dipole moments, nmr spectra, and x-ray diffraction measurements show that tropones, tropolones, and **45** display appreciable bond alternation[79] and these molecules, like fulvenes, must

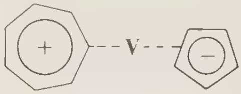
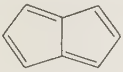
be regarded as nonaromatic, though with some aromatic character. Tropolones readily undergo aromatic substitution, emphasizing that the old and the new definitions of aromaticity are not always parallel.

Metallocenes containing tropylium ions have been prepared, e.g.,[80]

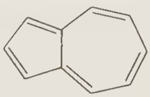


Other Systems Containing Aromatic Sextets

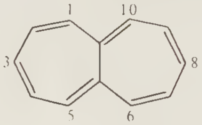
Simple resonance theory predicts that pentalene (**48**), azulene (**49**), and heptalene (**50**) should be aromatic, although no nonionic canonical form can have a double bond at the ring junction. Molecular-orbital calculations show that azulene should be stable but not the other two, and this



48



49



50

is borne out by experiment. Heptalene has been prepared[81] but reacts readily with oxygen, acids, and bromine, is easily hydrogenated, and polymerizes on standing. Analysis of its nmr spectrum shows that it is not planar.[82] The 3,8-dibromo and 3,8-dicarbomethoxy derivatives of **50** are stable in air at room temperature but are not diatropic.[83] Pentalene has not been prepared,[84] but the hexaphenyl derivative is known.[85] This compound is air-sensitive in solution. Pentalene and its methyl and dimethyl derivatives have been formed in solution, but they dimerize before they can be isolated.[86] Many other attempts to prepare these two systems have failed. One approach to hard-to-make aromatic systems involves preparation of ketones which can tautomerize to the desired phenolic systems. In such an attempt to produce a pentalene, **51** was prepared.[87] However, it did not tautomerize to the enol form (see p. 72):

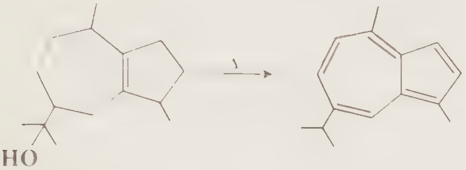
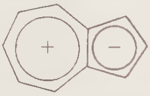
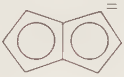
For pentalene, the only way each ring can have a sextet is for four electrons to be shared by the two rings, which is apparently not a stable situation. In heptalene, each ring can have six electrons, but then the two central carbons must belong to each sextet, and this is not a stable system either.

On the other hand, azulene can have six electrons in each ring if they share a pair (as in naphthalene). In sharp contrast to **48** and **50** azulene is quite stable, and many of its derivatives are known.[88] Many sesquiterpenes, found in nature, are easily converted to azulene derivatives, e.g., upon heating guaiol gives S-guaiazulene (see reaction **9-1**). Azulene readily undergoes aromatic substitution. Azulene may be regarded as a combination of **31** and **42** and, indeed, possesses a dipole moment of 0.8 D.[89] Interestingly, if two electrons are added to pentalene to give a dianion, each ring can have a sextet with one pair belonging to both. Such a dianion (**52**) has been prepared,[90] although pentalene itself has not been prepared. It can be concluded that an aromatic system of electrons will be spread over two rings only if 10 electrons (not 8 or 12) are available for aromaticity.



Guaiol S-Guaiazulene





52

Alternant and Nonalternant Hydrocarbons[91]

Aromatic hydrocarbons can be divided into two types. In alternant hydrocarbons, the conjugated carbon atoms can be divided into two sets such that no two atoms of the same set are directly linked. For convenience one set may be starred. Naphthalene is an alternant and azulene a nonalternant hydrocarbon:

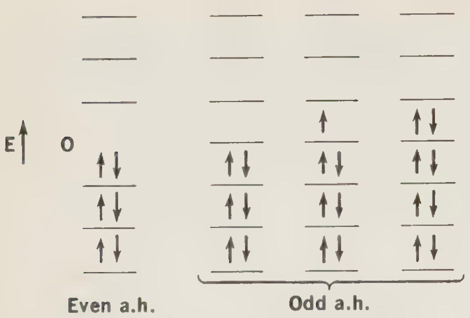

Figure 6 Energy levels in odd- and even-alternant hydrocarbons.[92] The arrows represent electrons. The orbitals are shown as having different energies, but some may be degenerate.

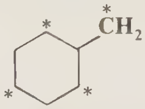
In alternant hydrocarbons, the bonding and antibonding orbitals occur in pairs; i.e., for every bonding orbital with an energy $-E$ there is an antibonding one with energy $+E$ (Figure 6). Even-alternant hydrocarbons are those with an even number of conjugated atoms, i.e., an equal number of starred and unstarred atoms. For these hydrocarbons all the bonding orbitals are filled and the π electrons are uniformly spread over the unsaturated atoms.

As with the allyl system, odd-alternant hydrocarbons (which must be carbonium ions, carbanions, or free radicals) in addition to equal and opposite bonding and antibonding orbitals also have a nonbonding orbital of zero energy. When an odd number of orbitals overlap, an odd number is created. Since orbitals of alternant hydrocarbons occur in $-E$ and $+E$ pairs, one orbital can have no partner and must therefore have zero bonding energy. For example, in the benzyl system the cation has an unoccupied nonbonding orbital, the free radical has one electron there, and the carbanion two (Figure 7). As with the allyl system, all three species have the same bonding energy. The charge distribution (or unpaired-electron distribution) over the entire molecule is also the same for the three species and can be calculated by a relatively simple process.[91]



For nonalternant hydrocarbons the energies of the bonding and antibonding orbitals are not equal and opposite, and charge distributions are not the same in cations, anions, and radicals. Calculations are much more difficult but have been carried out.[93]

Aromatic Systems with Electron Numbers Other than Six

Ever since the special stability of benzene was recognized, chemists have been thinking about homologous molecules and wondering whether this stability would also be associated with rings that are similar but of different sizes, such as cyclobutadiene (**53**), cyclooctatetraene (**54**), cyclo-

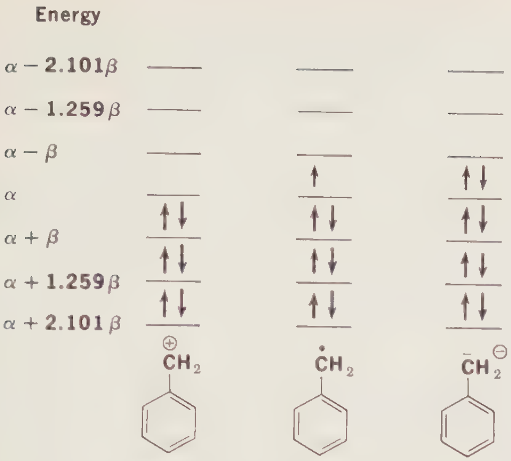

Figure 7 Energy levels for the benzyl cation, free radical, and carbanion. Since α is the energy of a *p* orbital (p. 32), the nonbonding orbital has no bonding energy.

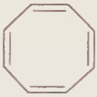
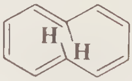
decapentaene[94] (**55**), etc. The general name *annulene* is given to these compounds, with benzene being [6]annulene, and **53** to **55** being called, respectively, [4]-, [8]-, and [10]annulene. By a naïve consideration of resonance forms, these annulenes, and higher ones, should be as aromatic as

53



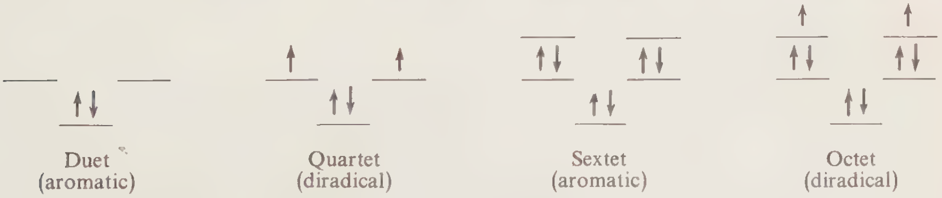
54



55

benzene. Yet they proved remarkably elusive. The benzene ring is ubiquitous, being found in thousands of natural products, in coal and petroleum, and being formed by strong treatment of many noncyclic compounds. None of the other annulene ring systems has ever been found in nature, and, except for cyclooctatetraene, their synthesis is not simple. Obviously, there is something special about the number six in a cyclic system of electrons.

Hückel's rule, based on molecular-orbital calculations, predicts that electron rings will constitute an aromatic system only if they contain a number of the form $4n + 2$, where n is any positive integer, including zero. Systems which contain $4n$ electrons are predicted to be nonaromatic. The rule predicts that rings of 2, 6, 10, 14, etc., electrons will be aromatic, while rings of 4, 8, 12, etc., will not be. This is actually a consequence of Hund's rule (p. 7). The first pair of electrons in an annulene goes into the π orbital of lowest energy. After that the bonding orbitals are degenerate, occurring in pairs of equal energy, so that when there is a total of four electrons,



---

[94] The cyclodecapentaene shown here is the cis-trans-cis-cis-trans form. For other stereoisomers, see p. 60.

Hund's rule predicts that two will be in the lowest orbital but the other two will be unpaired, so that the system will exist as a diradical rather than as two pairs. The degeneracy can be removed if the molecule is distorted from maximum molecular symmetry to a structure of lesser symmetry. For example, if **53** assumes a rectangular rather than a square shape, one of the previously degenerate orbitals has a lower energy than the other and will be occupied by two electrons. In this case, of course, the double bonds are essentially separate, and the molecule still is not aromatic. Distortions of symmetry can also occur when one or more carbons are replaced by hetero atoms or in other ways.[95] Molecular-orbital calculations predict[96] that the aromaticity of $4n + 2$ systems decreases with increasing n, so that large systems will show alternation of single and double bonds and no aromaticity.[97] Calculations show that alternation should begin at $n = 6$, so that the largest aromatic ring should have 22 electrons.[98]

In the following sections systems with various numbers of electrons are discussed. In looking for aromaticity we shall be looking for these things: (1) the presence of a diamagnetic ring current; (2) equal or approximately equal bond distances, except when the symmetry of the system is disturbed by a hetero atom or in some other way; (3) planarity; (4) chemical stability; and (5) the ability to undergo aromatic substitution.

Systems of Two Electrons[99]

Obviously, there can be no ring of two carbon atoms, though a double bond may be regarded as a degenerate case. However, in analogy to the tropylium ion, a three-membered ring with a double bond and a positive charge on the third atom (the *cyclopropenyl cation*) would be a $4n + 2$ system and hence would be expected to show aromaticity. The unsubstituted **56** has been prepared,[100] as well as several derivatives, e.g., the trichloro, diphenyl, and dipropyl derivatives, and these are stable despite the angles of only 60°. In fact, the tripropylcyclopropenyl ion is one of the most stable carbonium ions known, being stable even in water solution.[101] The tri-*t*-butylcyclopropenyl cation is also very stable.[102] In addition, cyclopropenone (**57**) and several of its derivatives are stable compounds,[103] in accord with the corresponding stability of the tropones.[104]

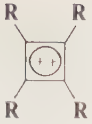
57



58

The ring system **56** is nonalternant, and the corresponding radical and anion (which do not have an aromatic duet) have electrons in antibonding orbitals, so that their energies are much higher. As with **31** and **42**, the equivalence of the three carbon atoms in the triphenylcyclopropenyl cation has been demonstrated by ^{14}C labeling experiments.[105] The interesting dications **58** (R = Me or Ph) have been prepared,[106] and they too should represent aromatic systems of two electrons.[107]

Systems of Four Electrons. Antiaromaticity

According to Hückel's rule, a closed loop of four electrons should not be aromatic. Many attempts have been made to prepare such systems: chiefly cyclobutadiene (**53**), cyclopropenyl anion (**59**), cyclopentadienyl cation (**60**),[107a] and their derivatives. The evidence to date is that not only are these systems not aromatic but actually *antiaromatic*. If they simply lacked aromaticity, we would expect them to be about as stable as similar nonaromatic compounds, but both theory and experiment show that they are in fact *much less stable*. For example, we may compare a conjugated **59** and an open-chain conjugated allyl carbanion.[108] By HMO theory, the latter is about 19 kcal mol more stable than a diradical conjugated **59.** Thus an allyl carbanion would be *destabilized* upon a hypothetical cyclization to **59,** though in $4n + 2$ systems, an open-chain conjugated system is *stabilized* by cyclizing to the aromatic system. We can therefore predict in the case of cyclopropenyl anion, not only that the canonical form **61** does not gain stability by conjugation but that it actually loses stability; i.e., *an unconjugated* **61** *is more stable than a conjugated* **59.**[109] The HMO theory is supported by experiment. Among other evidence, it has been shown that **62** (R = COPh) loses its proton in hydrogen-exchange reactions about 6000 times more slowly

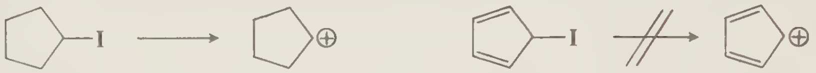
[109] For an example of molecular orbital calculations supporting this conclusion, see Clark, *Chem. Commun.* 637 (1969).

than **63** (R = COPh).[110] Where R = CN, the ratio is about 10,000.[111] This indicates that **62** are much more reluctant to form carbanions (which would have to be cyclopropenyl carbanions) than **63**, which form ordinary carbanions. Thus the carbanions of **62** are less stable than corresponding ordinary carbanions. There are also indications that **63** are not only weak acids kinetically but also thermodynamically:[112] the pK_a of 1,2,3-triphenylcyclopropene is extremely high.[113]

In compounds in which overlapping parallel *p* orbitals form a closed loop of $4n + 2$ electrons, the molecule is stabilized by resonance, and we have an aromatic ring. But the above evidence (and additional evidence cited below) indicates that when the closed loop contains $4n$ electrons, the molecule is destabilized by resonance. We define as *antiaromatic* any system in which cyclic electron delocalization raises the energy.[114]

Although derivatives of cyclopropenyl anion have been prepared as fleeting intermediates (as in the exchange reactions mentioned above), all attempts to prepare the ion or any of its derivatives as relatively stable species have so far met with failure.

In the case of **60**, the ion has been prepared and has been shown to be a diradical in the ground state,[115] as predicted by the discussion on p. 54.[116] Evidence that **60** is not only nonaromatic but also antiaromatic comes from studies on **64** and **66**.[117] When **64** is treated with silver perchlorate in propionic acid, the molecule is rapidly solvolyzed (a reaction in which the intermediate **65** is formed; see Chapter 5). Under the same conditions, **66** undergoes no solvolysis at all; i.e., **60** does not form. If **60** were merely nonaromatic, it should be about as stable as **65** (which of course has no resonance stabilization at all). The fact that it is so much more reluctant to form indicates that **60** is much less stable than **65**.



64 **65** **66** **60**

It is strong evidence for Hückel's rule that **59** and **60** are not aromatic while the cyclopropenyl cation (**56**) and the cyclopentadienyl anion (**31**) are, since simple resonance theory predicts no difference between **59** and **56** or between **60** and **31** (the same number of equivalent canonical forms can be drawn for **59** as for **56** and for **60** as for **31**).

The four-electron system which has received the most attention is cyclobutadiene (**53**). There is a long history of attempts to prepare this compound and its simple derivatives.[118] Though this goal has now been achieved, it is clear that simple cyclobutadienes are extremely unstable compounds which have very short lifetimes (they dimerize by a Diels-Alder reaction; see reaction 5-51) unless stabilized in matrixes (where the molecules are forced to remain apart from each other) at very low temperatures (generally below 35 K). The first successful preparation of **53** was that of Pettit and coworkers,[119] who treated a metallic complex of cyclobutadiene (see p. 59) with ceric ammonium nitrate at 0 C and condensed the resulting gas in a trap cooled with liquid nitrogen. The liquid thus obtained was assumed to be cyclobutadiene. When methyl propiolate was added to it, it gave small amounts of methyl benzoate, which would be expected to form in this manner (see reactions **5-51** and **8-32**):

53

Since then **53** and some of its simple derivatives have been prepared a number of times using the low-temperature matrix technique.[120] Infrared studies of **53** under these conditions show that it has a square planar geometry.[121] Other evidence, though not yet conclusive, shows that the molecule seems to be a diene in the ground state[122] and not a diradical. However, it has been found[123] that *o*-diphenylcyclobutadiene (which was not isolated) behaves like a mixture of 1,2- and 1,4-diphenylcyclobutadiene, which is possible only if the ring is rectangular and not square planar. The extreme reactivity of simple cyclobutadienes is not caused merely by steric strain, since the strain should be no greater than that of simple cyclopropenes, which are known compounds. It is probably caused by antiaromaticity.[124]

There are some cyclobutadienes known that are stable at room temperature for varying periods of time. These fall into three classes.

1. *Cyclobutadienes which contain bulky substituents.* Examples are tri-*t*-butylcyclobutadiene (**67**)[125] and the dithia compound **68**.[126] These compounds are relatively stable because dimeriza-

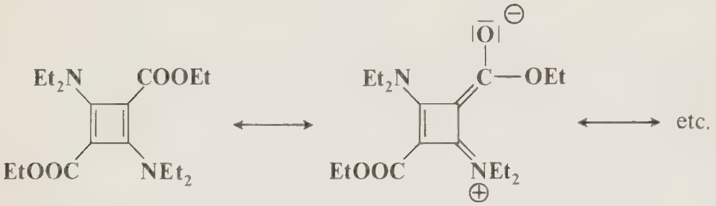
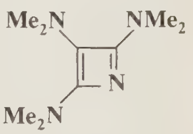
tion is sterically hindered. Examination of the nmr spectrum of **67** showed that the ring proton ($\tau = 4.62$) was shifted *upfield*, compared with the position expected for a nonaromatic proton, e.g., cyclopentadiene. As we shall see on p. 65, this indicates that the compound is antiaromatic. A similar investigation cannot be made for **68** because it has no ring proton, but x-ray crystallography showed that the central ring is a rectangular diene (as shown) with single- and double-bond lengths of 1.600 and 1.344 Å, respectively.[127] The unusually long single-bond distance may be due to repulsion between the methyl groups. Photoelectron spectroscopy showed that **68** is not a diradical.[128]

2. *Cyclobutadienes bearing two electron-donating and two electron-withdrawing groups.* These are stable in the absence of water.[129] An example is **69.** The stability of these compounds is generally attributed to the resonance shown, a type of resonance stabilization called the *push-pull effect,*[130] though it has been concluded from a photoelectron spectroscopy study that second-order bond fixation is more important.[131] An x-ray crystallographic study of **69** has shown[132] the ring to be a distorted square, with bond lengths of 1.46 Å and angles of 87 and 93 . The azacyclobutane **70** is also stable,[133] for similar reasons.



69



70

3. *Derivatives in which the cyclobutadiene system is fused to aromatic rings, the most important being biphenylene* (**71**).[134] However, annellation (p. 45) can result in an "empty" central ring

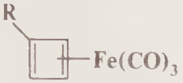
here, and all the evidence is that this is the case. Thus the bond lengths[135] are *a*, 1.52 Å, and *b*, 1.43 Å.

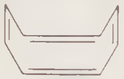
The unfused cyclobutadiene system is stable in complexes with metals[136] (see Chapter 3), but in these cases electron density is withdrawn from the ring by the metal and there is no aromatic quartet. In fact, these cyclobutadiene-metal complexes may be looked upon as systems containing an aromatic duet. The ring is square planar,[137] the compounds undergo aromatic substitution,[138] and nmr spectra of monosubstituted derivatives show that the C-2 and C-4 protons are equivalent.[138]



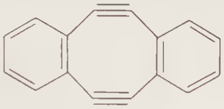
In summary, all the evidence to date indicates that **53**, **59**, and **60** and their simple derivatives are certainly not aromatic systems and very likely are antiaromatic.

Systems of Eight Electrons

Cyclooctatetraene[138a] (**54**) is not planar but tub-shaped.[139] Therefore it would be expected to be neither aromatic nor antiaromatic, since both these conditions require overlap of parallel *p* orbitals.



54



72

The reason for the lack of planarity is that a regular octagon has angles of 135°, while sp^2 angles are most stable at 120°. To avoid the strain, the molecule assumes a nonplanar shape, in which orbital overlap is greatly diminished. Single- and double-bond distances in **54** are, respectively, 1.46 and 1.33 Å, which is just what is expected for a compound made up of four individual double bonds.[139] Also the reactivity is what would be expected for a linear polyene. However, the cyclooctadiendiyne **72** is a planar conjugated eight-electron system (the four extra triple-bond electrons do not participate), which nmr evidence shows to be antiaromatic.[140] There is evidence that part of the reason for lack of planarity in **54** itself is that a planar molecule would have to be antiaromatic.[141] Complexes of cyclooctatetraene with metals undergo typical aromatic substitution

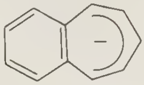
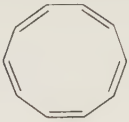
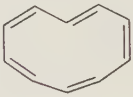
reactions[142] but are also nonplanar.[143] The cycloheptatrienyl anion (**41**) also has eight electrons but does not behave like an aromatic system.[72] The nmr spectrum of the benzocycloheptatrienyl anion (**73**) shows that, like **67** and **72**, this compound is antiaromatic.[144]



73



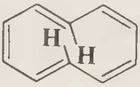
74



75

Systems of Ten Electrons[145]

There are three geometrically possible isomers of [10]annulene: the all-cis (**74**); the mono-trans (**75**); and the cis-trans-cis-cis-trans (**55**).[146] If Hückel's rule is to apply to these, they should be planar. But it is far from obvious that the molecules would adopt a planar shape, since in order to do so they must overcome considerable strain. For a regular decagon (**74**) the angles would have to be 144°, considerably larger than the 120° required for sp^2 angles. Some of this strain would also be present in **75**, but in **55** this kind of strain is eliminated, since all the angles are 120°. However, it was pointed out by Mislow[147] that the hydrogens in the 1 and 6 positions should interfere with each other and force the molecule out of planarity.



55

Compounds **74** and **75** have been prepared[148] as crystalline solids at −80°C. Nmr spectra show that all the hydrogens lie in the olefinic region and neither compound is aromatic. From ^{13}C and proton nmr spectra it has been deduced that neither is planar. Several derivatives of **74** and **75**, in which the ten-membered ring is fused to benzene rings, have also been prepared, and these likewise are nonaromatic and nonplanar.[149] However, that the angle strain is not insurmountable has been demonstrated by the preparation of several compounds which have large angles but are definitely planar 10-electron aromatic systems. Among these are the dianion **76**,

80

the anions **77** and **78**, and the azonine **79**.[150] **76**[151] has angles of about 135°, while **77**[152] and **79**[153] have angles of about 140°, which are not very far from 144°. The inner proton in **78**[154] (which is the mono-trans isomer of the all-cis **77**) is found far upfield in the nmr (13.5 τ). For **74** and **75**, the cost in strain energy to achieve planarity apparently outweighs the extra stability which would come from an aromatic ring. To emphasize the delicate balance between these factors, we add that the oxygen analog of **79** (oxonin) and the N-carbethoxy derivative of **79** are non-aromatic and nonplanar, while **79** itself is aromatic and planar.[155] Aromaticity in these cases seems to depend on the availability of the unshared pair. The azonine ring of the fused compound **80** is also nonaromatic.[156]

So far **55** has not been prepared, despite many attempts. However, there are various ways of avoiding the interference between the two inner protons. The approach which has been most successful involves bridging the 1 and 6 positions.[157] Thus, 1,6-methano[10]annulene (**81**)[158] and its oxygen and nitrogen analogs **82**[159] and **83**[160] have been prepared and are stable compounds which undergo aromatic substitution and are diatropic. For example, the perimeter protons of **81**

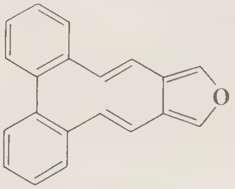
are found at 2.7 to 3.1 τ, while the bridge protons are at 10.5 τ. The crystal structure of the 2-carboxylic acid derivative of **81** shows that the perimeter is nonplanar, but the bond distances are in the range 1.38 to 1.42 Å.[161] Although **55** itself has not been prepared, a fused derivative (**84**) has been made.[162] However, the molecule is not diatropic. Further emphasizing the correctness of Mislow's analysis is the fact that there are two stereoisomers of **84**: one has the two inner hydrogens on the same side of the ring and the other on opposite sides.



84

It has therefore been amply demonstrated that a closed loop of 10 electrons is an aromatic system, although some molecules which could conceivably have such a system are distorted too much from planarity to be aromatic.

Systems of More than Ten Electrons: $4n + 2$ Electrons[163]

Extrapolating from the discussion of [10]annulene, we expect larger $4n + 2$ systems to be aromatic (if planar) at least up to about [22]- or [26]annulene (p. 54). Mislow[147] predicted that [14]annulene (**85**) would possess the same type of interference as **55**, though in lesser degree, and this is borne out by experiment. **85** is aromatic (it is diatropic: inner protons at 10.0 τ, outer protons at 2.4 τ),[164] but it is completely destroyed by light and air in 1 day. X-ray analysis shows that although there are no alternating single and double bonds, the molecule is not planar.[165] However, a number

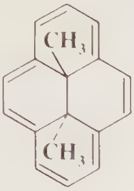
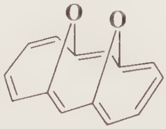
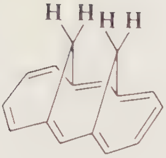
of stable bridged [14]annulenes have been prepared;[166] e.g., *trans*-15,16-dimethyldihydropyrene (**86**),[167] *syn*-1,6:8,13-bisoxido[14]annulene (**87**),[168] *syn*- and *anti*-1,6:8,13-bismethano[14]annulene (**88A** and **88B**),[169] and 1,6:8,13-propano[14]annulene (**89**).[170] The dihydropyrene **86** (and its



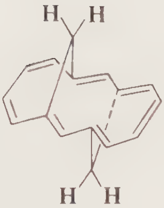
86



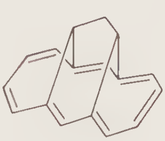
87



88A



88B



89

diethyl and dipropyl homologs) is undoubtedly aromatic: the π perimeter is approximately planar,[171] the bond distances are all 1.39 to 1.40 Å, and the molecule undergoes aromatic substitution[167] and is diatropic. The outer protons are found at 1.33 to 1.86 τ, while the CH_3 protons are at 14.25 τ. A comparison of the τ values of **85** and **86** would seem to indicate that the separation between inner and outer protons decreases with decreasing planarity, though the molecules are not quite comparable. **88A**, **87**, and **89** are also diatropic[172] (e.g., the bridge protons of **89** are found far upfield in the nmr spectrum[173]), although x-ray crystallography indicates that the π periphery in at least the latter two compounds is not quite planar.[174] **87** undergoes aromatic substitution.[168] However, **88B**, in which the geometry of the molecule greatly reduces overlap of the *p* orbitals at the bridgehead positions with adjacent *p* orbitals, is definitely not aromatic, as shown by nmr spectra[169] and x-ray crystallography, from which bond distances of 1.33 to 1.36 Å for the double bonds and 1.44 to 1.49 Å for the single bonds have been obtained.[175] In contrast, in **87** and **89**, all the bond distances are $\sim$1.38 to 1.40 Å.[174]

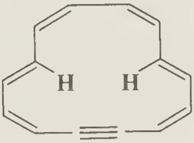
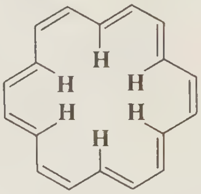
[175] Gramaccioli, Mimun, Mugnoli, and Simonetta, *Chem. Commun.* 796 (1971).

Another way of eliminating the hydrogen interferences of [14]annulene is to introduce one or more triple bonds into the system, as in dehydro[14]annulene (**90**).[175a] All five known dehydro[14]annulenes are diatropic. **90** can be nitrated or sulfonated.[176] The extra electrons of the triple bond do not form part of the aromatic system but simply exist as a localized π bond.



90



91

[18]Annulene (**91**) is diatropic:[177] the 12 outer protons are found at about $\tau = 1$ and the 6 inner protons at about $\tau = 13$. X-ray crystallography[178] shows that it is nearly planar, so that interference of the inner hydrogens is not important in annulenes this large. **91** is reasonably stable, being distillable at reduced pressures, and undergoes aromatic substitutions.[179] The C—C bond distances are not equal, but they do not alternate. There are 12 inner bonds of about 1.38 Å and 6 outer bonds of about 1.42 Å.[178] **91** has been estimated to have a resonance energy of about 37 kcal/mol, similar to that of benzene.[180] Most of the known dehydro[18]annulenes are also diatropic.[181] The dianions of open and bridged [16]annulenes are also 18-electron aromatic systems.[182]

[22]Annulene[183] and dehydro[22]annulene[184] are also diatropic. In the latter compound there are 13 outer protons at 1.55 to 3.75 τ and 7 inner protons at 6.55 to 9.30 τ. Some aromatic bridged [18]- and [22]annulenes are also known.[185] [26]Annulene has not yet been prepared, but while a tridehydro[26]annulene is not diatropic,[186] two monodehydro[26]annulenes are aromatic.[187]

Furthermore, the dianion of 1,3,7,9,13,15,19,21-octadehydro[24]annulene[188] is another 26-electron system which is aromatic. A tetra-*t*-butyldidehydro[30]annulene has been reported to be diatropic,[189] but a number of other dehydro and bridged [30]annulenes have been prepared and show no ring currents.[190]

There is now no doubt that $4n + 2$ systems of up to 22 electrons are aromatic if they can be planar, although **84** and **88B**, among others, demonstrate that not all such systems are in fact planar enough for aromaticity. The cases of **85**, **87**, and **89** prove that absolute planarity is not required for aromaticity, but that aromaticity decreases with decreasing planarity. Beyond 22 electrons there is still doubt about where aromaticity ends. Dewar and Gleicher predicted that the largest aromatic system should have 22 electrons,[98] but the reports of aromaticity in at least three 26-electron compounds and a 30-electron compound indicate that the limit is greater than 22.

Systems of More than Ten Electrons: 4*n* Electrons[163]

As we have seen (p. 55), these systems are expected to be not only nonaromatic but actually antiaromatic. The chief criterion for antiaromaticity in annulenes is the presence of a *paramagnetic* ring current,[191] which causes protons on the outside of the ring to be shifted *upfield* while any inner protons are shifted *downfield*, in sharp contrast to a diamagnetic ring current, which causes shifts in the opposite directions. Compounds which sustain a paramagnetic ring current are called *paratropic*: we have already seen such behavior in certain four- and eight-electron systems. As with aromaticity, we should expect that antiaromaticity will be at a maximum when the molecule is planar and when bond distances are equal. The [12]annulene **92**[192] (this isomer is called [12]-21-annulene)[193] has been prepared. In solution this molecule undergoes rapid conformational mobility (as do many other annulenes),[194] so that above a certain temperature, in this case −150 C, all protons are magnetically equivalent. However, at −170°C the mobility is greatly slowed, and at this temperature the three inner protons are found at about 2 τ while the nine outer protons are at about 4 τ. **92** suffers from hydrogen interference and is certainly not planar. It is very unstable, and above −50°C rearranges to **93**. Several bridged and dehydro[12]-annulenes are known, e.g., 5-bromo-1,9-didehydro[12]annulene (**94**),[195] cycl[3.3.3]azine (**95**),[196] and 1,7-methano[12]annulene (**96**).[197] In these compounds not only is hydrogen interference

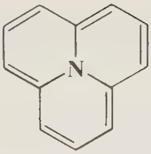
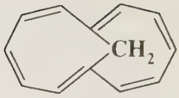
94



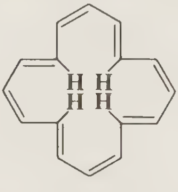
95



96

prevented but also conformational mobility. In **95** and **96** the bridge prevents conformational changes, while in **94** the bromine atom is too large to be found inside the ring. Nmr spectra show that all three compounds are paratropic, the inner proton of **94** being found at $-6.4\ \tau$.[198]

The results for [16]annulene are similar. The compound was synthesized in two different ways,[199] both of which gave [16]-85-annulene (**97**), which in solution is in equilibrium with [16]-91-annulene (see p. 115). Above $-50°C$ there is conformational mobility, resulting in the magnetic equivalence of all protons, but at $-130°C$ the compound is clearly paratropic: there are four protons at $-0.56\ \tau$ and twelve at $4.67\ \tau$. In the solid state, where the compound exists entirely as **97**, x-ray crystallography[200] showed that the molecules are nonplanar with almost complete bond alternation: the single bonds are 1.44 to 1.47 Å, and the double bonds 1.31 to 1.35 Å. A number of dehydro and bridged [16]annulenes have also been shown to be paratropic,[201] as have [20]annulene[202] and [24]annulene.[203]



97

As with aromaticity, antiaromaticity is predicted to end at about [24]annulene, but so far there is little evidence on this question, though a tetraaza[32]annulene and a bridged [36]annulene have been reported to be *atropic*,[204] i.e., neither diatropic nor paratropic.

The fact that many $4n$ systems are paratropic even though they may be nonplanar and have unequal bond distances indicates that if planarity were enforced, the ring currents might be even greater. That this is true is dramatically illustrated by the nmr spectrum of the dianion of **86** (and its diethyl and dipropyl homologs).[205] We may recall that in **86**, the outer protons were found

[198] For another paratropic 12-electron system, see Staley and Orvedal, *J. Am. Chem. Soc.* **95**, 3384 (1973).

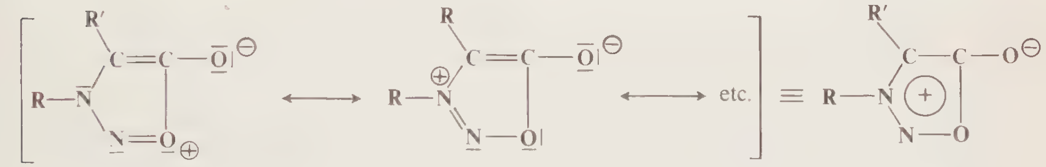
at 1.33 to 1.86 τ with the methyl protons at 14.25 τ. For the dianion, however, which is forced to have approximately the same planar geometry but now has 16 electrons, the outer protons are shifted to about 13 τ, while the methyl protons are found at about −11 τ, a shift of about 25 τ! We have already seen where the converse shift was made, when [16]annulenes which were antiaromatic were converted to 18-electron dianions which were aromatic.[182] In these cases, the changes in nmr chemical shifts were almost as dramatic.

We can therefore conclude that in 4*n* systems up to at least 24 electrons antiaromaticity will be at a maximum where the molecule is constrained to be planar (as in **59** or the dianion of **86**) but, where possible, the molecule will distort itself from planarity and avoid equal bond distances in order to reduce antiaromaticity. In some cases, such as cyclooctatraene, the distortion and bond alternation are great enough for antiaromaticity to be avoided completely, but in other cases, e.g., **92** or **97**, it is apparently not possible for the molecules to avoid at least some *p*-orbital overlap, and such molecules show paramagnetic ring currents and other evidence of antiaromaticity, though the degree of antiaromaticity is not as great as in such molecules as **59** or the dianion of **86**.

Other Aromatic Compounds

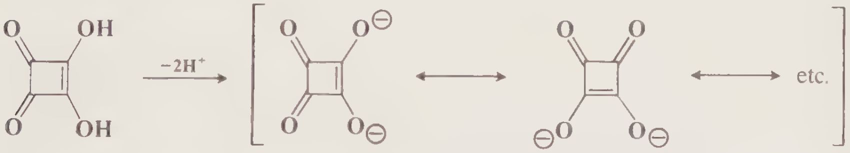
We shall briefly mention four other types of aromatic compounds.

1. *Mesoionic compounds*[206] cannot be satisfactorily represented by Lewis forms not involving charge separation. Nearly all known mesoionic compounds contain five-membered rings. The most common are the *sydnones* (**98**), stable aromatic compounds which undergo aromatic substitution when R′ is hydrogen.[207]



98

2. *The dianion of squaric acid*[208]



The stability of this system is illustrated by the fact that the pK_1 of squaric acid is about 1.5 and the pK_2 about 3.5,[209] which means that even the second proton is given up much more readily than the proton of acetic acid, for example. The analogous five- and six-membered ring compounds are also known.[210]

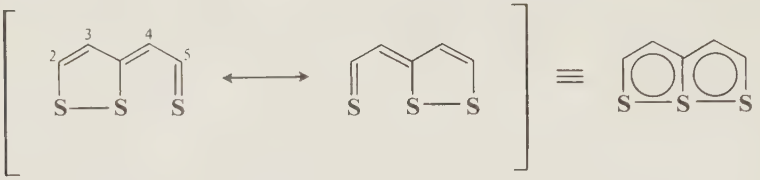
[209] Ireland and Walton, *J. Phys. Chem.* **71,** 751 (1967); MacDonald, *J. Org. Chem.* **33,** 4559 (1968).

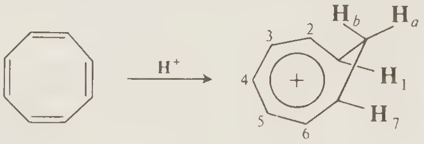
3. In *thiothiophthenes*[211] **99** (also called thiathiophthenes and 1,6,6*a*-S^{IV}-trithiapentalenes) each



99

canonical form has a pair of sulfur atoms with no bond at all. Nevertheless, in the parent compound and in the symmetrical 2,5-dimethyl derivative, the two sulfur-sulfur distances are equal, and the three sulfur atoms are in a straight line.[212] Furthermore, nmr chemical shifts indicate the presence of a diamagnetic ring current.[213] However, other symmetrical derivatives of **99** (e.g., the 2,5-diphenyl and 3,4-diphenyl compounds)[214] have been shown to have unequal S—S distances, and it has been argued that the system is not aromatic and that the two structures are better described as being in tautomeric equilibrium (p. 71) than as canonical forms.[215] If the system is aromatic, it is a naphthalene type of system with a total of ten π electrons.[216]

4. *Homoaromaticity.* When cyclooctatetraene is dissolved in concentrated H_2SO_4, a proton adds to one of the double bonds to form the homotropylium ion **100**.[217] In this species an



100

aromatic sextet is spread over seven carbons, as in the tropylium ion. The eighth carbon is an sp^3 carbon and so cannot take part in the aromaticity. Nmr spectra show the presence of a diatropic ring current: H_b is found at $\tau = 10.7$; H_a at 4.9 τ; H_1 and H_7 at 3.6 τ, and H_2 to H_6 at 1.5 τ. This ion is an example of a *homoaromatic* compound, which may be defined as a compound which contains one or more[218] sp^3-hybridized carbon atoms in an otherwise conjugated cycle.[219] In order for the orbitals to overlap most effectively so as to close a loop, the sp^3 atoms are forced to lie almost vertically above the plane of the aromatic atoms. In **100**, H_b is directly above the aromatic sextet and so is shifted far upfield in the nmr. Homoaromatic compounds of two and ten electrons are also known.

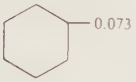
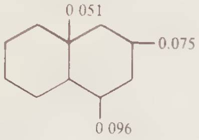
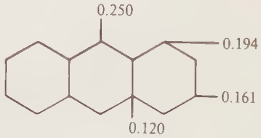
Free Valence

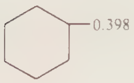
On p. 29 the concept of bond order was discussed. A closely related concept is that of free valence.[220] In the valence-bond method the free valence at a carbon is determined by adding the weights of all the structures in which a Dewar bond ends at that carbon. Free valences at various aromatic positions are shown:

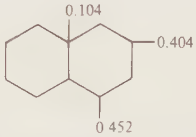


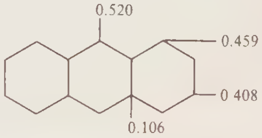




In the molecular-orbital method, free valence is defined as 1.732 minus the sum of the molecular-orbital bond orders to all carbons directly bound.[221] Molecular-orbital free valences for the same compounds are:







The absolute values of the two methods are not comparable, but the trends are similar in both. The free valence is supposed to be a measure of the ease of attack at a given position. Both methods are in accord with the fact that the 9 position of anthracene is the most reactive and that it is more reactive than any benzene carbon or any position of naphthalene. For free-valence values for other compounds, see Ref. 220.

HYPERCONJUGATION

All of the delocalization so far discussed involves π electrons. Another type, called *hyperconjugation*, involves σ electrons.[222] When a carbon attached to at least one hydrogen is attached to an unsaturated atom or one with an unshared orbital, canonical forms such as **101** can be drawn.

---

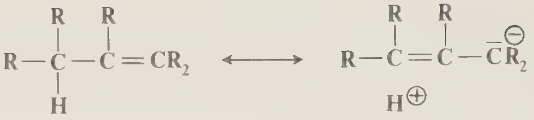
[218] If a compound contains two such atoms it is *bishomoaromatic*; if three, *trishomoaromatic*, etc. For examples of bishomotropylium ions, see Ahlberg, Harris, Roberts, Warner, Seidl, Sakai, Cook, Diaz, Dirlam, Hamberger, and Winstein, *J. Am. Chem. Soc.* **94**, 7063 (1972); Paquette, Broadhurst, Warner, Olah, and Liang, *J. Am. Chem. Soc.* **95**, 3386 (1973).

[219] For reviews, see Winstein, *Q. Rev., Chem. Soc.* **23**, 141–176 (1969); "Aromaticity," Ref. 33, pp. 5–45; and in Olah and Schleyer, "Carbonium Ions," John Wiley & Sons, Inc., vol. 3, 1972, the reviews by Story and Clark, 1007–1098, pp. 1073–1093; and Winstein, 965–1005. (The latter is a reprint of the *Q. Rev., Chem. Soc.* review mentioned above.)

[220] For reviews, see Greenwood and McWeeny, *Adv. Phys. Org. Chem.* **4**, 73–145 (1966); and Pullman and Pullman, *Prog. Org. Chem.* **4**, 31–71 (1958). For values of free valences for many compounds, see Coulson and Streitwieser, Ref. 13.

[221] 1.732 is chosen as the value for a "completely bonded" carbon. Anything less is the free part of the valence.

[222] For reviews, see Baker, "Hyperconjugation," Oxford University Press, Fair Lawn, N.J., 1952; Crawford, *Q. Rev., Chem. Soc.* **3**, 226–244 (1949); symposia in *Tetrahedron* **5**, 107–274 (1959), **17**, 125–289 (1962); and Dewar, "Hyperconjugation," The Ronald Press Company, New York, 1962.



$$\mathrm{R-\underset{H}{\overset{R}{C}}-\overset{R}{C}=CR_2 \longleftrightarrow R-\underset{H^{\oplus}}{\overset{R}{C}}=\overset{R}{C}-\overset{\ominus}{\underline{C}}R_2}$$

101

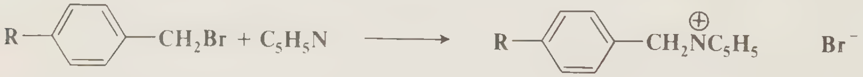
In such canonical forms there is no bond at all between the carbon and hydrogen, and this type of resonance is often called *no-bond resonance*. The hydrogen does not leave (because **101** does not exist but is only a canonical form which contributes to the actual structure of the molecule). The effect of **101** on the actual molecule is that the electrons in the C—H bond are closer to the carbon than they would be if **101** did not contribute at all.

Hyperconjugation in the above case may be regarded as an overlap of the σ orbital of the C—H bond and the π orbital of the C—C bond, analogous to the π-π-orbital overlap previously considered. As might be expected, those who reject the idea of resonance in butadiene (p. 33) believe it even less likely when it involves no-bond structures.

The concept of hyperconjugation arose from the discovery of apparently anomalous electron-release patterns for alkyl groups. By the field effect alone, the order of electron release for simple alkyl groups connected to an unsaturated system is *t*-butyl > isopropyl > ethyl > methyl, and this order is observed in many phenomena. Thus the dipole moments of the alkylbenzenes are, in the gas phase,[223]

Compound	Dipole moment, D
$PhCH_3$	0.37
PhC_2H_5	0.58
$PhCH(CH_3)_2$	0.65
$PhC(CH_3)_3$	0.70

However, Baker and Nathan observed that the rates of reaction with pyridine of *p*-substituted benzyl bromides (see p. 377) were about opposite that expected from inductive electron release.[224]

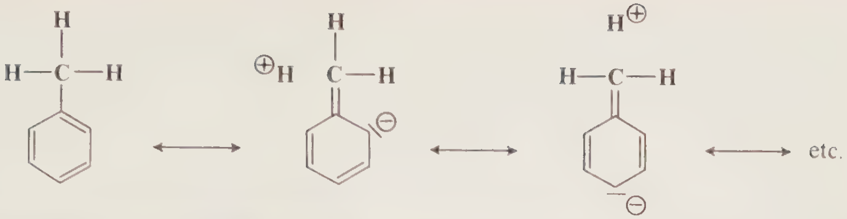


R	$k \times 10^4$ at 20°C
CH_3	2.02
C_2H_5	1.81
$CH(CH_3)_2$	1.63
$C(CH_3)_3$	1.65

This came to be called the *Baker-Nathan effect* and has since been found in many processes. Baker and Nathan explained it by considering that hyperconjugative forms contribute to the actual structure of toluene.

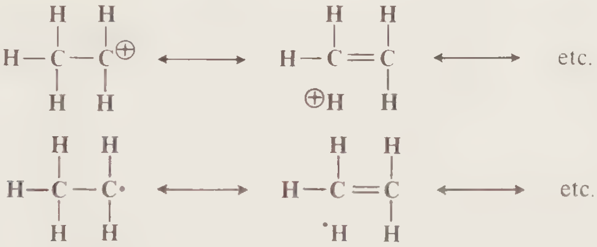
[223] Baker and Groves, *J. Chem. Soc.* 1144 (1939).

[224] Baker and Nathan, *J. Chem. Soc.* 1840, 1844 (1935).



For the other alkyl groups, hyperconjugation is diminished because the number of C—H bonds is diminished and in *t*-butyl there are none; hence, with respect to this effect, methyl is the strongest electron donor and *t*-butyl the weakest. The Baker-Nathan order may be considered to arise when the hyperconjugative resonance effect is greater than the field effect.

However, the fact that the Baker-Nathan order is observed in some processes and the inductive order in others has caused considerable controversy over the reality of hyperconjugation. Over the years, evidence from bond distances, bond energies, spectra, and reactivity has been brought forward to bolster the case for hyperconjugation, and all have been attacked as being otherwise caused.[225] Several other explanations have also been brought forward for the Baker-Nathan effect.[226] At present the evidence is against hyperconjugation in the ground states of neutral molecules.[227] However, for carbonium ions and free radicals[228] and for excited states of molecules,[229] there is evidence that hyperconjugation is important. In hyperconjugation in the ground state of neutral molecules, which Muller and Mulliken call *sacrificial hyperconjugation*,[230] the canonical forms involve not only no-bond resonance but also a charge separation not possessed by the main form. In free radicals and carbonium ions, the canonical forms display no more charge separation than the main form. Muller and Mulliken call this *isovalent hyperconjugation:*



Even here the main form contributes more to the hybrid than the others.

TAUTOMERISM

There remains one topic to be discussed in our survey of chemical bonding in organic compounds. For most compounds all the molecules have the same structure, whether or not this structure can be satisfactorily represented by a Lewis formula. But for many other compounds there is a

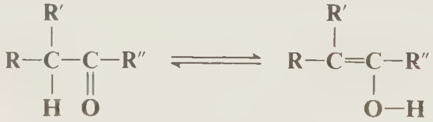
TABLE 1 The enol content of some carbonyl compounds[233]

Compound	Enol content, %
Acetone	1.5×10^{-4}
Acetaldehyde	No enol found[234]
CH_3COOEt	No enol found[234]
CH_3COEt	1.2×10^{-1}
CH_3COCH_2COOEt	8.0
$CH_3COCH_2COCH_3$	76.4
$PhCOCH_2COCH_3$	89.2
$EtOOCCH_2COOEt$	7.7×10^{-3}
$NCCH_2COOEt$	2.5×10^{-1}

mixture of two or more structurally distinct compounds which are in rapid equilibrium. When this phenomenon, called *tautomerism*,[231] exists, there is a rapid shift, back and forth, among the molecules. In nearly all cases, it is a proton which shifts from one atom of a molecule to another.

Keto-Enol Tautomerism[232]

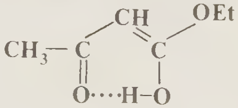
A very common form of tautomerism is that between a carbonyl compound containing an α hydrogen and its enol form:



$$\mathrm{R{-}\overset{\displaystyle R'}{\underset{\displaystyle H}{C}}{-}\underset{\displaystyle \overset{\|}{O}}{C}{-}R''} \rightleftharpoons \mathrm{R{-}\overset{\displaystyle R'}{C}{=}\underset{\displaystyle O{-}H}{C}{-}R''}$$

Keto form Enol form

In simple cases (R″ = H, alkyl, OR, etc.) the equilibrium lies well over to the left. The reason can be seen by examining the table of bond energies on p. 28. The keto form differs from the enol form in possessing a C—H, a C—C, and a C═O bond where the enol has a C═C, a C—O, and an O—H bond. The approximate sum of the first three is 360 kcal/mol and of the second three is 345 kcal/mol. The keto form is therefore more stable by about 15 kcal/mol. When R contains a multiple bond which can be in conjugation with the enolic double bond, a larger amount of enol is present and it may even be the predominant form (Table 1). As Table 1 shows, esters have a much smaller enolic content than ketones. In molecules like acetoacetic ester, the enol is also stabilized by internal hydrogen bonding, which is unavailable to the keto form:



---

[231] For reviews, see Kol'tsov and Kheifets, *Russ. Chem. Rev.* **40,** 773–788 (1971), **41,** 452-467 (1972); Forsén and Nilsson, in Zabicky, "The Chemistry of the Carbonyl Group," vol. 2, pp. 157–240, Interscience Publishers, Inc., New York, 1970; and Wheland, "Advanced Organic Chemistry," 3d ed., pp. 663–730, John Wiley & Sons, Inc., New York, 1960.

[232] The mechanism for conversion of one tautomer to another is discussed in Chapter 12 (reaction **2-3**).

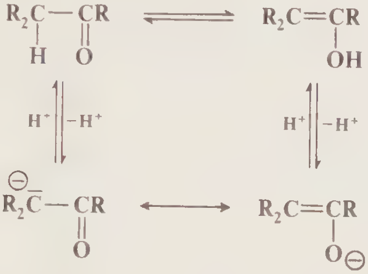
[233] Gero, *J. Org. Chem.* **19,** 469, 1960 (1954).

[234] Less than 1 part in 10 million.

Frequently, when the enol content is high, both forms can be isolated. The pure keto form of acetoacetic ester melts at −39°C, while the enol is a liquid even at −78°C. Each can be kept at room temperature for days if catalysts such as acids or bases are excluded.[235]

The extent of enolization is greatly affected by solvent, concentration, and temperature. Thus, acetoacetic ester has an enol content of 0.4% in water and 19.8% in toluene.[236] In this case, water reduces the enol concentration by hydrogen bonding with the carbonyl, making this group less available for internal hydrogen bonding.

When a strong base is present, both the enol and the keto form can lose a proton. The resulting anion (the *enolate ion*) is the same in both cases. Since **102** and **103** differ only in placement of electrons, *they* are not tautomers but canonical forms. The true structure of the enolate ion is a hybrid of **102** and **103**, though **103** contributes more, since in this form the negative charge is on the more electronegative atom.

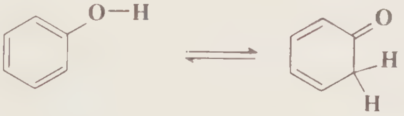


102 **103**

Other Proton-Shift Tautomerism

In all such cases, the anion resulting from removal of a proton from either tautomer is the same because of resonance. Some examples are:

1. Phenol-keto tautomerism:[237]



Phenol Cyclohexadienone

For most simple phenols this equilibrium lies well to the side of the phenol, since only on that side is there aromaticity. For phenol itself there is no evidence for the existence of the keto form. However, the keto form becomes important and may predominate: (1) where certain groups, such as a second OH group or an N=O group, are present;[238] (2) in systems of fused aromatic rings;[239] and (3) in heterocyclic systems. In many heterocyclic compounds in the liquid phase or in solution, the keto form is more stable[240] though in the vapor phase the positions of many of these equilibria are reversed.[241] For example, in the equilibrium between 4-pyridone (**104**) and 4-hydroxypyridine (**105**), **104** is the only form detectable in ethanolic solution, while **105** predominates in the vapor phase.[241]

---

[235] For an example of particularly stable enol and keto forms, which could be kept in the solid state for more than a year without significant interconversion, see Schulenberg, *J. Am. Chem. Soc.* **90**, 7008 (1968).

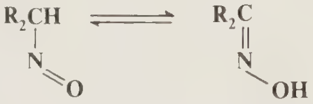
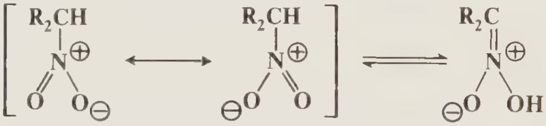
2. Nitroso-oxime tautomerism:



Nitroso Oxime

This equilibrium lies far over to the right, and as a rule nitroso compounds are stable only when there is no α-hydrogen.

3. Aliphatic nitro compounds are in equilibrium with aci forms.



Nitro form Aci form

The nitro form is much more stable than the aci form, in sharp contrast to the parallel case of nitroso-oxime tautomerism, undoubtedly because the nitro form has resonance not found in the nitroso case.

4. Imine-enamine tautomerism:

$$\underset{\text{Imine}}{R_2CH{-}CR{=}NR} \rightleftharpoons \underset{\text{Enamine}}{R_2C{=}CR{-}NHR}$$

Enamines are normally stable only when there is no hydrogen on the nitrogen ($R_2C{=}CR{-}NR_2$). Otherwise, the imine form predominates.[242]

Ring-chain tautomerism[243] (as in sugars) consists largely of cyclic analogs of the previous examples. There are many other highly specialized cases of proton-shift tautomerism.

Valence Tautomerism

This type of tautomerism is discussed on p. 1047.

[240] For reviews of tautomerism in heterocyclic compounds, see Katritzky, *Chimia* **24**, 134–146 (1970); Katritzky and Lagowski, *Adv. Heterocycl. Chem.* **1**, 311–437 (1963); **2**, 1–81 (1963).

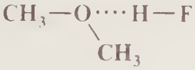
Three

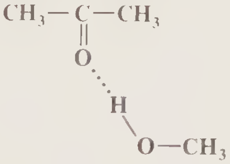
Bonding Weaker than Covalent

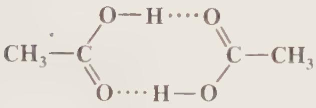
In the first two chapters we have discussed the structure of molecules each of which is an aggregate of atoms in a distinct three-dimensional arrangement held together by bonds whose energies are of the order of 50 to 100 kcal mol. There are also very weak attractive forces *between* molecules, on the order of a few tenths of a kilocalorie per mole. These forces, which are responsible for liquefaction of gases at sufficiently low temperatures, are caused by electrostatic attractions, such as those between dipole and dipole, induced dipole and induced dipole, etc. They are called *van der Waals forces*. The bonding to be discussed in this chapter has energies of the order of 2 to 10 kcal mol, intermediate between the two extremes, and produces clusters of molecules. We shall also discuss compounds in which portions of molecules are held together without any attractive forces at all.

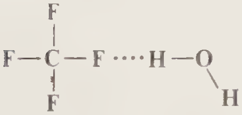
HYDROGEN BONDING

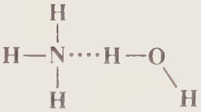
A *hydrogen bond* is a bond between a functional group A—H and an atom or group of atoms B in the same or a different molecule.[1] With exceptions to be noted later, hydrogen bonds are formed only when A is oxygen, nitrogen, or fluorine, and when B is oxygen, nitrogen, or fluorine. The oxygen may be singly or doubly bonded, and the nitrogen singly, doubly, or triply bonded. The bonds are usually represented by dotted lines, as shown in the following examples:





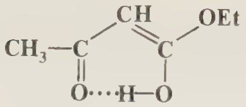


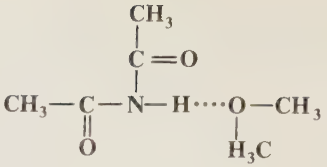


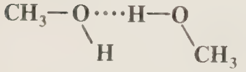


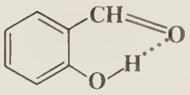
---

For reviews, see Pimentel and McClellan, *Annu. Rev. Phys. Chem.* **22,** 347–385 (1971); Kollman and Allen, *Chem. Rev.* **72,** 283–303 (1972); Huggins, *Angew. Chem. Int. Ed. Engl.* **10,** 147–151 (1971) [*Angew. Chem.* **83,** 163–168]; and Rochester, in Patai, "The Chemistry of the Hydroxyl Group," pt. 1, pp. 327–392, Interscience Publishers, Inc., New York, 1971; pp. 328–369. See also Hamilton and Ibers, "Hydrogen Bonding in Solids," W. A. Benjamin, Inc., New York, 1968.









Hydrogen bonds can exist in the solid and liquid phases and in solution. Even in the gas phase, compounds which form particularly strong hydrogen bonds may still be associated. Acetic acid, for example, exists in the gas phase as dimers, as shown above, except at very low pressures.[2] In solution and in the liquid phase, hydrogen bonds rapidly form and break. The mean lifetime of the $NH_3 \cdots\cdots H_2O$ bond is 2×10^{-12} sec.[3] Except for the $FH \cdots\cdots F^-$ bond, which has an energy of about 40 kcal/mol, the strongest hydrogen bonds are the $FH \cdots\cdots F$ bond and the bonds connecting one carboxylic acid with another. The energies of these bonds are in the range of 6 to 8 kcal/mol (for carboxylic acids, this refers to the energy of each bond). Other $OH \cdots\cdots O$ bonds and $NH \cdots\cdots N$ bonds have energies of 3 to 6 kcal/mol. To a first approximation, the strength of hydrogen bonds increases with increasing acidity of A—H and basicity of B,[4] but the parallel is far from exact.[5] A quantitative measure of the strengths of hydrogen bonds has been established. A parameter pK_{HB} has been devised, which measures the relative strengths with which an atom or group H—B forms hydrogen bonds with any suitable O—H reference acid[6] (in a similar way that pK_b is a measure of base strength).

The geometry of hydrogen bonds is difficult to determine, since hydrogen is not easy to detect in x-ray-diffraction measurements, but what little evidence there is is consistent with the hydrogen being on the straight line formed by A and B within about 15°,[7] except in some cases of intramolecular hydrogen bonding where the geometry forbids this.[8] It is significant that the vast majority of intramolecular hydrogen bonding occurs where *six-membered rings* (counting the hydrogen as one of the six) can be formed, in which linearity of the hydrogen bond is geometrically favorable, while five-membered rings, where linearity is usually not favored (though it is known), are much rarer. Except for the special case of $FH \cdots\cdots F^-$ bonds (see p. 78), the hydrogen is not equidistant between A and B. For example, in ice the O—H distance is 0.97 Å, while the $H \cdots\cdots O$ distance is 1.79 Å.[9]

Hydrogen bonding has been detected in many ways, including measurements of dipole moments, solubility behavior, freezing-point lowering, and heats of mixing, but the most important ways are by the effect of the hydrogen bond on ir[10] and other spectra. The ir frequencies of groups such as O—H or C=O are shifted when the group is hydrogen-bonded. Hydrogen bonding always moves the peak toward higher wavelengths, for both the A—H and the B groups, although the shift is greater for the former. For example, a free OH group absorbs at about 3600 to 3650 cm^{-1}, while a hydrogen-bonded OH group is found about 50 to 100 cm^{-1} lower, at 3500 to 3600 cm^{-1}.[11] In many cases there is partial hydrogen bonding, i.e., some OH groups are free and some are hydrogen-bonded. In such cases two peaks appear. Infrared spectroscopy can also distinguish between inter- and intramolecular hydrogen bonding, since intermolecular peaks are intensified by an increase in concentration while intramolecular peaks are unaffected. Other types of spectra which have been used for the detection of hydrogen bonding include Raman, electronic,[12] and nmr.[13] Since hydrogen bonding involves a rapid movement of protons from one atom to another, nmr records an average value. Hydrogen bonding can be detected because it usually produces a chemical shift to a lower field. Hydrogen bonding changes with temperature and concentration, and comparison of spectra taken under different conditions also serves to detect and measure it. As with infrared spectra, intramolecular hydrogen bonding can be distinguished from intermolecular by its constancy when the concentration is varied.

[9] Pimentel and McClellan, "The Hydrogen Bond," Ref. 1, p. 260.

Hydrogen bonds are important because of the effects they have on the properties of compounds, among them the following:

1. Intermolecular hydrogen bonding raises boiling points and frequently melting points.

2. If hydrogen bonding is possible between solute and solvent, this greatly increases solubility and often results in large or even infinite solubility where none would otherwise be expected. It is interesting to speculate what the effect on the human race would be if ethyl alcohol had the same solubility in water as ethane or ethyl chloride.

3. Hydrogen bonding causes lack of ideality in gas and solution laws.

4. As previously mentioned, hydrogen bonding changes the position of bands in all kinds of spectra.

5. Hydrogen bonding, especially the intramolecular variety, changes many chemical properties. For example, it is responsible for the large amount of enol present in certain tautomeric equilibria (see p. 72). Also, by influencing the conformation of molecules (see Chapter 4), it often plays a significant role in determining reaction rates.[14] Hydrogen bonding is also important in maintaining the three-dimensional structures of protein and nucleic acid molecules.

In addition to oxygen, nitrogen, and fluorine, mentioned earlier, there is evidence that weaker hydrogen bonding exists in other systems. Although many searches have been made for hydrogen bonding where A is carbon,[15] only three types of C—H bonds have been found which are acidic enough to form weak hydrogen bonds. These are found in terminal acetylenes, RC≡CH, chloroform and some other halogenated alkanes, and HCN. Weak hydrogen bonds are formed by compounds containing S—H bonds.[16] There has been much speculation regarding other possibilities for B. There is evidence that Cl can form weak hydrogen bonds[17] (e.g., *o*-chlorophenol is known to exhibit intramolecular hydrogen bonding[18]), but Br and I form very weak bonds if at all.[19] However, the *ions* Cl^-, Br^-, and I^- form hydrogen bonds which are much stronger than those of the covalently bonded atoms.[20] As we have already seen, the $FH \cdots\cdots F^-$ bond is especially strong. In this case the hydrogen is equidistant from the fluorines.[21] Similarly, a sulfur atom[16] can be the B component in weak hydrogen bonds,[22] but the SH^- ion forms much stronger bonds.[23] The $HS^- \cdots\cdots H_2S$ bond is particularly strong, with an energy of about 14 kcal/mol.[23] A system which seems to form rather strong hydrogen bonds is the isonitrile system $R-\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}}$.[24] There is evidence that double and triple bonds, aromatic rings,[25] and even cyclopropane rings[26] may be the B component of hydrogen bonds, but these bonds are very weak.

Deuterium also forms hydrogen bonds; in some systems these seem to be stronger than the corresponding hydrogen bonds; in others, weaker.[27]

ADDITION COMPOUNDS

When reaction of two compounds results in a product which contains all the mass of the two compounds, the product is called an *addition compound*.[28] There are several kinds of addition compounds. Two of these do not fall within the scope of this chapter, since they do not contain bonds weaker than covalent bonds:

1. Regular covalent compounds, such as the product of reaction of ethylene and bromine.
2. Compounds formed by overlap of an orbital containing an unshared pair with an empty orbital, e.g., $H_3\overset{\oplus}{N}-\overset{\ominus}{B}F_3$ (see Lewis acids and bases, p. 236).

In other addition compounds the molecules of the starting materials remain more or less intact, and weak bonds hold two or more molecules together in a cluster. We can divide these compounds into four broad classes: electron donor-acceptor complexes; complexes formed by crown ethers and similar compounds; inclusion compounds; and catenanes.

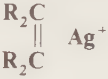
Electron Donor-Acceptor (EDA) Complexes[29]

In *EDA complexes*,[30] there is always a donor molecule and an acceptor. The donor may donate an unshared pair (an *n* donor) or a pair of electrons in a π orbital of a double bond or aromatic system (a π donor). One test for the presence of an EDA complex is the electronic spectrum. These complexes generally exhibit a spectrum (called a *charge-transfer spectrum*) which is not the same as the sum of the spectra of the two individual molecules.[31] Because the first excited state of the complex is relatively close in energy to the ground state, there is usually a peak in the visible or near-uv region, and EDA complexes are often colored. Many EDA complexes are unstable and exist only in solutions in equilibrium with their components, but others are stable solids. In most EDA complexes the donor and acceptor molecules are present in an integral ratio, most often 1 : 1, but some complexes with nonintegral ratios are also known. There are several types of acceptor, and we shall classify complexes into three groups, depending on the nature of the acceptor.

1. *Complexes in which the acceptor is a metal ion and the donor an olefin or an aromatic ring* (*n* donors do not give EDA complexes with metal ions but form covalent bonds instead).[32] Many metal ions form complexes, which are often stable solids, with olefins, dienes (usually conjugated, but not always), and aromatic rings. The generally accepted picture of the bonding in these complexes,[33] first proposed by Dewar,[34] can be illustrated for the complex in which silver ion is bonded to an olefin. There are two bonds between the metal ion and the olefin. One of



$$\begin{array}{l} R_2C \\ \;\;\;\| \quad Ag^+ \\ R_2C \end{array}$$

these is a σ bond formed by overlap of the filled π orbital of the olefin with the empty 5*s* orbital of the silver ion, and the other is a π bond formed by overlap of a filled 4*d* orbital of the silver ion and an empty antibonding π^* orbital of the olefin. The bond is not from the silver ion to one atom but to the whole π center, and the net result is that some electron density is transferred from the olefin to the metal ion.[35]

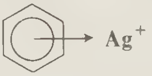
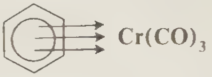
[33] For reviews, see Hartley, *Chem. Rev.* **73,** 163–190 (1973); *Angew. Chem. Int. Ed. Engl.* **11,** 596-606 (1972) [*Angew. Chem.* **84,** 657–667].

[34] Dewar, *Bull. Soc. Chim. Fr.* **18,** C79 (1951).

Among the compounds which form complexes with silver and other metals are benzene[36] (represented as in **1**) and cyclooctatetraene. When the metal involved has a coordination number greater than 1, more than one donor molecule participates. In many cases, this extra electron density comes from CO groups, which in these complexes are called carbonyl groups. Thus, benzenechromium tricarbonyl (**2**) is a stable compound.[37] Three arrows are shown, since all three aromatic bonding orbitals contribute some electron density to the metal. Metallocenes (p. 47) may be considered a special case of this type of complex, though the bonding in metallocenes is much stronger.

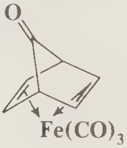


1



2

In a number of cases olefins which are too unstable for isolation have been isolated in the form of metal complexes. An example is norbornadienone, which was isolated in the form of its iron-tricarbonyl complex (**3**).[38] The free dienone spontaneously decomposes to carbon monoxide and benzene (reaction **7-38**).



3

2. *Complexes in which the acceptor is an organic molecule.* Picric acid, 1,3,5-trinitrobenzene, 2,4,7-trinitrofluorene, and similar polynitro compounds are the most important of these.[39] Picric acid forms addition compounds with many aromatic hydrocarbons, aromatic amines, aliphatic amines, olefins, and other compounds. These addition compounds are usually solids with definite melting points and are often used as derivatives of the compounds in question. They are called picrates, though they are not salts of picric acid but addition compounds. Unfortunately, salts of picric acid are also called picrates. Not only picric acid but other aromatic nitro compounds and even some aliphatic nitro compounds form similar addition compounds. Similar complexes are formed between phenols and quinones (quinhydrones).[40] Olefins which contain electron-withdrawing substituents also act as acceptor molecules. A particularly strong one is tetracyanoethylene.[41]

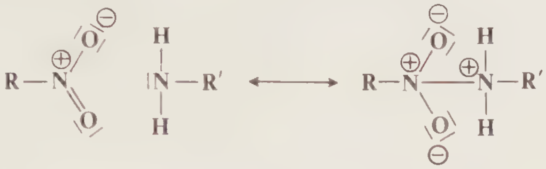
[41] For a review of complexes formed by tetracyanoethylene and other polycyano compounds, see Melby, in Rappoport, "The Chemistry of the Cyano Group," pp. 639–669, Interscience Publishers, Inc., New York, 1970.

The bonding in these cases is more difficult to explain than in the previous case, and indeed no really satisfactory explanation is available.[42] The difficulty is that although the donor has a pair of electrons to contribute (both *n* donors and π donors are found here), the acceptor does not have a vacant orbital. Simple attraction of the dipole induced-dipole type accounts for some of the bonding[43] but is too weak to explain the bonding in all cases;[44] e.g., nitromethane, with about the same dipole moment as nitrobenzene, forms much weaker complexes. Some other type of bonding clearly must also be present in many EDA complexes. The exact nature of this bonding, called *charge-transfer bonding*, is not well understood, but it presumably involves some kind of donor-acceptor interaction.

One theory is that resonance of the type



is responsible for attraction between nitro compounds and amines.[45] The amine (an *n* donor) thus contributes electrons to a partially filled orbital of the nitro group. Presumably, aromatic hydrocarbons and olefins behave similarly, though in these cases π electrons are donated. Another theory, a molecular-orbital one, suggests that electrons from one of the two original molecules can be transferred to higher vacant orbitals of the other.[46]

One difficulty with these explanations is that they predict that the functional groups should be close to each other, but this is not always so. Crystal structures, determined for a number of addition compounds, have shown that the molecules are stacked in parallel planes, consisting of alternate layers of donor and acceptor molecules.[47] The structure of the complex trinitrobenzene-benzidine is such that not only are the groups not close to each other, but even the rings do not

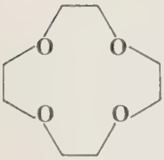
overlap.[48] The ability to form a plane seems to be important. Thus **4**, in which the two rings cannot be coplanar, did not form a complex with anthracene.[49]

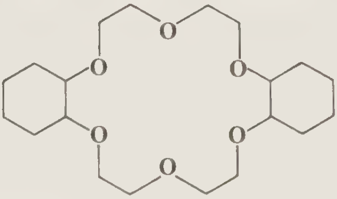
3. *Complexes in which the acceptor is* I_2, Br_2, *or even* Cl_2.[50] These molecules accept electrons from both *n* donors and π donors, presumably by expansion of the outer shell to hold 10 electrons. Such complexes are formed with amines, aromatic hydrocarbons, ketones, etc. This is the reason iodine is not its normal purple color in solvents such as acetone, ethanol, or benzene. IBr and ICl also form complexes, in which the iodine end of the molecule is the acceptor.[51] Even in these cases the bonding is not simple. The authors of a review article state[52] that despite the presumption about expansion of the octet, "a satisfactory theoretical interpretation of the observed geometry of the atomic arrangements associated with charge-transfer bonding [in these complexes] is still lacking." That there is charge transfer here seems certain, since the iodine-benzene complex has a dipole moment, though iodine and benzene are themselves nonpolar.[53] An important contribution to the bonding of the benzene-halogen complexes is quadrupole–induced dipole interaction (the benzene molecule is the quadrupole).[54]

Complexes Formed by Crown Ethers and Similar Compounds[55]

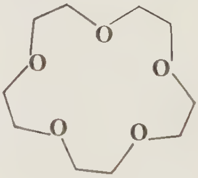
Crown ethers are large ring compounds containing several oxygen atoms, usually in a regular pattern. Examples are 12-crown-4 (**5**),[56] dicyclohexyl-18-crown-6 (**6**), and 15-crown-5 (**7**). These compounds have the property[57] of forming complexes with positive ions, generally metallic ions (though not usually ions of transition metals) or ammonium and substituted ammonium ions.



5



6



7

In most cases the ions are held tightly in the center of the cavity. Each crown ether binds different ions, depending on the size of the cavity. For example, **5** binds Li^+ [58] but not K^+, while **6** binds K^+ but not Li^+ or Na^+.[59] Similarly, **6** binds Hg^{2+} but not Cd^{2+} or Zn^{2+}. The complexes can frequently be prepared as well-defined sharp-melting solids.

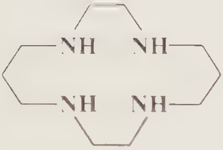
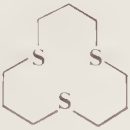
Apart from their obvious utility in separating mixtures of cations, crown ethers can be very useful in organic synthesis; e.g., saponification of an ester by KOH (reaction **0-11**) is much faster in the presence of a crown ether, because the ether ties up the K^+, leaving the OH^- freer to attack the ester.[60] Also, many salts, e.g., NaCl, *t*-BuOK, or $KMnO_4$, can be made to dissolve in nonpolar solvents like benzene by the addition of a crown ether. Since many organic molecules are soluble only in nonpolar solvents, this means that organic molecules and appropriate salts can be brought together in one phase, where reactions between the molecule and the salt take place much more rapidly than they do in two-phase systems (for examples of the use of crown ethers in organic synthesis, see pp. 324, 367, 1095).

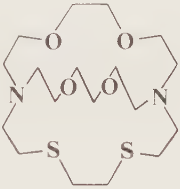
Macrocycles containing nitrogen or sulfur atoms, e.g., **8** and **9**[61], have similar properties, as do these containing more than one kind of hetero atom, e.g., **10**[62] and **11**[63].



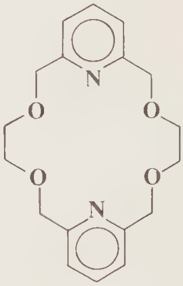
8



9



10



11

The bonding in these complexes is the result of ion-dipole attractions between the hetero atoms and the positive ions.

Inclusion Compounds[64]

This type of addition compound is different from either the EDA complexes or the crown ether type of complexes previously discussed. One of the compounds, called the *host*, forms a crystal lattice in which there are spaces large enough for the second compound, called the *guest*, to fit. There is no bonding between the host and the guest except van der Waals forces. There are two main types, depending on the shape of the space. The spaces in *inclusion compounds* are in the shape of long tunnels or channels, while the other type, often called *clathrate*, or *cage*, *compounds* have spaces which are completely enclosed. In both types the guest molecule must fit into the space, and potential guests which are too large or too small will not go into the lattice, so that the addition compound will not form.

The most important host molecule among the inclusion compounds is urea. Ordinary crystalline urea is tetragonal, but when a guest is present, urea crystallizes in a hexagonal lattice, containing the guest in long channels.[65] The hexagonal type of lattice can form only when a guest molecule is present, showing that van der Waals forces between the host and the guest, while small, are essential to the stability of the structure. The diameter of the channel is about 5 Å,

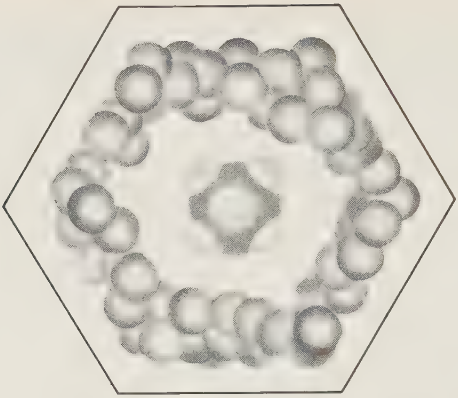
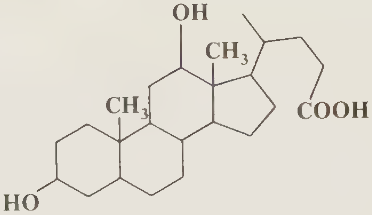
[65] This picture is taken from a paper by Montel, *Bull. Soc. Chim. Fr.* 1013 (1955).



and which molecules can be guests is dependent only on their shapes and sizes and not on any electronic or chemical effects. For example, octane and 1-bromooctane are suitable guests for urea, but 2-bromooctane, 2-methylheptane, and 2-methyloctane are not. Also both dibutyl maleate and dibutyl fumarate are guests; neither diethyl maleate or diethyl fumarate is a guest, but dipropyl fumarate is a guest and dipropyl maleate is not.[66] In these complexes, there is usually no integral molar ratio (though by chance there may be). For example, the octane-urea ratio is 1 : 6.73.[67]

The complexes are solids but are not useful as derivatives, since they melt, with decomposition of the complex, at the melting point of urea. They are useful, however, in separating isomers which would be quite difficult to separate otherwise.

Thiourea also forms inclusion compounds although with channels of larger diameter, so that *n*-alkanes cannot be guests but, for example, 2-bromooctane, cyclohexane, and chloroform readily fit. There are a number of other host compounds which form inclusion compounds, the most notable of which is deoxycholic acid:



Clathrate Compounds[68]

The most important host for this type of compound is hydroquinone. Three molecules, held together by hydrogen bonding, make a cage in which fits one molecule of guest. Typical guests are methanol (but not ethanol), SO_2, CO_2, and argon (but not neon). In contrast to the inclusion compounds, the crystal lattices here can exist partially empty. Another host is water. Usually six molecules of water form the cage, and many guest molecules, among them Cl_2 and methyl iodide, can fit. The water clathrates, which are solids, can normally be kept only at low temperatures; at room temperature they decompose.[69]

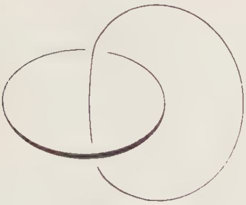
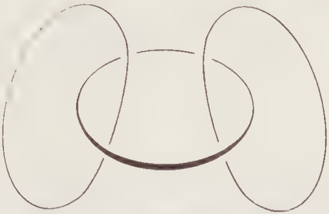
Catenanes and Rotaxanes[70]

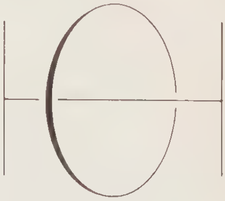
These compounds contain two or more independent portions which are not bonded to each other by any valence forces but nevertheless must remain linked. *Catenanes* are made up of two or more rings held together as links in a chain, while in *rotaxanes* a linear portion is threaded through a ring and cannot get away because of bulky end groups. Catenanes and rotaxanes can be prepared by statistical methods or by directed syntheses. An example of a statistical synthesis of a rotaxane would be a reaction where a compound **A** is bonded at two positions to another compound **B** in the presence of a large ring **C**. In this case it is hoped that some **A** molecules would by chance be threaded through **C** before combining with the two **B** molecules, so that some rotaxane (**D**) would be formed along with the normal product **E**.[71] For examples of statistical syntheses of catenanes, see p. 1136. In a directed synthesis, the separate parts of the molecule are held together by other bonds, which are later cleaved. An example of a directed synthesis of a catenane is given on p. 1137.[72]



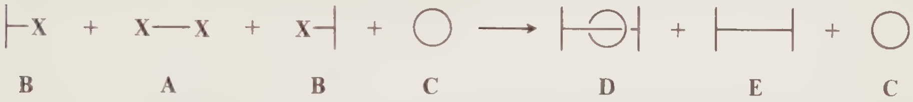
A [2]catenane



A [3]catenane



A rotaxane



Only a few syntheses of catenanes or rotaxanes have been reported by either the statistical or the directed approach,[73] though it is likely that additional examples will be forthcoming.

[73] Ref. 70 has a complete discussion.

Four

Stereochemistry

In the previous chapters we have described what is known about electron distribution in organic molecules. In this chapter we shall discuss the three-dimensional structure of organic compounds.[1] The structure may be such that *stereoisomerism*[2] is possible. Stereoisomers are compounds made up of the same atoms bonded by the same bonds but having different three-dimensional structures which are not interchangeable. These three-dimensional structures are called *configurations*.

OPTICAL ACTIVITY AND CHIRALITY

A material which rotates the plane of polarized light is said to be *optically active*. If a pure compound is optically active, the molecule is nonsuperimposable on its mirror image. If a molecule is superimposable on its mirror image, the compound does not rotate the plane of polarized light; it is *optically inactive*. The property of nonsuperimposability of an object on its mirror image is called *chirality*. If a molecule is not superimposable on its mirror image, it is *chiral*. If it is superimposable on its mirror image, it is *achiral*. Although the relationship between optical activity and chirality is empirical, it is absolute. No exceptions are known, and many thousands of cases have been found in accord with it (however, see p. 89). The ultimate criterion, then, for optical activity is chirality (nonsuperimposability on the mirror image). This is both a necessary and a sufficient condition. This fact has been used as evidence for the structure determination of many compounds, and historically the tetrahedral nature of carbon was deduced from the hypothesis that the relationship might be true.

If a molecule is nonsuperimposable on its mirror image, the mirror image must be a different molecule (since superimposability is the same as identity), and in each case of optical activity of a pure compound there are two and only two isomers, called *enantiomers* (sometimes *enantiomorphs*), which differ in structure only in the left- and the right-handedness of their orientations (Figure 1). Enantiomers have identical physical and chemical properties except in two important respects:

1. They rotate the plane of polarized light in opposite directions, though in equal amounts. The isomer which rotates the plane to the left (counterclockwise) is called the *levo isomer* and is designated (−), while the one which rotates the plane to the right (clockwise) is called the *dextro isomer* and is designated (+).

2. They react at different rates with other chiral compounds. These rates may be so close together

---

[1] For excellent lengthy treatments of this subject, see Eliel, "Stereochemistry of Carbon Compounds," McGraw-Hill Book Company, New York, 1962, "Elements of Stereochemistry," John Wiley & Sons, Inc., New York, 1969; Mislow, "Introduction to Stereochemistry," W. A. Benjamin, Inc., New York, 1965; Wheland, "Advanced Organic Chemistry," 3d ed., pp. 195–514, John Wiley & Sons, Inc., New York, 1960; and Shriner, Adams, and Marvel, in Gilman, "Advanced Organic Chemistry," vol. 1, 2d ed., pp. 214–488, John Wiley & Sons, Inc., New York, 1943. Although the last review is not recent, most of it remains quite valid and useful.

[2] The IUPAC 1974 Recommendations, Section E, Fundamental Stereochemistry, give definitions for most of the terms used in this chapter, as well as rules for naming the various kinds of stereoisomers. They can be found in *Pure Appl. Chem.* **45**, 13–30 (1976).

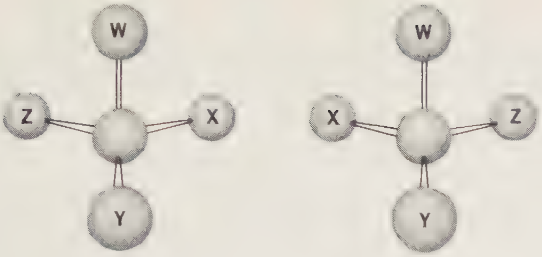

Figure 1 Enantiomers

as to make the distinction practically useless, or they may be so far apart that one enantiomer undergoes the reaction at a convenient rate while the other does not react at all. It is for this reason that many compounds are biologically active while their enantiomers are not. Enantiomers react at the same rate with achiral compounds.

In general it may be said that enantiomers have identical properties in a symmetric environment, but in an asymmetric environment their properties may differ. Besides the important differences previously noted, enantiomers may react at different rates with achiral molecules if there is an optically active *catalyst* present; they may have different solubilities in an optically active *solvent*; they may have different indexes of refraction or absorption spectra *when examined with circularly polarized light*, etc. In most cases these differences are too small to be useful and are often too small to be measured.

Although pure compounds are always optically active if they are composed of chiral molecules, mixtures of equal amounts of enantiomers are optically inactive, since the rotations cancel. Such mixtures are called *racemic mixtures*.[3] Their properties are not always the same as those of the individual enantiomers. Usually the properties in the gaseous or liquid state, or in solution, are the same, since such a mixture is nearly ideal, but properties involving the solid state, such as melting points and solubilities, are often different. Thus racemic tartaric acid has a melting point of 204–206°C and a solubility in water at 20°C of 206 g/liter; while for the (+) or the (−) enantiomer, the corresponding figures are 170°C and 1390. The separation of a racemic mixture into its two optically active components is called *resolution.*

Dependence of Rotation on Conditions of Measurement

The *amount* of rotation α is not a constant for a given enantiomer; it depends on the length of the sample vessel, the temperature, the solvent[4] and concentration (for solutions), the pressure (for gases), and the wavelength of light used. Of course, rotations determined for the same compound under the same conditions are identical. The length of the vessel and the concentration or pressure determine the number of molecules in the path of the beam, and α is linear with this. Therefore, a number is defined, called the *specific rotation* $[\alpha]$, which is,

$$[\alpha] = \begin{cases} \dfrac{\alpha}{lc} & \text{for solutions} \\[2ex] \dfrac{\alpha}{ld} & \text{for pure compounds} \end{cases}$$

---

[3] Strictly speaking, the term *racemic mixture* applies only when the mixture of molecules is present as separate solid phases, but in this book we shall use this expression to refer to any equimolar mixture of enantiomeric molecules, liquid, solid, gaseous, or in solution.

[4] A good example is found in Kumata, Furukawa, and Fueno, *Bull. Chem. Soc. Jpn.* **43**, 3920 (1970).

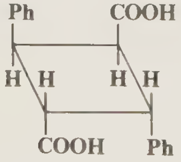
where α is the observed rotation, l is the cell length in decimeters, c is the concentration in grams per milliliter, and d is the density in the same units. The specific rotation is usually given along with the temperature and wavelength, in this manner: $[\alpha]^{25}_{546}$. These conditions must be duplicated for comparison of rotations, since there is no way to put them into a simple formula. The expression $[\alpha]_D$ means that the rotation was measured with sodium D light; i.e., $\lambda = 589$ nm. The molar rotation $[M]^t_\lambda$ is the specific rotation times the molecular weight, divided by 100.

It must be emphasized that although the value of α changes with conditions, the molecular structure is unchanged. This is true even when the changes in conditions are sufficient to change not only the amount of rotation but even the direction. Thus one of the enantiomers of aspartic acid, when dissolved in water, has $[\alpha]_D$ equal to $+4.36°$ at 20°C and $-1.86°$ at 90°C, though the molecular structure is unchanged. A consequence of cases like this is that there is a temperature at which there is *no* rotation (in this case 75°C). Of course, the other enantiomer exhibits opposite behavior. Other cases are known in which the direction of rotation is reversed by changes in wavelength (this is common; see the discussion of optical rotatory dispersion on p. 135), solvent, and even concentration.[5] In theory, there should be no change in $[\alpha]$ with concentration, since this is taken into account in the formula, but associations, dissociations, and solute-solvent interactions often cause nonlinear behavior. For example, $[\alpha]^{24}_D$ for (−)-2-ethyl-2-methylsuccinic acid in $CHCl_3$ is $-5.0°$ at $c = 16.5$, $-0.7°$ at $c = 10.6$, $+1.7°$ at $c = 8.5$, and $+18.9°$ at $c = 2.2$.[6]

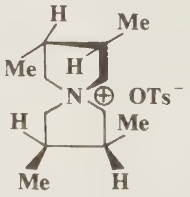
It should be noted that any single reading of the polarimeter must be ambiguous. A reading of say, 38°, could also be 218°, or 398°, or any number of the form $38 \pm 180n$ degrees, where n is any integer. However, it is relatively simple to determine the true reading by measuring another sample of the substance at a different concentration or cell length. For example, if the correct reading is 38°, a solution of one-fifth the concentration will give a value of 7.6°. If the correct reading was 218°, the new reading will be 43.6°, etc.

What Kinds of Molecules Display Optical Activity?

Although the ultimate criterion is, of course, nonsuperimposability on the mirror image (chirality), other tests may be used, which are simpler to apply but not always accurate. One such test is the presence of a *plane of symmetry*. A plane of symmetry[7] (also called a *mirror plane*) is a plane passing through an object such that the part on one side of the plane is the exact reflection of the part on the other side (the plane acting as a mirror). *Compounds possessing such a plane are always optically inactive*, but there are a few cases known in which compounds lack a plane of symmetry and are nevertheless inactive. Such compounds possess a *center of symmetry*, such as in α-truxillic acid (**1**), or an *alternating axis of symmetry* as in **2**.[8] A center of symmetry[7] is a point within an



1



2

---

[5] For examples, see Shriner, Adams, and Marvel, Ref. 1, pp. 291–301.

[6] Krow and Hill, *Chem. Commun.* 430 (1968).

[7] The definitions of plane, center, and alternating axis of symmetry are taken from Eliel, "Elements of Stereochemistry," Ref. 1, pp. 6, 7.

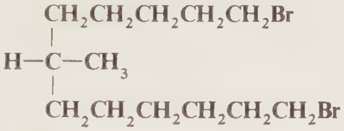
[8] McCasland and Proskow, *J. Am. Chem. Soc.* 77, 4688 (1955).

object such that a straight line drawn from any part or element of the object to the center and extended an equal distance on the other side encounters an equal part or element. An alternating axis of symmetry[7] of order n is an axis such that when an object containing such an axis is rotated by 360 n about the axis and then reflection is effected across a plane at right angles to the axis, a new object is obtained which is indistinguishable from the original one.

A molecule which contains just one *asymmetric carbon atom* (defined as a carbon atom connected to four different groups) is always chiral and hence optically active. As seen in Figure 1, such a molecule cannot have a plane of symmetry, whatever the identity of W, X, Y, and Z, so long as they are all different. However, the presence of an asymmetric carbon is neither a necessary nor a sufficient condition for optical activity, since optical activity may be present in molecules with no asymmetric atom and since some molecules with two or more asymmetric carbon atoms are superimposable on their mirror images and hence inactive. Examples of such compounds will be discussed subsequently.

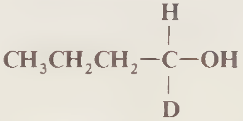
Optically active compounds may be classified into several categories.

1. *Compounds with an asymmetric carbon atom.* If there is only one such atom, the molecule must be optically active. This is so no matter how slight the differences are among the four groups. For example, optical activity is present in



$$\begin{array}{l} \quad\;\; CH_2CH_2CH_2CH_2CH_2Br \\ \quad\;\; | \\ H-C-CH_3 \\ \quad\;\; | \\ \quad\;\; CH_2CH_2CH_2CH_2CH_2CH_2Br \end{array}$$

Optical activity has been detected even in such cases[9] as 1-butanol-1-*d*, where one group is hydrogen and another deuterium:[10]



$$\begin{array}{c} \qquad\qquad\qquad H \\ \qquad\qquad\qquad | \\ CH_3CH_2CH_2-C-OH \\ \qquad\qquad\qquad | \\ \qquad\qquad\qquad D \end{array}$$

However, the amount of rotation is greatly dependent on the nature of the four groups, in general increasing with increasing differences in polarizabilities among the groups. Alkyl groups have very similar polarizabilities,[11] and the optical activity of 5-ethyl-5-propylundecane was too low to be measurable at any wavelength between 2800 and 5800 Å.[12]

2. *Compounds with other quadrivalent asymmetric atoms.*[13] Any molecule containing an atom which has four bonds pointing to the corners of a tetrahedron will be optically active if the four groups are different. Among atoms in this category are Si, Ge, N (in quaternary salts or N-oxides) and certain metals, such as Mn,[14] Cu, Be, and Zn, which form tetrahedral coordination compounds. In sulfones the sulfur bonds tetrahedrally, but since two of the groups are always oxygen, no optical activity can normally result. However, the preparation[15] of an optically active sulfone in which one oxygen is ^{16}O and the other ^{18}O illustrates the point that slight differences in groups are all that is necessary:

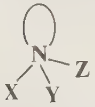
3. *Compounds with tervalent asymmetric atoms.* Atoms with pyramidal bonding[16] might be expected to give rise to optical activity if the atom is connected to three different groups, since the unshared pair of electrons is analogous to a fourth group, necessarily different from the others.



For example, a secondary or tertiary amine where X, Y, and Z are different would be expected to be chiral and thus resolvable. Many attempts have been made to resolve such compounds, but until recently all of them failed because of the *umbrella effect* (also called *pyramidal inversion*).[17] The umbrella effect is a rapid oscillation of the unshared pair from one side of the XYZ plane to the other, thus converting the molecule into its enantiomer. For ammonia there are 2 × 10^{11} inversions every second. The inversion is less rapid in substituted ammonias[18] (amines, amides, etc.). Two types of nitrogen atom invert particularly slowly, namely, a nitrogen atom in a three-membered ring and a nitrogen atom connected to another atom bearing an unshared pair. Even in such compounds, however, the umbrella effect has proved too rapid to permit isolation of separate isomers, and this goal was accomplished only when compounds were synthesized in which both features are combined: a nitrogen atom in a three-membered ring connected to an atom containing an unshared pair. For example, the two isomers of 1-chloro-2-methylaziridine (**3** and **4**) were separated, and do not interconvert at room temperature.[19] Similarly, it has been shown that aziridines in which the ring nitrogen atom is connected to a nitrogen or oxygen atom are also conformationally stable. For example, nmr spectra show that two of the ring protons of 1-aminoaziridine (**5**) are not equivalent to the other two,[20] which indicates that the amino group

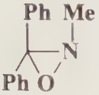
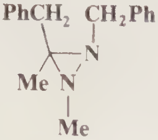
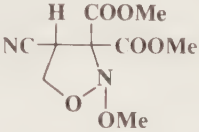
stays on the same side of the ring as two of the hydrogens and does not interconvert at room temperature. In none of the above cases, however, was a compound prepared which was optically active solely because of an asymmetric ternary nitrogen atom. This has now been accomplished with the syntheses of several oxaziridines, e.g., **6**.[21] Both enantiomers of **6**, a compound which is chiral solely because of an asymmetric ternary nitrogen atom, have been prepared. Note that in this case too, the nitrogen is connected to an atom with an unshared pair. Conformational stability has also been demonstrated for diaziridines, e.g., **7**,[22] and for 1,2-oxazolidines, e.g., **8**,[23] even though in this case the ring is five-membered. However, note that the nitrogen atom here is connected to two oxygen atoms. The (+) isomer of **9** has been prepared.[24] It was completely racemized upon standing for 4 days at 0°C.



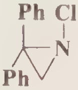
6



7



8



9

In molecules in which the nitrogen atom is at a bridgehead, pyramidal inversion is of course prevented, and such molecules, if chiral, can be resolved even without the presence of the two structural features noted above. For example, optically active **10** (Tröger's base) has been prepared.[25] Phosphorus inverts more slowly and arsenic still more slowly.[26] Optically active nonbridgehead phosphorus, arsenic, and antimony compounds have been resolved, e.g., **11**.[27] Sulfur exhibits pyramidal bonding in sulfoxides, sulfinic esters, sulfonium salts, and sulfites.[28] Examples of

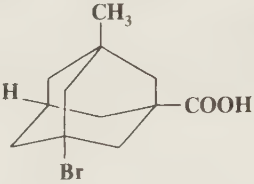
each of these have been resolved.[29] An interesting example is (+)-$Ph^{12}CH_2SO^{13}CH_2Ph$, a sulfoxide in which the two alkyl groups differ only in ^{12}C versus ^{13}C but which has $[\alpha]_{280} = +0.71°$.[30]

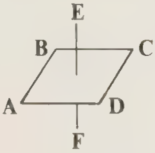
4 *Suitably substituted adamantanes.* Adamantanes bearing four different substituents at the bridgehead positions are chiral and optically active, and **12**, for example, has been resolved.[31]



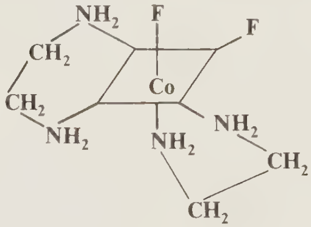
12

This type of molecule is a kind of expanded tetrahedron and has the same symmetry properties as any other tetrahedron.

5. *Compounds containing suitable substituted octahedral atoms.* Many metal ions, among them Cr(III), Pt(IV), and, most commonly, Co(III), form coordination compounds where six ligands surround the central atom. These ligands are usually found at the corners of an octahedron. If the ligands are sufficiently different, the compounds may be chiral. For example, if the six ligands are all different (as in **13**), the compound is theoretically resolvable, though no such example has yet been resolved.[32] However, many compounds with bidentate ligands, e.g., the *cis*-difluoro-bis(ethylenediamine)cobalt(III) ion (**14**), have been resolved.[33]



13



14

6. *Restricted rotation giving rise to perpendicular disymmetric planes.* Certain compounds which do not contain asymmetric atoms are nevertheless chiral because they contain a structure which can be schematically represented as in Figure 2. For these compounds we can draw two perpendicular planes neither of which can be bisected by a plane of symmetry. If either plane could be so bisected, the molecule would be superimposable on its mirror image, since such a plane would be a plane of symmetry. These points will be illustrated by examples.

Biphenyls containing four large groups in the ortho positions cannot freely rotate about the central bond because of steric hindrance.[34] In such compounds the two rings are in perpendicular

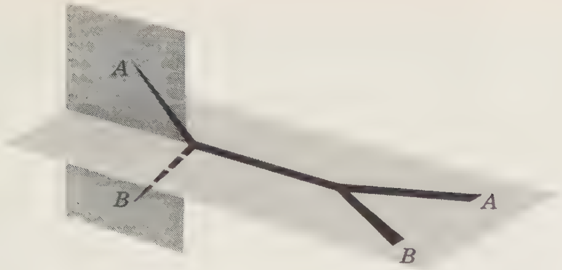

Figure 2 Perpendicular disymmetric planes.

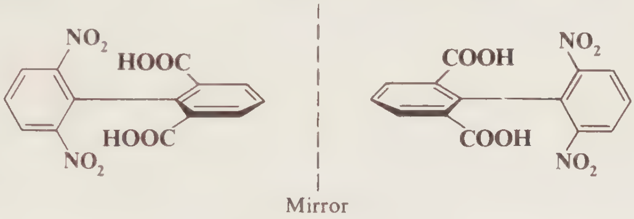
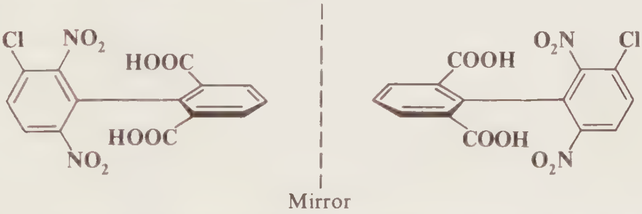
planes. Three cases can be distinguished: both rings symmetric, one symmetric, neither symmetric. In the first case, e.g.,



NO₂
HOOC
HOOC
NO₂
COOH
COOH
NO₂
NO₂
Mirror

the molecule has two planes of symmetry. If a plane is drawn containing all atoms and groups in either ring, it is a *symmetrical* perpendicular bisector of the other ring. Such molecules are not chiral and, by the scheme in Figure 2, can be represented as $AA \cdots BB$.

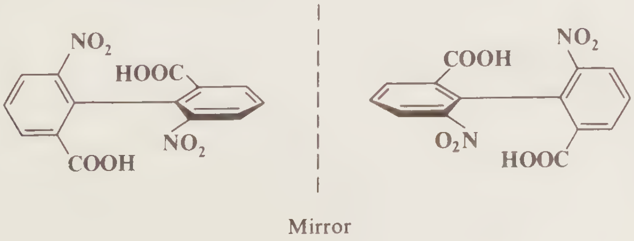
In the second case only one ring is symmetric:



Cl
NO₂
HOOC
HOOC
NO₂
COOH
COOH
O₂N
Cl
O₂N
Mirror

A plane drawn in the ring containing the nitro groups symmetrically bisects the other ring, but the plane of the ring containing the carboxyl groups is not a plane of symmetry. Nevertheless, one plane of symmetry is sufficient to make the compound achiral, and it is. The case can be symbolized as $AB \cdots CC$.

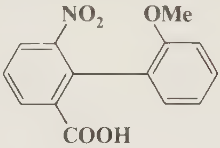
In the third case neither ring is symmetric:



NO₂
HOOC
NO₂
COOH
COOH
NO₂
O₂N
HOOC
Mirror

There is no plane of symmetry, and the molecule is chiral; many such compounds have been resolved. This corresponds to *AB* ··· *AB*. Of course *AB* ··· *CD* cases are also chiral. It is important to note that, if *either* ring is symmetrical, the molecule has a plane of symmetry and is achiral and that groups in the para position cannot cause lack of symmetry. Isomers which can be separated only because rotation about single bonds is prevented or greatly slowed are called *atropisomers.*

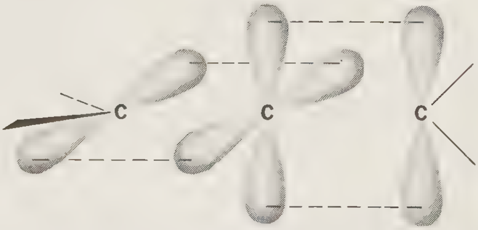
It is not always necessary for four large ortho groups to be present in order for rotation to be prevented. Compounds with three and even two groups, if large enough, can have hindered rotation and, if suitably substituted, can be resolved. An example is biphenyl-2,2′-bissulfonic acid.[35] In some cases, the groups may be large enough to slow rotation greatly but not prevent it completely. In such cases, optically active compounds can be prepared which slowly racemize on standing. Thus, **15** loses its optical activity with a half-life of 9.4 min in ethanol at 25°C.[36] Compounds with greater rotational stability can often be racemized if higher temperatures are used to supply the energy necessary to force the groups past each other.

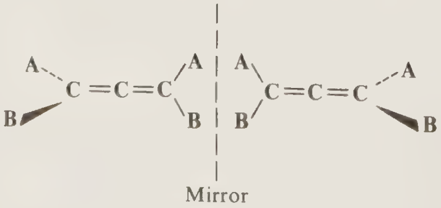


15

Many analogous cases are known, where optical activity arises from hindered rotation of other types of aromatic ring, e.g., binaphthyls, bipyrryls, etc.

In allenes the central carbon is *sp*-bonded. The remaining two *p* orbitals are perpendicular to each other, and each overlaps with the *p* orbital of one adjacent carbon atom, forcing the two remaining bonds of each carbon into perpendicular planes. Thus allenes fall into the category represented by Figure 2:



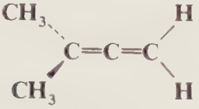


---

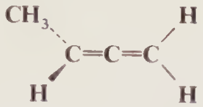
[35] Patterson and Adams, *J. Am. Chem. Soc.* **57**, 762 (1935).

[36] Stoughton and Adams, *J. Am. Chem. Soc.* **54**, 4426 (1932).

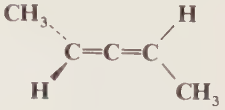
Like biphenyls, allenes are chiral only if both sides are dissymmetric.[37] Compounds corresponding to the three biphenyl cases are



Inactive
AA ··· *BB*



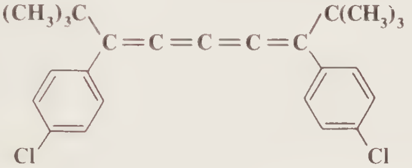
Inactive
AB ··· *CC*



Active
AB ··· *AB*

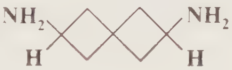
These cases are completely different from the cis-trans isomerism of compounds with one double bond (p. 113). In the latter cases the four groups are all in one plane, the isomers are not enantiomers, and neither is chiral, while in allenes the groups are in two perpendicular planes and the isomers are a pair of optically active enantiomers.

When three, five, or any *odd* number of cumulative double bonds exist, orbital overlap causes the four groups to occupy one plane, and cis-trans isomerism is observed. When four, six, or any *even* number of cumulative double bonds exist, the situation is analogous to that in the allenes, and optical activity is possible. **16** has been resolved.[38]

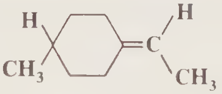


16

Among other types of compounds which contain the system illustrated in Figure 2 and which are similarly chiral if they are *AB* ··· *AB* substituted are spiranes, e.g., **17**, and compounds with exocyclic double bonds, e.g., **18**.



17



18

7. *Chirality due to a helical shape.* Several compounds have been prepared which are chiral because they have a shape which is actually helical and can therefore be left- or right-handed in orientation. The entire molecule is usually less than one full turn of the helix, but this does not alter the possibility of left- and right-handedness. An example is hexahelicene[39] (**19**), in which one side of the molecule must lie above the other because of crowding.[40] Another is *trans*-

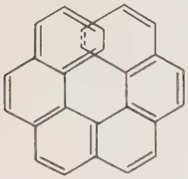
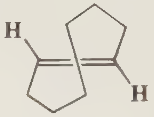
[39] Newman and Lednicer, *J. Am. Chem. Soc.* **78**, 4765 (1956). Optically active heptahelicene has also been prepared, as have higher helicenes: Flammang-Barbieux, Nasielski, and Martin, *Tetrahedron Lett.* 743 (1967); Martin, Flammang-Barbieux, Cosyn, and Gelbcke, *Tetrahedron Lett.* 3507 (1968); Martin, Morren, and Schurter, *Tetrahedron Lett.* 3683 (1969); Martin and Schurter, *Tetrahedron* **28**, 1749 (1972); Martin and Marchant, *Tetrahedron* **30**, 343 (1974); Martin and Baes, *Tetrahedron* **31**, 2135 (1975); Bernstein, Calvin, and Buchardt, *J. Am. Chem. Soc.* **94**, 494 (1972), **95**, 527 (1973). Even pentahelicene is crowded enough to be chiral: Goedicke and Stegemeyer, *Tetrahedron Lett.* 937 (1970); Bestmann and Röth, *Chem. Ber.* **107**, 2923 (1974).

[40] For a review of the helicenes, see Martin, *Angew. Chem. Int. Ed. Engl.* **13**, 649-660 (1974) [*Angew. Chem.* **86**, 727-738].

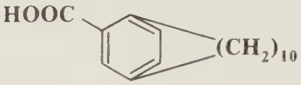
cyclooctene (**20**) (see p. 115), in which the carbon chain must lie above the plane of the double bond on one side and below it on the other.[41]



19

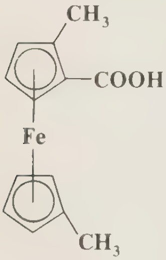


20

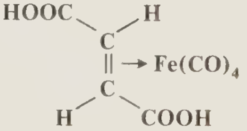


21

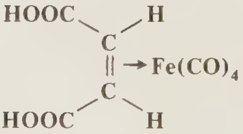
8. *Chirality caused by restricted rotation of other types.* Substituted paracyclophanes may be optically active, and **21**, for example, has been resolved.[42] In this case chirality results because the benzene ring cannot rotate in such a way that the carboxyl group goes through the alicyclic ring. Metallocenes substituted with at least two different groups on one ring are also chiral.[43] More than



22



23



24

200 such compounds have been resolved, one example being **22.** Chirality is also found in other metallic complexes of suitable geometry.[44] For example, fumaric acid -iron tetracarbonyl (**23**) has been resolved.[45] The corresponding maleic acid compound (**24**) has a plane of symmetry and is not resolvable.

An interesting type of chirality has been proposed, though no example is yet known.[46] Rings containing 50 or more members should be able to exist as knots:

[46] Frisch and Wasserman, *J. Am. Chem. Soc.* **83**, 3789 (1961).

Such a knot would be nonsuperimposable on its mirror image. Catenanes and rotaxanes (see p. 85) can also be chiral if suitably substituted.[47]

Creation of a Chiral Center

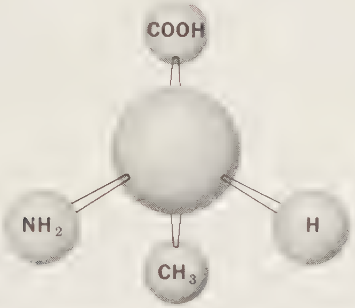
Any structural feature of a molecule which gives rise to optical activity may be called a chiral center. In many reactions a new chiral center is created, e.g.,

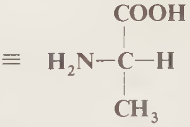
$$\mathrm{CH_3CH_2COOH + Br_2 \xrightarrow{P} CH_3CHBrCOOH}$$

If the reagents and reaction conditions are all symmetric, the product must be a racemic mixture. No optically active material can be created if all starting materials and conditions are optically inactive.[48] This statement also holds when one begins with a racemic mixture. Thus racemic 2-butanol, treated with HBr, must give racemic 2-bromobutane.

The Fischer Projection

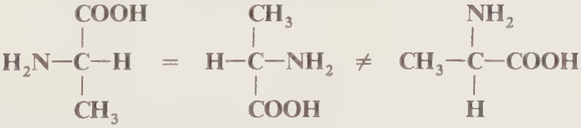
For a thorough understanding of stereochemistry it is useful to examine molecular models (like those depicted in Figure 1). However, when writing on paper or on the blackboard this is not feasible, and in 1891 Emil Fischer greatly served the interests of chemistry by inventing the Fischer projection, a method of representing tetrahedral carbons on paper. By this convention, the model is held so that the two bonds in front of the paper are horizontal and those behind the paper are vertical:





$$\equiv \begin{array}{c} \mathrm{COOH} \\ | \\ \mathrm{H_2N{-}C{-}H} \\ | \\ \mathrm{CH_3} \end{array}$$

In order to obtain proper results from these formulas, it should be remembered that they are projections and must be treated differently from the models in testing for superimposability. Every plane is superimposable on its mirror image; hence with these formulas there must be added the restriction they they may not be taken out of the plane of the blackboard or paper. Also they may not be rotated 90°, though 180° rotation is permissible:



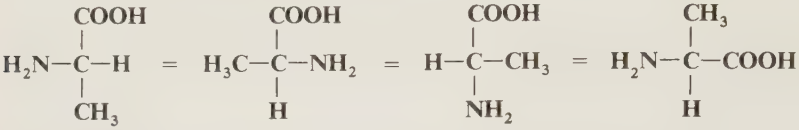
$$\begin{array}{c} \mathrm{COOH} \\ | \\ \mathrm{H_2N{-}C{-}H} \\ | \\ \mathrm{CH_3} \end{array} = \begin{array}{c} \mathrm{CH_3} \\ | \\ \mathrm{H{-}C{-}NH_2} \\ | \\ \mathrm{COOH} \end{array} \neq \begin{array}{c} \mathrm{NH_2} \\ | \\ \mathrm{CH_3{-}C{-}COOH} \\ | \\ \mathrm{H} \end{array}$$

---

[47] For a discussion of the stereochemistry of these compounds, see Schill, "Catenanes, Rotaxanes, and Knots," pp. 11–18, Academic Press, Inc., New York, 1971.

[48] There is one exception to this statement. In a very few cases racemic mixtures may crystallize from solution in such a way that all the (+) molecules go into one crystal and the (−) molecules into another. If one of the crystals crystallizes before the other, a rapid filtration results in optically active material. For a discussion, see Pincock and Wilson, *J. Chem. Educ.* **50**, 455 (1973).

It is also permissible to keep any one group fixed and to rotate the other three clockwise or counterclockwise (because this can be done with models):



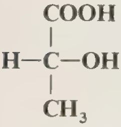
$$\begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ \mathrm{H_2N}- & \mathrm{C} & -\mathrm{H} \\ & | & \\ & \mathrm{CH_3} & \end{array} = \begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ \mathrm{H_3C}- & \mathrm{C} & -\mathrm{NH_2} \\ & | & \\ & \mathrm{H} & \end{array} = \begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{CH_3} \\ & | & \\ & \mathrm{NH_2} & \end{array} = \begin{array}{rcl} & \mathrm{CH_3} & \\ & | & \\ \mathrm{H_2N}- & \mathrm{C} & -\mathrm{COOH} \\ & | & \\ & \mathrm{H} & \end{array}$$

However, the *interchange* of any two groups results in the conversion of an enantiomer into its mirror image (this applies to models as well as to the Fischer projections).

With these restrictions Fischer projections may be used instead of models to test whether a molecule containing asymmetric carbons is superimposable on its mirror image. However, there are no such conventions for molecules whose chirality arises from anything other than asymmetric atoms, and when such molecules are examined on paper, three-dimensional pictures must be used and there are no restrictions about the plane of the paper.

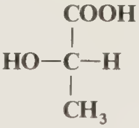
Absolute Configuration

Suppose we have two test tubes, one containing (−)-lactic acid, and the other the (+) enantiomer. One test tube contains **25** and the other **26**. How do we know which is which? Chemists in the early part of this century pondered this problem and decided that they could not know—for lactic acid or any other compound. Therefore Rosanoff proposed that one compound be chosen as a standard and a configuration be arbitrarily assigned to it. The compound chosen was glyceraldehyde because of its relationship to the sugars. The (+) isomer was assigned the configuration shown in **27**, and it was given the label D. The (−) isomer, designated to be **28**, was given the label L. Once a standard was chosen, other compounds could then be related to it. For example, (+)-glyceraldehyde, oxidized with mercuric oxide, gives (−)-glyceric acid:



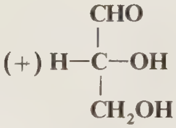
$$\begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{CH_3} & \end{array}$$

25



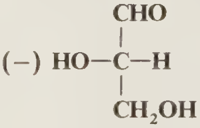
$$\begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ \mathrm{HO}- & \mathrm{C} & -\mathrm{H} \\ & | & \\ & \mathrm{CH_3} & \end{array}$$

26



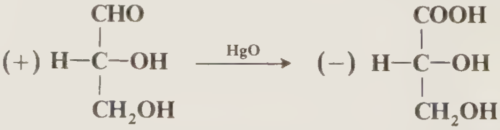
$$\begin{array}{rcl} & \mathrm{CHO} & \\ & | & \\ (+)\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{CH_2OH} & \end{array}$$

27



$$\begin{array}{rcl} & \mathrm{CHO} & \\ & | & \\ (-)\ \mathrm{HO}- & \mathrm{C} & -\mathrm{H} \\ & | & \\ & \mathrm{CH_2OH} & \end{array}$$

28



$$\begin{array}{rcl} & \mathrm{CHO} & \\ & | & \\ (+)\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{CH_2OH} & \end{array} \xrightarrow{\mathrm{HgO}} \begin{array}{rcl} & \mathrm{COOH} & \\ & | & \\ (-)\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{CH_2OH} & \end{array}$$

Since it is highly improbable that the configuration at the central carbon changed, it can be concluded that (−)-glyceric acid has the same configuration as (+)-glyceraldehyde, and therefore (−)-glyceric acid is also called D. This example emphasizes that molecules with the same configuration need not rotate the plane of polarized light in the same direction. This fact should not surprise us when we remember that the same compound can rotate the plane in opposite directions under different conditions.

Once the configuration of the glyceric acids was known (in relation to the glyceraldehydes), it was then possible to relate other compounds to either of these, and each time a new compound was related, others could be related to *it*. In this way many thousands of compounds have now been related, indirectly, to D- or L-glyceraldehyde, and it has been determined that **25**, which has the D configuration, is the isomer which rotates the plane of polarized light to the left. Even compounds without asymmetric atoms, such as biphenyls[49] and allenes,[50] have been placed in the D or L series.[51] When a compound has been placed in the D or L series, its *absolute configuration* is said to be known.

In 1951 it became possible to determine whether Rosanoff's guess had been right. Ordinary x-ray crystallography is powerless to distinguish between a D and an L isomer, but by use of a special technique, Bijvoet was able to examine sodium rubidium tartrate and found that Rosanoff had made the correct choice.[52] By this time the fact was interesting to know, but it would have made no difference to organic chemists if he had made the wrong choice, since this would not have affected the important thing, which is the relationship of one compound to another. It was perhaps historically fitting that the first true absolute configuration should have been determined on a salt of tartaric acid, since Pasteur made his great discoveries on another salt of this acid.

In spite of the former widespread use of D and L to denote absolute configuration, the method is not without faults. The designation of a particular enantiomer as D or L often depends on which compounds it is related to. Examples are known where an enantiomer can, by five or six steps, be related to a known D compound, and by five or six other steps, be related to the L enantiomer of the same compound. In a case of this sort, an arbitrary choice of D or L must be used. Because of this and other flaws, the DL system is seldom used today, except for certain groups of compounds such as carbohydrates and amino acids.

The system which has essentially replaced the DL system is the *Cahn-Ingold-Prelog* system, in which the four groups on an asymmetric carbon are ranked according to a set of sequence rules.[53] For our purposes we may confine ourselves to only a few of these rules, which are sufficient to deal with the vast majority of chiral compounds:

1. Substituents are listed in order of decreasing atomic number of the atom directly joined to the carbon.

2. Where two or more of the atoms connected to the asymmetric carbon are the same, the atomic number of the second atom determines the order. For example, in the molecule $Me_2CH—CHBr—CH_2OH$, the CH_2OH group takes precedence over the Me_2CH group because oxygen has a higher atomic number than carbon. Note that this is so even though there are two carbons in Me_2CH and only one oxygen in CH_2OH. If two or more atoms connected to the second atom are the same, the third atom determines the precedence, etc.

3. All atoms except hydrogen are formally given a valence of 4. Where the actual valence is less (as in nitrogen, oxygen, or a carbanion), phantom atoms are used to bring the valence up to four. These phantom atoms are assigned an atomic number of zero and necessarily rank lowest. Thus the ligand $—\overset{+}{N}HMe_2$ would rank higher than $—NMe_2$.

[50] Eliel, *Tetrahedron Lett.* no. 8, 16 (1960); Jones, Loder, and Whiting, *Proc. Chem. Soc.* 180 (1960).

[51] The use of small *d* and *l* is now discouraged, since some authors used it for rotation, and some for configuration. However, a racemic mixture is still a *dl* mixture, since there is no ambiguity here.

[52] Bijvoet, Peerdeman, and van Bommel, *Nature* **168**, 271 (1951). For a list of organic structures whose absolute configurations have been determined by this method, see Allen and Rogers, *Chem. Commun.* 838 (1966), Allen, Neidle, and Rogers, *Chem. Commun.* 308 (1968), 452 (1969); Neidle, Rogers, and Allen, *J. Chem. Soc. C* 2340 (1970).

[53] For descriptions of the system and sets of sequence rules, see Ref. 2; Cahn, Ingold, and Prelog, *Angew. Chem. Int. Ed. Engl.* **5**, 385–415 (1966) [*Angew. Chem.* **78**, 413–447]; Cahn, *J. Chem. Educ.* **41**, 116 (1964); and Fernelius, Loening, and Adams, *J. Chem. Educ.* **51**, 735 (1974).

4. A tritium atom takes precedence over deuterium, which in turn takes precedence over ordinary hydrogen. Similarly, any higher isotope (such as ^{14}C) takes precedence over any lower one.

5. Double and triple bonds are counted as if they were split into two or three single bonds, respectively, as in these examples (note the treatment of the phenyl group):

Group	Treated as if it were
 $-\overset{H}{\overset{\vert}{C}}=O$	$-CH=CH_2$	$-C\equiv CH$	$-C_6H_5$	
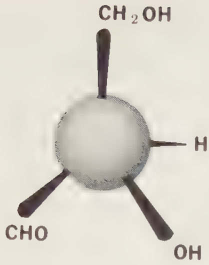
The subscript $_0$ denotes a phantom atom. Note that in a C=C double bond, the two carbon atoms are *each* regarded as being connected to two carbon atoms and that one of the latter is counted as having three phantom substituents.

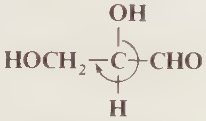
As an exercise, we shall compare the four groups shown above. The first atoms are connected, respectively, to (H, O, O), (H, C, C), (C, C, C), and (C, C, C). That is enough to establish that —CHO ranks first and $-CH=CH_2$ last, since even one oxygen outranks three carbons, and three carbons outrank two carbons and a hydrogen. To classify the remaining two groups we must proceed further along the chains. We note that $-C_6H_5$ has two of its (C, C, C) carbons connected to (C, C, H), while the third is $(_0, _0, _0)$ and is thus preferred to $-C\equiv CH$, which has only one (C, C, H) and two $(_0, _0, _0)$s.

By application of the above rules, some groups in descending order of precedence are COOH, COPh, COMe, CHO, $CH(OH)_2$, *o*-tolyl, *m*-tolyl, *p*-tolyl, phenyl, C≡CH, *t*-butyl, cyclohexyl, vinyl, isopropyl, benzyl, neopentyl, allyl, *n*-pentyl, ethyl, methyl, deuterium, hydrogen. Thus the four groups of glyceraldehyde are to be arranged in the sequence: OH, CHO, CH_2OH, H.

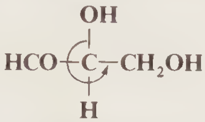
Once the order is determined, the molecule is held so that the lowest group in the sequence is pointed away from the viewer. Then if the other groups, in the order listed, are oriented clockwise, the molecule is designated *R*, and if counterclockwise, *S*. For glyceraldehyde, the (+) enantiomer is *R*:



Note that when a compound is written in the Fischer projection, the configuration can easily be determined without constructing the model. If the lowest-ranking group is at the bottom, the *R* configuration is present if the other three groups in descending order are clockwise, e.g.,

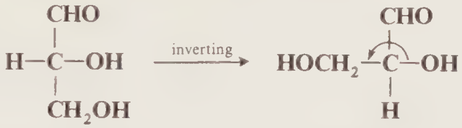


(*R*)-Glyceraldehyde



(*S*)-Glyceraldehyde

If the lowest ranking group is not at the bottom, one can simply interchange it with the bottom group, bearing in mind that in so doing, one is inverting the isomer:



(*S*)-Glyceraldehyde

Therefore the original compound was (*R*)-glyceraldehyde.

The Cahn-Ingold-Prelog system is unambiguous and easily applicable in most cases. Whether to call an enantiomer *R* or *S* does not depend on correlations, but of course the configuration must be known before the system can be applied, and this does depend on correlations. The Cahn-Ingold-Prelog system has also been extended to chiral compounds which do not contain asymmetric atoms.[54]

Methods of Determining Configuration[55]

In all the methods[56] it is necessary to relate the compound of unknown configuration to another whose configuration is known. The most important methods of doing this are:

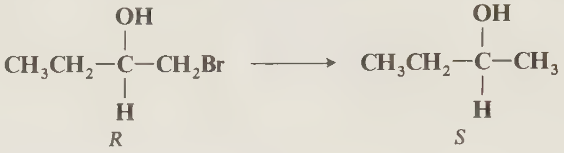
1. Conversion of the unknown to, or formation of the unknown from, a compound of known configuration without disturbing the chiral center. See the glyceraldehyde glyceric acid example above (p. 98). Since the chiral center was not disturbed, the unknown obviously has the same configuration as the known. This does not necessarily mean that if the known is *R*, the unknown is also *R*. This will be so if the sequence is not disturbed but not otherwise. For example, when (*R*)-1-bromo-2-butanol is reduced to 2-butanol without disturbing the chiral center, the product

---

[54] For a discussion of these rules, as well as for a review of methods for establishing configurations of chiral compounds not containing asymmetric atoms, see Krow, *Top. Stereochem.* **5**, 31–68 (1970).

[55] For reviews, see Brewster, in Bentley and Kirby, "Elucidation of Organic Structures by Physical and Chemical Methods," 2d ed. (vol. 4 of Weissberger, "Techniques of Chemistry"), pt. 3, pp. 1–249, John Wiley & Sons, Inc., New York, 1972; Klyne and Scopes, *Prog. Stereochem.* **4**, 97–166 (1969); Schlenk, *Angew. Chem. Int. Ed. Engl.* **4**, 139–145 (1965) [*Angew. Chem.* **77**, 161–168]; and Mills and Klyne, *Prog. Stereochem.* **1**, 177–222 (1954). For a monograph on the determination of absolute configuration in coordination compounds, see Hawkins, "Absolute Configuration of Metal Complexes," John Wiley & Sons, Inc., New York, 1971.

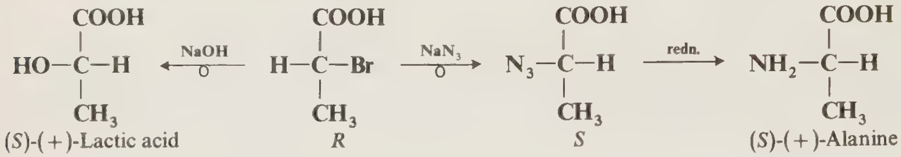
[56] Except the x-ray method of Bijvoet.



$$\underset{R}{CH_3CH_2-\overset{\displaystyle OH}{\underset{\displaystyle H}{C}}-CH_2Br} \longrightarrow \underset{S}{CH_3CH_2-\overset{\displaystyle OH}{\underset{\displaystyle H}{C}}-CH_3}$$

is the *S* isomer, even though the configuration is unchanged, because CH_3CH_2 ranks lower than $BrCH_2$ but higher than CH_3.

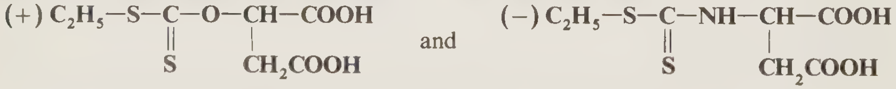
2. Conversion at the chiral center if the mechanism is known. Thus, the SN2 mechanism proceeds with inversion of configuration at an asymmetric carbon (see p. 267). It was by a series of such transformations that lactic acid was related to alanine (the symbol $\xrightarrow[o]{}$ is used to signify inversion of configuration):



$$\underset{(S)\text{-}(+)\text{-Lactic acid}}{HO-\overset{\displaystyle COOH}{\underset{\displaystyle CH_3}{C}}-H} \xleftarrow[o]{NaOH} \underset{R}{H-\overset{\displaystyle COOH}{\underset{\displaystyle CH_3}{C}}-Br} \xrightarrow[o]{NaN_3} \underset{S}{N_3-\overset{\displaystyle COOH}{\underset{\displaystyle CH_3}{C}}-H} \xrightarrow{redn.} \underset{(S)\text{-}(+)\text{-Alanine}}{NH_2-\overset{\displaystyle COOH}{\underset{\displaystyle CH_3}{C}}-H}$$

See also the discussion on pp. 267–268.

3. The method of quasi racemates.[57] It was mentioned (p. 87) that a solid racemic mixture often has a melting point which differs from that of the two enantiomers. In many such cases the molecules of the *R* isomer fit better into the lattice when they are next to molecules of *S* isomer, and there are fairly strong van der Waals forces between the *R* and *S* molecules. Such mixtures are known as *racemic compounds* and are recognizable by characteristic melting-point curves. In some cases it has been found that "racemic compounds" are formed between the *R* isomer of one compound and the *S* isomer of another compound which is similar to but not identical with the first. These *quasi racemates* are recognizable because their melting-point curves look like the curves of true racemic compounds. Mixtures are prepared of the unknown compound with known *R* and *S* forms of a similar compound. If the unknown is *R*, the mixture with the known *S* may be a quasi racemate but the mixture with the known *R* will not be. For example, two compounds which form a quasi racemate and hence have opposite configurations are



$$(+)\,C_2H_5-S-\underset{\displaystyle S}{\underset{\|}{C}}-O-\underset{\displaystyle CH_2COOH}{\underset{|}{CH}}-COOH \quad \text{and} \quad (-)\,C_2H_5-S-\underset{\displaystyle S}{\underset{\|}{C}}-NH-\underset{\displaystyle CH_2COOH}{\underset{|}{CH}}-COOH$$

4. Biochemical methods. In a series of similar compounds, such as amino acids or certain types of steroids, a given enzyme will usually attack only those molecules with one kind of configuration. If the enzyme attacks only the L form of eight amino acids, say, then attack on the unknown ninth amino acid will also be on the L form.

5. Optical comparison. It is sometimes possible to use the sign and extent of rotation to determine which isomer has which configuration. In a homologous series, the rotation usually changes gradually and in one direction. If the configurations of enough members of the series are known, the configurations of the missing ones can be determined by extrapolation. Also certain groups contribute more or less fixed amounts to the rotation of the parent molecule, especially when the parent is a rigid system such as a steroid.

---

[57] For reviews, see Fredga, *Tetrahedron* **8**, 126–144 (1960), *Bull. Soc. Chim. Fr.* 173–182 (1973).

6. The special x-ray method of Bijvoet gives direct answers and has been used in a number of cases.[52]

Other methods have also been used, including optical rotatory dispersion (see p. 135) and asymmetric synthesis (see p. 107). It must be remembered that no method is completely foolproof, and false assignments are sometimes made.

The Cause of Optical Activity

The question may be asked: Just why does a chiral molecule rotate the plane of polarized light? Theoretically, the answer to this question is known and in a greatly simplified form may be explained as follows.[58]

Whenever any light hits any molecule in a transparent material, the light is slowed because of interaction with the molecule. This phenomenon on a gross scale is responsible for the refraction of light, and the decrease in velocity is proportional to the refractive index of the material. The extent of interaction depends on the polarizability of the molecule. Plane-polarized light may be regarded as being made up of two kinds of circularly polarized light. Circularly polarized light has the appearance (or would have, if one could see the wave) of a helix propagating around the axis of light motion, and one kind is a left-handed and the other a right-handed helix. As long as the plane-polarized light is passing through a symmetrical region, the two circularly polarized components travel at the same speed. However, a chiral molecule has polarizability which is different depending on whether it is approached from the left or the right. One circularly polarized component approaches the molecule, so to speak, from the left and sees a different polarizability (hence on a gross scale, a different refractive index) than the other and is slowed to a different extent. This would seem to mean that the left- and right-handed circularly polarized components travel at different velocities, since each has been slowed to a different extent. However, it is not possible for two components of the same light to be traveling at different velocities. What actually takes place, therefore, is that the faster component "pulls" the other toward it, resulting in rotation of the plane. These ideas can be expressed mathematically, and in principle it is possible to calculate the sign and amount of rotation for any molecule (this represents an additional way of determining absolute configuration). However, it is necessary to use wave equations, the limitations of which were discussed in Chapter 1. Hence, in practice, the sign and amount of rotation have been calculated for very few molecules, and the results have been wrong about as often as they have been right. Empirical methods for the prediction of the sign and amount of rotation based on bond refractions and on polarizabilities of groups in a molecule have been devised,[59] and these methods have given fairly good results in many cases.

In liquids and gases the molecules are randomly oriented. A molecule which is optically inactive because it has a plane of symmetry will very seldom be oriented so that the plane of the polarized light coincides with the plane of symmetry. When it is so oriented, that particular molecule does not rotate the plane but all others not oriented in that manner do rotate the plane, even though the molecules are achiral. There is no net rotation because, the molecules being present in large number and randomly oriented, there will always be another molecule later on in the path of the light which is oriented exactly opposite and will rotate the plane back again. Even though nearly all molecules are rotating the plane individually, the total rotation is zero. For chiral molecules, however (if there is no racemic mixture), no opposite orientation is present, and there is a net rotation.

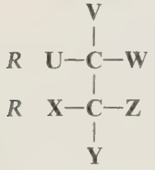
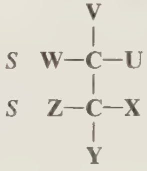
Molecules with More than One Chiral Center

When a molecule has two chiral centers, each center has its own configuration. Each center can be classified *R* or *S* by the Cahn-Ingold-Prelog method. There is a total of four isomers, since the first center may be *R* or *S* and so may the second. Since a molecule can have only one mirror image, only one of the other three can be the enantiomer of **29.** This is **30. 31** and **32** are a second pair of enantiomers, and the relationship of these to **29** and **30** is designated by the term *diastereomer*. Diastereomers may be defined as *stereoisomers which are not enantiomers*. **31** and **32,** being enantiomers, must have identical properties, except as noted on p. 86, and the same is true for **29** and **30.** However, the properties of **29** and **30** are not identical with those of **31** and **32.** They have different melting points, boiling points, solubilities, reactivity, and all other physical and chemical properties. The properties are usually *similar* but not *identical*. In particular, diastereomers have different specific rotations; indeed one diastereomer may be chiral and rotate the plane of polarized light while another may be achiral and not rotate at all (we shall see an example below).



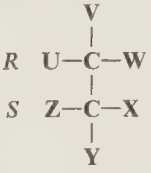
$$\begin{array}{rccc} & & \mathrm{V} & \\ & & | & \\ R & \mathrm{U}- & \mathrm{C} & -\mathrm{W} \\ & & | & \\ R & \mathrm{X}- & \mathrm{C} & -\mathrm{Z} \\ & & | & \\ & & \mathrm{Y} & \end{array}$$

29



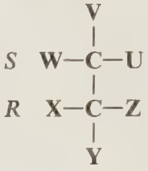
$$\begin{array}{rccc} & & \mathrm{V} & \\ & & | & \\ S & \mathrm{W}- & \mathrm{C} & -\mathrm{U} \\ & & | & \\ S & \mathrm{Z}- & \mathrm{C} & -\mathrm{X} \\ & & | & \\ & & \mathrm{Y} & \end{array}$$

30



$$\begin{array}{rccc} & & \mathrm{V} & \\ & & | & \\ R & \mathrm{U}- & \mathrm{C} & -\mathrm{W} \\ & & | & \\ S & \mathrm{Z}- & \mathrm{C} & -\mathrm{X} \\ & & | & \\ & & \mathrm{Y} & \end{array}$$

31

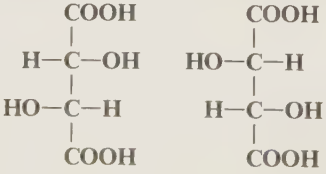


$$\begin{array}{rccc} & & \mathrm{V} & \\ & & | & \\ S & \mathrm{W}- & \mathrm{C} & -\mathrm{U} \\ & & | & \\ R & \mathrm{X}- & \mathrm{C} & -\mathrm{Z} \\ & & | & \\ & & \mathrm{Y} & \end{array}$$

32

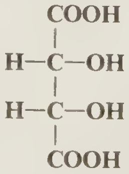
It is now possible to see why, as mentioned on p. 86, enantiomers react at different rates with other chiral molecules but at the same rate with achiral molecules. In the latter case, the activated complex formed from the *R* enantiomer and the other molecule is the mirror image of the activated complex formed from the *S* enantiomer and the other molecule. Since the two activated complexes are enantiomeric, their energies are the same and the rates of the reactions in which they are formed must be the same (see Chapter 6). However, when an *R* enantiomer reacts with a chiral molecule which has, say, the *R* configuration, the activated complex has two chiral centers, with configurations *R* and *R*, while the activated complex formed from the *S* enantiomer will have the configurations *S* and *R*. The two activated complexes are diastereomeric, do not have the same energies, and consequently are formed at different rates.

Although four is the usual (and the maximum possible) number of isomers when the compound has two chiral centers (chiral compounds without an asymmetric carbon, or with one asymmetric carbon and another type of chiral center also follow the rules described here), some compounds have fewer. When the three groups on one asymmetric atom are the same as those on the other, one of the isomers (called a *meso* form) has a plane of symmetry and hence is optically inactive, even though it has two asymmetric carbons. Tartaric acid is a typical case:



$$\begin{array}{ccc} & \mathrm{COOH} & \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ \mathrm{HO}- & \mathrm{C} & -\mathrm{H} \\ & | & \\ & \mathrm{COOH} & \end{array} \qquad \begin{array}{ccc} & \mathrm{COOH} & \\ & | & \\ \mathrm{HO}- & \mathrm{C} & -\mathrm{H} \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{COOH} & \end{array}$$

dl pair

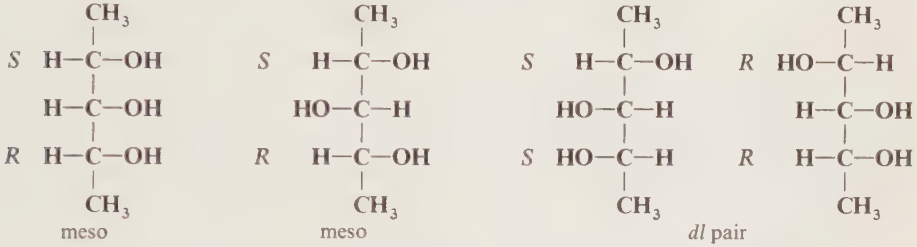


$$\begin{array}{ccc} & \mathrm{COOH} & \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ \mathrm{H}- & \mathrm{C} & -\mathrm{OH} \\ & | & \\ & \mathrm{COOH} & \end{array}$$

meso

There are only three isomers of tartaric acid: a pair of enantiomers and an inactive meso form.

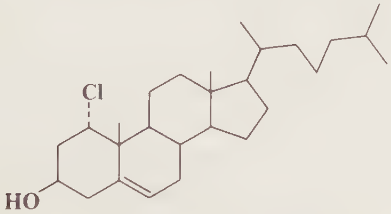
In most cases with more than two chiral centers, the number of isomers can be calculated from the formula 2^n, where n is the number of chiral centers, although in some cases the actual number is less than this, owing to meso forms. An interesting case is that of 2,3,4-pentanetriol (or any similar molecule). The middle carbon is not asymmetric when the 2- and 4-carbons are both *R* (or both *S*) but is asymmetric when one of them is *R* and the other *S*. Such a carbon is called a *pseudoasymmetric* carbon. In these cases there are four isomers: two meso forms and one *dl* pair:



The student should satisfy himself, remembering the rules governing use of the Fischer projections, that these isomers are different, that the meso forms are superimposable on their mirror images, and that there are no other stereoisomers. Two diastereomers which have a different configuration at only one chiral center are called *epimers*.

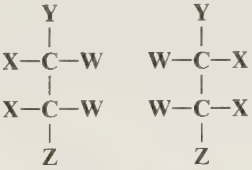
In compounds with two or more chiral centers, the absolute configuration must be separately determined for each center. The usual procedure is to determine the configuration at one center by the methods discussed on pp. 101–103 and then to relate the configuration at that center to the others in the molecule. One method for doing this is x-ray crystallography, which, as previously noted, cannot be used to determine the absolute configuration at any chiral center but which does give relative configurations of all of the chiral centers in a molecule and hence the absolute configurations of all once the first is independently determined. Other physical and chemical methods have also been used for this purpose (see, for example, pp. 116, 135).

The problem arises how to name the different stereoisomers of a compound when there are more than two.[2] Enantiomers are virtually always called by the same name, being distinguished by *R* and *S*, or D and L, or (+) and (−). In the early days of organic chemistry, it was customary to give each pair of enantiomers a different name, or at least a different prefix (such as *epi-*, *peri-*, etc.). Thus the aldohexoses are called glucose, mannose, idose, etc., though they are all 2,3,4,5,6-pentahydroxyhexanal. This practice was partially due to lack of knowledge of which isomers had which configurations. In recent years it has been customary to describe *each chiral position* separately, as either *R* or *S* or, in special fields, using other symbols. Thus, in the case of steroids, groups above the "plane" of the ring system are designated β, and those below it α. Solid lines are used to depict β groups, and dashed lines for α groups. An example is



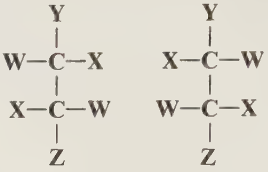
1α-Chloro-5-cholesten-3β-ol

For many open-chain compounds prefixes are used which are derived from the names of the corresponding sugars and which describe the whole system rather than each chiral center separately. Two such prefixes in common use are *erythro-* and *threo-*, which are applied to systems containing two asymmetric carbons when two of the groups are the same and the third is different.



$$\begin{array}{c}Y\\|\\X-C-W\\|\\X-C-W\\|\\Z\end{array}\qquad\begin{array}{c}Y\\|\\W-C-X\\|\\W-C-X\\|\\Z\end{array}$$

erythro *dl* pair



$$\begin{array}{c}Y\\|\\W-C-X\\|\\X-C-W\\|\\Z\end{array}\qquad\begin{array}{c}Y\\|\\X-C-W\\|\\W-C-X\\|\\Z\end{array}$$

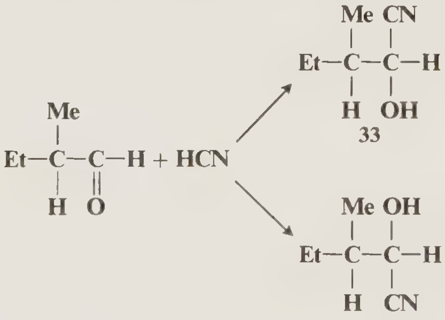
threo *dl* pair

The erythro pair has the identical groups on the same side when drawn in the Fischer convention, and if Y were changed to Z, it would be meso. The threo pair has them on opposite sides, and if Y were changed to Z, it would still be a *dl* pair.

Asymmetric Synthesis[60]

As mentioned before, optically active materials cannot be created from inactive starting materials and conditions; hence true asymmetric synthesis is impossible, except in the manner previously noted.[48] However, when a new chiral center is created, the two possible configurations need not be formed in equal amounts if anything is present which is not symmetric. Such syntheses, usually called *asymmetric syntheses*, may be discussed under four headings.

1. *Active substrate*. If a new chiral center is created in a molecule which is already optically active, the two diastereomers are not (except fortuitously) formed in equal amounts. The reason is that the direction of attack by the reagent is determined by the groups already there. For certain additions to the carbon-oxygen double bond of ketones containing an asymmetric α-carbon, *Cram's rule* predicts which diastereomer will predominate.[61] If the molecule is observed along



$$\begin{array}{c}Me\\|\\Et-C-C-H\\|\quad\|\\H\quad O\end{array} + HCN \longrightarrow \begin{array}{c}Me\;\;CN\\|\quad|\\Et-C-C-H\\|\quad|\\H\;\;\;OH\end{array}\;(33) \quad\text{or}\quad \begin{array}{c}Me\;\;OH\\|\quad|\\Et-C-C-H\\|\quad|\\H\;\;\;CN\end{array}\;(34)$$

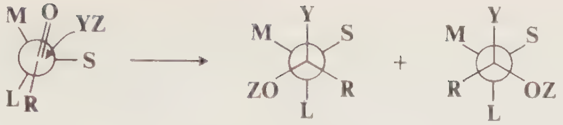
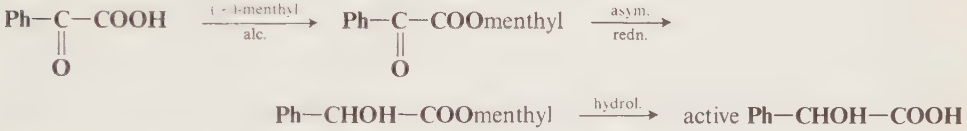
For reviews, see Ref. 3 in Chapter 16. For discussions, see Eliel, "Stereochemistry of Carbon Compounds," Ref. 1, pp. 68–74; and Salem, *J. Am. Chem. Soc.* **95**, 94–101 (1973).



35 Major product Minor product

its axis, it may be represented as in **35** (see p. 124), where S, M, and L stand for small, medium, and large, respectively. The oxygen of the carbonyl orients itself so as to be between the small- and the medium-sized groups. The rule is that the incoming group preferentially attacks on the side of the plane containing the small group. By this rule, it can be predicted that **34** will be formed in larger amount than **33**.

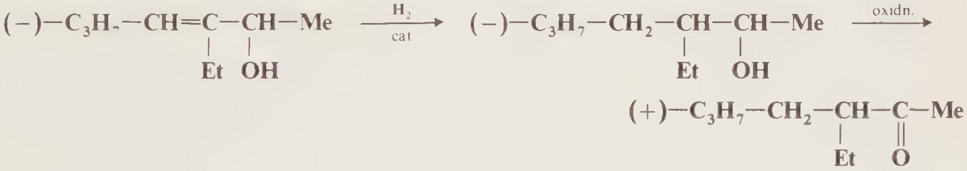
Many reactions of this type are known, in some of which the extent of favoritism approaches 100%. The farther away the reaction site is from the chiral center, the less influence the latter has and the more equal the amounts of diastereomers formed. In some cases the product may easily be cleaved at a point between the old chiral center and the new one. It is not surprising that in a case such as



$$\mathrm{Ph-\underset{\underset{O}{\|}}{C}-COOH} \xrightarrow[\text{alc.}]{(-)\text{-menthyl}} \mathrm{Ph-\underset{\underset{O}{\|}}{C}-COOmenthyl} \xrightarrow[\text{redn.}]{\text{asym.}}$$

$$\mathrm{Ph-CHOH-COOmenthyl} \xrightarrow{\text{hydrol.}} \text{active } \mathrm{Ph-CHOH-COOH}$$

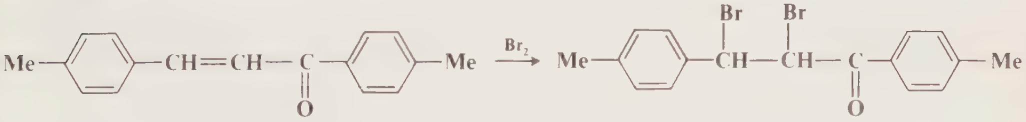
an investigator may feel that he has actually carried out an asymmetric synthesis. Another set of reactions which seems at first glance uncanny also involves the use of one chiral center to create another with subsequent destruction of the first, though in this case without cleavage.[62]



$$(-)\mathrm{-C_3H_7-CH{=}\underset{\underset{Et}{|}}{C}-\underset{\underset{OH}{|}}{CH}-Me} \xrightarrow[\text{cat}]{H_2} (-)\mathrm{-C_3H_7-CH_2-\underset{\underset{Et}{|}}{CH}-\underset{\underset{OH}{|}}{CH}-Me} \xrightarrow{\text{oxidn.}}$$

$$(+)\mathrm{-C_3H_7-CH_2-\underset{\underset{Et}{|}}{CH}-\underset{\underset{O}{\|}}{C}-Me}$$

A special case of this type of asymmetric synthesis was reported by Penzien and Schmidt.[63] The molecules of 4,4′-dimethylchalcone (**36**) are of course achiral, but the crystals are chiral; and when only one of the enantiomeric forms of the crystal (in the solid state) was treated with bromine, optically active **37**, of about 6% optical purity, was obtained.



36 **37**

2. *Active reagent*. A pair of enantiomers can be separated by an active reagent which reacts with one of them faster than it does with the other (this is also a method of resolution). If the absolute configuration of the reagent is known, the configuration of the enantiomers can often be

---

[62] Arcus and Smyth, *J. Chem. Soc.* 34 (1955).

[63] Penzien and Schmidt, *Angew. Chem. Int. Ed. Engl.* **8**, 608 (1969) [*Angew. Chem.* **81**, 628]. See also Elgavi, Green, and Schmidt, *J. Am. Chem. Soc.* **95**, 2058 (1973).

determined by a knowledge of the mechanism and by seeing which diastereomer is preferentially formed.[64] Creation of a new asymmetric center in an inactive molecule can also be accomplished with an active reagent, though it is rare for 100% selectivity to be observed. An example[65] is reduction of isopropyl phenyl ketone with the Grignard reagent from (+)-1-chloro-2-phenylbutane to obtain isopropylphenylcarbinol which contains 91% of the (+) and 9% of the (−) isomer. (For another example, see p. 720.)

3. *Active catalyst or solvent.* A number of such examples are present in the literature, the most important of which involve reduction of ketones and substituted alkenes to optically active (though not optically pure) secondary alcohols and substituted alkanes by treatment with hydrogen and a chiral homogeneous hydrogenation catalyst (reactions **6-27** and **5-12**). In some instances, the ratio of enantiomers prepared in this way has reached as high as 80 : 20.[66] Other examples of the use of a chiral catalyst or solvent are the conversion of benzaldehyde to optically active mandelonitrile by treatment with HCN in the presence of an enzyme[67] and the preparation of optically active alcohols by the treatment of Grignard reagents with aldehydes in optically active ether solvents.[68]

4. *Reactions in the presence of circularly polarized light.*[69] If the light used to initiate a photochemical reaction (Chapter 7) of achiral reagents is circularly polarized, then in theory, a chiral product richer in one enantiomer might be obtained. A number of such experiments have been run, and the results have been disappointing. In certain instances, the use of left and right circularly polarized light *has* given products with opposite rotations[70] (showing that the principle is valid), but up to now the extent of favoritism has always been less than 1%. In a similar procedure, optically active products were obtained when reactions were run under the simultaneous influence of electric and magnetic fields,[70a] but here too, only a small degree of favoritism has been achieved.

Methods of Resolution[71]

A pair of enantiomers can be separated in several ways, of which conversion to diastereomers and separation of these by fractional crystallization is by far the most often used. In this method, and in some of the others, both isomers can be recovered, but in some methods it is necessary to destroy one.

1. *Conversion to diastereomers.* If the racemic mixture to be resolved contains a carboxyl group (and no strongly basic group), it is possible to form a salt with an optically active base. Since the base used is, say, the *S* form, there will be a mixture of two salts produced having the configurations *SS* and *RS*:

Although the acids are enantiomers, the salts are diastereomers and have different properties. The property most often utilized is differential solubility. The mixture of diastereomeric salts is allowed to crystallize from a suitable solvent. Since the solubilities are different, the initial crystals formed will be richer in one diastereomer. Filtration at this point will already have achieved a partial resolution. Unfortunately, the difference in solubilities is rarely if ever great enough to effect total separation with one crystallization. Usually fractional crystallizations must be used, and the process is long and tedious. Nevertheless, it is the best general method known. Fortunately, naturally occurring optically active bases (mostly alkaloids) are readily available. Among the most commonly used are brucine, ephedrine, strychnine, and morphine. Once the two diastereomers have been separated, it is easy to convert the salts back to the free acids, and the recovered base can be used again.

Most resolution is done on carboxylic acids, and often, when a molecule does not contain a carboxyl group, it is converted to a carboxylic acid before resolution is attempted. However, the principle of conversion to diastereomers is not confined to carboxylic acids, and other groups[72] may serve as handles to be coupled to an optically active reagent.[73] Racemic bases can be converted to diastereomeric salts with active acids. Alcohols[74] can be converted to diastereomeric esters, aldehydes to diastereomeric hydrazones, etc. Even hydrocarbons can be converted to diastereomeric inclusion compounds with optically active deoxycholic acid (see p. 84) or even with urea. Urea is not chiral, but the cage structure is.[75] Chiral crown ethers (p. 82) have been used to separate mixtures of ènantiomeric alkyl and arylammonium ions, by the formation of diastereomeric complexes.[76] In this case, separation is often simplified by fact that one diastereomer may form much more rapidly than the other. *trans*-Cyclooctene (**20**) was resolved by conversion to a platinum complex containing an optically active amine.[77]

Although fractional crystallization is by far the most common method for the separation of diastereomers, its tediousness and the fact that it is limited to solids have prompted a search for other methods. Fractional distillation has given only limited separation, but gas chromatography[78] and preparative liquid chromatography[79] have proved more useful and may in time supplant fractional crystallization.

2. *Differential absorption.* When a racemic mixture is placed on a chromatographic column, if the column consists of chiral substances, then in principle the enantiomers should move down the column at different rates and should be separable without having to be converted into diastereomers. This has been successfully accomplished with paper, column, and gas chromatography.[80] For example, racemic mandelic acid has been almost completely resolved by column chromatography on starch,[81] and racemic cysteine has been resolved by paper chromatography.[82] The cellulose in the paper is, of course, chiral. Gil-Av and others have achieved separations with gas chromatography by the use of columns packed with chiral absorbents.[83] In a variation of this method, an achiral absorbent was used, but the racemic mixture was mixed with an appropriate optically active compound before injection.[83a]

3. *Biochemical processes.* The chiral compound which reacts at different rates with the two enantiomers may be present in a living organism. For instance, a certain bacterium may digest one enantiomer and not the other. This method is limited, since it is necessary to find the proper organism and since one of the enantiomers is destroyed in the process. However, when the proper organism is found, the method leads to a high extent of resolution since biological processes are usually very stereoselective.

4. *Mechanical separation.* This is the method by which Pasteur proved that racemic acid was actually a mixture of (+)- and (−)-tartaric acids.[84] In the case of racemic sodium ammonium tartrate the enantiomers crystallize separately, all the (+) molecules going into one crystal and all the (−) into another. Since the crystals too are nonsuperimposable, their appearance is not identical, and a trained crystallographer can separate them with tweezers.[85] However, this is seldom a practical method, since few compounds are known which crystallize in this manner. Even sodium ammonium tartrate does so only when it is crystallized below 27°C. A more useful variation of the method, though still not very common, is the seeding of a racemic solution with something which will cause only one enantiomer to crystallize.[86] An interesting example of the mechanical separation technique was reported in the isolation of heptahelicene (p. 95). One enantiomer of this compound, which incidentally has the extremely high rotation of $[\alpha]_D^{20} = +6200$, spontaneously crystallizes from benzene.[87]

[83a] Maestas and Morrow, *Tetrahedron Lett.* 1047 (1976).

[84] Besides discovering this method of resolution, Pasteur also discovered the method of conversion to diastereomers and separation by fractional crystallization and the method of biochemical separation.

[85] This is a case of optically active materials arising from inactive materials. However, it may be argued that an optically active investigator is required to use the tweezers. Perhaps a hypothetical human being constructed entirely of inactive molecules would be unable to tell the difference between left- and right-handed crystals.

[86] For a review of the seeding method, see Secor, *Chem. Rev.* **63,** 297 (1963).

5. *Differential reactivity.* Since enantiomers react with chiral compounds at different rates, it is sometimes possible to effect a partial separation by stopping the reaction before completion.[88] This method is very similar to the asymmetric syntheses discussed on p. 107. The most important application of this method[89] is the resolution of racemic alkenes by treatment with optically active diisopinocampheylborane, since alkenes do not easily lend themselves to conversion to diastereomers if no other functional groups are present. Circularly polarized light has been used to destroy selectively one enantiomer in the presence of the other. Racemic camphor was converted to a 60 : 40 mixture of enantiomers in this way,[90] but the disadvantage of this method is that the extent of favoritism increases as the extent of the reaction increases and it was necessary to destroy 99% of the starting material in order to get the 60 : 40 mixture, making the method virtually useless as a synthetic tool. However, the fact that it can be done at all is evidence that the original generation of optical activity on earth (before the origin of life) might possibly have occurred in this way.

Optical Purity[91]

Suppose we have just attempted to resolve a racemic mixture by one of the methods described in the previous section. How do we know that the two enantiomers we have obtained are pure? For example, how do we know that the (+) isomer is not contaminated by, say, 20% of the (−) isomer, and vice versa? If we knew the value of $[\alpha]$ for the pure material ($[\alpha]_{\max}$), we could easily determine the purity of our sample by measuring its rotation. For example, if $[\alpha]_{\max}$ is $+80°$ and our (+) enantiomer contains 20% of the (−) isomer, $[\alpha]$ for our sample will be $+48°$.[92] We define *optical purity* as

$$\text{Percent optical purity} = \frac{[\alpha]_{\text{obs}}}{[\alpha]_{\max}} \times 100$$

Assuming that there is a linear relationship between $[\alpha]$ and concentration, which is true for most cases, the optical purity is equal to the percent excess of one enantiomer over the other:

$$\text{Optical purity} = \text{percent excess} = \frac{[R]-[S]}{[R]+[S]} \times 100 = \%R - \%S$$

But how do we determine the value of $[\alpha]_{\max}$? It is plain that we have two related problems here; namely, what are the optical purities of our two samples, and what is the value of $[\alpha]_{\max}$, and that if we solve one, the other is also solved. Several methods for solving these problems are known.

One of these methods involves the use of nmr.[93] Suppose we have a nonracemic mixture of two enantiomers and wish to know the proportions. We convert the mixture into a mixture of diastereomers with an optically pure reagent and look at the nmr spectrum of the resulting mixture, e.g.,

[91] For a review, see Raban and Mislow, *Top. Stereochem.* **2,** 199–230 (1967).

[92] If a sample contains 80% (+) and 20% (−) isomer, the (−) isomer cancels an equal amount of (+) isomer and the mixture behaves as if 60% of it were (+) and the other 40% inactive. Therefore the rotation is 60% of 80°, or 48°. This type of calculation, however, is not valid for cases in which $[\alpha]$ is dependent on concentration (p. 88); see Horeau, *Tetrahedron Lett.* 3121 (1969).

\end{array}$$

If we examined the nmr spectrum of the starting mixture, we would find only one peak (split into a doublet by the C—H) for the Me protons, since enantiomers give identical nmr spectra.[94] But the two amides are not enantiomers, and each Me will give its own doublet. From the intensity of the two peaks, the relative proportions of the two diastereomers (and hence of the original enantiomers) can be determined. Alternatively, the unsplit OMe peaks could have been used. This method was satisfactorily used to determine the optical purity of a sample of 1-phenylethylamine (the case shown above),[95] and in other cases as well, but it is obvious that sometimes corresponding groups in diastereomeric molecules will give nmr signals which are too close together for resolution. In such cases one may resort to the use of a different optically pure reagent.

A closely related method does not require conversion of enantiomers to diastereomers but relies on the fact that (in principle, at least) enantiomers have different nmr spectra *in a chiral solvent*. In some cases the peaks are separated enough to permit the proportions of enantiomers to be determined from their intensities.[96] Another variation, which gives better results in many cases, is to use an achiral solvent but with the addition of a *chiral lanthanide shift reagent* such as tris[3-trifluoroacetyl-*d*-nopinonato]europium(III) or tris[3-trifluoroacetyl-*d*-camphorato]europium-(III).[97] Lanthanide shift reagents have the property of spreading nmr peaks of compounds with which they can form coordination compounds, e.g., alcohols, carbonyl compounds, amines, etc. Chiral lanthanide shift reagents shift the peaks of the two enantiomers of many such compounds to different extents.

Another method, involving gas chromatography,[98] is similar in principle to the nmr method. A mixture of enantiomers whose purity is to be determined is converted by means of an optically pure reagent into a mixture of two diastereomers. These diastereomers are then separated by gas chromatography (p. 110) and the ratios determined from the peak heights. Once again the ratio of diastereomers is the same as that of the original enantiomers. High-pressure liquid chromatography has been used in a similar manner.[99]

---

[94] Though enantiomers give identical nmr spectra, the spectrum of a single enantiomer may be different from that of the racemic mixture, even in solution. See Williams, Pitcher, Bommer, Gutzwiller, and Uskoković, *J. Am. Chem. Soc.* **91,** 1871 (1969).

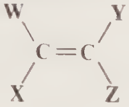
Other methods involve isotopic dilution,[100] kinetic resolution,[101] circular polarization of luminescence,[102] and calorimetry.[103]

CIS-TRANS ISOMERISM

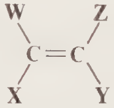
Compounds in which rotation is restricted may exhibit cis-trans isomerism.[104] These compounds do not rotate the plane of polarized light (unless they also happen to be chiral), and the properties of the isomers are not identical. The two most important types are isomerism resulting from double bonds and that resulting from rings.

Cis-Trans Isomerism Resulting from Double Bonds

It has been mentioned (p. 12) that the two carbon atoms of a $C{=}C$ double bond and the four atoms directly attached to them are all in the same plane and that rotation around the double bond is prevented. This means that in the case of a molecule $WXC{=}CYZ$, isomerism exists when $W \neq X$ and $Y \neq Z$. There are two and only two isomers (**38** and **39**), each superimposable on its mirror image unless one of the groups happens to carry a chiral center. Note that **38** and **39** are diastereomers, by the definition given on p. 104. There are two ways to name such isomers. In the older method, one isomer is called *cis* and the other *trans*. When $W = Y$, **38** is the cis and **39** the trans isomer. Unfortunately, there is no easy way to apply this method when the four groups are different. The newer method, which can be applied to all cases, is based on the Cahn-Ingold-Prelog system (p. 99). The two groups at each carbon are ranked by the sequence rules. Then that isomer which has the two higher-ranking groups on the same side of the double bond is called *Z* (for the German word *zusammen* meaning *together*); the other is *E* (for *entgegen* meaning *opposite*).[105] A few examples are shown. Note that the *Z* isomer is not necessarily the one that would be called cis under the older system (e.g., **40, 41**). Like cis and trans, *E* and *Z* are used as prefixes; e.g., **41** is called (*Z*)-1-bromo-1,2-dichloroethene.



38



39

This type of isomerism is also possible with other double bonds, such as $C{=}N$,[106] $N{=}N$, or even $C{=}S$,[107] although in these cases only two or three groups are connected to the double-

E

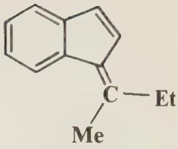
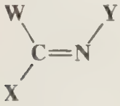
41

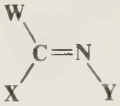


E

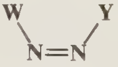
bond atoms. In the case of imines, oximes, and other C=N compounds, if W = Y, **42** is usually called syn and **43** anti, though cis, trans, *E*, and *Z* are sometimes used here too. In azo compounds there is no ambiguity, and **44** is always cis, syn, or *Z* regardless of the nature of W and Y.



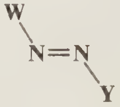
42



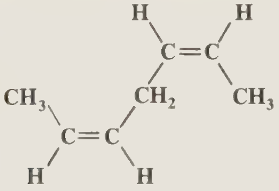
43



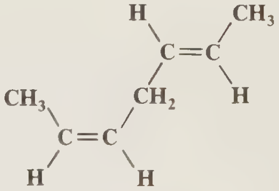
44



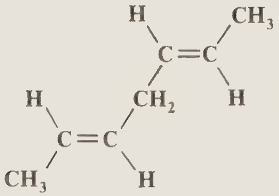
If there is more than one double bond in a molecule and if, for each, W ≠ Y and Y ≠ Z, the number of isomers in the most general case is 2^n, although this number may be decreased if some of the substituents are the same, as in



cis-cis or
Z, *Z*

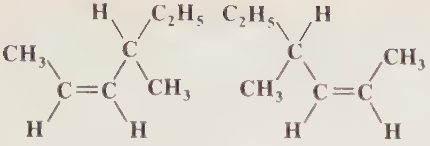


cis-trans or
Z, *E*

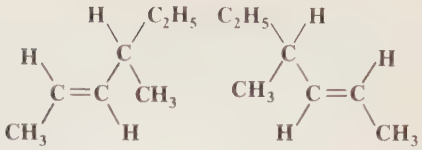


trans-trans or
E, *E*

Of course, allenes do not show cis-trans isomerism at all (see p. 94). When a molecule contains a double bond and an asymmetric carbon, there are four isomers, a cis pair of enantiomers and a trans pair:

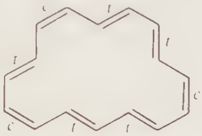


Z or cis *dl* pair



E or trans *dl* pair

An interesting system has been devised for designating the stereochemistry of annulenes, which are troublesome to name by the ordinary cis-trans or *Z*, *E* systems because there are so many double bonds (see Chapter 2). In this system,[108] a cis double bond is given the number 0 and a trans double bond the number 1. The geometry of each double bond is then cited in sequence around the ring, forming a binary number, e.g.,

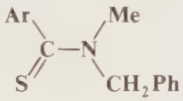


c t c t t c t t
0 1 0 1 1 0 1 1

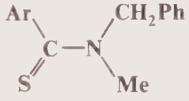
This binary number, 01011011, is $2^6 + 2^4 + 2^3 + 2^1 + 2^0 = 91$, so the compound is [16]-91-annulene. Since different binary numbers will result from starting at different double bonds, a rule is needed for deciding where to begin the sequence. The rule is to begin at whichever position will give the lowest binary number.

Double bonds in small rings are so constrained that they must be cis. From cyclopropene (a known system) to cycloheptene, double bonds in a ring cannot be trans. However, the cyclooctene ring is large enough to permit trans double bonds to exist (see **20**), and for rings larger than 10- or 11-membered, trans isomers are more stable.[109]

In a few cases, single-bond rotation is so slowed that cis and trans isomers can be isolated even where no double bond exists. One example is N-methyl-N-benzylthiomesitylide (**A** and **B**),[110]



A



B

Ar = mesityl

the isomers of which are stable in the crystalline state but interconvert with a half-life of about 25 hr in $CDCl_3$ at 50°C. This type of isomerism is rare; it is found chiefly in certain amides and thioamides, because resonance gives the single bond some double-bond character and slows rotation. (For other examples of restricted rotation about single bonds, see p. 149.)

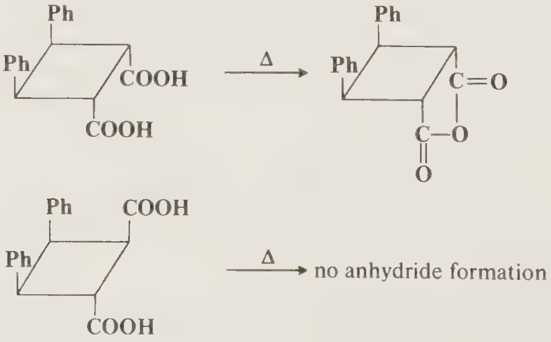
TABLE 1 Some properties of maleic and fumaric acids

Property	 Maleic acid	 Fumaric acid
Melting point, °C	130	286
Solubility in water at 25°C, g/liter	788	7
K_1 (at 25°C)	1.5×10^{-2}	1×10^{-3}
K_2 (at 25°C)	2.6×10^{-7}	3×10^{-5}

Since they are diastereomers, cis-trans isomers always differ in properties; the differences may range from very slight to considerable. The properties of maleic acid are so different from those of fumaric acid (Table 1) that it is not surprising they have different names. Since they generally have more symmetry than cis isomers, trans isomers usually have higher melting points and lower solubilities in inert solvents. The cis isomer usually has a higher heat of combustion, which indicates a lower thermochemical stability. For this reason, cis compounds can often be transformed into the trans isomers by heating, which at a high enough temperature supplies enough energy to cause rotation about the double bond. Since this is a process leading to thermodynamic equilibrium, trans compounds can seldom be converted to the cis isomers in this manner.[111] Other noticeably different properties are densities, acid strengths, boiling points, and various types of spectra, but the differences are too involved to be discussed here. It should be emphasized that the principles discussed in this paragraph are no more than general rules and that many exceptions are known. One important class of exceptions is the ten 1,2-dihaloethenes, for each of which (except the diiodo compound) the cis isomer is more stable than the trans.

There are many ways of telling which of a pair of isomers is cis and which is trans. The most dependable are x-ray and electron diffraction, though these methods have not often been used for this purpose. Other physical methods include ir, uv, and nmr spectra, the measurement of dipole moments (a trans isomer of the type WYC=CWY has no dipole moment, while the cis isomer usually has one), and a comparison of melting points, solubilities, etc., according to the rules mentioned in the preceding paragraph. The most foolproof *chemical* method is that of closing or opening a ring. Thus, if two groups capable of combining are cis-oriented, they often can be treated so as to close a ring, but not if the orientation is trans; e.g.,



---

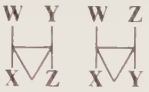
[111] For a review of cis-trans isomerization see Wyman, *Chem. Rev.* **55**, 625–657 (1955).

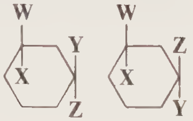
Note that if the absolute configuration at one of the COOH positions is known, this experiment establishes the configuration at the other position. Similarly, if only one isomer can be prepared by a ring opening, it is the cis isomer. For example, only maleic and not fumaric acid can be prepared by oxidation of benzene (reaction **9-11**). Other chemical methods of distinguishing cis from trans isomers involve correlation with known compounds and reaction by routes of known mechanism.

Cis-Trans Isomerism of Monocyclic Compounds

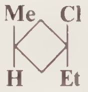
Although rings of four carbons and larger are not generally planar (see p. 132), they will be treated as such in this section, since the correct number of isomers can be determined when this is done[111a] and the principles are easier to visualize (see p. 130).

The presence of a ring, like that of a double bond, prevents rotation, and cis and trans isomers are possible whenever there are two carbons on a ring each of which is substituted by two different groups. The two carbons need not be adjacent. Examples are



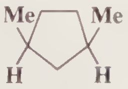


As with double bonds, W may equal Y and X may equal Z, but W may not equal X and Y may not equal Z if cis and trans isomers are to be possible. There is an important difference from the double-bond case: the substituted carbons are asymmetric. This means that there are not *only* two isomers. In the most general case, where W ≠ X ≠ Y ≠ Z, there are four isomers, since neither the cis nor the trans isomer is superimposable on its mirror image. This is true regardless of ring size or which carbons are involved, except that in rings of even-numbered size when the asymmetric carbons are opposite each other, no chirality is present, e.g., in **45.** Note that a plane of symmetry exists in such compounds. When W = Y and X = Z, the cis isomer is always superimposable on its mirror image and hence is a meso compound, while the trans isomer consists of a *dl* pair, except in the case noted above,

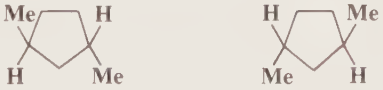


meso

45



cis meso



trans *dl* pair

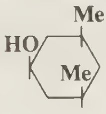
Again, the cis isomer has a plane of symmetry while the trans does not.

Rings with more than two differently substituted carbons can be dealt with on similar principles. In some cases it is not easy to tell by inspection just how many isomers there are. The best method for the student is to count the number n of differently substituted carbons (these will normally be asymmetric, but not always, e.g., in **45**) and then draw 2^n structures, crossing out those which can be superimposed on others (usually the easiest method is to look for a plane of symmetry). By this means it can be determined that for 1,2,3-cyclohexanetriol there are two meso compounds and a *dl* pair; and for 1,2,3,4,5,6-hexachlorocyclohexane there are seven meso compounds and a *dl* pair. The drawing of these structures is left as an exercise for the student.

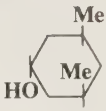
[111a] For a discussion of why this is so, see Leonard, Hammond, and Simmons, *J. Am. Chem. Soc.* **97**, 5052 (1975).

Similar principles apply to heterocyclic rings as long as there are carbons (or other ring atoms) containing two different groups.

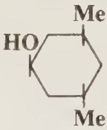
Cyclic stereoisomers containing only two differently substituted carbons are named either cis or trans, as previously indicated. The *Z*, *E* system is not used for cyclic compounds. However, if one tries to name ring compounds with more than two differently substituted atoms using only the prefixes cis and trans, one soon runs into difficulties, and yet until recently this was the way they were most commonly named. For example, **46** could unambiguously be given the prefix cis, cis, but **47** might be trans, trans or, perhaps with equal justice, cis, trans. For chiral compounds, a way out of this dilemma is to use the *R*, *S* system to label each asymmetric carbon, but this could hardly be applied to cases like **46** and **47,** where C-1 is not asymmetric. A solution to this problem is the following system, in which the configuration of each group is given with respect to a reference group, which is chosen as the group attached to the lowest-numbered ring member bearing a substituent giving rise to cis-trans isomerism. The reference group is indicated by the symbol *r*. Thus, **46** is *c*-3,*c*-5-dimethylcyclohexan-*r*-1-ol; **47** is *t*-3,*t*-5-dimethylcyclohexan-*r*-1-ol; and **48** is *c*-3,*t*-5-dimethylcyclohexan-*r*-1-ol. The last example demonstrates the rule that when there are two otherwise equivalent ways of going around the ring, one chooses the path that gives cis attachment to the first substituent after the reference. Another example is *r*-2,*c*-4-dimethyl-*t*-6-ethyl-1,3-dioxane (**49**). This system is clear and unambiguous.



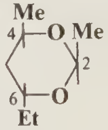
46



47



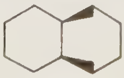
48



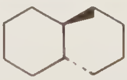
49

Cis-Trans Isomerism of Fused-Ring Systems

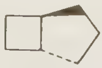
Where the rings are fused through adjacent atoms, there is no new principle. The fusion may be cis or trans, as illustrated by *cis*- and *trans*-decalin. However, when the rings are small enough, the trans configuration is impossible and the junction must be cis. The smallest trans junction which has been prepared when one ring is four-membered is a four-five junction: *trans*-bicyclo-[3.2.0]heptane (**50**) is known.[112] For the bicyclo[2.2.0] system (a four-four fusion) only cis com-



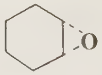
cis-Decalin



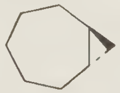
trans-Decalin



50



51



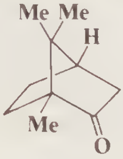
52

---

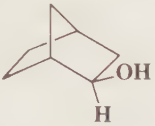
[112] Meinwald, Tufariello, and Hurst, *J. Org. Chem.* **29,** 2914 (1964).

pounds have been made. Trans junctions are also unknown when one ring is three-membered and the other six-membered or smaller; e.g., only *cis*-cyclohexene oxide (**51**) is known, though *trans*-bicyclo[5.1.0]octane (**52**) and some of its derivatives have been prepared.[113]

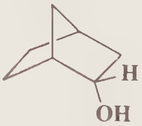
Rings which are fused through nonadjacent atoms are called *bridged*. In bridged-ring systems there may be fewer than 2^n isomers because of the structure of the system. For example, there are only two isomers of camphor (**53**) (a *dl* pair) although it has two asymmetric carbons. In both isomers the methyl and hydrogen are cis. The trans pair of enantiomers is impossible in this case, since the bridge *must* be cis. When one of the bridges contains a substituent, the question arises as to how to name the isomers involved. When the two bridges which do *not* contain the substituent are of unequal length, the rule generally followed is that the prefix *endo-* is used when the substituent is closer to the longer of the two unsubstituted bridges; the prefix *exo-* is used when the substituent is closer to the shorter bridge; e.g.,



53

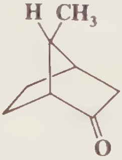


exo-2-Norborneol

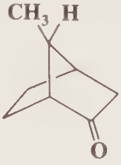


endo-2-Norborneol

When the two bridges not containing the substituent are of equal length, this convention cannot be applied, but in some cases a decision can still be made; e.g., if one of the two bridges contains a functional group, the endo isomer is the one in which the substituent is closer to the functional group:



endo-7-Methyl-2-norcamphor



exo-7-Methyl-2-norcamphor

Out-In Isomerism

Another type of stereoisomerism, called *out-in isomerism*, is found in salts of tricyclic diamines with nitrogen at the bridgeheads. In cases where k, l, and $m > 6$, the N—H bonds can be inside the molecular cavity or outside, giving rise to three isomers, as shown. Simmons and Park[114] have

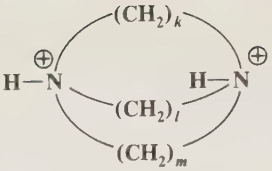
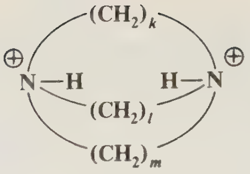
out-out isomer



out-in isomer

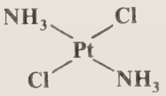


in-in isomer

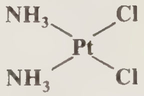
isolated several such isomers, with k, l, and m varying from 6 to 10. In the 9,9,9 compound, the cavity of the in-in isomer is large enough to encapsulate a chloride ion which is hydrogen-bonded to the two N—H groups (see also p. 82). Out-in and in-in isomers have also been prepared in analogous all-carbon tricyclic systems.[115]

Inorganic Cis-Trans Isomerism[116]

There are several types of cis-trans isomerism in inorganic compounds; we shall mention only two. In coordination compounds whose geometry is square planar, cis and trans isomerism may exist, as in

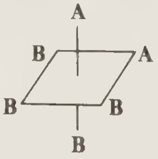


trans

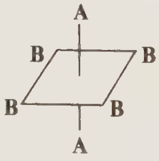


cis

In octahedral coordination compounds of the type MA_2B_4, cis-trans isomerism also exists.[117] Similarly, there are 2 isomers of MA_3B_3; 5 of $MA_2B_2C_2$, and 15 of MABCDEF. As an exercise, the student may wish to verify these numbers.



cis



trans

Enantiotopic and Diastereotopic Atoms, Groups, and Faces[118]

Many molecules contain atoms or groups which appear to be equivalent but which a close inspection will show to be actually different. We can test to see whether two atoms are equivalent by replacing each of them in turn with some other atom or group. If the new molecules which are created by this process are identical, the original atoms are equivalent; otherwise not. We can distinguish three cases.

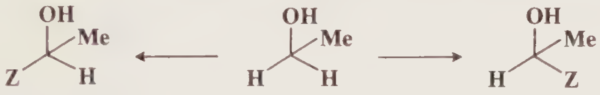
[116] For a review, see Gillespie and Nyholm, *Q. Rev., Chem. Soc.* **11,** 339–380 (1957).

[117] For a discussion of isomerism in octahedral and other coordination compounds, see Hawkins, Ref. 55, pp. 2–15.

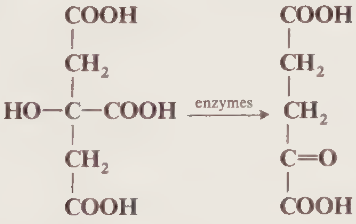
[118] These terms were coined by Mislow. For a lengthy discussion of this subject, see Mislow and Raban, *Top. Stereochem.* **1,** 1–38 (1967). See also Ault, *J. Chem. Educ.* **51,** 729 (1974); Kaloustian and Kaloustian, *J. Chem. Educ.* **52,** 56 (1975); Jennings, *Chem. Rev.* **75,** 307–322 (1975).

1. In the case of malonic acid $CH_2(COOH)_2$, propane CH_2Me_2, or any other molecule of the form CH_2Y_2,[119] if we replace either of the CH_2 hydrogens by a group Z, the identical compound results. The two hydrogens are thus equivalent. Equivalent atoms and groups need not, of course, be located on the same carbon atom. For example, all the chlorine atoms of hexachlorobenzene are equivalent, as are the two bromine atoms of 1,3-dibromopropane.

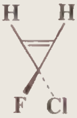
2. In the case of ethanol CH_2MeOH, if we replace one of the CH_2 hydrogens by a group Z, we get one enantiomer of the compound ZCHMeOH (**54**), while replacement of the other hydrogen gives the *other* enantiomer (**55**). Since the two compounds which result upon replacement of H by Z (**54** and **55**) are not identical but enantiomeric, the hydrogens are *not* equivalent. We define as *enantiotopic* two atoms or groups which upon replacement with a third group give enantiomers. In any symmetric environment the two hydrogens behave as equivalent, but in a dissymmetric environment they may behave differently. For example, in a reaction with a chiral reagent they may be attacked at different rates. This has its most important consequences in enzymatic reactions[120] since enzymes are capable of much greater discrimination than ordinary chiral reagents. An example is the biological conversion of citric acid (**56**) to α-oxoglutaric acid (**57**).



54 **55**



56 **57**



58

The two CH_2COOH groups are enantiotopic, and labeling experiments have shown that only one of these is converted to the COCOOH group.[121] Note that the X atoms or groups of any molecule of the form CX_2WY are always enantiotopic, though enantiotopic atoms and groups may also be found in other molecules, e.g., the hydrogen atoms in 3-fluoro-3-chlorocyclopropene (**58**). In this case, substitution of an H by a group Z makes the C-3 atom asymmetric, and substitution at C-1 gives the opposite enantiomer from substitution at C-2.

The term *prochiral*[122] is used for a compound or group which has two enantiotopic atoms or groups, e.g., CX_2WY. That atom or group X which would lead to an *R* compound if preferred to the other is called *pro-R*. The other is *pro-S*; e.g.,

---

[119] In the case where Y is itself a chiral group this statement is only true when the two Y groups have the same configuration.

[120] For a nonenzymatic example, see Job and Bruice, *J. Am. Chem. Soc.* **96**, 809 (1974).

[121] The experiments were carried out by Evans and Slotin, *J. Biol. Chem.* **141**, 439 (1941) and Wood, Werkman, Hemingway, and Nier, *J. Biol. Chem.* **142**, 31 (1942). The correct interpretation was given by Ogston, *Nature* **162**, 963 (1948). For discussion, see Hirschmann, in Florkin and Stotz, "Comprehensive Biochemistry," vol. 12, pp. 236–260, Elsevier Publishing Company, Amsterdam, 1964; Cornforth, *Tetrahedron* **30**, 1515 (1974); and Vennesland, *Top. Curr. Chem.* **48**, 39–65 (1974).

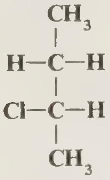
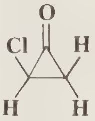
H^2 = pro-*S*
H^1 = pro-*R*

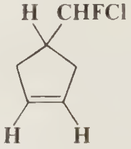
3. Where two atoms or groups in a molecule are in such positions that replacing each of them in turn by a group Z gives rise to diastereomers, the atoms or groups are called *diastereotopic*. Some examples are the CH_2 groups of 2-chlorobutane (**59**) and chlorocyclopropane (**60**) and the two olefinic hydrogens of **61**. Note that in **60** one hydrogen from the CH_2 group is cis to the Cl while the other is trans, so that they are obviously different. Diastereotopic atoms and groups are different in any environment, symmetric or asymmetric. These hydrogens react at different rates with achiral reagents, but an even more important consequence is that in nmr spectra, diastereotopic hydrogens theoretically give different peaks and split each other. This is in sharp contrast to equivalent or enantiotopic hydrogens, which are indistinguishable in the nmr, except when chiral solvents are used, in which case enantiotopic (but not equivalent) protons give different peaks.[123] The term *isochronous* is used for hydrogens which are indistinguishable in the nmr.[124] In practice, the nmr signals from diastereotopic protons are often found to be indistinguishable, but this is merely because they are very close together. Theoretically they are distinct, and they have been resolved in many cases. When they appear together, it is sometimes possible to resolve them by the use of lanthanide shift reagents[125] (p. 112) or by changing the solvent or concentration. Note that X atoms or groups in CX_2WY are diastereotopic if either W or Y is chiral.



59

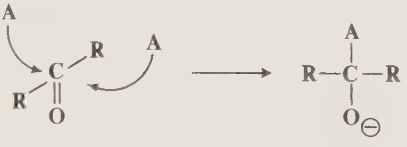


60

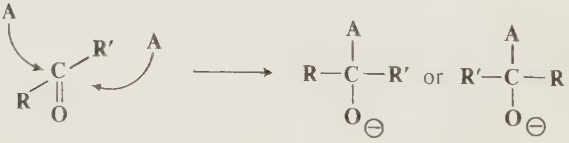


61

Just as there are enantiotopic and diastereotopic atoms and groups, so we may distinguish *enantiotopic and diastereotopic faces* in trigonal molecules. Again we have three cases: (1) In formaldehyde or acetone (**62**) attack by an achiral reagent A from either face of the molecule gives

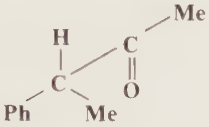


62

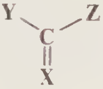


63

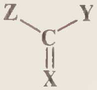
rise to the same transition state and product, and the two faces are thus equivalent. (2) In butanone or acetaldehyde (**63**) attack by an achiral A at one face gives a transition state and product which are the enantiomers of those arising from attack at the other face. Such faces are enantiotopic. As we have already seen (p. 97), a racemic mixture must result in this situation. However, attack at an enantiotopic face by a chiral reagent gives diastereomers, which are not formed in equal amounts. (3) In a case like **64**, the two faces are obviously not equivalent and are called diastereotopic. Enantiotopic and diastereotopic faces can be named by an extension of the Cahn-Ingold-Prelog system.[122] If the three groups as arranged by the sequence rules have the order X > Y > Z, that face in which the groups in this sequence are clockwise (as in **65**) is the *re* face (from Latin *rectus*) whereas **66** shows the *si* face (from Latin *sinister*).



64



65



66

The word *stereoheterotopic* has been suggested[126] as a term which would include both enantiotopic and diastereotopic atoms, groups, and faces. Equivalent atoms, groups, and faces would then be *homotopic*.

Stereospecific and Stereoselective Syntheses

Any reaction in which only one of a set of stereoisomers is formed exclusively or predominantly is called a *stereoselective* synthesis.[127] The same term is used when a mixture of two or more stereoisomers is exclusively or predominantly formed at the expense of other stereoisomers. In a *stereospecific* reaction, a given isomer leads to one product while another stereoisomer leads to the opposite product. All stereospecific reactions are necessarily stereoselective, but the converse is not true. These terms are best illustrated by examples. Thus, if maleic acid treated with bromine gives the *dl* pair of 2,3-dibromosuccinic acid while fumaric acid gives the meso isomer (this is the case), the reaction is stereospecific as well as stereoselective because two opposite isomers give two opposite isomers:

---

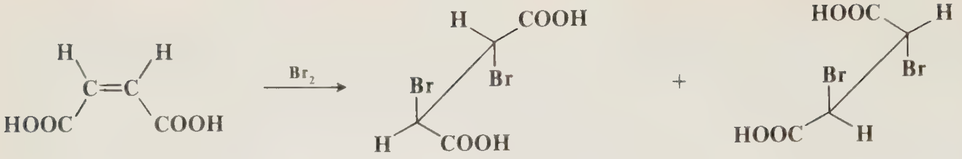
[123] Pirkle, *J. Am. Chem. Soc.* **88**, 1837 (1966); Burlingame and Pirkle, *J. Am. Chem. Soc.* **88**, 4294 (1966); Pirkle and Burlingame, *Tetrahedron Lett.* 4039 (1967).

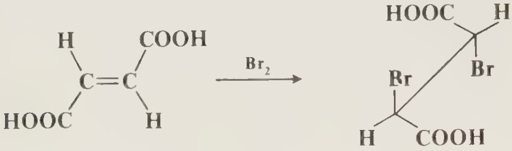
[124] For a review of isochronous and nonisochronous nuclei in the nmr, see van Gorkom and Hall, *Q. Rev., Chem. Soc.* **22**, 14–29 (1968).

[125] For example, see Schiemenz and Rast, *Tetrahedron Lett.* 4685 (1971).

[126] Eliel, *J. Chem. Educ.* **48**, 163 (1971).

[127] For a further discussion of these terms and of stereoselective reactions in general, see Eliel, "Stereochemistry of Carbon Compounds," Ref. 1, pp. 434–446.





However, if both maleic and fumaric acid gave the *dl* pair or a mixture in which the *dl* pair predominated, the reaction would be stereoselective but not stereospecific. If more or less equal amounts of *dl* and meso forms were produced in each case, the reaction would be nonstereoselective. A consequence of these definitions is that if a reaction is carried out on a compound which has no stereoisomers, it cannot be stereospecific, but at most stereoselective. For example, addition of bromine to methylacetylene could (and does) result in preferential formation of *trans*-1,2-dibromopropene, but this can be only a stereoselective and not a stereospecific reaction. Unfortunately, the term stereospecific is sometimes used in the literature where stereoselective is meant.

CONFORMATIONAL ANALYSIS

If two different three-dimensional arrangements in space of the atoms in a molecule are interconvertible merely by free rotation about bonds, they are called *conformations*; if not, *configurations*.[128] Configurations represent *isomers* which can be separated, as previously discussed in this chapter. Conformations represent *conformers*, which are rapidly interconvertible and thus nonseparable. The term "conformational isomer" (unfortunately, sometimes, just "isomer") is often used instead of "conformer."

Conformation in Open-Chain Systems

In an open-chain system there are an infinite number of conformations possible, each of which has a certain energy associated with it. For ethane there are two extremes, a conformation of highest and one of lowest potential energy, depicted in **67** and **68** and, by another type of diagram, in **69** and **70**. In the latter type of diagram, called the *Newman projection formula*, the observer is looking at the C—C bond head on. The three lines emanating from the center of the circle represent the valences of the front carbon, with respect to the observer.

---

[128] For treatises on conformational analysis, see Eliel, Allinger, Angyal, and Morrison, "Conformational Analysis," Interscience Publishers, Inc., New York, 1965; Hanack, "Conformation Theory," Academic Press, Inc., New York, 1965; and Chiurdoglu, "Conformational Analysis," Academic Press, Inc., New York, 1971. 67
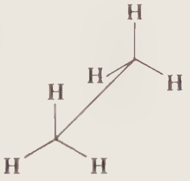
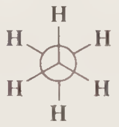
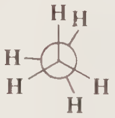
Staggered



68
Eclipsed

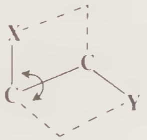


69
Staggered



70
Eclipsed

The staggered conformation (**67** or **69**) is the conformation of lowest potential energy for ethane. As the bond rotates, the energy gradually increases until the eclipsed conformation (**68** or **70**) is reached, when the energy is at a maximum. Further rotation decreases the energy again. Figure 3 illustrates this. The *angle of torsion*, which is a dihedral angle, is the angle between the XCC and the CCY planes, as shown:

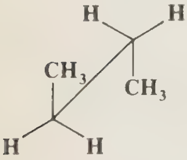


For ethane the difference in energy is about 2.9 kcal/mol.[129] This difference is called the *energy barrier*, since in free rotation about a single bond there must be enough rotational energy present to cross the barrier every time two hydrogen atoms are opposite each other. The cause of such barriers is not yet understood.[130] At ordinary temperatures enough rotational energy is present for the ethane molecule to be rapidly rotating, though it still spends most of its time at or near the energy minimum. Groups larger than hydrogen cause larger barriers, and when the barriers are large enough, as in the case of suitably substituted biphenyls (p. 92), rotation at room temperature is completely prevented and we speak of configurations and not conformations. Even for compounds with small barriers, cooling to low temperatures may remove enough rotational energy for what would otherwise be conformational isomers to become configurational isomers.

---

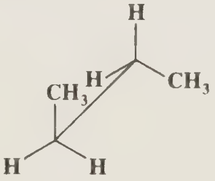
[129] Lide, *J. Chem. Phys.* **29**, 1426 (1958); Weiss and Leroi, *J. Chem. Phys.* **48**, 962 (1968).

A slightly more complicated case than ethane is that of a 1,2-disubstituted ethane (YCH_2-CH_2Y or YCH_2-CH_2X), such as *n*-butane, for which there are four extremes: a fully staggered conformation, called *anti* or *antiperiplanar* (**71**); another staggered conformation, called *gauche* or *synclinal* (**73**); and two types of eclipsed conformations, called *synperiplanar* (**74**) and *anticlinal* (**72**). An energy diagram for this system is given in Figure 4. Although there is constant rotation about the central bond, it is possible to estimate what percentage of the molecules are in each conformation at a given time. For example, for 1,2-dichloroethane in CCl_4 solution at 25°C about 70% of the molecules are in the anti and about 30% in the gauche conformation.[131] The corresponding figures for 1,2-dibromoethane are 89% anti and 11% gauche. The eclipsed conformations are unpopulated and serve only as pathways from one staggered conformation to another. Solids normally consist of a single conformer.



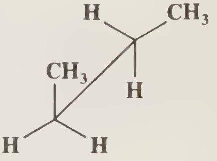
anti or
antiperiplanar

71



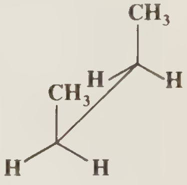
anticlinal

72



gauche or
synclinal

73



synperiplanar

74

It may be observed that the gauche conformation of butane (**73**) or of any other similar molecule is chiral. The lack of optical activity in such compounds arises from the fact that **73** and its mirror image are always present in equal amounts and interconvert too rapidly for separation.

For butane and for most other molecules of the forms YCH_2-CH_2Y and YCH_2-CH_2X, the anti conformer is the most stable, but exceptions are known. One group of exceptions consists of molecules containing small electronegative atoms, especially fluorine and oxygen. Thus 2-fluoroethanol,[132] 1,2-difluoroethane,[133] and 2-fluoroethyl trichloroacetate[134] ($FCH_2CH_2OCOCCl_3$) exist almost entirely in the gauche form, and compounds such as 2-chloroethanol and 2-bromoethanol[132] also prefer the gauche form. There is as yet no generally accepted explanation

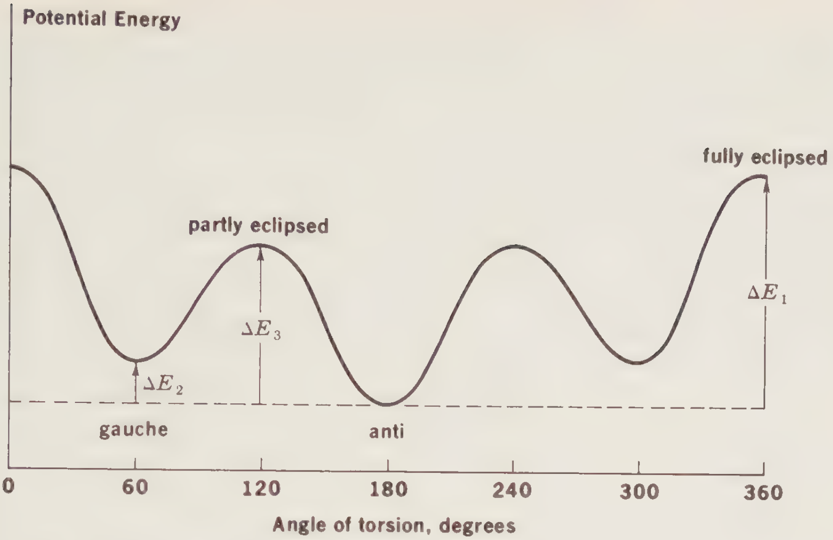

Figure 4 Conformational energy for $YCH_2—CH_2Y$ or $YCH_2—CH_2X$. For *n*-butane, $\Delta E_1 = 4$ to 6, $\Delta E_2 = 0.8$, and $\Delta E_3 = 3.4$ kcal/mol.

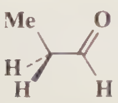
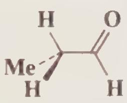
for this behavior.[135] It had been believed that the favorable gauche conformation of 2-fluoroethanol was the result of intramolecular hydrogen bonding, but this explanation of course will not do for molecules like 2-fluoroethyl trichloroacetate and it has in fact been ruled out for 2-fluoroethanol as well.[136] Other exceptions are known, where small electronegative atoms are absent. For example, 1,1,2,2-tetrachloroethane and 1,1,2,2-tetrabromoethane both prefer the gauche conformation.[137]

All the conformations so far discussed have involved rotation about sp^3-sp^3 bonds. Many studies have also been made of compounds with sp^3-sp^2 bonds.[138] For example, propionaldehyde (or any similar molecule) has four extreme conformations, two of which are called *eclipsing* and



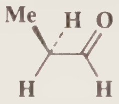
eclipsing

75

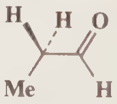


eclipsing

76



bisecting



bisecting

the other two *bisecting*. For propionaldehyde the eclipsing conformations have lower energy than the other two, with **75** favored over **76** by about 900 cal/mol.[139] As we have already pointed

[135] It has been proposed that the preference for the gauche conformation in these molecules is an example of a more general phenomenon, known as the *gauche effect*, i.e., a tendency to adopt that structure which has the maximum number of gauche interactions between adjacent electron pairs or polar bonds. This effect is ascribed to nuclear-electron attractive forces between the groups or unshared pairs: Wolfe, Rauk, Tel, and Csizmadia, *J. Chem. Soc. B* 136 (1971); Wolfe, *Acc. Chem. Res.* **5**, 102-111 (1972). See also Phillips and Wray, *J. Chem. Soc., Chem. Commun.* 90 (1973); Radom, Hehre, and Pople, *J. Am. Chem. Soc.* **94**, 2371 (1972); and Zefirov, *J. Org. Chem. USSR* **10**, 1147 (1974).

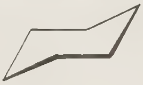
out (p. 115), for a few of these compounds, rotation is slow enough to permit cis-trans isomerism, though for simple compounds rotation is rapid. For example, acetaldehyde has a lower rotational barrier (about 1 kcal/mol) than ethane.[140]

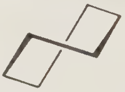
Conformation in Six-membered Rings[141]

If the six carbons of cyclohexane were to lie in a plane, the bond angles would have to be 120° since these are the angles of a regular hexagon. Since the normal tetrahedral angle is about 109.5°, there would be strain. The existence of cyclopropane proves that molecules may contain a good deal more strain than this. However, cyclopropane *must* be planar (there is no other conformation possible), whereas for cyclohexane there are two extreme conformations in which all the angles are tetrahedral.[142] These are called the *boat* and the *chair* conformations, and in each the ring is said to be *puckered*. The chair conformation is a rigid structure, but the boat form is flexible[143] and can easily pass over to a somewhat more stable form known as the *twist* conformation, also called the *skew boat* form. The twist form is about 1.5 kcal/mol more stable than the boat because it has less eclipsing interaction (see p. 145).[144] The chair form is more stable than the twist form by about 5 kcal/mol.[145] In the vast majority of compounds containing a cyclohexane ring, the molecules exist almost entirely in the chair form. Yet it is known that the boat or twist form exists transiently. An inspection of the chair form shows that six of its bonds are directed differently from the other six:

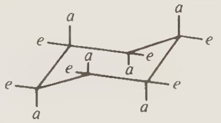
Boat



Chair



Twist



On each carbon one bond is directed up or down, and the other, more or less in the "plane" of the ring. The up or down bonds are called *axial* and the others *equatorial*. The axial bonds point alternately up and down. If a molecule were frozen into a chair form, there would be isomerism in monosubstituted cyclohexanes. For example, there would be an equatorial methylcyclohexane and an axial isomer. However, it has never been possible to isolate isomers of this type at room temperature. This proves the transient existence of the boat or twist form, since in order for the two types of methylcyclohexane to be nonseparable, there must be rapid interconversion of one chair form to another (in which all axial bonds become equatorial and vice versa) and this is possible only through a boat or twist conformation. Conversion of one chair form to another requires an activation energy of about 10 kcal/mol[146] and is very rapid at room temperature.[147] However, by working at low temperatures, Jensen and Bushweller have been able to obtain the pure equatorial conformers of chlorocyclohexane and trideuteriomethoxycyclohexane, as solids and in solution.[148] Equatorial chlorocyclohexane has a half-life of 22 years in solution at −160°C.

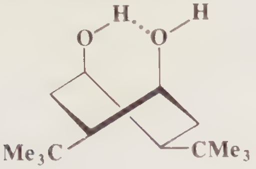
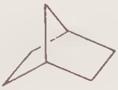
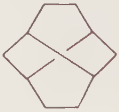
In some molecules the twist conformation is actually preferred.[149] An example is **77**, in which hydrogen bonding stabilizes the otherwise high-energy form. Of course in certain bicyclic compounds the six-membered ring is forced to maintain a boat or twist conformation, as in norbornane (**78**) or twistane (**79**).



77



78



79

In monosubstituted cyclohexanes, the substituent normally prefers the equatorial position because in the axial position there is interaction between the substituent and the axial hydrogens in the 3 and 5 positions, but the extent of this preference depends greatly on the nature of the group. Alkyl groups have a greater preference than polar groups, and for alkyl groups the preference increases with size. For polar groups, size seems to be unimportant. Both the large HgBr[150] and HgCl[151] groups and the small F group have been reported to have little or no conformational preference (the HgCl group actually shows a slight preference for the axial position). Table 2 gives approximate values of the free energy required for various groups to go from the equatorial position to the axial,[152] though it must be kept in mind that these values vary somewhat with physical state, temperature, and solvent.[153]

In disubstituted compounds, the rule for nonpolar groups is that the conformation will be such that as many groups as possible adopt the equatorial position. How far it is possible depends on the configuration. In a *cis*-1,2-disubstituted cyclohexane, one substituent must be axial and the other equatorial. In a *trans*-1,2 compound both may be equatorial or both axial. This is also true for 1,4-disubstituted cyclohexanes, but for 1,3 compounds, the reverse holds: the trans isomer must have the *ae* conformation, and the cis isomer may be *aa* or *ee*. For alkyl groups, the diequatorial conformation predominates over the diaxial, but for other groups this is not necessarily so. For example, both *trans*-1,4-dibromocyclohexane and the corresponding dichloro compound have the *ee* and *aa* conformations about equally populated,[154] and most *trans*-1,2-

OH	0.92–0.97	***t*-Bu**	>4

dihalocyclohexanes exist predominantly in the *aa* conformation.[158] Note that in the latter case the two halogen atoms are anti in the *aa* conformation but gauche in the *ee* conformation.

Since compounds with alkyl equatorial substituents are generally more stable, *trans*-1,2 compounds, which can adopt the *ee* conformation, are thermodynamically more stable than their *cis*-1,2 isomers, which must exist in the *ae* conformation. For the 1,2-dimethylcyclohexanes, the difference in stability is about 2 kcal/mol. Similarly, *trans*-1,4 and *cis*-1,3 compounds are more stable than their stereoisomers.

Incidentally, we can now see, in one case, why the correct number of stereoisomers could be predicted by assuming planar rings even though they are not planar (p. 117). In the case of both a *cis*-1,2-XX-disubstituted and a *cis*-1,2-XY-disubstituted cyclohexane, the molecule is nonsuperimposable on its mirror image; neither has a plane of symmetry. However, in the former case (**80**) conversion of one chair form to the other (which of course happens rapidly) turns the molecule into its mirror image, while in the latter case

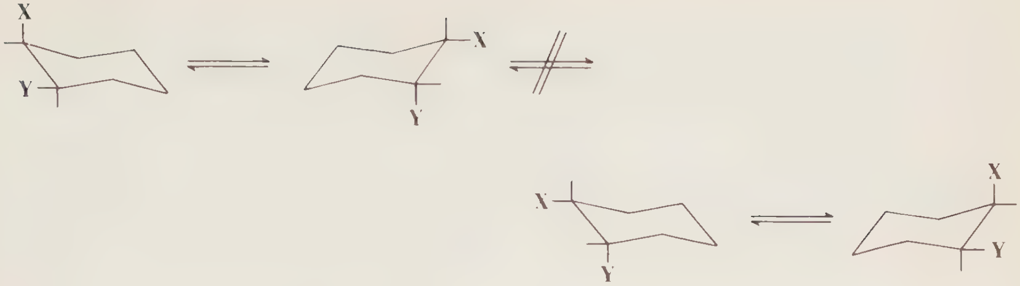
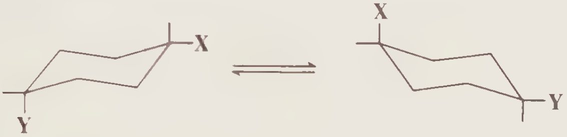
[158] Hageman and Havinga, *Recl. Trav. Chim. Pays-Bas* **88**, 97 (1969); Klaeboe, *Acta Chem. Scand.* **25**, 695 (1971); and references cited in these papers.



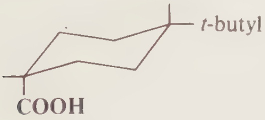
rapid interconversion does not give the mirror image but merely the conformer in which the original axial and equatorial substituents exchange places. Thus the optical inactivity of **80** is not due to a plane of symmetry but to a rapid interconversion of the molecule and its mirror image. A similar situation obtains for *cis*-1,3 compounds. However, for *cis*-1,4 isomers (both XX and XY) optical inactivity arises from a plane of symmetry in both conformations:



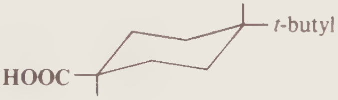
Symmetric Symmetric

All *trans*-1,2- and *trans*-1,3-disubstituted cyclohexanes are chiral (whether XX or XY), while *trans*-1,4 compounds (both XX and XY) are achiral, since all conformations have a plane of symmetry.

The conformation of a group can be frozen into a desired position by putting into the ring a large alkyl group (most often *t*-butyl), which must adopt the equatorial position.[159] For example, it was desired to compare the acidity of the carboxyl group in the axial and in the equatorial position. For this purpose the *cis*- and *trans*-4-*t*-butylcyclohexanecarboxylic acids were synthesized. The geometry is such that in the cis compound the equatorial *t*-butyl group forces the carboxyl group to be axial, while in the trans compound it must be equatorial:



cis; *ae*



trans; *ee*

The equatorial COOH has the greater acidity.[160]

The principles involved in the conformational analysis of six-membered rings containing one or two trigonal atoms, e.g., cyclohexanone and cyclohexene, are similar.[161]

---

[159] This idea was suggested by Winstein and Holness, *J. Am. Chem. Soc.* **77**, 5562 (1955).

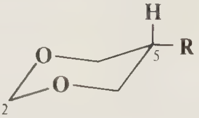
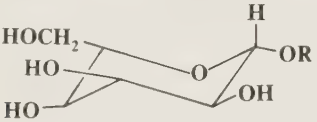
Conformation in Six-membered Rings Containing Hetero Atoms[162]

In six-membered rings containing hetero atoms, the basic principles are the same; i.e., there are chair, twist, and boat forms, axial and equatorial groups, etc., but in certain compounds a number of new factors enter the picture. We shall deal with only two of these.[163]

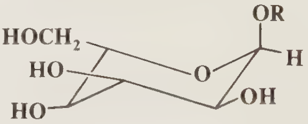
1. In 5-alkyl-substituted 1,3-dioxanes, the 5-substituent has a much smaller preference for the equatorial position than in cyclohexane derivatives;[164] the values of $-\Delta G^\circ$ are much lower. This indicates that the lone pairs on the oxygens have a smaller steric requirement than the C—H bonds in the corresponding cyclohexane derivatives. Similar behavior is found in the 1,3-dithianes.[165] With certain nonalkyl substituents (e.g., F, NO_2, SOMe, $NMe_3{}^+$) the axial position is actually preferred.[165a]



2. An alkyl group located on a carbon α to a hetero atom prefers the equatorial position, which is of course the normally expected behavior, but a *polar* group in such a location prefers the *axial* position. An example of this phenomenon, known as the *anomeric effect*,[166] is the greater stability of α-glucosides over β-glucosides. The reason for the anomeric effect is not completely understood, though several explanations have been offered.[167]



A β-glucoside



An α-glucoside

Conformation in Other Rings

Three-membered rings must be planar, but they seem to be the only saturated rings which generally are. Cyclobutane[168] is not planar but exists as in **81**, with an angle between the planes

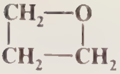
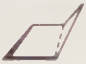
81

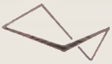


82

of about 35°.[169] The deviation from planarity is presumably caused by eclipsing in the planar form (see p. 145). Oxetane (**82**), in which eclipsing is less, is planar.[170] Cyclopentane might be expected to be planar, since the angles of a regular pentagon are 108°, but it is not so, also because of eclipsing effects.[171] There are two puckered conformations, the *envelope* and the *half-chair*. There is little energy difference between these two forms, and many five-membered ring systems have conformations somewhere in between them.[172] Although in the envelope conformation one carbon is shown above the others, ring motions cause each of the carbons in rapid succession to assume this position. The puckering rotates around the ring in what may be called a *pseudorotation*.[173] In substituted cyclopentanes, and in five-membered rings in which at least one atom does not contain two substituents (such as tetrahydrofuran, cyclopentanone, etc.), one conformer may be more stable than the others. The barrier to planarity in cyclopentane has been reported to be 5.2 kcal/mol.[174]



Envelope



Half-chair

Rings larger than six-membered are always puckered[175] unless they contain a large number of sp^2 atoms (see the section on strain in medium rings, p. 145).

Methods for Determining Conformations[176]

X-ray- and electron-diffraction techniques, which are capable of measuring bond distances and angles, obviously can give conformations too. X-ray diffraction, which can be used only on solids, has been more successful in this respect, because all the molecules in a crystal have the same

[169] Dows and Rich, *J. Chem. Phys.* **47**, 333 (1967); Stone and Mills, *Mol. Phys.* **18**, 631 (1970); Miller and Capwell, *Spectrochim. Acta, Part A* **27**, 947 (1971); Miller, Capwell, Lord, and Rea, *Spectrochim. Acta, Part A* **28**, 603 (1972). However, some cyclobutane derivatives are planar, at least in the solid state: for example, see Margulis and Fischer, *J. Am. Chem. Soc.* **89**, 223 (1967); Adman and Margulis, *J. Am. Chem. Soc.* **90**, 4517 (1968); Margulis, *Chem. Commun.* 215 (1969), *J. Am. Chem. Soc.* **93**, 2193 (1971).

[176] For reviews, see Lau, *Angew. Chem.* **73**, 423–432 (1961); Klyne, *Prog. Stereochem.* **1**, 36–89 (1954); and Eliel, Allinger, Angyal, and Morrison, Ref. 128, pp. 129–188.

conformation. However, this very virtue is also a drawback, because the conformation of the solid is not necessarily the same as that of the molecules in other phases. Dipole moments can often be used to determine conformations. For example, 1,2-dibromoethane should have no dipole moment in the anti conformation but should have a moment in the gauche conformation. Since the compound has a dipole moment of 0.93 D, it must exist at least partially in the gauche form. A consideration of dipole moments and polarizabilities led to the conclusion that 89% of the molecules are in the anti and 11% in the gauche conformations.[131] Conformations have also been determined from ir, Raman, uv, nmr, and microwave[177] spectra. For example, each conformer has its own ir spectrum, and the peak positions are often different. For example, the C—F bond in equatorial fluorocyclohexane absorbs at 1062 cm^{-1}, while the axial C—F bond absorbs at 1129 cm^{-1}.[178] Many relationships of this kind are known, and it is often possible to tell which conformation a molecule has and, for mixtures, what percentage is in each conformation. Because of the relationship between configuration and conformation in cyclic compounds (see p. 129), configuration can frequently be determined too.

As for nmr,[179] if a molecule can exist in several conformations which rapidly interconvert, then any proton in the molecule assumes all possible positions in a very short time and the nmr spectrum represents an average. This is the case in most open-chain compounds. Even in cyclohexanes the chair-chair interconversion is so rapid that the nmr spectrum shows only one peak. However, in cases where interconversion of conformers is slowed or prevented (either by cooling the compound or by the inherent structure of the molecule) the hydrogens of each conformer appear separately (in cases where only one is stable only that one appears). An example is the cooling of cyclohexane to −110°C, at which temperature two peaks appear. Only the chair form is present, and one peak is due to the equatorial and the other to the axial hydrogens.[180]

When axial and equatorial protons do appear at different positions, they can often be told apart, since axial protons usually absorb at a slightly higher field than equatorials.[181] However, care must be taken, since this is not always the case.[182] When the peaks due to axial and equatorial protons have been identified, the proportions of the conformers can be established by measuring the area under the peaks.[183] Another aid to conformational determination is the fact that the nmr coupling constant J is higher for coupling between two adjacent axial hydrogens than for two equatorials or for an axial and an equatorial.[184] In fact J_{anti} is usually greater than J_{gauche} in most cases. ^{13}C nmr has also been used to obtain conformational information.[185]

Energy barriers and rates of conversion from one conformer to another can be obtained from the shape of nmr peaks and the way they split with decreasing temperature[186] (see also p. 202).

Another important method for determining conformation when the absolute configuration is

---

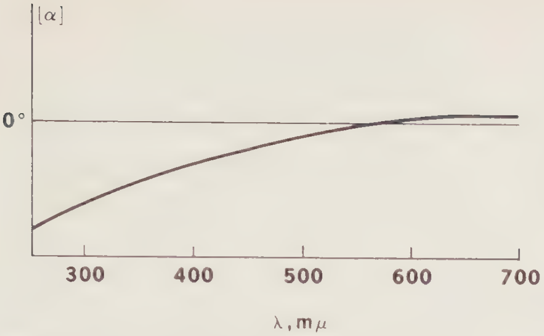

Figure 5 A plain curve

known depends on measuring the *optical rotatory dispersion* (ord).[187] It has been mentioned that when a chiral compound rotates the plane of polarized light, the amount of rotation depends on the wavelength of the polarized light. In ord, rotations are measured over a range of wavelengths rather than at a single wavelength, usually covering the uv as well as the visible region. Instruments which do this and plot the rotation as a continuous function of the wavelength are commercially available. Some compounds give what is called a *plain curve* (Figure 5), while others illustrate the *Cotton effect* (Figure 6). In a *positive* Cotton effect, as the wavelength decreases, the rotation takes a fairly sharp increase, reaches a peak, and then precipitously sinks to a trough, after which it rises again. The descending line always crosses the zero axis at a wavelength at which the compound absorbs light, though not all such wavelengths show the Cotton effect. A *negative* Cotton effect is the reverse: as the wavelength decreases, there is first a drop and then a sharp rise. Obviously, if any compound shows a positive Cotton effect, its enantiomer must show a negative one.

Plain curves are much less useful than curves which show a Cotton effect, but sometimes a comparison of the plain curves of two similar compounds can show the absolute configuration of one if the configuration of the other is known. Another use for plain curves is in the detection of optical activity when a measurement at the usual wavelength (589 nm corresponding to the D line of Na) does not indicate activity. In some cases the rotation at 589 nm is so low that it is undetectable, but it is usually greater in the uv region.

Curves which exhibit Cotton effects have been much more useful, yielding information on structure, configuration, and conformation, though the relationships are largely empirical. The basic method is one of comparison of the peaks of unknown with those of known compounds. Most of the early studies were performed on cyclic ketones. The keto group absorbs in the ultraviolet at about 280 to 290 nm, and this absorption generally gives rise to a Cotton effect. Cyclic compounds are more rigid than acyclic ones and thus more amenable to conformational study.

An illustration of the type of correlations made possible by a comparison of Cotton-effect curves

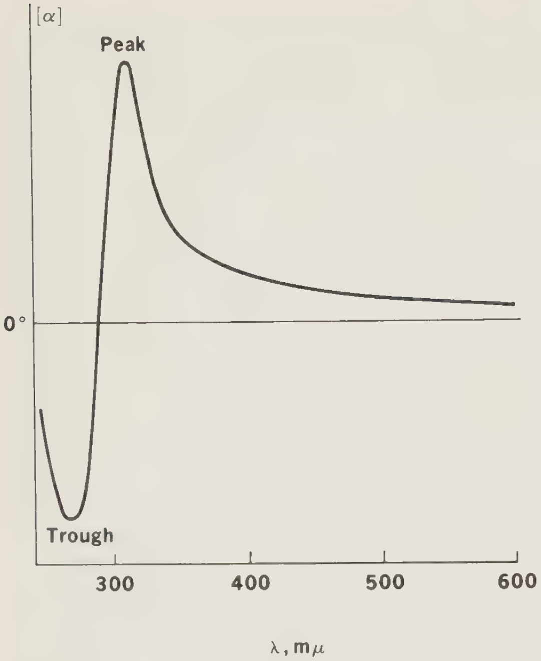

Figure 6 An ord curve showing a positive Cotton effect.

can be obtained by a consideration of the *octant rule*.[188] According to this rule, a carbonyl compound is cut into octants by three perpendicular planes which meet at the carbonyl carbon (Figure 7). For a six-membered ring (**83**) one plane is the plane which includes C-1, C-2, C-6, and the carbonyl oxygen. In the diagram this plane lies below C-3, C-4, and C-5. The second plane is perpendicular to the first, includes C-1, C-4, and the oxygen, and bisects the ring. In the diagram, C-2 and C-3 lie behind this plane and C-5 and C-6 in front of it. The third plane includes C-1 and is perpendicular to the other two. In **83** only the oxygen lies to the left of the third plane; all other atoms lie to the right. The three planes cut the molecule into eight sections, four of which, in this case, are unoccupied by atoms. The octant rule can then be stated for the four octants which are occupied in **83.** Substituents which are *in the planes* (unmarked in **84**) have little or no effect on the ord curve; substituents in the lower right and upper left octants (marked *) make a positive contribution to the Cotton-effect curve; and substituents in the upper right and lower left octants

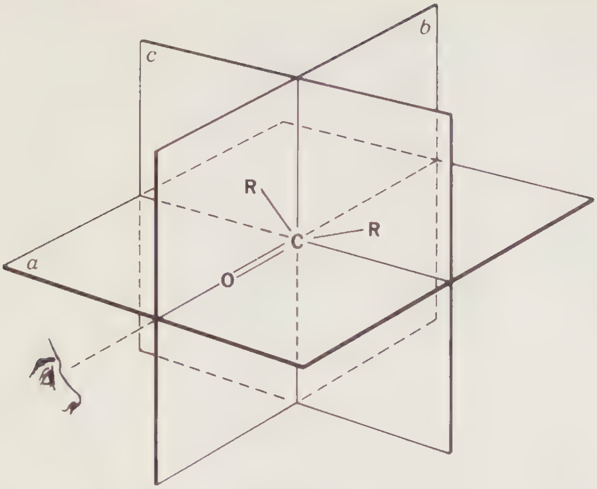

Figure 7 The three perpendicular planes of the octant rule.

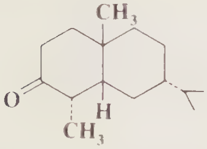
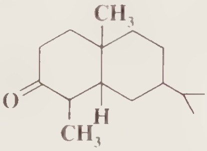
(marked ‡) make a negative contribution. For the other four octants (these are occupied in some compounds with fused ring systems) the contributions are reversed.[189]

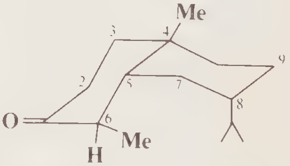
An example of the use of ord to establish conformation can be seen for the *cis*-tetrahydrocyperones, the absolute configurations of which are known and are shown in **85** and **86.** The



85



86



87

question in each case is: Is the isopropyl group axial or equatorial? If **85** has an axial isopropyl group, it has the configuration shown in **87.** If we number the ketone ring as in **83,** we see that the C-4 methyl group makes no contribution but that the isopropyl group projects into the lower right octant and thus makes a positive contribution, as does the C-6 methyl. A look at the model (Figure 8*a*) shows that the positive contributions outweigh the negative, and **87** should show a positive, though weak, Cotton effect. Similarly, a photograph of the conformation which would result if the isopropyl group in **85** were equatorial (Figure 8*b*) shows that this conformer should exhibit a strong positive Cotton effect. The actual ord curve for **85** showed a strong positive Cotton effect, indicating that **85** has the conformation shown in Figure 8*b*, with an equatorial isopropyl group. Similarly, **86** exhibited a weak negative Cotton effect,[190] showing that in this isomer too the isopropyl group is equatorial (Figure 8*c*). If the isopropyl group had been axial, the Cotton effect would have been strongly positive (Figure 8*d*).

Rules similar to the carbonyl group octant rule have been established for other chromophores, e.g., lactones,[191] azides,[192] carbon-carbon double bonds,[193] and allenes.[194] In many cases, compounds may be made amenable to ord study by conversion of a group which does not absorb in the visible to one that does (if this change does not affect the stereochemistry). For example, the OH group can be converted to the ONO group. In some cases, e.g., chiral biphenyls, where the chromophore itself is chiral, the Cotton effect is created almost entirely by the chromophore alone, so that almost regardless of what other groups are present, the sign of the Cotton effect will show the absolute configuration of the chiral center.[195]

If the conformation is known, ord can be used to establish configuration. This is done by comparison of the ord curve of the compound of unknown configuration with that of a substance of known configuration, provided that the two compounds contain the same light-absorbing group

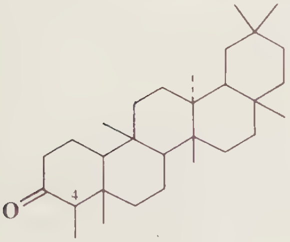
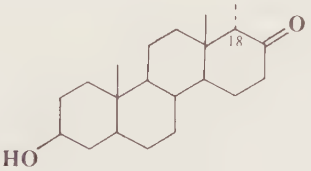
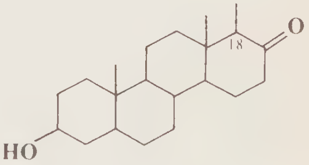
in the same environment. For example, a comparison of the ord curve of friedelin (**88**) with those of the known compounds **89** and **90** (which differ only in configuration at C-18) shows that **88** and **90** have almost identical curves while that of **89** is much shallower. Although the configuration at C-4 of friedelin was already known, ord provided confirmatory evidence.[196]



88



89



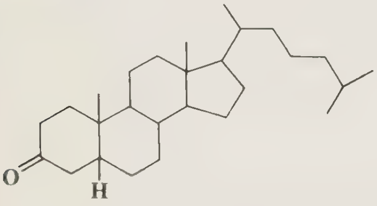
90

---

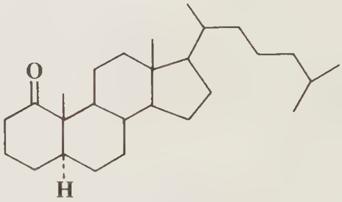
[196] Djerassi, Riniker, and Riniker, *J. Am. Chem. Soc.* **78**, 6362 (1956).

A technique closely related to ord is *circular dichroism* (cd).[197] In this method the molecular extinction coefficients (p. 209) of a compound are measured with both left and right circularly polarized light, and the difference between these values (called $\Delta\varepsilon$) is plotted against the wavelength of the light used. Instruments are available which automatically plot $\Delta\varepsilon$ against λ in the visible and ultraviolet regions of the spectrum. As with ord, information is obtained chiefly in regions where the molecule absorbs light. Circular-dichroism curves are typically bell-shaped, with a maximum or a minimum at the absorption peak. In Figure 9 an ord curve and a cd curve for the same compound are compared.[198] As illustrated in Figure 9, a positive Cotton effect is associated with a positive $\Delta\varepsilon$. Of course, the enantiomer of the compound illustrated in Figure 9 would have a negative Cotton effect and a negative $\Delta\varepsilon$. As with ord, interpretation of cd curves is largely empirical, and information is obtained by comparison of curves of known and unknown compounds. The octant rule also applies to cd, and it is used to determine conformations and configurations, in ways similar to those described for ord.

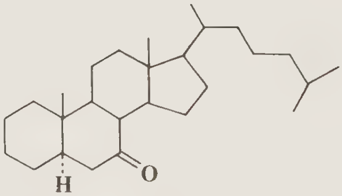
In many cases either ord or cd can be used with equal success to solve the same types of structural and configurational problems. However, cd has the advantage that the curves are generally simpler and easier to interpret. This is largely due to the fact that each absorption peak in a molecule gives rise to a cd peak which is relatively uninfluenced by other parts of the molecule, while an ord peak in a given absorption region is often complicated by background effects from other regions, so that the result is an overlapping of effects. On the other hand, this very complexity often becomes an advantage for ord, since a more complicated curve often yields more information. For example, the cd curves for 3-coprostanone (**91**), 1-cholestanone (**92**), and 7-cholestanone (**93**) are similar because each is a saturated ketone, but the ord curves are different because of contributions from the rest of the molecule. The two methods are therefore complementary.



91



92



93

STRAIN

Steric strain exists in a molecule when bonds are forced to make angles which are abnormal. This results in a higher energy than would be the case in the absence of angle distortions. There are, in general, two kinds of structural features which result in sterically caused abnormal bond angles. One of these is found in small-ring compounds, where the angles must be less than those resulting from normal orbital overlap. Such strain is called *small-angle strain.* The other arises where nonbonded atoms are forced into close proximity by the geometry of the molecule. These are called *nonbonded interactions.*

[198] From Djerassi, *Proc. Chem. Soc.* 315 (1964).

Strain in Small Rings[199]

Three-membered rings have a great deal of angle strain, since 60° angles represent a large departure from the tetrahedral angles. In sharp contrast to other ethers, ethylene oxide is quite reactive, the ring being opened by many reagents (see p. 326). Ring opening, of course, relieves the strain. Cyclopropane,[200] which is even more strained than ethylene oxide, is also cleaved more easily than would be expected for an alkane. Thus, pyrolysis at 450 to 500°C converts it to propene, bromination gives 1,3-dibromopropane,[201] and it can be hydrogenated to propane (though at high pressure).[202] Other three-membered rings are similarly reactive.[203]

There is much evidence, chiefly derived from nmr coupling constants, that the bonding in cyclopropanes is not the same as in compounds which lack small-angle strain.[204] For a normal carbon atom, one *s* and three *p* orbitals are hybridized to give four approximately equivalent sp^3 orbitals (see p. 25), each containing about 25% *s* character. But for a cyclopropane carbon atom, the four hybrid orbitals are far from equivalent. The two orbitals directed to the outside bonds have more *s* character than a normal sp^3 orbital, while the two orbitals involved in ring bonding have less, because the more *p*-like they are the more they resemble ordinary *p* orbitals, whose preferred bond angle is 90° rather than 109.5°. Since the small-angle strain in cyclopropanes is the difference between the preferred angle and the real angle of 60°, this additional *p* character relieves some of the strain. The external orbitals have about 33% *s* character, so that they are approximately sp^2 orbitals, while the internal orbitals have about 17% *s* character, so that they may be called approximately sp^5 orbitals.[205] Each of the three carbon-carbon bonds of cyclopropane is therefore formed by overlap of two sp^5 orbitals. Molecular-orbital calculations show that such bonds are not completely σ in character. In normal C—C bonds, sp^3 orbitals overlap in such a way that the straight line connecting the nuclei becomes an axis about which the electron density is symmetrical. But in cyclopropane, the electron density is directed *away from* the ring. Figure 10 shows the direction of orbital overlap.[206] For cyclopropane, the angle (marked θ) is 21°. Cyclobutane exhibits the same phenomenon but to a lesser extent, θ being 7°.[206] These bonds, called *bent* or *banana bonds* (see also p. 13), are intermediate in character between σ and π, so that cyclopropanes behave in some respects like double-bond compounds.[207] For one thing, there is much evidence, chiefly from uv spectra,[208] that a cyclopropane ring is conjugated with an adjacent double bond and that this conjugation is greatest for the conformation shown in *a* in

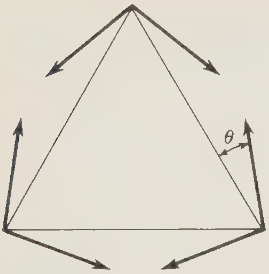

Figure 10 Orbital overlap in cyclopropane. The arrows point toward the center of electron density.

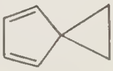
Figure 11 and least or absent for the conformation shown in *b*, since overlap of the double-bond π orbital with two of the *p*-like orbitals of the cyclopropane ring is greatest in conformation *a*. However, the conjugation between a cyclopropane ring and a double bond is less than that between two double bonds.[209] In **94**, the conjugation is enough to impart some aromatic character to the five-membered ring.[210] For other examples of the similarities in behavior of a cyclopropane ring and a double bond, see p. 691.



94

Four-membered rings also exhibit angle strain,[211] but much less, and are less easily opened. Cyclobutane is more resistant than cyclopropane to bromination, and though it can be hydrogenated to butane, more strenuous conditions are required. Nevertheless, pyrolysis at 420°C gives two molecules of ethylene. As mentioned earlier (p. 132), cyclobutane is not planar.

In recent years quite a few highly strained compounds containing fused small rings have been prepared,[212] showing that organic molecules can exhibit much more strain than simple cyclopropanes or cyclobutanes. Table 3 shows some of these compounds. Perhaps the most interesting are

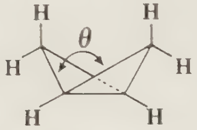
cubane and prismane, since preparation of these ring systems had been the object of much endeavor. Prismane has the structure which Ladenburg proposed as a possible structure for benzene. The bicyclobutane molecule is bent, with the angle θ between the planes equal to



126 ± 3°.[224] The rehybridization effect, described above for cyclopropane, is even more extreme in this molecule, and calculations have shown that the central bond is essentially formed by overlap of two p orbitals, with little or no s character.[225]

Strain in Medium Rings[226]

In rings larger than four-membered, there is no small-angle strain, but there are three other kinds of strain. First let us examine the chair form of cyclohexane, which does not exhibit any of the three kinds of strain. Each carbon-carbon bond in the chair form can be represented as in **95**; i.e., each bond is in the gauche conformation. In five-membered rings and in rings containing from 7 to 13 carbons any conformation in which all the bonds are as in **95** contains transannular interac-

TABLE 4 Heats of combustion in the gas phase for cycloalkanes, per CH_2 group[229]

Size of ring	$-\Delta H_c(g)$, kcal mol	Size of ring	$-\Delta H_c(g)$, kcal/mol
3	166.3	10	158.6
4	163.9	11	158.4
5	158.7	12	157.8
6	157.4	13	157.7
7	158.3	14	157.4
8	158.6	15	157.5
9	158.8	16	157.5

tions, i.e., interactions between the substituents on C-1 and C-3, or C-1 and C-4, etc. These interactions occur because the internal space is not large enough for all the quasi-axial hydrogen atoms to fit without coming into conflict. The molecule can adopt other conformations in which this *transannular strain* is reduced, but then some of the carbon-carbon bonds must adopt eclipsed (**96**) or partially eclipsed conformations. The strain resulting from eclipsed conformations is called *Pitzer strain*. For saturated rings from 3- to 13-membered (except for the chair form of cyclohexane) there is no escape from at least one of these two types of strain. In practice each ring adopts conformations which minimize both sorts of strain as much as possible. For cyclopentane, as we have seen (p. 133), this means that the molecule is not planar. In rings larger than 9-membered, Pitzer strain seems to disappear, but transannular strain is still present.[227] For 9- and 10-membered rings, some of the transannular and Pitzer strain may be relieved by the adoption of a third type of strain, *large-angle strain*. Thus, C—C—C angles of 115 to 120° have been found in x-ray diffraction of cyclononylamine hydrobromide and 1,6-diaminocyclodecane dihydrochloride.[228]

The amount of strain in cycloalkanes can be seen in Table 4,[229] which lists heats of combustion per CH_2 group. As can be seen, cycloalkanes larger than 13-membered are as strain-free as cyclohexane.

Transannular interactions may exist across rings from 8- to 11-membered and even larger.[230] Spectral and dipole measurements on **97** show that the carbonyl group is affected by the nitrogen.[231] **98** is probably another canonical form. It is significant that when this base accepts a proton,

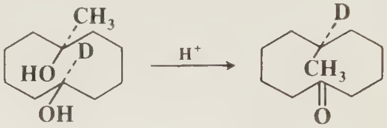
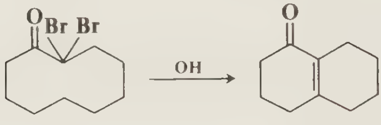
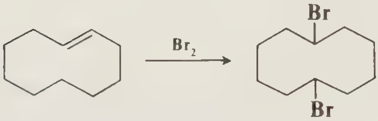
it goes to the oxygen rather than to the nitrogen. Many examples of transannular reactions are known. A few are given below.[232]







In summary, we can divide saturated rings into four groups, of which the first and third are more strained than the other two.

1. *Small rings* (3- and 4-membered). Small-angle strain predominates.
2. *Common rings* (5-, 6-, and 7-membered). Largely unstrained. The strain that is present is mostly Pitzer strain.
3. *Medium rings* (8- to 11-membered). Considerable strain; Pitzer, transannular, and large-angle strain.
4. *Large rings* (12-membered and larger). Little or no strain.

Unsaturated Rings[233]

Double bonds can exist in rings of any size. As we would expect, the most highly strained are the 3-membered rings. Small-angle strain, which is so important in cyclopropane, is even greater in cyclopropene because the ideal angle is greater. In cyclopropane, the bond angle is forced to be 60°, about 50° smaller than the tetrahedral angle; but in cyclopropene, the angle, also about 60°, is now about 60° smaller than the ideal angle of 120°. Thus, the angle in cyclopropene is about 10° more strained than in cyclopropane. However, this additional strain is offset by a decrease in strain arising from another factor. Cyclopropene, lacking two hydrogens, has none of the eclipsing strain present in cyclopropane. Cyclopropene has been prepared[234] and is stable at liquid-nitrogen temperatures, though on warming even to −80°C it rapidly polymerizes. Many other cyclopropenes are stable at room temperature and above.[235] The highly strained benzocyclopropene[236] (**99**), in which the cyclopropene ring is fused to a benzene ring, has been prepared[237] and is

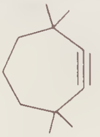
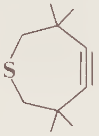
99

stable for weeks at room temperature, though it decomposes on distillation at atmospheric pressure. As in cyclopropanes, the orbitals of cyclopropenes are not directed along the straight line connecting the nuclei, and rehybridization often causes the strained double bond to behave like a triple bond.[233]

As previously mentioned, double bonds in relatively small rings must be cis. A stable trans double bond first appears in an 8-membered ring, and above about 11 members, the trans isomer is more stable than the cis.[109] The smallest unstrained cyclic triple bond is found in cyclononyne.[238] Cyclooctyne has been isolated,[239] but its heat of hydrogenation shows that it is considerably strained. There have been a few compounds isolated with triple bonds in 7-membered rings. 3,3,7,7,-Tetramethylcycloheptyne (**100**) dimerizes within an hour at room temperature,[240] but 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne (**101**) is indefinitely stable even at 140°C.[241] Cycloheptyne itself has not been isolated, though its transient existence has been shown.[242] Transient triple bonds have also been demonstrated in 6-, 5-, and even 4-membered rings.[243] Although cycloheptyne and cyclohexyne have not been isolated, Pt(0) complexes of these compounds have been prepared and are stable.[244] The smallest cyclic allene so far isolated is 1,2-cyclonanadiene,[245] but cyclic allenes are in general less strained than their acetylenic isomers.[246] The transient existence of 1,2-cyclooctadiene, 1,2-cycloheptadiene, and 1,2-cyclohexadiene has been demonstrated,[247] and the first two have been isolated in platinum complexes.[248]



100



101

In bridged bicyclic compounds double bonds at the bridgehead are impossible in small systems. This is the basis of *Bredt's rule*,[249] which states that in a case like **102** elimination always leads

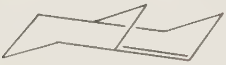
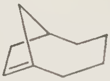
102

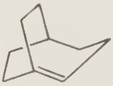
away from the bridgehead. This rule no longer applies when the rings are large enough. In determining whether a bicyclic system is large enough to accommodate a bridgehead double bond, we can use the *S* number,[250] which is defined as the sum of the number of atoms in the bridges of a bicyclic system. Thus the [2.2.1] system shown above has an *S* number of 5. The smallest *S* number for which stable compounds have been prepared with double bonds at a bridgehead is 7, and several of these are known, e.g., bicyclo[3.3.1]non-1-ene[251] (**103**) and bicyclo[4.2.1]non-1(8)-ene[252] (**104**). However, the *S* number is not the only factor. The size of the ring in which the double bond is located is also important. Both **103** and **104** may be looked upon as derivatives of *trans*-cyclooctene, and **103** has been shown to have a strain energy of the same order of magnitude as that of *trans*-cyclooctene.[253] Bicyclo[3.2.2]non-1-ene (**105**) also has an *S* number of 7, but in this case the double bond is in a 7-membered ring, so that it is a derivative of *trans*-cycloheptene, which is as yet unknown. **105** has been prepared but (despite its *S* number of 7) dimerized before it could be isolated.[254] No bridgehead double bond has yet been demonstrated in a stable bicyclic compound with *S* smaller than 7 (all such compounds would have to contain *trans*-cycloalkenes of 7 members or less), though a few of them have been shown to have transient existence.[255]



103



104



105

Strain Due to Unavoidable Crowding[256]

In some molecules, large groups are so close to each other than they cannot fit into the available space in such a way that normal bond angles are maintained. It has proved possible to prepare compounds with a high degree of this type of strain. For example, success has been achieved in synthesizing benzene rings containing ortho *t*-butyl groups. The 1,2,3-tri-*t*-butyl compounds **106**[257] (see p. 796) and **107**[258] have been prepared, as well as the 1,2-di-*t*-butyl compounds **108** and **109**.[259] So far no 1,2,3,4-tetra-*t*-butylbenzene is known, though a compound has been prepared

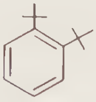
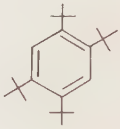
107



108



109

in which a benzene ring has four ferrocenyl groups in the 1, 2, 3, and 4 positions.[260] That the ortho di-*t*-butyl molecules are strained is demonstrated by uv and ir spectra, which showed that in 1,2,4-tri-*t*-butylbenzene the ring is not planar, and by a comparison of the heats of reaction of this compound and its 1,3,5 isomer, which show that the 1,2,4 compound possesses about 22 kcal mol more strain energy than its isomer.[261] Even smaller groups may sterically interfere in ortho positions. The van der Waals radius for chlorine is 1.80 Å, which means that two chlorine atoms whose centers are 3.60 Å apart or more should not interfere with each other. However, the distance between the centers of the chlorine atoms in 1,2-dichlorobenzene is 3.10 Å, so that there is crowding in this molecule.[262] There is even more crowding in ortho dibromobenzenes and diiodobenzenes. In hexaisopropylbenzene, prepared by Arnett and Bollinger, the six isopropyl groups are so crowded that they cannot rotate but are lined up around the benzene ring, all pointed in the same direction.[263] In another similar instance, it has proved possible to prepare cis and trans isomers of 5-amino-2,4,6-triiodo-N,N,N′,N′-tetramethylisophthalamide because there is no room for the CONMe$_2$ groups to rotate, caught as they are between two bulky iodine atoms.[264] The trans isomer is chiral and has been resolved, while the cis isomer is a meso form. Another example of cis-trans isomerism resulting from restricted rotation about single bonds[265] is found in 1,8-di-*o*-tolylnapthalene.[266]

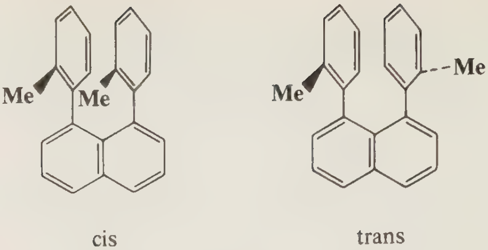
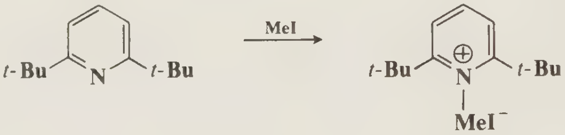
[266] Clough and Roberts, *J. Am. Chem. Soc.* **98,** 1018 (1976).



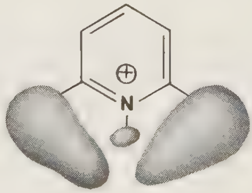
There are many other cases of intramolecular crowding resulting in distortion of bond angles. We have already mentioned hexahelicene (**19**, p. 96). The compounds tri-*t*-butylamine and tetra-*t*-butylmethane are as yet unknown. In the latter, there is no way for the strain to be relieved, and it is questionable whether this compound can ever be made. In tri-*t*-butylamine the crowding can be eased somewhat if the three bulky groups assume a planar instead of the normal pyramidal configuration. In tri-*t*-butylcarbinol, coplanarity of the three *t*-butyl groups is prevented by the presence of the OH group, and yet this compound has been prepared.[267] Tri-*t*-butylamine should have less steric strain than tri-*t*-butylcarbinol, and it should be possible to prepare it.

An interesting example of steric hindrance was reported by Okamoto and Shimagawa.[268] The compound 2,6-di-*t*-butylpyridine reacted with methyl iodide under high pressure to give the corresponding quaternary salt (**110**):



110

110 was remarkably stable, subliming under reduced pressure at 250°C without decomposition. In contrast, the corresponding 2,6-dimethyl salt was completely dissociated into 2,6-dimethylpyridine and methyl iodide under these conditions. It is likely that the inert character of **110** is caused by a structure in which the methyl group is essentially imprisoned between the two bulky *t*-butyl groups:



It is not easy to put the methyl group into its "prison" (the reaction does not succeed at ordinary pressures), and once it is there, it is not easy to get it out.

Five

Carbonium Ions, Carbanions, Free Radicals, Carbenes, and Nitrenes

There are four known types of organic species in which a carbon atom has a valence of only 2 or 3.[1] These are usually very short-lived, and most are present (at least in solution) only as intermediates which are quickly converted to more stable molecules. However, some are more stable than others, and fairly stable examples have been prepared of three of the four types. The four types of species are *carbonium ions*[2] (**1**), *free radicals* (**2**), *carbanions* (**3**), and *carbenes* (**4**). Of the four, only carbanions have a complete octet around the carbon. There are many other organic ions and radicals with charges and unpaired electrons on atoms other than carbon, but of these we shall discuss only *nitrenes* (**5**), which are the nitrogen analogs of carbenes (see p. 184). We shall discuss each of the five types in a separate section, which in each case includes brief summaries of the ways in which the species form and react. These summaries are short and schematic. The generation and fate of the five types are more fully treated in appropriate places in Part 2 of this book.

CARBONIUM IONS[3]

Stability and Structure

Carbonium ions are intermediates in several kinds of reaction, and the more stable ones have been prepared in solution and in a few cases even as solid salts. In solution the carbonium ion may be free (this is more likely in polar solvents, in which it is solvated) or may exist as an ion pair,[4] which means that it is closely associated with a negative ion, called a *counterion*. Ion pairs are more likely in nonpolar solvents.

---

[1] For general references, see Isaacs, "Reactive Intermediates in Organic Chemistry," John Wiley & Sons, Inc., New York, 1974; and McManus, "Organic Reactive Intermediates," Academic Press, Inc., New York, 1973.

[2] It was suggested as long ago as 1902 [Gomberg, *Ber.* **35**, 2397 (1902)] that "carbonium ion" is an inappropriate name for these species, since "-onium" usually refers to a covalency higher than that of the neutral atom. Recently the name *carbocation* has been proposed for all ions with a positive charge on a carbon atom. Tricoordinated ions (such as **1**) would be called *carbenium ions* and tetra- and pentacoordinated ions (such as CH_5^+) would be *carbonium ions*, both types being subclasses of carbocations [Olah, *Chem. Technol.* **1**, 566 (1971), *J. Am. Chem. Soc.* **94**, 808 (1972)]. However, the name "carbonium ion" has been used for many years to represent **1**, and we shall continue to use it in this book.

Chem.* **85**, 183–225] (this review has been reprinted as Olah, "Carbocations and Electrophilic Reactions," John Wiley & Sons, Inc., New York, 1974); Buss, Schleyer, and Allen, *Top. Stereochem.* **7**, 253–293 (1973); Olah and Pittman, *Adv. Phys. Org. Chem.* **4**, 305–347 (1966); Deno, *Prog. Phys. Org. Chem.* **2**, 129–193 (1964), *Chem. Eng. News* **42** (40), 88 (Oct. 5, 1964).

Evidence for the existence of carbonium ions is obtained from nmr and other spectra,[5] freezing-point lowering, chemical reactions, and conductivity.[6] The latter method detects only free carbonium ions and not ion pairs.

Among simple alkyl carbonium ions[7] the order of stability is tertiary > secondary > primary. Many examples are known of rearrangements of primary or secondary systems to tertiary. Since simple alkyl carbonium ions are not stable in ordinary strong-acid solutions, e.g., H_2SO_4, the study of these species was greatly facilitated by the discovery that many of them could be kept indefinitely in stable solutions in mixtures of fluorosulfonic acid and antimony pentafluoride. Such mixtures, usually dissolved in SO_2 or SO_2ClF, are among the strongest acidic solutions known and are often called *super acids*. The original experiments involved the addition of alkyl fluorides to SbF_5.[8] Subsequently it was found that the same cations could also be generated from alcohols

$$\mathbf{RF + SbF_5 \longrightarrow R^+ \quad SbF_6^-}$$

by solution in super acid–SO_2 at −60°C[9] and from alkenes by the addition of a proton from super acid or HF–SbF_5 in SO_2 or SO_2ClF at low temperatures.[10] Even alkanes give carbonium ions in super acid by loss of H^-. For example,[11] isobutane gives the *t*-butyl cation[12]

$$\mathbf{Me_3CH \xrightarrow{FSO_3H-SbF_5} Me_3C^+ \quad SbF_5FSO_3^- + H_2}$$

No matter how they are generated, study of the simple alkyl cations has provided dramatic evidence for the stability order. Both propyl fluorides gave isopropyl cation; all four butyl fluorides[13] gave *t*-butyl cation, and all seven of the pentyl fluorides which were tried gave *t*-pentyl cation. *n*-Butane, in super acid, gave only *t*-butyl cation, formed by rearrangement of the initially produced *n*-butyl cation. To date no primary cation has survived long enough for detection. Neither methyl nor ethyl fluoride gave the corresponding cations when treated with SbF_5. At low temperatures, methyl fluoride gave only an SbF_5–FMe complex,[14] while ethyl fluoride rapidly formed *t*-butyl and *t*-hexyl cations by addition of the initially formed ethyl cation to ethylene molecules also formed.[15] At room temperature, methyl fluoride also gave *t*-butyl cation.[16] In accord with the stability order, hydride ion is abstracted from alkanes by super acid most readily from tertiary and least readily from primary positions.

[12] We adopt the nomenclature of Deno (Ref. 3). "*t*-Butyl carbonium ion" is ambiguous, since it could mean either Me_3C^+ or $Me_3CCH_2^+$.

[13] The *sec*-butyl cation has been prepared by slow addition of *sec*-butyl chloride to SbF_5–SO_2ClF solution at −110 C [Saunders, Hagen, and Rosenfeld, *J. Am. Chem. Soc.* **90**, 6882 (1968)] and by allowing molecular beams of the reagents to impinge on a very cold surface [Saunders, Cox, and Ohlmstead, *J. Am. Chem. Soc.* **95**, 3018 (1973)].

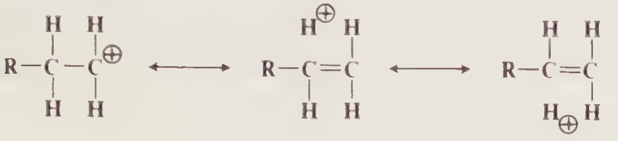
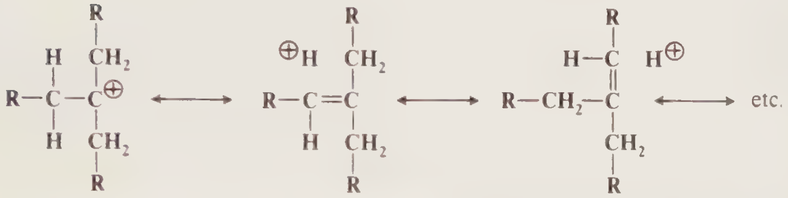
[15] Olah and Olah, Ref. 7, p. 722.

[16] Olah, DeMember, and Schlosberg, Ref. 14.

The stability order can be explained by hyperconjugation and by the field effect. If we compare a primary carbonium ion with a tertiary, it is seen that many more canonical forms are possible for the latter:



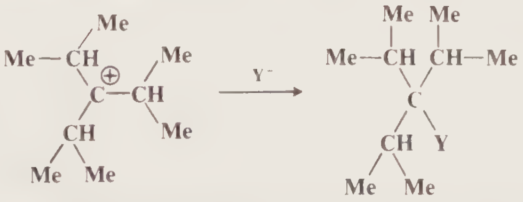


In the examples shown the primary ion has only two hyperconjugative forms while the tertiary has six. According to rule 6 (p. 37), the more equivalent forms, the more resonance stability. Muller and Mulliken have calculated resonance (hyperconjugation) energies for aliphatic carbonium ions:[17]

$CH_3CH_2^{\oplus}$	36 kcal/mol
$(CH_3)_2CH^{\oplus}$	66 kcal/mol
$(CH_3)_3C^{\oplus}$	84 kcal/mol

The field effect explanation is that the electron-donating effect of alkyl groups increases the electron density at the charge-bearing carbon, reducing the net charge on the carbon and in effect spreading the charge over the α-carbons. It is a general rule that the more concentrated any charge is, the less stable the species bearing it will be.

Another factor responsible for the greater stability of tertiary carbonium ions is B strain (see p. 249), although this becomes important only when large groups are present on the central carbon. For example, the bond angles at the central carbon of the triisopropylmethyl cation are 120°, but if a fourth group came in, the three isopropyl groups would have to crowd in together to allow the central carbon to attain the tetrahedral angle, causing the compression from nonbonded interactions known as B strain.

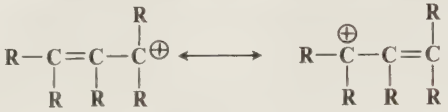


The most stable of all simple alkyl carbonium ions is the *t*-butyl cation. Even the relatively stable *t*-pentyl and *t*-hexyl cations fragment at higher temperatures to produce the *t*-butyl cation, as do all other alkyl cations with four or more carbons so far studied.[18] Methane,[19] ethane, and propane, treated with super acid, also yield *t*-butyl cations as the main product (see reaction **2-16**). Even paraffin wax and polyethylene gave *t*-butyl cation. Solid salts of *t*-butyl and *t*-pentyl cations, e.g., $Me_3C^+SbF_6^-$, have been prepared from super-acid solutions and are stable below −20°C.[20]

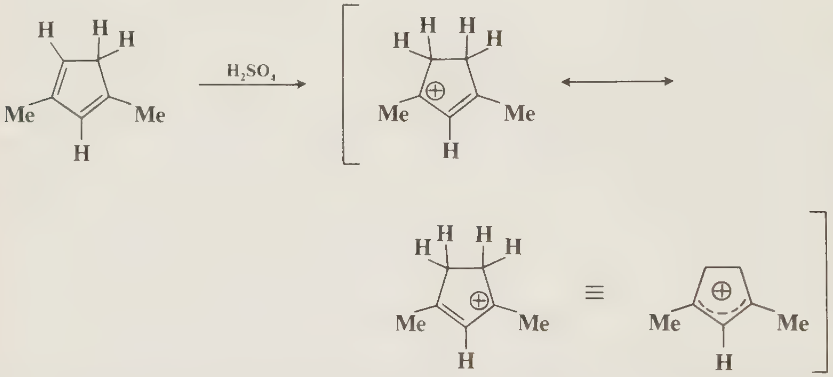
---

[17] Muller and Mulliken, *J. Am. Chem. Soc.* **80**, 3489 (1958).

Where the positive carbon is in conjugation with a double bond the stability is greater because of increased delocalization due to resonance and because the positive charge is spread over two atoms instead of being concentrated on one (see the molecular-orbital picture of this species on p. 34). Each of the two atoms has a charge of about $\frac{1}{2}$ (the charge is exactly $\frac{1}{2}$ if all of the R groups are the same). Stable allylic-type cations[21] have been prepared by the solution of conjugated dienes in concentrated sulfuric acid, e.g.,[22]



$$\mathrm{R{-}\underset{R}{C}{=}\underset{R}{C}{-}\underset{R}{\overset{R}{C}}{}^{\oplus}} \longleftrightarrow \mathrm{R{-}\underset{R}{\overset{\oplus}{C}}{-}\underset{R}{C}{=}\underset{R}{\overset{R}{C}}}$$



The nmr spectrum of this ion demonstrates that the two canonical forms indeed contribute equally. There are only three peaks, one due to the six methyl hydrogens, one to the four methylene hydrogens, and one to the single C—H hydrogen, and the area ratios are 6 : 4 : 1, as expected.[22] Both cyclic and acyclic allylic cations have been produced in this way. Stable allylic cations have also been obtained by the reaction between alkyl halides, alcohols, or olefins (by hydride extraction) and SbF_5 in SO_2 or SO_2ClF.[23] Divinylmethyl cations[24] are more stable than the simple allylic type, and some of these have been prepared in concentrated sulfuric acid.[25] However, many open-chain examples cyclize to the more stable cyclic allylic type.[24] Open-chain trivinylmethyl

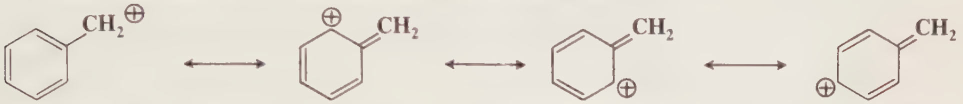
cations are stable at low temperatures (−55°C) in fluorosulfonic acid but cyclize at room temperature in this solvent or in H_2SO_4.[26] Propargyl cations ($RC{\equiv}CCR_2^+$) have also been prepared.[27]

Similar canonical forms can be drawn for benzylic cations,[28] e.g.,



A number of benzylic cations have been obtained in solution as the SbF_6^- salts.[29] Diphenylmethyl and triphenylmethyl cations are still more stable. Triphenylchloromethane ionizes in polar solvents which do not, like water, react with the ion. In SO_2, the equilibrium

$$Ph_3CCl \rightleftharpoons Ph_3C^+ + Cl^-$$

has been known for many years. Both triphenylmethyl and diphenylmethyl cations have been isolated as solid salts.[30] Arylmethyl cations are further stabilized if they have electron-donating substituents in ortho or para positions.[31]

Cyclopropylmethyl cations[32] are even more stable than the benzyl type. **8** has been prepared by solution of the corresponding alcohol in 96% sulfuric acid,[33] and **6**, **7** and similar ions by solution of the alcohols in FSO_3H–SO_2–SbF_5.[34] This special stability, which increases with each additional cyclopropyl group, is a result of conjugation between the bent orbitals of the cyclopropyl rings (p. 141) and the vacant *p* orbital of the carbonium-ion carbon. Nmr and other studies have shown that the vacant *p* orbital lies parallel to the C-2,C-3 bond of the cyclopropane ring and not perpendicular to it.[35] In this respect the geometry is similar to that of a cyclopropane

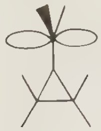
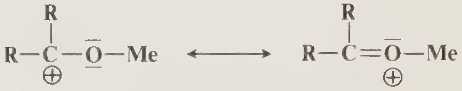
[35] For example, see Ree and Martin, *J. Am. Chem. Soc.* **92**, 1660 (1970); Kabakoff and Namanworth, *J. Am. Chem. Soc.* **92**, 3234 (1970); Buss, Gleiter, and Schleyer, *J. Am. Chem. Soc.* **93**, 3927 (1971); Poulter and Spillner, *J. Am. Chem. Soc.* **96**, 7591 (1974); and Ref. 33.



ring conjugated with a double bond (p. 142). Stable cations have also been obtained (at −50°C) where the central carbon is conjugated with both a cyclopropyl group and a double bond.[36] Cyclopropylmethyl cations are further discussed on pp. 298–300. The stabilizing effect just discussed is unique to cyclopropyl groups. Cyclobutyl and larger cyclic groups are about as effective at stabilizing a carbonium ion as ordinary alkyl groups.[37]

Another structural feature which increases carbonium-ion stability is the presence, adjacent to the cationic center, of a hetero atom bearing an unshared pair, e.g., oxygen, nitrogen,[38] or halogen.[39] Such ions are stabilized by resonance:



$$\mathrm{R-\underset{\oplus}{\overset{R}{C}}-\overline{\underline{O}}-Me \longleftrightarrow R-\overset{R}{C}=\underset{\oplus}{\overline{O}}-Me}$$

The methoxymethyl cation can be obtained as a stable solid, $\mathrm{MeOCH_2^+}$ $\mathrm{SbF_6^-}$.[40] Simple acyl cations, $\mathrm{RCO^+}$, have been prepared[41] in solution and in the solid state.[42] The 2,4,6-trimethylbenzoyl and 2,3,4,5,6-pentamethylbenzoyl cations are especially stable (for steric reasons) and are easily formed in 96% H_2SO_4.[43] These ions are stabilized by a canonical form containing a triple bond (**10**), though the positive charge is principally located on the carbon,[44] so that **9** contributes more than **10**.

$$\mathrm{R-\underset{\oplus}{C}=\overline{\underline{O}} \longleftrightarrow R-C\equiv\overline{O}^{\oplus}}$$

9 **10**

The stabilities of most other stable carbonium ions may also be attributed to resonance. Among these are the tropylium, cyclopropenium, and other aromatic cations discussed in Chapter 2. Where resonance stability is completely lacking, as in the phenyl or vinyl cations, the ion is usually very short-lived. Neither vinyl[45] nor phenyl cation has as yet been prepared as a stable species in solution.[46] Vinyl cations are probably more stable than the corresponding primary alkyl cations but less stable than the corresponding secondary alkyl cations.[47]

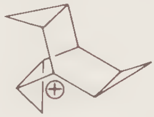
$$\mathrm{RCH_2^{\oplus}} \;<\; \mathrm{R\overset{\oplus}{C}{=}CH_2} \;<\; \mathrm{R\overset{\oplus}{C}H{-}CH_3}$$

Various quantitative methods have been developed to express the relative stabilities of carbonium ions.[48] One of the most common of these, though useful only for relatively stable cations which are formed by ionization of alcohols in acidic solutions, is based on the equation[49]

$$H_{\mathrm{R}} = \mathrm{p}K_{\mathrm{R}^+} - \log \frac{C_{\mathrm{R}^+}}{C_{\mathrm{ROH}}}$$

$\mathrm{p}K_{\mathrm{R}^+}$ is the pK for the reaction $\mathrm{R^+ + 2H_2O \rightleftharpoons ROH + H_3O^+}$ and is a measure of the stability of the carbonium ion. H_{R} (formerly called C_0 and J_0) is an easily obtainable measurement of the acidity of a solvent (see p. 234) and approaches pH at low concentrations of acid. In order to obtain $\mathrm{p}K_{\mathrm{R}^+}$ for a carbonium ion R^+, one dissolves the alcohol ROH in an acidic solution of known H_{R}. Then the concentrations of R^+ and ROH are obtained, generally from electronic spectra, and $\mathrm{p}K_{\mathrm{R}}$ can easily be calculated. Another quantitative method is based on nmr measurements.[50]

Since the central carbon of carbonium ions has only three bonds, and no other valence electrons, the bonds are sp^2 and should be planar.[51] Raman, ir, and nmr spectroscopic data on simple alkyl cations show this to be so.[52] Other evidence is that carbonium ions are difficult or impossible to form at bridgeheads,[53] where they cannot be planar (see p. 272). However, the adamantyl cation has been prepared, as the $\mathrm{SF_6^-}$ salt.[54] This represents an unusual type of bridgehead carbonium ion, and it may be planar or near-planar even though the positive charge is at a bridgehead. Another bridgehead carbonium ion which has been prepared in super-acid solution at -78°C is the 1-trishomobarrelyl cation (**11**).[55] In this case the instability



11

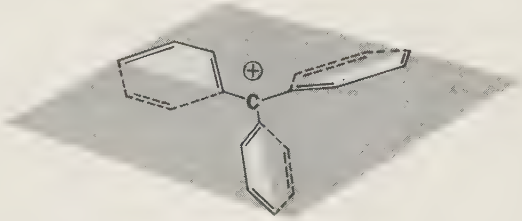
TABLE 1 ^{13}C Chemical-shift values, in parts per million from $^{13}CS_2$, for some carbonium ions in $SO_2ClF-SbF_5$, $SO_2-FSO_3H-SbF_5$, or SO_2-SbF_5[57]

Ion	Chemical shift	Temp., °C	Ion	Chemical shift	Temp., °C
Et_2MeC^+	−139.4	−20	$C(OH)_3^+$	+28.0	−50
Me_2EtC^+	−139.2	−60	$PhMe_2C^+$	−61.1	−60
Me_3C^+	−135.4	−20	$PhMeCH^+$	−40[58]	
Me_2CH^+	−125.0	−20	Ph_2CH^+	−5.6	−60
Me_2COH^+	−55.7	−50	Ph_3C^+	−18.1	−60
$MeC(OH)_2^+$	−1.6	−30	Me_2(cyclopropyl)C^+	−86.8	−60
$HC(OH)_2^+$	+17.0	−30			

of the bridgehead position is balanced by the extra stability gained from the conjugation with the three cyclopropyl groups.

Triarylmethyl cations are propeller-shaped, though the central carbon and the three ring carbons connected to it are in a plane.[55a]



The three benzene rings cannot be all in the same plane because of steric hindrance, though increased resonance energy would be gained if they could.

An important tool for the investigation of carbonium-ion structure is measurement of the ^{13}C nmr chemical shift of the carbon atom bearing the positive charge.[56] This shift approximately correlates with electron density on the carbon (p. 19). ^{13}C chemical shifts for a number of ions are given in Table 1.[57] As shown in the table, the substitution of an ethyl for a methyl or of a methyl for a hydrogen causes a downfield shift, indicating that the central carbon becomes somewhat more positive. On the other hand, the presence of hydroxy or phenyl groups decreases the positive character of the central carbon. The ^{13}C chemical shifts are not always in exact order of carbonium-ion stabilities as determined in other ways. Thus the chemical shift shows that the triphenylmethyl cation has a more positive central carbon than diphenylmethyl cation, though the former is more stable. Also, the 2-cyclopropylpropyl and 2-phenylpropyl cations have shifts of −86.8 and −61.1, respectively, though we have seen that according to other criteria a cyclopropyl group is better than a phenyl group at stabilizing a carbonium ion.[59] The reasons for this discrepancy are not fully understood.[56, 59]

Nonclassical Carbonium Ions

These are discussed at pp. 284–302.

The Generation and Fate of Carbonium Ions

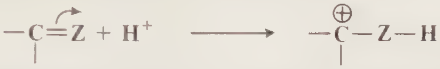
Carbonium ions, stable or unstable, are usually generated in one of two general ways:

1. A direct ionization, in which a group attached to a carbon atom leaves with its pair of electrons (see Chapters 10, 13, 17, 18):

$$R{-}X \longrightarrow R^+ + X^-$$

(may be reversible)

2. A proton or other positive species adds to one atom of an unsaturated system, leaving the adjacent carbon atom with a positive charge (see Chapters 11, 15, 16):



$$-\underset{|}{C}{=}Z + H^+ \longrightarrow -\overset{\oplus}{\underset{|}{C}}{-}Z{-}H$$

Formed by either process, carbonium ions are most often short-lived transient species and react further without being isolated. There are several ways in which a carbonium ion may react, some of them giving stable products and others leading to different carbonium ions, which themselves must react further to give stable products.

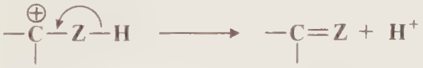
The two chief pathways by which carbonium ions react to give stable products are the reverse of the two pathways just described.

1. The carbonium ion may combine with a species possessing an electron pair (a Lewis acid-base reaction, see Chapter 8):

$$R^+ + Y^- \longrightarrow R{-}Y$$

This species may be H$^-$, OH$^-$, halide ion, or any other negative ion; or it may be a neutral species with a pair to donate, in which case, of course, the immediate product must bear a positive charge (see Chapters 10, 13, 15, 16).

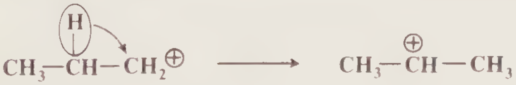
2. The carbonium ion may lose a proton (or much less often, another positive ion) from the adjacent atom (see Chapters 11, 17):



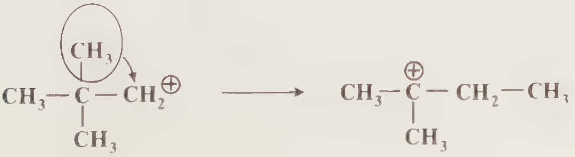
$$-\overset{\oplus}{\underset{|}{C}}{-}Z{-}H \longrightarrow -\underset{|}{C}{=}Z + H^+$$

Two pathways which lead to other carbonium ions are:

3. *Rearrangement.* An alkyl or aryl group or a hydrogen (sometimes another group) migrates with its electron pair to the positive center, leaving another positive charge behind (see Chapter 18):

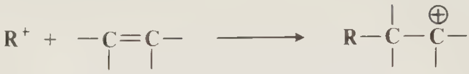


$$CH_3{-}\overset{H}{\overset{|}{C}}H{-}CH_2^{\oplus} \longrightarrow CH_3{-}\overset{\oplus}{C}H{-}CH_3$$



$$CH_3{-}\overset{CH_3}{\overset{|}{\underset{\underset{CH_3}{|}}{C}}}{-}CH_2^{\oplus} \longrightarrow CH_3{-}\overset{\oplus}{\underset{\underset{CH_3}{|}}{C}}{-}CH_2{-}CH_3$$

4. *Addition.* A carbonium ion may add to a double bond, generating a positive charge at a new position (see Chapters 11, 15):



$$R^+ + -\underset{|}{C}=\underset{|}{C}- \longrightarrow R-\overset{|}{\underset{|}{C}}-\overset{\oplus}{\underset{|}{C}}-$$

12

Whether formed by pathway 3 or 4, the new carbonium ion normally reacts further in an effort to stabilize itself, usually by pathway 1 or 2. However, **12** may add to another olefin molecule, and this product may add to still another, etc. This is one of the mechanisms for vinyl polymerization.

CARBANIONS

Stability and Structure[60]

There are many compounds known with a bond between carbon and a metal. Many carbon-metal bonds, e.g., carbon-mercury bonds, are undoubtedly covalent, but in bonds between carbon and the more active metals the electrons are closer to the carbon. Whether the position of the electrons in a given bond is close enough to the carbon to justify calling the bond ionic and the carbon moiety a carbanion depends on the metal, on the structure of the carbon moiety, and on the solvent and in many cases is a matter of speculation. In this section we shall discuss carbanions with little reference to the metal. In the next section we shall deal with the structures of organometallic compounds.

By definition, every carbanion possesses an unshared pair of electrons and is therefore a base. When it accepts a proton, it is converted into its conjugate acid (see Chapter 8). The stability of the carbanion is directly related to the strength of the conjugate acid. The weaker the acid, the greater the base strength and the lower the stability of the carbanion.[61] By stability here we mean stability toward a proton donor: the lower the stability, the more eager the carbanion is to accept a proton from any available source and hence to end its existence as a carbanion. Thus the determination of the order of stability of a series of carbanions is equivalent to a determination of the order of strengths of the conjugate acids, and one can obtain information about relative carbanion stability from a table of acid strengths like Table 1 in Chapter 8.

Unfortunately, it is not easy to measure acid strengths of very weak acids like the conjugate acids of simple unsubstituted carbanions. There is little doubt that these carbanions are very unstable in solution, and in contrast to the situation with carbonium ions, efforts to prepare solutions in which carbanions such as ethyl or isopropyl exist in a relatively free state have not yet been successful. Nevertheless, there have been several approaches to the problem. Applequist and O'Brien[62] studied the position of equilibrium for the reaction

$$\mathrm{RLi + R'I \rightleftharpoons RI + R'Li}$$

in ether and in ether-pentane. The reasoning in these experiments was that the R group which forms the more stable carbanion would be more likely to be bonded to lithium than to iodide.

[61] For a review of hydrocarbon acidity, see Fischer and Rewicki, *Prog. Org. Chem.* **7**, 116–161 (1968).

[62] Applequist and O'Brien, *J. Am. Chem. Soc.* **85**, 743 (1963).

Carbanion stability was found to be in this order: vinyl > phenyl > cyclopropyl > ethyl > *n*-propyl > isobutyl > neopentyl > cyclobutyl > cyclopentyl. In a somewhat similar approach, Dessy and coworkers[63] treated a number of alkylmagnesium compounds with a number of alkylmercury compounds in tetrahydrofuran, setting up the equilibrium

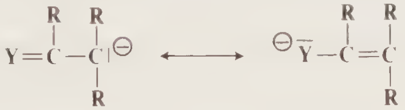
$$R_2Mg + R'_2Hg \rightleftharpoons R_2Hg + R'_2Mg$$

where the group of greater carbanion stability is linked to magnesium. The carbanion stability determined in this way was in the order phenyl > vinyl > cyclopropyl > methyl > ethyl > isopropyl. The two stability orders are in fairly good agreement, and they show that stability of simple carbanions decreases in the order methyl > primary > secondary. It was not possible by the experiments of Dessy and coworkers to determine the position of *t*-butyl, but there seems little doubt that it is still less stable. We can interpret this stability order solely as a consequence of the field effect since resonance is absent. The electron-donating alkyl groups of isopropyl result in a greater negative charge density at the central carbon atom (compared with methyl), thus decreasing its stability. The results of Applequist and O'Brien show that β branching also decreases carbanion stability. Cyclopropyl occupies an apparently anomalous position, but this is probably due to the large amount of *s* character in the carbanionic carbon (see p. 163).

A different approach to the problem of hydrocarbon acidity and hence carbanion stability was that of Shatenshtein and coworkers, who treated hydrocarbons with deuterated potassium amide and measured the rates of hydrogen exchange.[64] The experiments did not measure *thermodynamic* acidity, since rates were measured and not positions of equilibria. They measured *kinetic* acidity, i.e., which compounds gave up protons most rapidly (see p. 194 for the distinction between thermodynamic and kinetic control of product). Measurements of rates of hydrogen exchange enable one to compare acidities of a series of acids against a given base even where the positions of the equilibria cannot be measured because they lie too far to the side of the starting materials, i.e., where the acids are too weak to be converted to their conjugate bases in measurable amounts. Although the correlation between thermodynamic and kinetic acidity is far from perfect,[64a] the results of the rate measurements, too, indicated that the order of carbanion stability is methyl > primary > secondary > tertiary.[64]

Many carbanions are far more stable than the simple kind mentioned above. The increased stability is due to certain structural features:

1. *Conjugation of the unshared pair with an unsaturated bond:*



$$Y{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{}^{\ominus} \longleftrightarrow {}^{\ominus}\bar{Y}{-}\overset{R}{C}{=}\underset{R}{\overset{R}{C}}$$

In cases where a double or triple bond is located α to the carbanionic carbon, the ion is stabilized by resonance in which the unshared pair overlaps with the π electrons of the double bond. This factor is responsible for the stability of the allylic[65] and benzylic[66] types of carbanions:

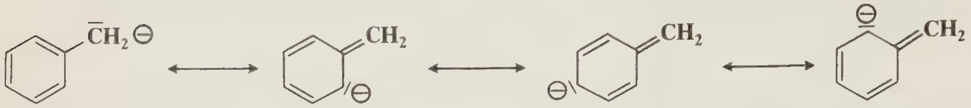
[64] For reviews, see Jones, *Surv. Prog. Chem.* **6**, 83–112 (1973); Shatenshtein and Shapiro, *Russ. Chem. Rev.* **37**, 845–854 (1968); and Shatenshtein, *Adv. Phys. Org. Chem.* **1**, 153–201 (1963).

[64a] For example, see Bordwell, Matthews, and Vanier, *J. Am. Chem. Soc.* **97**, 442 (1975).

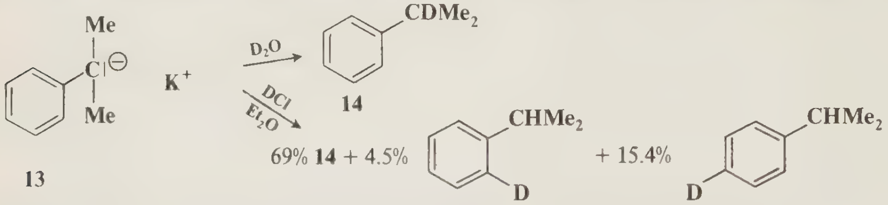
[65] For a review of allylic anions, see Richey, Ref. 21, pp. 67–77.

[66] Although benzylic carbanions are more stable than the simple alkyl type, they have so far not proved stable enough for isolation. The benzyl carbanion has been formed and studied in submicrosecond times: Bockrath and Dorfman, *J. Am. Chem. Soc.* **96**, 5708 (1974).

$$R{-}CH{=}CH{-}\bar{C}H_2^{\ominus} \longleftrightarrow R{-}\overset{\ominus}{\bar{C}}H{-}CH{=}CH_2$$



There is direct evidence for resonance in benzylic systems. When **13** was treated with D_2O, only **14** was obtained, but with DCl in ether, about 20% of the product contained deuterium in the ring.[67] Under these conditions, cumene itself did not exchange with deuterium. Diphenylmethyl and triphenylmethyl anions are still more stable and can be kept in solution indefinitely if water is rigidly excluded. Even more stable yet are completely chlorinated triphenylmethyl anions. The salt tetraethylammonium perchlorotriphenylmethide is so stable that it can be obtained in the solid form and does not react with water or ethanol, though it does take a proton from dilute HCl.[68] When a CH_2 group is α to both a double and a triple bond, it can lose two protons to a strong base to give the dicarbanion **15**, where both negative charges are formally on the same carbon.[69]



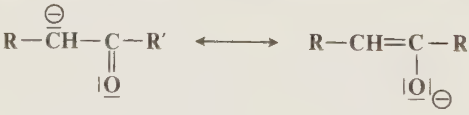
13

14

$$RC{\equiv}C{-}CH_2{-}CR{=}CR_2 \xrightarrow{2\,BuLi} RC{\equiv}C{-}\overset{\ominus}{\underline{\bar{C}}}{-}CR{=}CR_2$$

15

Where the carbanionic carbon is conjugated with a carbon-oxygen or carbon-nitrogen multiple bond (Y = O or N), stability of the ion is greater than that of unchlorinated triarylmethyl anions, since these electronegative atoms are better capable than carbon of bearing a negative charge. However, it is questionable whether ions of this type should be called carbanions at all, since in the case of enolate ions, for example, **17** contributes more to the hybrid than **16**, although



16 17

such ions more often react at the carbon than at the oxygen. Enolate ions can also be kept in stable solutions. A nitro group is particularly effective in stabilizing a negative charge on an

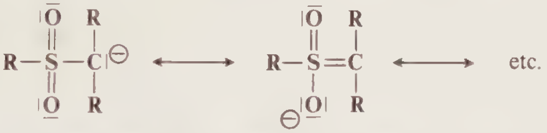
adjacent carbon, and the anions of simple nitro alkanes can exist in water. Thus pK_a for nitromethane is 10.2, which means that at a pH of 10.2 an aqueous solution of nitromethane contains equal amounts of nitromethane and its conjugate base, and at higher pH values there is even more of the carbanion. Dinitromethane is even more acidic ($pK = 3.6$).

In contrast to the stability of cyclopropylmethyl cations (p. 155), the cyclopropyl group exerts only a weak stabilizing effect on an adjacent carbanionic carbon.[70]

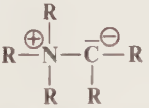
2. *Carbanions increase in stability with an increase in the amount of s character at the carbanionic carbon.* Thus the order of stability is $RC{\equiv}C^- > R_2C{=}CH^- \approx Ar^- > R_3C{-}CH_2^-$. Acetylene, where the carbon is *sp*-hybridized with 50% *s* character, is much more acidic than ethylene[71] (sp^2, 33% *s*), which in turn is more acidic than ethane, with 25% *s* character. Increased *s* character means that the electrons are closer to the nucleus and hence of lower energy. As previously mentioned, cyclopropyl carbanions are more stable than methyl, owing to the larger amount of *s* character as a result of strain (see p. 141).

3. *Stabilization by sulfur or phosphorus.* Attachment to the carbanionic carbon of a sulfur or phosphorus atom causes an increase in carbanion stability, although the reasons for this are in dispute. One theory is that there is overlap of the unshared pair with an empty *d* orbital[72] ($p\pi$-$d\pi$ bonding, see p. 39). For example, a carbanion containing the SO_2R group would be written



Evidence that this type of conjugation is important in stabilizing such ions comes from a study of H-D exchange rates of Me_4N^+, Me_4P^+, and Me_3S^+.[73] Me_4P^+ exchanged 2.4×10^6 times faster than Me_4N^+. There is no normal conjugation in these ions, and the electron-withdrawing field effect of positive nitrogen is greater than that of positive phosphorus, so that the only factor which could be causing the increased acidity is the presence of unoccupied low-lying *d* orbitals of the phosphorus. An even greater rate ratio ($2.0 \times 10^7 : 1$) was found for Me_3S^+ compared with Me_4N^+. However, there is evidence against *d*-orbital overlap in these cases, and the stabilizing effects have been attributed to other causes.[74]

4. *Field effects.* Most of the groups which stabilize carbanions by resonance effects (either the kind discussed in paragraph 1 above or the kind discussed in paragraph 3) have electron-withdrawing field effects and thereby stabilize the carbanion further by spreading the negative charge, though it is difficult to separate the field effect from the resonance effect. However, in a nitrogen ylide (see p. 40), where a positive nitrogen is adjacent to the carbanionic carbon, only the field effect is operating:



$$R_3\overset{\oplus}{N}-\overset{\ominus}{C}R_3$$

Ylides are more stable than the corresponding simple carbanions.

5. Certain carbanions are stable because they are aromatic (see the cyclopentadienyl anion p. 46, and other aromatic anions in Chapter 2).

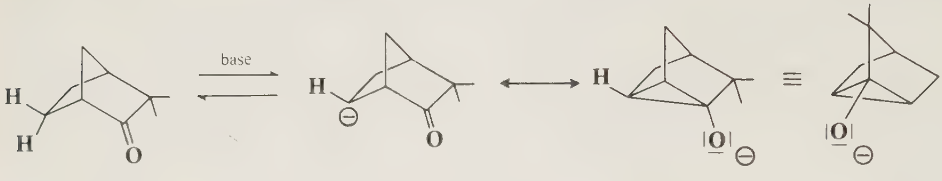
[74] Bernardi, Csizmadia, Mangini, Schlegel, Whangbo, and Wolfe, *J. Am. Chem. Soc.* **97**, 2209 (1975).

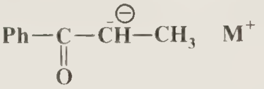
6. *Stabilization by a nonadjacent π bond.*[75] In contrast to the situation with carbonium ions (see pp. 284–302), there have only been a few reports of a carbanion stabilized by interaction with a nonadjacent π bond. One that may be mentioned is **20**, formed when optically active camphenilone (**18**) was treated with a strong base (potassium *t*-butoxide).[76] That **20** was truly formed was shown by the following facts: (1) A proton was abstracted; ordinary CH_2 groups are not acidic enough for this base; (2) recovered **18** was racemized: **20** is symmetrical and can be attacked equally well from either side; (3) when the experiment was performed in deuterated solvent, the rate of deuterium uptake was equal to the rate of racemization; and (4) recovered **18** contained up to three atoms of deuterium per molecule, though if **19** were the only ion, no more than two could be taken up.



18 **19** **20**

Overall, functional groups in the α position stabilize carbanions in the following order: $NO_2 > RCO > SO_2 > COOR > CN \approx CONH_2 > Hal > H > R$.

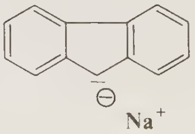
It is unlikely that free carbanions exist in solution. Like carbonium ions, they are usually in ion pairs[4] or else solvated.[77] Among experiments which demonstrated this was the treatment of **21** with ethyl iodide, where M was lithium, sodium, or potassium. The half-lives of the reaction



$$Ph{-}\underset{\underset{O}{\|}}{C}{-}\overset{\ominus}{C}H{-}CH_3 \quad M^+$$

21

were[78] for Li, 31×10^{-6}; Na, 0.39×10^{-6}; and K, 0.0045×10^{-6}, demonstrating that the species involved were not identical. Hogen-Esch and Smid have shown that sodium fluorenide



exists in tetrahydrofuran at room temperature as an intimate ion pair, but at 80°C as a solvent-separated ion pair; i.e., molecules of solvent are between the two ions.[79] This was shown by a study of the change in the visible and uv spectrum of the solution on going from 25 to −80°C: a peak at 355 nm disappears, while new peaks appear at 373 and 521 nm. The species are therefore different, but neither is the free carbanion since neither solution showed appreciable conductivity. Where ion pairs are unimportant, carbanions are solvated. Cram[60] has demonstrated solvation of carbanions in many solvents.

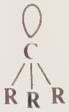
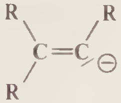
The structure of simple unsubstituted carbanions is not known with certainty since they have not been isolated, but it seems likely that the central carbon is sp^3-hybridized, with the unshared pair occupying one apex of the tetrahedron. Carbanions would thus have pyramidal structures, similar to those of amines:



If this structure is correct, and if the three R groups are different, the carbanion should be asymmetric (see Chapter 4) and reactions in which it is an intermediate should give retention of configuration. Attempts have been made to demonstrate this but without success.[80] A possible explanation is that the umbrella effect exists here, as in amines, so that the unshared pair and the central carbon rapidly oscillate from one side of the plane to the other. There is, though, other evidence for the sp^3 nature of the central carbon and for its tetrahedral structure. Carbons at bridgeheads, though extremely reluctant to undergo reactions in which they must be converted to carbonium ions, undergo with ease reactions in which they must be carbanions, and stable bridgehead carbanions are known.[81] Also, reactions at vinyl carbons proceed with retention,[82] indicating that the intermediate **22** has sp^2 hybridization and not the sp hybridization which



22

23

would be expected in the analogous carbonium ion. There is evidence that a cyclopropyl anion (**23**) can also hold its configuration.[83]

Carbanions in which the negative charge is stabilized by resonance involving overlap of the unshared-pair orbital with the π electrons of a multiple bond are essentially planar, as would be expected by the necessity for planarity in resonance, though unsymmetrical solvation or ion-pairing effects may cause the structure to deviate somewhat from true planarity.[84] Cram and coworkers have shown that where asymmetric carbanions possessing this type of resonance are generated, retention, inversion, or racemization can result depending on the solvent (see p. 526).

---

[80] Retention of configuration has never been observed with simple carbanions. Cram has obtained retention with carbanions stabilized by resonance. However, these carbanions are known to be planar or nearly planar, and retention was caused by asymmetric solvation of the planar carbanions (see p. 526).

[81] For other evidence that carbanions are pyramidal, see Streitwieser and Young, *J. Am. Chem. Soc.* **91**, 529 (1969).

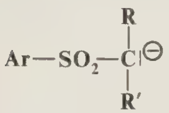
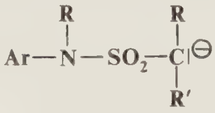
[84] See the discussion in Cram, "Fundamentals of Carbanion Chemistry," pp. 85–105, Academic Press, Inc., New York, 1965.

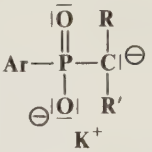
This result is explained by unsymmetrical solvation of planar or near-planar carbanions. However, some carbanions which are stabilized by *d*-orbital overlap, e.g.,



$\text{Ar}-\text{SO}_2-\overset{\text{R}}{\underset{\text{R}'}{\text{C}}}|^{\ominus}$



$\text{Ar}-\overset{\text{R}}{\text{N}}-\text{SO}_2-\overset{\text{R}}{\underset{\text{R}'}{\text{C}}}|^{\ominus}$



$\text{Ar}-\overset{|\overline{\text{O}}}{\underset{^{\ominus}|\underline{\text{O}}|}{\text{P}}}-\overset{\text{R}}{\underset{\text{R}'}{\text{C}}}|^{\ominus}\quad \text{K}^+$

are inherently asymmetric, since retention of configuration is observed where they are generated, even in solvents which cause racemization or inversion with other carbanions.[85] There has been a controversy over whether this inherent asymmetry is the result of a pyramidal structure which does not invert or of a structure which is planar at the carbanionic carbon but is asymmetric because rotation about the C—S bond is hindered. The question is not yet settled.[86]

The Structure of Organometallic Compounds[87]

Whether the carbon-metal bond is ionic or polar-covalent is determined chiefly by the electronegativity of the metal and the structure of the organic part of the molecule. Ionic bonds become more likely as the negative charge on the metal-bearing carbon is decreased by resonance or field effects. Thus the sodium salt of acetoacetic ester has a more ionic carbon-sodium bond than methylsodium does.

Most organometallic bonds are polar-covalent. Only the alkali metals have electronegativities low enough to form ionic bonds with carbon, and even here the behavior of lithium alkyls is more covalent than ionic. The simple alkyls and aryls of sodium, potassium,[88] rubidium, and cesium are nonvolatile solids insoluble in benzene or other organic solvents, while alkyllithiums are soluble, though they too are generally nonvolatile solids. Alkyllithiums do not exist as monomeric species in hydrocarbon solvents or ether.[89] In benzene and cyclohexane, freezing-point-depression studies have shown that alkyllithiums are normally hexameric unless steric interactions favor tetrameric aggregates.[90] Where steric hindrance is great enough, as in menthyllithium, dimeric aggregates are found in hydrocarbon solvents.[91] In such cases the alkyllithium is much more reactive than ordinary alkyllithiums. Boiling-point-elevation studies have been performed in ether solutions, where alkyllithiums exist in two- to fivefold aggregates.[92] The structure of alkyllithium tetramers in ether has been shown by evidence obtained from ^{13}C–^{7}Li nmr coupling to be tetrahedral, with the four lithium atoms at the corners of a tetrahedron and one alkyl group directly over the center of each face of the tetrahedron.[93] Even in the gas phase[94] and in the solid state,[95] alkyllithiums exist as aggregates. X-ray crystallography has shown that methyllithium has the same tetrahedral structure in the solid state as in ether solution.[95]

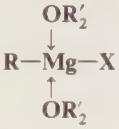
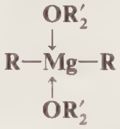
It is fairly certain that the C—Mg bond in Grignard reagents is covalent and not ionic. Thus, organolithiums, organomagnesiums, and Grignard reagents have virtually identical nmr spectra when the alkyl group is the same.[96] The actual structure of Grignard reagents in solution has been a matter of much controversy over the years.[97] In 1929 it was discovered[98] that the addition of dioxane to an ethereal Grignard solution precipitates all the magnesium halide and leaves a solution of R_2Mg in ether; i.e., there can be no RMgX in the solution since there is no halide. The following equilibrium, now called the *Schlenk equilibrium*, was proposed as the composition of the Grignard solution:

$$\mathrm{2RMgX} \rightleftharpoons \mathrm{R_2Mg + MgX_2} \rightleftharpoons \underset{\mathbf{24}}{\mathrm{R_2Mg{\cdot}MgX_2}}$$

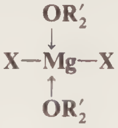
in which **24** is a complex of some type. Much work in recent years has demonstrated that the Schlenk equilibrium actually exists and that the position of the equilibrium is dependent on the identity of R, X, the solvent, the concentration, and the temperature.[99] It has been known for many years that the magnesium in a Grignard solution, no matter whether it is RMgX, R_2Mg, or MgX_2, can coordinate with two molecules of ether in addition to the two covalent bonds:



$$\mathrm{R}-\underset{\underset{\mathrm{OR'_2}}{\uparrow}}{\overset{\overset{\mathrm{OR'_2}}{\downarrow}}{\mathrm{Mg}}}-\mathrm{X}$$

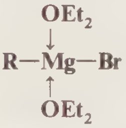


$$\mathrm{R}-\underset{\underset{\mathrm{OR'_2}}{\uparrow}}{\overset{\overset{\mathrm{OR'_2}}{\downarrow}}{\mathrm{Mg}}}-\mathrm{R}$$



$$\mathrm{X}-\underset{\underset{\mathrm{OR'_2}}{\uparrow}}{\overset{\overset{\mathrm{OR'_2}}{\downarrow}}{\mathrm{Mg}}}-\mathrm{X}$$

Rundle and coworkers performed x-ray-diffraction studies on solid phenylmagnesium bromide dietherate and on ethylmagnesium bromide dietherate, which they obtained by cooling ordinary ethereal Grignard solutions until the solids crystallized.[100] They found that the structures were monomeric:



$$\mathrm{R}-\underset{\underset{\mathrm{OEt_2}}{\uparrow}}{\overset{\overset{\mathrm{OEt_2}}{\downarrow}}{\mathrm{Mg}}}-\mathrm{Br} \qquad \mathrm{R} = \text{ethyl, phenyl}$$

A similar result was found by Schröder for phenylmagnesium bromide crystallized from a Grignard solution prepared in tetrahydrofuran.[101] These solids still contained ether or tetrahydrofuran. When ordinary ethereal Grignard solutions prepared from methyl bromide, methyl chloride, ethyl bromide, and ethyl chloride were evaporated at about 100°C under vacuum, so that the solid remaining contained no ether, x-ray diffraction showed *no* RMgX but a mixture of R_2Mg and MgX_2.[102] These results indicate that in the presence of ether $RMgX \cdot 2Et_2O$ is the preferred structure, while the loss of ether drives the Schlenk equilibrium to $R_2Mg + MgX_2$. However, conclusions drawn from a study of the solid materials do not necessarily apply to the structures in solution.

Boiling-point-elevation and freezing-point-depression measurements have demonstrated that in tetrahydrofuran at all concentrations and in ether at low concentrations (up to about 0.1 *M*) Grignard reagents prepared from alkyl bromides and iodides are monomeric; i.e., there are few or no molecules with two magnesium atoms.[103] Thus, part of the Schlenk equilibrium is operating

$$2RMgX \rightleftharpoons R_2Mg + MgX_2$$

but not the other part; i.e, **24** is not present in measurable amounts. That the equilibrium between RMgX and R_2Mg lies far over to the left for "ethylmagnesium bromide" in ether was shown by Smith and Becker, who mixed 0.1 *M* ethereal solutions of Et_2Mg and $MgBr_2$ and found that a reaction occurred with a heat evolution of 3.6 kcal/mol of Et_2Mg, and that the product was *monomeric* (by boiling-point-elevation measurements).[104] When either solution was added little by little to the other, there was a linear output of heat until almost a 1 : 1 molar ratio was reached. Addition of an excess of either reagent gave no further heat output. In tetrahydrofuran also, mixing of solutions of R_2Mg and MgX_2 gave RMgX, though in this case heat was absorbed on mixing because tetrahydrofuran coordinates more strongly with $MgBr_2$ than it does with EtMgBr.[105] These results show that at least under some conditions *the Grignard reagent is largely RMgX* (coordinated with solvent) but that the equilibrium can be driven to R_2Mg by evaporation of all the ether or by addition of dioxane.

For some aryl Grignard reagents it has proved possible to distinguish separate nmr chemical shifts for ArMgX and Ar_2Mg.[106] From the area under the peaks the concentrations of the two species can be calculated and from them, equilibrium constants for the Schlenk equilibrium. These data show[106] that the position of the equilibrium depends very markedly on the aryl group and the solvent but that conventional aryl Grignard reagents in ether are largely ArMgX, while in tetrahydrofuran the predominance of ArMgX is less, and with some aryl groups there is actually more Ar_2Mg present. Separate nmr chemical shifts have also been found for alkyl RMgBr and R_2Mg in hexamethylphosphoric triamide (HMPT)[107] and in ether at low temperatures.[108] When Grignard reagents from alkyl bromides or chlorides are prepared in triethylamine the predominant species is RMgX.[109] Thus the most important factor determining the position of the Schlenk equilibrium is the solvent. For primary alkyl groups the equilibrium constant for the reaction as written above is lowest in Et_3N, higher in ether, and still higher in tetrahydrofuran.[110]

However, Grignard reagents prepared from alkyl bromides or iodides in ether at higher concentrations (0.5 to 1 *M*) contain dimers, trimers, and higher polymers, and those prepared from alkyl chlorides in ether at all concentrations are dimeric,[111] so that **24** is in solution, probably in equilibrium with RMgX and R_2Mg; i.e., the complete Schlenk equilibrium seems to be present. The structure of **24** is probably **25**,[112] though some **26** might also be present. X-ray analysis of

solid EtMgBr coordinated with diisopropyl ether or with triethylamine showed **25** to be the species present.[113] Also, solutions of alkylmagnesium fluorides in ether or tetrahydrofuran are entirely dimeric, because of the unusual stability of the Mg—F—Mg bridgeheads.[114]

The Grignard reagent prepared from 1-chloro-3,3-dimethylpentane in ether undergoes rapid inversion of configuration at the magnesium-containing carbon (demonstrated by nmr; this compound is not chiral).[115] The mechanism of this inversion is not completely known.

It might be mentioned that matters are much simpler for organometallic compounds with less polar bonds. Thus Et_2Hg and EtHgCl are both definite compounds, the former a liquid and the latter a solid.

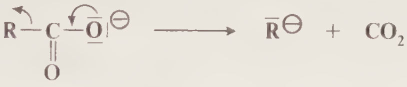
The Generation and Fate of Carbanions

The two principal ways in which carbanions are generated are parallel with the ways of generating carbonium ions.

1. A group attached to a carbon leaves without its electron pair:

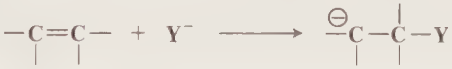
$$R—H \longrightarrow \overline{R}^{\ominus} + H^+$$

The leaving group is most often a proton. This is a simple acid-base reaction, and a base is required to remove the proton. However, other leaving groups are known (see Chapter 12):



$$R—\underset{\underset{O}{\|}}{C}—\overline{\underline{O}}|^{\ominus} \longrightarrow \overline{R}^{\ominus} + CO_2$$

2. A negative ion adds to a carbon-carbon double or triple bond (see Chapter 15):



$$—\underset{|}{C}=\underset{|}{C}— + Y^- \longrightarrow \overset{\ominus}{—}\underset{|}{C}—\overset{|}{\underset{|}{C}}—Y$$

The addition of a negative ion to a carbon-oxygen double bond does not give a carbanion, since the negative charge resides on the oxygen.

The most common reaction of carbanions is combination with a positive species, usually a proton, or with another species which has an empty orbital in its outer shell (a Lewis acid-base reaction):

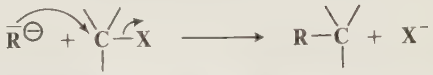
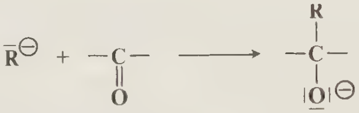
Carbanions may also form a bond with a carbon which already has four bonds, by pushing out one of the four groups (SN2 reaction, see Chapter 10):



Like carbonium ions, carbanions may also react in ways in which they are converted to species which are still not neutral molecules. They may add to double bonds (usually C=O double bonds; see Chapters 10 and 16),



$$\bar{R}^{\ominus} + -\underset{\underset{O}{\|}}{C}- \longrightarrow -\overset{\overset{R}{|}}{\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}}-$$

or rearrange, though this is rare (see Chapter 18),

$$Ph_3C\bar{C}H_2^{\ominus} \longrightarrow Ph_2\overset{\ominus}{\bar{C}}CH_2Ph$$

or be oxidized to free radicals.

Organometallic compounds which are not ionic but polar-covalent behave very much as if they were ionic and give similar reactions.

FREE RADICALS

Stability and Structure[116]

A free radical may be defined as a species which contains one or more unpaired electrons. Note that this definition includes certain stable inorganic molecules such as NO and NO_2, as well as many individual atoms, such as Na and Cl. Associated with the spin of an electron is a magnetic moment, which can be expressed by a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$. According to the Pauli principle, any two electrons occupying the same orbital must have opposite spins, so that the total magnetic moment is zero for any species in which all the electrons are paired. In free radicals, however, one or more electrons are unpaired, so that there is a net magnetic moment and the species is paramagnetic. Free radicals can therefore be detected by magnetic-susceptibility measurements, but for this technique a relatively high concentration of free radicals is required. A much more important technique is *electron spin resonance* (esr), also called *electron paramagnetic resonance* (epr).[117] The principle of esr is similar to that of nmr, except that electron spin is involved rather than nuclear spin. Like protons, electrons have two possible spin states when placed within a strong magnetic field; and as in nmr, a strong external field is applied, and electrons are caused to flip from the lower state to the higher by the application of the appropriate radio-frequency signal. Inasmuch as two electrons paired in one orbital must have opposite spins which cancel, an esr spectrum arises only from species which have one or more unpaired electrons, i.e., free radicals.

Since only free radicals give an esr spectrum, the method can be used to detect the presence of free radicals, and determine their concentration. The method is very sensitive (much more sensitive than nmr), and concentrations as low as 10^{-7} *M* can be detected. Furthermore, information concerning the electron distribution (and hence the structure) of free radicals can be obtained from the splitting pattern of the esr spectrum (esr peaks are split by nearby protons).[118] Fortunately (for the existence of most free radicals is very short), it is not necessary for a radical to have a long lifetime in order for an esr spectrum to be obtained. Esr spectra have been observed for radicals with lifetimes considerably less than 1 sec.[119] Because there is an equal probability that a given unpaired electron will have a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$, free radicals cause two lines to appear on an electronic spectrum, and are often referred to as *doublets*.

As with carbonium ions and carbanions, simple alkyl radicals are very reactive. In solution their lifetimes are extremely short, but they can be kept for relatively long periods frozen within the crystal lattices of other molecules,[120] and many esr and other spectral[121] measurements have been made on radicals trapped in this manner. Even under these conditions the methyl radical decomposes with a half-life of 10 to 15 min in a methanol lattice at 77 K.[122]

Another magnetic technique for the detection of free radicals uses an ordinary nmr instrument. It was discovered[123] that if an nmr spectrum is taken during the course of a reaction, certain signals may be enhanced, either in a positive or negative direction; others may be reduced. When this type of behavior, called *chemically induced dynamic nuclear polarization*[124] (CIDNP), is found in the product of a reaction, it means that *at least a portion of that product was formed via the intermediacy of a free radical*. For example, the question was raised whether free radicals were intermediates in the exchange reaction between ethyl iodide and ethyllithium (reaction **2-38**)

$$\mathbf{EtI + EtLi \rightleftharpoons EtLi + EtI}$$

Curve *a* in Figure 1[125] shows an nmr spectrum taken during the course of the reaction. Curve *b* is a reference spectrum of ethyl iodide (CH_3 protons at $\tau = 8.15$; CH_2 protons at $\tau = 6.8$). Note that in curve *a* some of the ethyl iodide signals are enhanced; others go below the base line (*negative enhancement*; also called *emission*). Thus the ethyl iodide formed in the exchange shows CIDNP and hence was formed via a free-radical intermediate. CIDNP results when protons in a reacting molecule become dynamically coupled to an unpaired electron while traversing the path

The signals at 8.4 to 9.0 τ are due to butane, some of which is also formed in the reaction. (*b*) Reference spectrum of EtI.

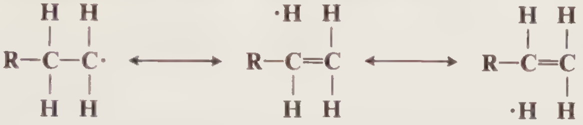
from reactants to products.[126] Although the presence of CIDNP always means that a free radical is involved, its absence does not prove that a free-radical intermediate is necessarily absent, since reactions involving free-radical intermediates can also take place without observable CIDNP. Also, the presence of CIDNP does not prove that *all* of a product was formed via a free-radical intermediate, only that some of it was.

Simple alkyl radicals have also been detected in the gas phase, and indeed this was the first proof of their existence. In a typical experiment tetramethyllead vapor in a stream of inert gas was passed through a glass tube which was heated at one spot. At that spot a lead mirror was deposited, and ethane was found in the condensate. When another organometallic compound, say, trimethylbismuth, was passed through the tube, which was heated at a spot ahead of the lead deposit, a new deposit (of bismuth) appeared at the freshly heated spot and the old mirror disappeared, though neither the carrier gas nor the ethane product could remove the mirror. Although at this point trimethylbismuth was being passed through the tube, tetramethyllead was found in the condensate. The rate of disappearance of the mirror increased with increased distance between the original deposit and the new position of heating. All this and other evidence may be taken as proof of the existence of alkyl radicals,[127] which stabilized themselves by dimerization unless a metallic surface was available for reaction to give an organometallic compound.

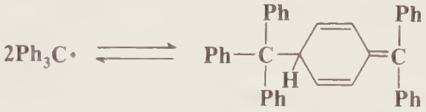
---

[126] Information about the nature of the free radicals involved can also be derived from CIDNP spectra: see Kaptein, *Chem. Commun.* 732 (1971).

As with carbonium ions, the stability order of free radicals is tertiary > secondary > primary, explainable by hyperconjugation, analogous to that in carbonium ions (p. 153):

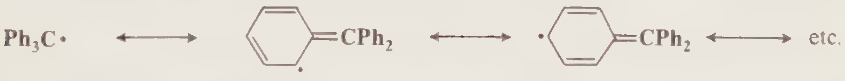


With resonance possibilities, the stability of free radicals increases, and some may be kept indefinitely.[128] Benzylic and allylic radicals for which canonical forms can be drawn similar to those shown for the corresponding cations (pp. 154, 155) and anions (pp. 161, 162) are more stable than simple alkyl radicals but still have only a transient existence. However, the triphenylmethyl and similar radicals[129] are stable enough to exist in solution at room temperature, though in equilibrium with a dimeric form. The concentration of triphenylmethyl radical in benzene solution



27

is about 2% at room temperature. For many years it had been assumed that $Ph_3C\cdot$, the first stable free radical known,[130] dimerized to hexaphenylethane ($Ph_3C{-}CPh_3$), but uv and nmr investigation has shown that the true structure is **27**.[131] Although triphenylmethyl-type radicals are stabilized by resonance:



it is steric hindrance to dimerization and not resonance that is the major cause of their stability. This fact was demonstrated by the preparation of the radicals **28** and **29**.[132] These radicals are electronically very similar, but **28**, being planar, has much less steric hindrance to dimerization than $Ph_3C\cdot$, while **29**, with six groups in ortho positions, has much more. On the other hand, the planarity of **28** means that it has a maximum amount of resonance stabilization, while **29** must

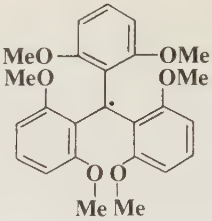
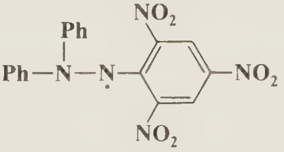
28



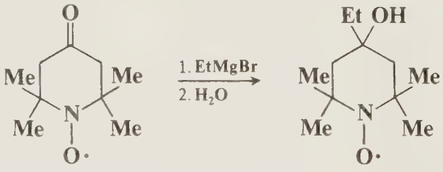
29

have much less, since its degree of planarity should be even less than $Ph_3C\cdot$, which itself is propeller-shaped and not planar. Thus if resonance is the chief cause of the stability of $Ph_3C\cdot$, **29** should dimerize and **28** should not, but if steric hindrance is the major cause, the reverse should happen. In the event, it was found[132] that **29** gave no evidence of dimerization, even in the solid state, while **28** existed primarily in the dimeric form, which is dissociated to only a small extent in solution,[133] indicating that steric hindrance to dimerization is the major cause for the stability of triarylmethyl free radicals.

Completely chlorinated triarylmethyl free radicals are more stable than the unsubstituted kind, probably for steric reasons, and many are quite inert in solution and in the solid state.[134] Certain radicals with the unpaired electron not on a carbon are also very stable. Diphenylpicrylhydrazyl (**30**) is a solid which can be kept for years, and **31** is so stable that reactions can be performed on it without affecting the unpaired electron.[135]



30



31

Dissociation energies (D values) of R—H bonds provide a measure of the relative stability of free radicals R. Table 2 lists such values.[136] The higher the D value, the less stable the radical.

There are two possible structures for simple alkyl radicals. They might have sp^2 bonding, in which case the structure would be planar, with the odd electron in a p orbital, or the bonding

TABLE 2 D_{298} values (see p. 26) for some R—H bonds[136]
Free-radical stability is in the reverse order

R	D, kcal/mol	R	D, kcal/mol	R	D, kcal/mol
$CF_3\cdot$	106	$Me_3CCH_2\cdot$	99.3	Cyclohexyl	94
$CH_3\cdot$	104.0	$C_2H_5\cdot$	98.0	$Me_3C\cdot$	91.0
$C_6H_5\cdot$	104	$CH_3CH_2CH_2\cdot$	98	$CH_2{=}CHCH_2\cdot$	88.4
$CH_2{=}CH\cdot$	104	$CCl_3\cdot$	95.7	$HCO\cdot$	88
Cyclopropyl	101	$Me_2CH\cdot$	94.5	$C_6H_5CH_2\cdot$	85

might be sp^3, which would make the structure pyramidal and place the odd electron in an sp^3 orbital. Esr spectra of $CH_3\cdot$ and other simple alkyl radicals indicate that these radicals have planar structures.[137] This is in accord with the known loss of optical activity when a free radical is generated at an asymmetric carbon.[138] Kinetic evidence obtained from iodine exchange reactions also indicates that simple alkyl radicals are planar.[139] In addition, electronic spectra of the CH_3 and CD_3 radicals (generated by flash photolysis) in the gas phase have definitely established that under these conditions the radicals are planar or near-planar,[140] and infrared spectra of $CH_3\cdot$ trapped in solid argon led to a similar conclusion.[141]

Evidence from studies on bridgehead compounds shows that though a planar configuration is more stable, pyramidal structures are not impossible. In contrast to the situation with carbonium ions, free radicals have often been generated at bridgeheads, although studies have shown that bridgehead free radicals are less rapidly formed than the corresponding open-chain radicals.[142] In sum, the available evidence indicates that though simple alkyl free radicals prefer a planar or near-planar shape, the energy difference between a planar and a pyramidal free radical is not great. However, free radicals in which the carbon is connected to atoms of high electronegativity, e.g., $CF_3\cdot$,[143] prefer a pyramidal shape;[144] increasing the electronegativity increases the deviation from planarity.[145]

Free radicals with resonance are definitely planar, though triphenylmethyl-type radicals are propeller-shaped,[146] like the analogous carbonium ions (p. 158).

A number of diradicals are known,[147] either stable or as intermediates. When the unpaired electrons of a diradical are widely separated, e.g., as in $\cdot CH_2CH_2CH_2CH_2\cdot$, the species behaves spectrally like two doublets, but when they are close enough for interaction or can interact through an unsaturated system (as in trimethylenemethane, **32**), they can have total spin numbers of $+1$, 0, or -1, since each electron could be either $+\frac{1}{2}$ or $-\frac{1}{2}$. Spectroscopically they are called *triplets*,[148]

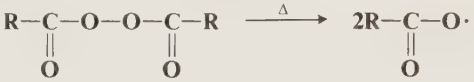
32

since each of the three possibilities is represented among the molecules and gives rise to its own spectral peak. In triplet *molecules* the two unpaired electrons have the same spin. Radicals with both unpaired electrons on the same carbon are discussed under carbenes (p. 178).

The Generation and Fate of Free Radicals[149]

Free radicals are formed from molecules by breaking a bond so that each fragment keeps one electron.[150] The energy necessary to break the bond is supplied in one of two ways.

1. *Thermal cleavage*. Subjection of any organic molecule to a high enough temperature in the gas phase results in the formation of free radicals. When the molecule contains bonds with D values of 20 to 40 kcal/mol, cleavage can be caused in the liquid phase. Two common examples are cleavage of acyl peroxides and of azo compounds:

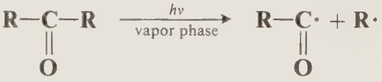


$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R} \xrightarrow{\Delta} 2\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O\cdot}$$

$$\mathrm{R{-}N{=}N{-}R} \xrightarrow{\Delta} 2\mathrm{R\cdot} + \mathrm{N_2}$$

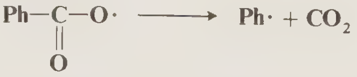
2. *Photochemical cleavage* (see p. 214). The energy of light of 600 to 300 nm is 48 to 96 kcal/mol, which is of the order of magnitude of covalent-bond energies. Typical examples are photochemical cleavage of chlorine and of ketones:

$$\mathrm{Cl_2} \xrightarrow{h\nu} 2\mathrm{Cl\cdot}$$



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R} \xrightarrow[\text{vapor phase}]{h\nu} \mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}\cdot} + \mathrm{R\cdot}$$

Free radicals are also formed from other free radicals, either by the reaction between a radical and a molecule (which *must* give another radical, since the total number of electrons is odd) or by cleavage of a radical to give another radical, e.g.,



$$\mathrm{Ph{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O\cdot} \longrightarrow \mathrm{Ph\cdot} + \mathrm{CO_2}$$

Free radicals may also be formed by oxidation or reduction, including electrolytic methods.

---

[148] For discussions of the triplet state, see Wagner and Hammond, *Adv. Photochem.* **5**, 21-156 (1968); and Turro, *J. Chem. Educ.* **46**, 2-6 (1969).

[149] For a review on formation of free radicals, see Walling, "Free Radicals in Solution," pp. 467-563, John Wiley & Sons, Inc., New York, 1957.

[150] It is also possible for free radicals to be formed by collision of two nonradical species. For a review, see Harmony, *Methods Free-Radical Chem.* **5**, 101-176 (1974).

Reactions of free radicals either give stable products (termination reactions) or lead to other radicals, which themselves must usually react further (propagation reactions). The most common termination reactions are simple combinations of similar or different radicals:

$$\mathrm{R\cdot + R'\cdot \longrightarrow R{-}R'}$$

Another termination process is disproportionation:[151]

$$\mathrm{2CH_3{-}CH_2\cdot \longrightarrow CH_3{-}CH_3 + CH_2{=}CH_2}$$

There are four principal propagation reactions, of which the first two are most common:

1. *Abstraction of another atom or group, usually a hydrogen atom* (see Chapter 14):

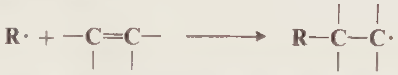
$$\mathrm{R\cdot + R'{-}H \longrightarrow R{-}H + R'\cdot}$$

The hydrogen may also be abstracted from a position which would give the same radical, e.g.,

$$\mathrm{CH_3{-}CH_2{-}CH_2\cdot + CH_3{-}CH_2{-}CH_3 \longrightarrow CH_3{-}CH_2{-}CH_3 + CH_3{-}CH_2{-}CH_2\cdot}$$

This of course leads to no net structural change.[152]

2. *Addition to a multiple bond* (Chapter 15):

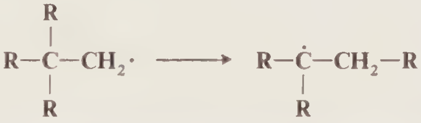


$$\mathrm{R\cdot + {-}\underset{|}{C}{=}\underset{|}{C}{-} \longrightarrow R{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\cdot}$$

The radical formed here may add to another double bond, etc. This is one of the chief mechanisms for vinyl polymerization.

3. *Decomposition.* This can be illustrated by the decomposition of the benzoxy radical (p. 176).

4. *Rearrangement:*



$$\mathrm{R{-}\overset{R}{\underset{R}{C}}{-}CH_2\cdot \longrightarrow R{-}\underset{R}{\dot{C}}{-}CH_2{-}R}$$

This is less common than rearrangement of carbonium ions, but it does occur (though not when R = alkyl or hydrogen; see Chapter 18).

In addition to these reactions, free radicals may be oxidized to carbonium ions or reduced to carbanions.

Radical Ions[153]

Several types of radical ions are known with the unpaired electron, or the charge, or both on atoms other than carbon. Important examples are semiquinones (**33**) and ketyls (**34**). Only a few radical ions are known where both the unpaired electron and the charge reside on carbon atoms. One

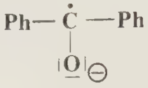
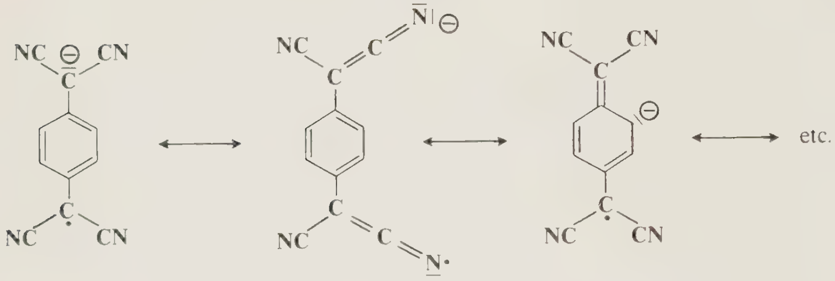
33

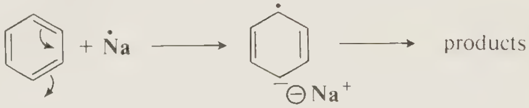


34



35

stable example is **35**.[154] Reactions in which alkali metals are reducing agents often involve radical ion intermediates, e.g., reaction **5-13**:



Several types of radical cations are also known.

CARBENES

Stability and Structure[155]

Carbenes are highly reactive species, practically all having lifetimes considerably under 1 sec. Carbenes have been isolated only by entrapment in matrices at low temperatures (77 K or less).[156] The parent species CH_2 is usually called *methylene*, although derivatives are more often named by the carbene nomenclature. Thus CCl_2 is generally known as dichlorocarbene, though it can also be called dichloromethylene.

The two nonbonded electrons of a carbene may be either paired or unpaired. If they are paired, the species is spectrally a *singlet*, while, as we have seen (p. 176), two unpaired electrons appear as a *triplet*. An ingenious method of distinguishing between the two possibilities was developed by Skell,[157] based on the common reaction of addition of carbenes to double bonds to form cyclopropane derivatives (reaction **5-53**). If the singlet species adds to *cis*-2-butene, the resulting

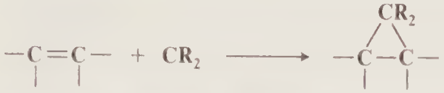
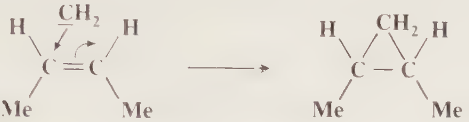
Chem. Educ.* **42**, 260 (1965); Kirmse, *Prog. Org. Chem.* **6**, 164–213 (1964); and Chinoporos, *Chem. Rev.* **63**, 235–255 (1963).

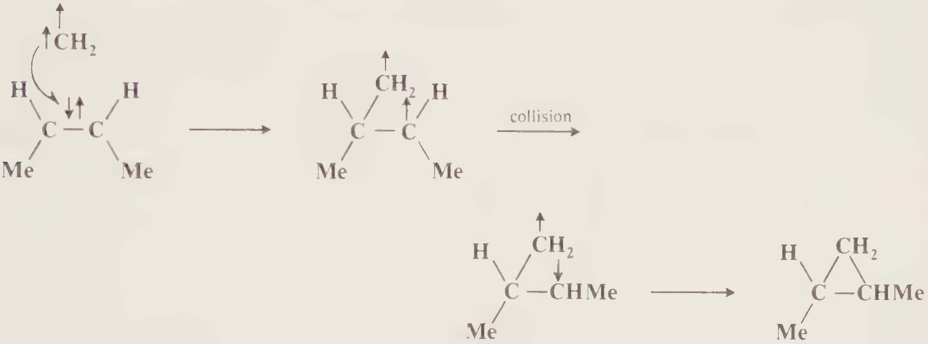
[156] For example, see Murray, Trozzolo, Wasserman, and Yager, *J. Am. Chem. Soc.* **84**, 3213 (1962); Brandon, Closs, and Hutchison, *J. Chem. Phys.* **37**, 1878 (1962); Milligan, Mann, Jacox, and Mitsch, *J. Chem. Phys.* **41**, 1199 (1964); Trozzolo and Gibbons, *J. Am. Chem. Soc.* **89**, 239 (1967); Trozzolo, *Acc. Chem. Res.* **1**, 329–335 (1968); and Nefedov, Maltsev, and Mikaelyan, *Tetrahedron Lett.* 4125 (1971).



cyclopropane should be the cis isomer since the movements of the two pairs of electrons should occur either simultaneously or with one succeeding another rapidly. However, if the attack is by



a triplet species, the two unpaired electrons cannot *both* go into a new covalent bond, since by Hund's rule they have parallel spins. So one of the unpaired electrons will form a bond with the electron from the double bond which has the opposite spin, leaving two unpaired electrons which



cannot form a bond at once but must wait until, by some collision process, one of the electrons can reverse its spin. During this time, there is free rotation, and a mixture of *cis*- and *trans*-1,2-dimethylcyclopropanes should result.[158]

The results of this type of experiment show that CH_2 itself is usually formed as a singlet species, which can decay to the triplet state, which consequently has a lower energy (molecular-orbital calculations show that the difference in energy between singlet and triplet CH_2 is about 11 kcal mol[159]). However, it is possible to prepare triplet CH_2 directly, by a photosensitized decomposition of diazomethane.[160] CH_2 is so reactive that it generally reacts as the singlet before it has a chance to decay to the triplet state. As to other carbenes, some react as triplets, some as singlets, and others as singlets or triplets, depending on how they are generated. For gaseous reactions it is possible to increase the amount of carbene which reacts as the triplet by generating the carbene in the presence of an inert gas, since collisions with these molecules cause singlet carbenes to decay to the triplet state.[161]

---

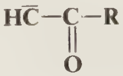
Soc.* **96,** 253 (1974). See also Frey, *J. Chem. Soc., Chem. Commun.* 1024 (1972); Frey and Kennedy, *J. Chem. Soc., Chem. Commun.* 233 (1975).

[160] Kopecky, Hammond, and Leermakers, *J. Am. Chem. Soc.* **83,** 2397 (1961), **84,** 1015 (1962); Duncan and Cvetanović, *J. Am. Chem. Soc.* **84,** 3593 (1962).

There is a limitation to the use of stereospecificity of addition as a diagnostic test for singlet or triplet carbenes. When carbenes are generated by photolytic methods, they are often in a highly excited singlet state. When they add to the double bond, the addition is stereospecific; but the cyclopropane formed carries excess energy; i.e., it is in an excited state. It has been shown that under certain conditions (low pressures in the gas phase) the excited cyclopropane may undergo cis-trans isomerization *after* it is formed, so that triplet carbene may seem to be involved although in reality the singlet was present.[162]

The most common carbenes are CH_2 and CCl_2,[163] but many others have been reported, e.g.,[164]

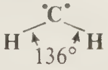
$\cdot\dot{C}Ph_2$ $\qquad$ $R_2C{=}C{=}\overline{C}$



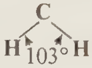
$H\overline{C}-\underset{\underset{O}{\|}}{C}-R$

Studies of the infrared spectrum of CCl_2 trapped at low temperatures in solid argon indicate that the ground state for this species is the singlet.[165] A dicarbene, $\overline{C}{=}C{=}\overline{C}$, is the major constituent of carbon vapor.[166]

The geometrical structure of triplet methylene can be investigated by esr measurements, since triplet species are diradicals. Such measurements made on triplet CH_2 trapped in matrices at very low temperatures (4 K) show that triplet CH_2 is a bent molecule, with an angle of about 136°.[167] Epr measurements cannot be made on singlet species, but from electronic spectra of CH_2 formed in flash photolysis of diazomethane it was concluded that singlet CH_2 is also bent, with an angle of about 103°.[168] It had previously been thought that electronic spectra showed



Triplet
methylene



Singlet
methylene

triplet CH_2 to be linear, but a reinterpretation of the spectra indicates that they are compatible with a bent structure.[169] Theoretical treatments also predict that triplet CH_2 should have an angle of about 136°.[170] Singlet CCl_2[165] and CBr_2[171] are also bent, with angles of about 100 and 114°, respectively. It had long been known that triplet aryl carbenes are bent. In one particularly convincing experiment, two conformations each of 1- and 2-naphthylcarbene were detected by esr.[172] If the Ar—C—H bond were linear, only one conformation could exist.

The intermediate **36** has been proposed in the photolysis of diethyl mercurybisdiazoacetate. This intermediate, which would be a *carbyne*, was trapped by reaction with cyclohexene.[173]

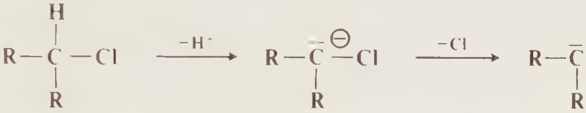
$$\mathrm{Hg(N_2CCOOEt)_2} \xrightarrow{h\nu} 2\cdot\bar{\mathrm{C}}\mathrm{-COOEt} + \mathrm{Hg} + 2\mathrm{N_2}$$

36

The Generation and Fate of Carbenes[174]

Carbenes are chiefly formed in two ways, though other pathways are also known.

1. In α elimination a carbon loses a group without its electron pair, usually a proton, and then a group with its pair, usually a halide ion:[175]

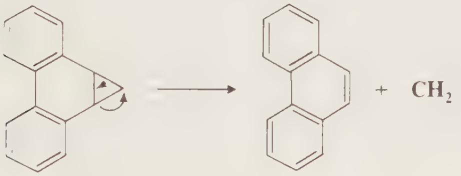


$$\mathrm{R{-}\underset{R}{\overset{H}{C}}{-}Cl} \xrightarrow{-\mathrm{H}^+} \mathrm{R{-}\underset{R}{\overset{\ominus}{\bar{C}}}{-}Cl} \xrightarrow{-\mathrm{Cl}^-} \mathrm{R{-}\underset{R}{\bar{C}}}$$

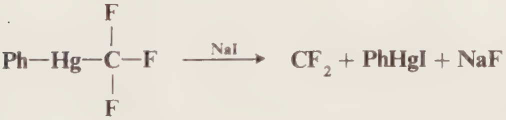
The most common example of this is formation of dichlorocarbene by treatment of chloroform with a base (see reaction **0-3**), but many other examples are known, a few of which are

$$\mathrm{CCl_3{-}COO^-} \xrightarrow{\Delta} \mathrm{CCl_2} + \mathrm{CO_2} + \mathrm{Cl^-} \qquad \text{Ref. 176}$$

$$\mathrm{Ph{-}\underset{Li}{CH}{-}OPh} \longrightarrow \mathrm{PhCH} + \mathrm{PhOLi} \qquad \text{Ref. 177}$$



+ CH_2 Ref. 178



$$\mathrm{Ph{-}Hg{-}\underset{F}{\overset{F}{C}}{-}F} \xrightarrow{\mathrm{NaI}} \mathrm{CF_2} + \mathrm{PhHgI} + \mathrm{NaF} \qquad \text{Ref. 179}$$

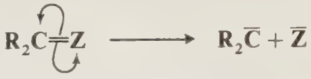
Engl.* **10**, 529–537 (1971) [*Angew. Chem.* **83**, 595–603]; Griffin, *Angew. Chem. Int. Ed. Engl.* **10**, 537–547 (1971) [*Angew. Chem.* **83**, 604–613].

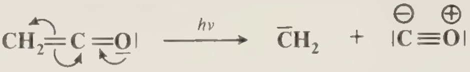
[179] Seyferth, Hopper, and Darragh, *J. Am. Chem. Soc.* **91**, 6536 (1969); Seyferth, *Acc. Chem. Res.* **5**, 65–74 (1972).

Though in most cases of α elimination the positive group is lost first, it is also possible for the negative group to be lost first[180] and for the two to be lost simultaneously.

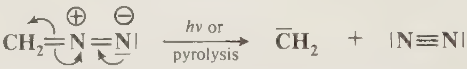
2. Disintegration of compounds containing certain types of double bonds.



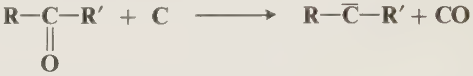
The two most important ways of forming CH_2 are examples: the photolysis of ketene



and the isoelectronic decomposition of diazomethane

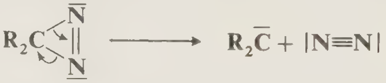


Another example is the treatment of aldehydes and ketones with carbon atoms under high vacuum at −196°C, in a reaction known as deoxygenation:[181]



$$R{-}\underset{\underset{O}{\|}}{C}{-}R' + C \longrightarrow R{-}\overline{C}{-}R' + CO$$

Diazirines (isomeric with diazoalkanes) also give carbenes:[182]

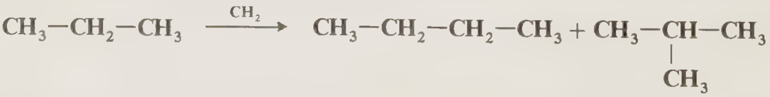


Because carbenes are so reactive, it is often difficult to prove that they are actually present in a given reaction. In many instances where a carbene is *apparently* produced by an α elimination or by disintegration of a double-bond compound there is evidence that no free carbene is actually involved. The neutral term *carbenoid* is used where it is known that a free carbene is not present or in cases where there is doubt. α-Halo organometallic compounds R_2CXM are often called carbenoids because they readily give α-elimination reactions (for example, see p. 568).

The reactions of carbenes are more varied than those of the species previously discussed in this chapter.

1. Additions to carbon-carbon double bonds have already been mentioned. Carbenes also add to aromatic systems, but the immediate products rearrange, usually with ring enlargement (see reaction **5-53**). Additions of carbenes to other double bonds, such as C=N (reactions **6-65** to **6-67**), and to triple bonds have also been reported.

2. An unusual reaction of carbenes is that of insertion into C—H bonds (reaction **2-18**). Thus CH_2 reacts with methane to give ethane and with propane to give *n*-butane and isobutane. This



$$CH_3{-}CH_2{-}CH_3 \xrightarrow{CH_2} CH_3{-}CH_2{-}CH_2{-}CH_3 + CH_3{-}\underset{\underset{CH_3}{|}}{CH}{-}CH_3$$

reaction is virtually useless for synthetic purposes but illustrates the extreme reactivity of carbene. Treatment in the liquid phase of an alkane such as pentane with carbene formed from the photolysis of diazomethane gives the three possible products in statistical ratios[183] demonstrating that carbene is displaying no selectivity. It is a general principle that the lower the selectivity, the higher the reactivity. Singlet CH_2 generated by photolysis of diazomethane is probably the most reactive organic species known, but triplet CH_2 is somewhat less reactive, and other carbenes are still less reactive. The following series of carbenes of decreasing reactivity has been proposed on the basis of discrimination between insertion and addition reactions: $CH_2 > HCCOOR > PhCH > BrCH \approx ClCH$.[184] Dihalocarbenes generally do not give insertion reactions at all. Insertion of carbenes into other bonds has also been demonstrated, though not insertion into C—C bonds.[185]

3. It would seem that dimerization should be an important reaction of carbenes

$$R_2\bar{C} + R_2\bar{C} \longrightarrow R_2C{=}CR_2$$

but it is not, because the reactivity is so great that the carbene species do not have time to find each other and because the dimer generally has so much energy that it dissociates again. Apparent dimerizations have been observed, but it is likely that the products in many reported instances of "dimerization" do not arise from an actual dimerization of two carbenes but from attack by a carbene on a molecule of carbene precurser, e.g.,

$$R_2\bar{C} + R_2CN_2 \longrightarrow R_2C{=}CR_2 + N_2$$

4. Alkylcarbenes can undergo rearrangement, with migration of alkyl or hydrogen. Indeed these rearrangements are generally so rapid that additions to multiple bonds and insertion reactions, which are so common for CH_2, are seldom encountered with alkyl or dialkyl carbenes. Unlike rearrangement of the species previously encountered in this chapter, most rearrangements of carbenes directly give stable molecules. Some examples are[186]

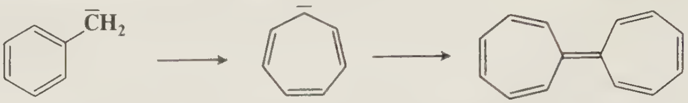
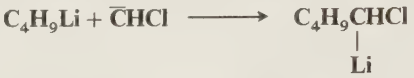
The rearrangement of acylcarbenes to ketenes is called the Wolff rearrangement (reaction **8-9**).[187] A few rearrangements in which carbenes rearrange to other carbenes are also known.[188] These are mostly rearrangements of arylcarbenes to ring-expanded aromatic carbenes, e.g.,



Of course, the new carbene must stabilize itself in one of the ways we have mentioned; in the above example it dimerized.

Carbenes may react with a Lewis base such as a carbanion[189] or even butyllithium:[190]



$$\mathrm{C_4H_9Li + \overline{C}HCl \longrightarrow \underset{\displaystyle Li}{C_4H_9\underset{|}{C}HCl}}$$

Carbenes, both triplet (which would be expected because they are free radicals) and singlet,[191] can abstract hydrogen or other atoms to give free radicals:

$$\mathrm{CH_2 + CH_3CH_3 \longrightarrow CH_3\cdot + CH_3CH_2\cdot}$$

A number of other possible carbene reactions are known but are less important.

NITRENES

Nitrenes,[192] R—N, are the nitrogen analogs of carbenes, and most of what we have said about carbenes also applies to them. Nitrenes are too reactive for isolation under ordinary conditions. Alkyl nitrenes have been isolated by trapping in matrices at 4 K,[193] while aryl nitrenes, which are less reactive, can be trapped at 77 K.[194] The ground state of NH, and probably of most

$$\underset{\text{Singlet}}{\mathrm{R{-}\overline{\underline{N}}}} \qquad \underset{\text{Triplet}}{\mathrm{R{-}\overline{\underset{\bullet}{N}}\cdot}}$$

nitrenes, is a triplet, though nitrenes can be generated in both triplet and singlet states. In additions of EtOOC—N to C=C double bonds two species are involved, one of which adds stereospecifically and the other not. By analogy with Skell's proposal involving carbenes (p. 179) these are taken to be the singlet and triplet species, respectively.[195]

The two principal means of generating nitrenes are analogous to those used to form carbenes.

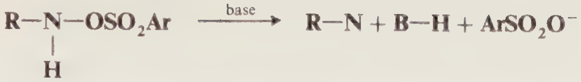
[194] Smolinsky, Wasserman, and Yager, *J. Am. Chem. Soc.* **84,** 3220 (1962).

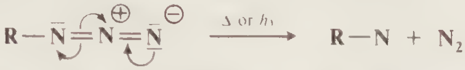
[195] McConaghy and Lwowski, *J. Am. Chem. Soc.* **89,** 2357, 4450 (1967); Mishra, Rice, and Lwowski, *J. Org. Chem.* **33,** 481 (1968).

1. *α Elimination.* An example is



$$\underset{\displaystyle H}{R-\underset{|}{N}-OSO_2Ar} \xrightarrow{\text{base}} R-N + B-H + ArSO_2O^-$$

2. *Disintegration of certain double-bond compounds.* The most common method of forming nitrenes is photolytic or thermal decomposition of azides[196]

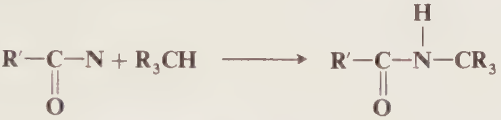


$$R-\bar{N}=\overset{\oplus}{N}=\underline{\overset{\ominus}{N}} \xrightarrow{\Delta \text{ or } h\nu} R-N + N_2$$

The unsubstituted nitrene NH has been generated by photolysis of or electric discharge through NH_3, N_2H_4, or HN_3.

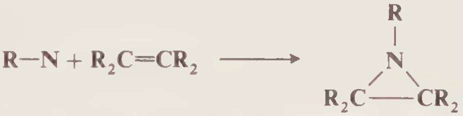
The reactions of nitrenes are also similar to those of carbenes. As in that case, many reactions in which nitrene intermediates are suspected probably do not involve free nitrenes. It is often very difficult to obtain proof in any given case that a free nitrene is or is not an intermediate.

1. *Insertion* (see reaction **2-11**). Nitrenes, especially acyl nitrenes and sulfonyl nitrenes, can insert into C—H and certain other bonds, e.g.,



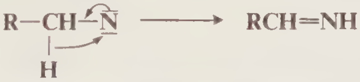
$$R'-\underset{\underset{\displaystyle O}{\|}}{C}-N + R_3CH \longrightarrow R'-\underset{\underset{\displaystyle O}{\|}}{C}-\overset{\overset{\displaystyle H}{|}}{N}-CR_3$$

2. *Addition to* C=C *bonds* (see reaction **5-45**)



This reaction is most common for acyl nitrenes. There is no compelling evidence that aryl nitrenes can add to double bonds.[197] Though aziridines have been obtained in many such cases, they may have been formed by pathways not involving free nitrenes.[198]

3. *Rearrangements.* Alkyl nitrenes do not generally give either of the two preceding reactions because rearrangement is more rapid, e.g.,



$$R-\underset{\underset{\displaystyle H}{|}}{CH}-\underline{N} \longrightarrow RCH=NH$$

Such rearrangements are so rapid that it is usually difficult to exclude the possibility that a free nitrene was never present at all, i.e., that migration takes place at the same time that the nitrene is formed[199] (see p. 1003).

4. *Abstraction,* e.g.,

$$R-N + R-H \longrightarrow R-\dot{\underline{N}}-H + R\cdot$$

[197] Smith, in Lwowski, "Nitrenes," Ref. 192, p. 112. See, however, Abramovitch and Challand, *J. Chem. Soc., Chem. Commun.* 1160 (1972).

[198] For example, through triazoline intermediates (see reaction **5-45**).

[199] For example, see Moriarty and Reardon, *Tetrahedron* **26**, 1379 (1970); Abramovitch and Kyba, *J. Am. Chem. Soc.* **93**, 1537 (1971).

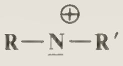
5. *Dimerization.* One of the principal reactions of NH is dimerization to diimide N_2H_2. Azobenzenes are often obtained in reactions where aryl nitrenes are implicated:

$$2\text{Ar—N} \longrightarrow \text{Ar—N=N—Ar}$$

It would thus seem that dimerization is more important for nitrenes than it is for carbenes, but again it has not been proved that free nitrenes are actually involved.

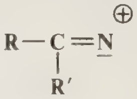
6. *Disproportionation.* NH can disproportionate to give the thermodynamically stable nitrogen and hydrogen: $2NH \rightarrow N_2 + H_2$.

At least two types of *nitrenium ions,* the nitrogen analogs of carbonium ions, can exist as intermediates, though much less work has been done in this area than on carbonium ions. In one type (**37**) the nitrogen is bonded to two atoms and in the other (**38**) to only one.[200] When



$$R-\overset{\oplus}{\underline{N}}-R'$$

37



$$R-\underset{R'}{\underset{|}{C}}=\overset{\oplus}{\underline{N}}$$

38

R = H in **37**, the species is a protonated nitrene. Like carbenes and nitrenes, nitrenium ions can exist in singlet or triplet states.[201]

Six

Mechanisms and Methods of Determining Them

A mechanism is the actual process by means of which a reaction takes place—which bonds are broken, in what order, how many steps are involved, the relative rate of each step, etc. In order to state a mechanism completely, we should have to specify the positions of all atoms, including those in solvent molecules, and the energy of the system, at every point in the process. A proposed mechanism must fit all the facts available. It is always subject to change as new facts are discovered. The usual course is that the gross features of a mechanism are the first to be known and then increasing attention is paid to finer details. The tendency is always to probe more deeply, to get more detailed descriptions.

Although for most reactions gross mechanisms can be written today with a good degree of assurance, no mechanism is known completely. There is much about the fine details which is still puzzling, and for some reactions even the gross mechanism is still not clear. Many facts are not yet understood. The problems involved are very difficult because there are so many variables. Many examples are known where reactions proceed by different mechanisms under different conditions. In many cases there are several proposed mechanisms each of which completely explains all the data.

Types of Mechanism

In any reaction bonds are broken and/or bonds are formed. We can divide all mechanisms into three basic types, depending on how the bonds break.

1. If a bond breaks in such a way that both electrons remain with one fragment, the mechanism is called *polar* or *heterolytic*. Polar reactions do not necessarily involve ionic intermediates, though they often do. The important thing is that the electrons are never unpaired. For most reactions it is convenient to call one reactant the *attacking reagent* and the other the *substrate*. In this book we shall always designate as the substrate that molecule which supplies carbon to the new bond. When carbon-carbon bonds are formed, it is necessary to be arbitrary about which is the substrate and which the attacking reagent. In polar reactions the reagent generally brings a pair of electrons to the substrate or takes a pair of electrons from it. A reagent which brings an electron pair is called a *nucleophile*, and the reaction is called *nucleophilic*. A reagent which takes an electron pair is called an *electrophile* and the reaction is *electrophilic*. In a reaction in which the substrate molecule becomes cleaved, part of it (the part not containing the carbon) is usually called the *leaving group*. A leaving group which carries away an electron pair is called *nucleofugal*. If it comes away without the electron pair, it is called *electrofugal*.

2. If a bond breaks in such a way that each fragment gets one electron, free radicals are formed and such reactions are said to take place by *free-radical mechanisms*.

3. It would seem that all bonds must break in one of the two ways previously noted. But there is a third type of mechanism in which electrons (usually six, but sometimes four or some other number) move in a closed ring. There are no intermediates, ions or free radicals, and it is impossible to say whether the electrons are paired or unpaired. Reactions with this type of mechanism are called *pericyclic*.[1]

Examples of all three types of mechanism will be given in the next section.

Types of Reaction

The number and range of organic reactions is so great as to seem bewildering, but actually almost all of them can be fitted into just six categories. In the description of the six types, which follows, the immediate products are shown, though in many cases they then react with something else. All the species are shown without charges, since differently charged reactants may undergo analogous changes. The descriptions given here are purely formal and are for the purpose of classification and comparison. All are discussed in detail in Part 2 of this book.

1. *Substitutions.* If polar, these can be classified as nucleophilic or electrophilic depending on which reactant is designated as the substrate and which as the attacking reagent (very often Y must first be formed by a previous bond cleavage).

a. Nucleophilic substitution (Chapters 10, 13)

$$A\wr{-}X + \bar{Y} \longrightarrow A{-}Y + \bar{X}$$

b. Electrophilic substitution (Chapters 11, 12)

$$A{-}\wr X + Y \longrightarrow A{-}Y + X$$

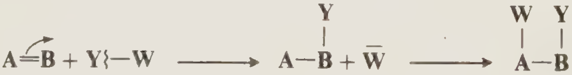
c. Free-radical substitution (Chapter 14)

$$A{-}X + Y\cdot \longrightarrow A{-}Y + X\cdot$$

In free-radical substitution, Y• is usually produced in situ by a free-radical cleavage, and X• goes on to react further.

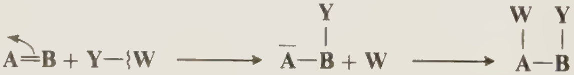
2. *Additions to double or triple bonds* (Chapters 15, 16). These reactions may take place by all three of the mechanistic possibilities.

a. Electrophilic addition (polar)



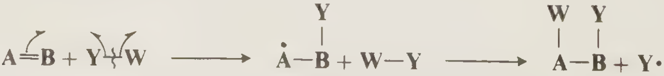
$$A{=}B + Y\wr{-}W \longrightarrow A{-}\overset{\overset{\textstyle Y}{|}}{B} + \bar{W} \longrightarrow \overset{\overset{\textstyle W}{|}}{A}{-}\overset{\overset{\textstyle Y}{|}}{B}$$

b. Nucleophilic addition (polar)



$$A{=}B + Y{-}\wr W \longrightarrow \bar{A}{-}\overset{\overset{\textstyle Y}{|}}{B} + W \longrightarrow \overset{\overset{\textstyle W}{|}}{A}{-}\overset{\overset{\textstyle Y}{|}}{B}$$

c. Free-radical addition

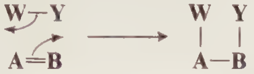


$$A{=}B + Y\wr W \longrightarrow \dot{A}{-}\overset{\overset{\textstyle Y}{|}}{B} + W{-}Y \longrightarrow \overset{\overset{\textstyle W}{|}}{A}{-}\overset{\overset{\textstyle Y}{|}}{B} + Y\cdot$$

---

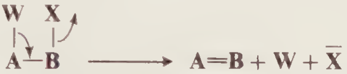
[1] For a classification of pericyclic reactions, see Hendrickson, *Angew. Chem. Int. Ed. Engl.* **13**, 47–76 (1974) [*Angew. Chem.* **86**, 71–100].

d. Simultaneous addition (pericyclic)

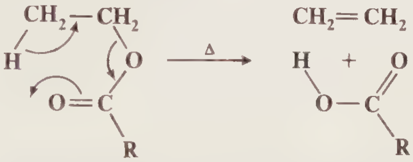


The examples show Y and W as coming from the same molecule, but very often (except in simultaneous addition) they come from different molecules. Also, the examples show the Y—W bond cleaving at the same time that Y is bonding to B, but often (again except for simultaneous addition) this cleavage takes place earlier.

3. *β-elimination* (Chapter 17).



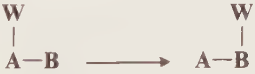
These reactions may take place by polar or pericyclic mechanisms, an example of the latter being (reaction **7-3**)



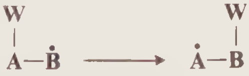
Free-radical β-eliminations are extremely rare. In polar eliminations W and X may or may not leave simultaneously, and they may or may not combine.

4. *Rearrangement* (Chapter 18). Many rearrangements involve migration of an atom or group from one atom to another. There are three types, depending on how many electrons the migrating atom or group carries with it.

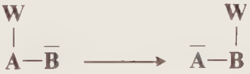
a. Migration with electron pair (nucleophilic)



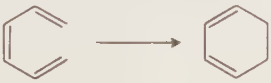
b. Migration with one electron (free-radical)



c. Migration without electrons (electrophilic; rare)



The illustrations show 1,2 rearrangements, in which the migrating group moves to the adjacent atom. These are the most common, although longer rearrangements are also possible. There are also some rearrangements which do not involve simple migration at all (see Chapter 18). Some of the latter involve pericyclic mechanisms. An example (reaction **8-32**) is



5. *Oxidation and reduction* (Chapter 19). Many oxidation and reduction reactions fall naturally into one of the four types mentioned above, but many others do not. For a description of oxidation-reduction mechanistic types, see p. 1075.

6. Combinations of the above.

Note that arrows are used to show movement of *electrons*. An arrow always follows motion of electrons and never of a nucleus or anything else, it being understood that the rest of the molecule follows behind the electrons. Ordinary arrows (double-headed) follow electron pairs, while single-headed arrows follow unpaired electrons. Double-headed arrows are also used in pericyclic reactions for convenience, although in these reactions we do not really know how or in which direction the electrons are moving.

Thermodynamic Requirements for Reaction

In order for a reaction to take place spontaneously, the free energy of the products must be lower than the free energy of the reactants; i.e., ΔG must be negative. Reactions may go the other way, of course, but only if free energy is added. Like water on the surface of the earth, which only flows downhill and never uphill (though it can be carried or pumped uphill), molecules seek the lowest possible potential energy. Free energy is made up of two components, enthalpy H and entropy S. These quantities are related by the equation

$$\Delta G = \Delta H - T\Delta S$$

The enthalpy change in a reaction is essentially the difference in bond energies (including resonance, strain, and solvation energies) between the reactants and the products. The enthalpy change can be calculated by totaling the bond energies of all the bonds broken, subtracting from this the total of the bond energies of all the bonds formed, and adding any changes in resonance, strain, or solvation energies. Entropy changes are quite different, and refer to the disorder or randomness of the system. The less order in a system, the greater the entropy. The preferred conditions in nature are *low* enthalpy and *high* entropy, and in reacting systems, enthalpy spontaneously decreases while entropy spontaneously increases.

For many reactions entropy effects are negligible, and the enthalpy alone determines whether the reaction can take place spontaneously. However, in certain types of reaction entropy is important and can dominate enthalpy. We shall discuss several examples.

1. In general, liquids have lower entropies than gases, since the molecules of gas have much more freedom and randomness. Solids, of course, have still lower entropies. Any reaction in which the reactants are all liquids and one or more of the products is a gas is therefore thermodynamically favored by the increased entropy: the equilibrium constant for that reaction will be higher than it would otherwise be. Similarly, the entropy of a gaseous substance is higher than that of the same substance dissolved in a solvent.

2. In a reaction in which the number of product molecules is equal to the number of reactant molecules, e.g., $A + B \rightarrow C + D$, entropy effects are usually small, but if the number of molecules is increased, e.g., $A \rightarrow B + C$, there will be a large gain in entropy because more arrangements in space are possible when more molecules are present. Reactions in which a molecule is cleaved into two or more parts are therefore thermodynamically favored by the entropy factor. Conversely, reactions in which the number of product molecules is less than the number of reactant molecules show entropy decreases, and in such cases there must be a sizable decrease in enthalpy to overcome the unfavorable entropy change.

3. Although reactions in which molecules are cleaved into two or more pieces have favorable entropy effects, many potential cleavages do not take place because of large increases in enthalpy.

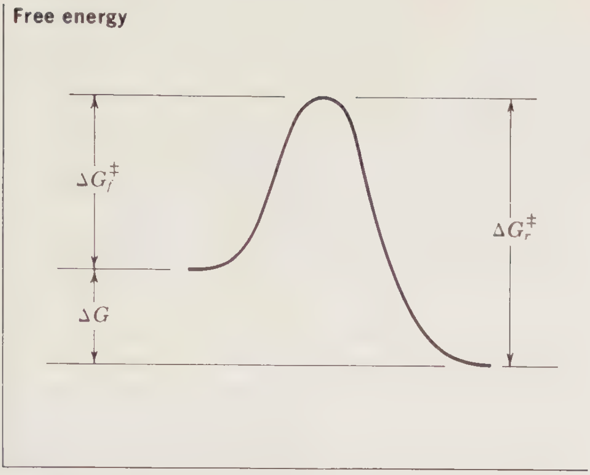


Figure 1 Free-energy profile of a reaction without an intermediate where the products have a lower free energy than the reactants

An example is cleavage of ethane into two methyl radicals. In this case a bond of about 79 kcal mol is broken, and no new bond is formed to compensate for this enthalpy increase. However, ethane can be cleaved at very high temperatures, which illustrates the principle that *entropy becomes more important as the temperature increases*, as is obvious from the equation $\Delta G = \Delta H - T\Delta S$. The enthalpy term is independent of temperature, while the entropy term is directly proportional to the absolute temperature. In a qualitative way, we can see that molecules have more freedom at higher temperatures.

4. An open-chain molecule has more entropy than a similar cyclic molecule because there are more conformations (compare hexane and cyclohexane). Ring opening therefore means a gain in entropy and ring closing a loss.

Kinetic Requirements for Reaction

Just because a reaction has a negative ΔG does not necessarily mean that it will take place in a reasonable period of time. A negative ΔG is a *necessary* but not a *sufficient* condition for a reaction to occur spontaneously. For example, the reaction between H_2 and O_2 to give H_2O has a negative ΔG, but mixtures of H_2 and O_2 can be kept at room temperature for many centuries without reacting to any significant extent. In order for a reaction to take place, *free energy of activation* $\Delta G^{\ddagger}$ must be added.[2] This situation is illustrated in Figure 1,[3] which is an energy profile[4] for a one-step reaction without an intermediate. In this type of diagram the horizontal axis signifies the progression of the reaction. $\Delta G_f^{\ddagger}$ is the free energy of activation for the forward reaction. If the reaction shown in Figure 1 is reversible, $\Delta G_r^{\ddagger}$ must be greater than $\Delta G_f^{\ddagger}$, since it is the sum of ΔG and $\Delta G_f^{\ddagger}$.

---

[2] For mixtures of H_2 and O_2 this can be done by striking a match.

[3] Strictly speaking, this is an energy profile for a reaction of the type $XY + Z \rightarrow X + YZ$. However, it may be applied, in a rough way, to other reactions.

[4] For a fuller discussion, see Frost and Pearson, "Kinetics and Mechanism," 2d ed., pp. 77–102, John Wiley & Sons, Inc., New York, 1961.

When a reaction between two or more molecules has progressed to the point corresponding to the top of the curve, the term *transition state* is applied to the positions of the nuclei and electrons. The transition state possesses a definite geometry and charge distribution. The system at this point is called an *activated complex*.

In the *transition-state theory* the starting materials and the activated complex are taken to be in equilibrium, the equilibrium constant being designated $K^{\ddagger}$. According to the theory, all activated complexes go on to product at the same rate (which, though at first sight surprising, is not unreasonable, when we consider that they are all "falling downhill") so that the rate constant (see p. 199) of the reaction depends only on the position of the equilibrium between the starting materials and the activated complex, i.e., on the value of $K^{\ddagger}$. $\Delta G^{\ddagger}$ is related to $K^{\ddagger}$ by

$$\Delta G^{\ddagger} = -2.3RT \log K^{\ddagger}$$

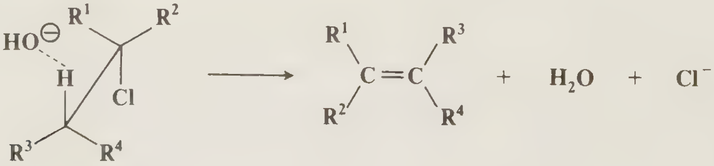
so that a higher value of $\Delta G^{\ddagger}$ indicates a smaller rate constant. The rate of a reaction almost always increases with increasing temperature because the additional energy thus supplied helps the molecules to overcome the activation energy barrier. Some reactions have no free energy of activation at all, meaning that $K^{\ddagger}$ is essentially infinite and that virtually all collisions lead to reaction. Such processes are said to be *diffusion-controlled.*

Like ΔG, $\Delta G^{\ddagger}$ is made up of enthalpy and entropy components

$$\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\,\Delta S^{\ddagger}$$

$\Delta H^{\ddagger}$, the *enthalpy of activation*, is the difference in bond energies, including strain, resonance, and solvation energies, between the starting compounds and the *transition state*. In many reactions old bonds have been broken or partially broken by the time the transition state is reached, and the energy necessary for this is $\Delta H^{\ddagger}$. It is true that additional energy will be supplied by the formation of new bonds, but if this occurs after the transition state, it can affect only ΔH and not $\Delta H^{\ddagger}$.

Entropy of activation $\Delta S^{\ddagger}$, which is the difference in entropy between the starting compounds and the transition state, becomes important when two reacting molecules must approach each other in a specific orientation in order for the reaction to take place. For example, the reaction between a simple noncyclic alkyl chloride and hydroxide ion to give an alkene (reaction **7-13**) takes place



only if, in the transition state, the reactants are oriented as shown. Not only must the OH^- be near the hydrogen, but the hydrogen must be oriented anti to the chlorine atom.[5] When the two reacting molecules collide, if the OH^- should be near the chlorine atom or near R^1 or R^2, no reaction can take place. In order for a reaction to occur, the molecules must surrender the freedom they normally have to assume many possible arrangements in space and adopt only that one which leads to reaction. Thus, a considerable loss in entropy is involved; i.e., $\Delta S^{\ddagger}$ is negative.

Entropy of activation is also responsible for the difficulty in closing rings larger than six-membered. Consider a ring-closing reaction in which the two groups which must interact are

---

[5] As we shall see in Chapter 17, with some molecules elimination is also possible if the hydrogen is oriented syn, instead of anti, to the chlorine atom. Of course, this orientation also requires a considerable loss of entropy.

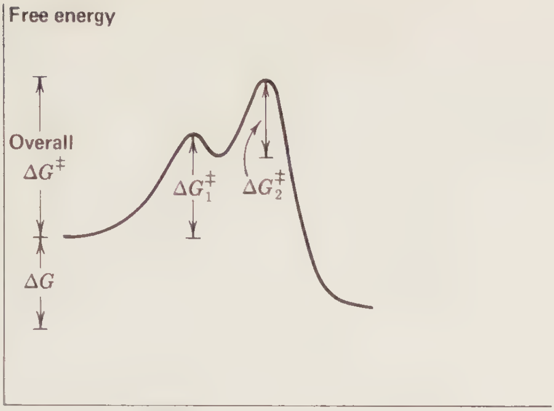


Figure 2 Free-energy profile for a reaction with an intermediate. ΔG_1‡ and ΔG_2‡ are the free energy of activation for the first and second stages, respectively.

situated on the ends of a ten-carbon chain. In order for reaction to take place, the groups must encounter each other. But a ten-carbon chain has many conformations, and in only a few of these are the ends of the chain near each other. Thus, forming the transition state requires a great loss of entropy.[6] This factor is also present, though less so, in closing rings of six members or less (except three-membered rings), but with rings of this size the entropy loss is less than that of bringing two individual molecules together. For example, a reaction between an OH group and a COOH group in the same molecule to form a lactone with a five- or six-membered ring takes place much faster than the same reaction between a molecule containing an OH group and another containing a COOH group. Though $\Delta H^{\ddagger}$ is about the same, $\Delta S^{\ddagger}$ is much less for the cyclic case. However, if the ring to be closed has three or four members, small-angle strain is introduced and the favorable $\Delta S^{\ddagger}$ may not be sufficient to overcome the unfavorable $\Delta H^{\ddagger}$ change.

Reactions in which the transition state has more disorder than the starting compounds, e.g., the pyrolytic conversion of cyclopropane to propene, have positive $\Delta S^{\ddagger}$ values and are thus favored by the entropy effect.

Reactions with intermediates are two-step (or more) processes. In these reactions there is an energy "well." There are two transition states, each with an energy higher than the intermediate (Figure 2). The deeper the well, the more stable the intermediate. In Figure 2 the second peak is higher than the first. The opposite situation is shown in Figure 3. Note that in reactions in which the second peak is higher than the first, the overall $\Delta G^{\ddagger}$ is less than the sum of the $\Delta G^{\ddagger}$ values for the two steps. Minima in free-energy-profile diagrams correspond to real species which have a finite though very short existence. These may be the carbonium ions, carbanions, free radicals, etc., discussed in Chapter 5, or they may be molecules in which all the atoms have their normal valences. In either case, under the reaction conditions they do not live long (because $\Delta G_2^{\ddagger}$ is small) but rapidly go on to products. Maxima in these curves, however, do not correspond to actual species but only to transition states in which bond breaking and/or bond making have partially taken place. Transition states have only a transient existence with an essentially zero lifetime.

---

[6] Reaction rates can be greatly enhanced by restricting the conformational possibilities of the substrate to those which are in favorable positions for reaction. For examples, see Milstien and Cohen, *J. Am. Chem. Soc.* **94**, 9158 (1972); Borchardt and Cohen, *J. Am. Chem. Soc.* **94**, 9166, 9175 (1972), **95**, 8308, 8313, 8319 (1973); Karle and Karle, *J. Am. Chem. Soc.* **94**, 9182 (1972).

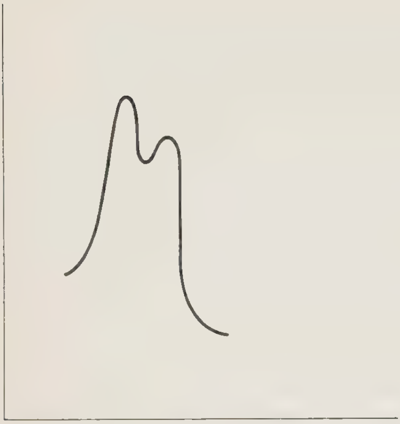

Figure 3 Free-energy profile for a reaction with an intermediate in which the first peak is higher than the second.

Kinetic and Thermodynamic Control

There are many cases in which a compound under a given set of reaction conditions may undergo competing reactions to give different products:

$$A \begin{array}{l} \nearrow B \\ \searrow C \end{array}$$

Figure 4 shows a free-energy profile for a reaction in which B is thermodynamically more stable than C (lower ΔG), but C is formed faster (lower $\Delta G^{\ddagger}$). If neither reaction is reversible, C will be formed in larger amount because it is formed faster. The product is said to be *kinetically controlled*. However, if the reactions are reversible, this will not necessarily be the case. If such a process is stopped well before the equilibrium has been established, the reaction will be kinetically controlled since more of the faster-formed product will be present. However, if the reaction is permitted to approach equilibrium, the predominant or even exclusive product will be B. Under these conditions the C which is first formed reverts to A, while the more stable B does so much less. Here we say the product is *thermodynamically controlled*. Of course, Figure 4 does not describe all reactions in which a compound A can give two different products. In many cases the more stable product is also the one which is formed faster. In such cases the product of kinetic control is also the product of thermodynamic control.

The Hammond Postulate

Since transition states have essentially zero lifetimes, it is impossible to observe them directly and information about their geometries must be obtained from inference. In some cases our inferences can be very strong. For example, in the SN2 reaction (p. 266) between CH_3I and I^- (a reaction in which the product is identical to the starting compound) the transition state should be perfectly symmetrical. In most cases, however, we cannot reach such easy conclusions, and we are greatly aided by the *Hammond postulate*,[7] which states that for any single reaction step, *the geometry of the*

---

[7] Hammond, *J. Am. Chem. Soc.* **77**, 334 (1955). For a discussion, see Fărcasiu, *J. Chem. Educ.* **52**, 76–79 (1975).

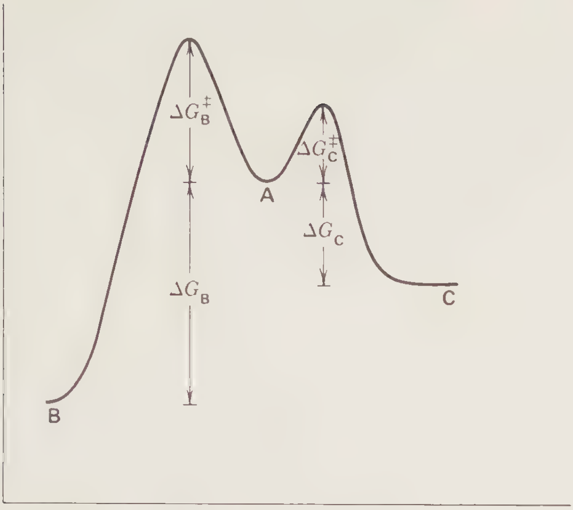

Figure 4 Free-energy profile illustrating kinetic versus thermodynamic control of product. The starting compound (**A**) can react to give either **B** or **C**

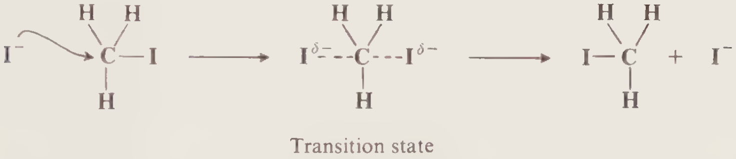


transition state for that step resembles the side to which it is closer in free energy. Thus, for an exothermic reaction like that shown in Figure 1, the transition state resembles the reactants more than the products, though not much more, because there is a substantial $\Delta G^{\ddagger}$ on both sides. The postulate is most useful in reactions with intermediates. In the reaction illustrated in Figure 2, the first transition state lies much closer in energy to the intermediate than it does to the reactants, and we can predict that the geometry of the transition state resembles that of the intermediate more than it does that of the reactants. Likewise, the second transition state also has a free energy much closer to that of the intermediate than to the products, so that both transition states resemble the intermediate more than they do the products or reactants. This is generally the case in reactions which involve very reactive intermediates. Since we usually know more about the structure of intermediates than of transition states, we often use our knowledge of intermediates to draw conclusions about the transition states (for examples, see pp. 316, 688).

Microscopic Reversibility

In the course of a reaction the nuclei and electrons assume positions which at each point correspond to the lowest free energies possible. If the reaction is reversible, these positions must be the same in the reverse process, too. This means that the forward and reverse reactions (run under the same conditions) must proceed by the same mechanism. This is called the *principle of microscopic reversibility*. For example, if in a reaction A → B there is an intermediate C, then C must also be an intermediate in the reaction B → A. This is a useful principle since it enables us to know the mechanism of reactions in which the equilibrium lies far over to one side. Reversible photochemical reactions are an exception, since a molecule which has been excited photochemically does not have to lose its energy in the same way (Chapter 7).

METHODS OF DETERMINING MECHANISMS

There are a number of commonly used methods for determining mechanisms.[8] In most cases one method is not sufficient, and the problem is generally approached from several directions.

Identification of Products

Obviously any mechanism proposed for a reaction must account for all the products obtained and for their relative proportions, including products formed by side reactions. Incorrect mechanisms for the von Richter reaction (**3-26**) were accepted for many years because it was not realized that nitrogen was a major product. A proposed mechanism cannot be correct if it fails to predict the products in approximately their correct proportions. Any mechanism for the reaction

$$CH_4 + Cl_2 \xrightarrow{h\nu} CH_3Cl$$

which fails to account for the formation of a small amount of ethane cannot be correct (see reaction **4-1**).

Determination of the Presence of an Intermediate

In many reactions, intermediates are postulated. There are several ways, none of them foolproof, for attempting to learn whether or not an intermediate is present and, if so, the structure of the intermediate.

1. *Isolation of an intermediate.* It is sometimes possible to isolate an intermediate from a reaction mixture by stopping the reaction after a short time or by the use of very mild conditions. For example, in the reaction

$$RCONH_2 + NaOBr \longrightarrow RNH_2$$

the intermediate RCONHBr has been isolated (see reaction **8-17**). If it can then be shown that the isolated compound gives the same product when subjected to the reaction conditions and at a rate no slower than the starting compound, this constitutes strong evidence that the reaction involves that intermediate, though it is not conclusive, since the compound may arise by an alternate path and by coincidence give the same product.

2. *Detection of an intermediate.* In many cases an intermediate cannot be isolated but can be detected by ir, nmr, or other spectra. The detection by Raman spectra of NO_2^+ was regarded as strong evidence that this is an intermediate in the nitration of benzene (see reaction **1-2**). Free-radical and triplet intermediates can often be detected by esr[9] and by CIDNP (see Chapter 5).

3. *Trapping of an intermediate.* In some cases, the suspected intermediate is known to be one which reacts in a given way with a certain compound. The intermediate can then be detected by running the reaction in the presence of that compound. For example, benzynes (p. 588) react with dienes in the Diels-Alder reaction (reaction **5-51**). In any reaction where a benzyne is a suspected

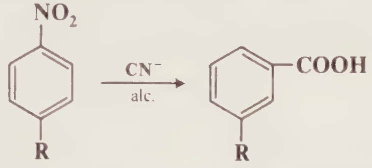
---

[8] For a treatise on this subject, see Lewis and Hammes, "Investigation of Rates and Mechanisms of Reactions," 3d ed. (vol. 6 of Weissberger, "Techniques of Chemistry"), 2 pts., John Wiley & Sons, Inc., New York, 1974.

[9] For a review of esr spectra of triplets, see Thomson, *Q. Rev., Chem. Soc.* **22**, 45–74 (1968).

intermediate, the addition of a diene and the detection of the Diels-Alder adduct indicate that the benzyne was probably present.

4. *Addition of a suspected intermediate.* If a certain intermediate is suspected, and if it can be obtained by other means, then under the same reaction conditions it should give the same products. This kind of experiment can provide conclusive negative evidence: if the same products are not obtained, the suspected compound is not an intermediate. However, if the correct products are obtained, this is not conclusive since they may arise by coincidence. The von Richter reaction (**3-26**) provides us with a good example here too. For many years it had been assumed that an aryl cyanide was an intermediate, since cyanides are easily hydrolyzed to carboxylic acids (reaction **6-5**). In fact, in 1954, *p*-chlorobenzonitrile was shown to give *p*-chlorobenzoic acid under the normal von Richter conditions.[10] However, when the experiment was repeated with 1-cyanonaphthalene, no 1-naphthoic acid was obtained, although 2-nitronaphthalene gave 13% 1-naphthoic acid under the same conditions.[11] This proved that 2-nitronaphthalene must have been converted to 1-naphthoic acid by a route which did not involve 1-cyanonaphthalene. It also showed that even the conclusion that *p*-chlorobenzonitrile was an intermediate in the conversion of *m*-nitrochlorobenzene to *p*-chlorobenzoic acid must now be suspected, since it is not likely that the mechanism would substantially change in going from the naphthalene to the benzene system.



The Study of Catalysis[12]

Much information about the mechanism of a reaction can be obtained from a knowledge of which substances catalyze the reaction, which inhibit it, and which do neither. Of course, just as a mechanism must be compatible with the products, so must it be compatible with its catalysts. In general, catalysts perform their actions by providing an alternate pathway for the reaction in which $\Delta G^{\ddagger}$ is less than it would be without the catalyst. Catalysts do not change ΔG.

Isotopic Labeling[13]

Much useful information has been obtained by using molecules which have been isotopically labeled and tracing the path of the reaction in that way. For example, in the reaction

$$\mathrm{RCOO^- + BrCN \longrightarrow RCN}$$

does the CN group in the product come from the CN in the BrCN? The use of ^{14}C supplied the answer, since $\mathrm{R^{14}CO_2^-}$ gave *radioactive* RCN.[14] This surprising result saved a lot of labor, since it ruled out a mechanism involving the replacement of $\mathrm{CO_2}$ by CN (see reaction **6-63**).

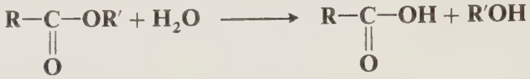
[14] Douglas, Eccles, and Almond, *Can. J. Chem.* **31,** 1127 (1953); Douglas and Burditt, *Can. J. Chem.* **36,** 1256 (1958).

Other radioactive isotopes are also frequently used as tracers, but even stable isotopes may be used. An example is the hydrolysis of esters.



$$R-\underset{\underset{O}{\|}}{C}-OR' + H_2O \longrightarrow R-\underset{\underset{O}{\|}}{C}-OH + R'OH$$

Which bond of the ester is broken, the acyl—O or the alkyl—O bond? The answer is found by the use of $H_2{}^{18}O$. If the acyl—O bond breaks, the labeled oxygen will appear in the acid; otherwise it will be in the alcohol (see reaction **0-11**). Although neither compound is radioactive, the one which contains ^{18}O can be determined by submitting both to mass spectrometry. In a similar way, deuterium can be used as a label for hydrogen. In this case it is not necessary to use mass spectrometry, since ir and nmr spectra can be used to determine when deuterium has been substituted for hydrogen.

In the labeling technique, it is not generally necessary to use completely labeled compounds. Partially labeled material is usually sufficient. There are some reactions, *exchange reactions*, which cannot be studied by any method which does not involve labeling, e.g.,[15] the iodide exchange reaction on p. 195.

Stereochemical Evidence[16]

If the products of a reaction are capable of existing in more than one stereoisomeric form, which form is obtained may give information about the mechanism. For example, (+)-malic acid was discovered by Walden[17] to give (−)-chlorosuccinic acid when treated with PCl_5 and the (+) enantiomer when treated with $SOCl_2$, showing that the mechanisms of these apparently similar conversions could not be the same (see pp. 267, 302). Much useful information has been obtained about nucleophilic substitution, elimination, rearrangement, and addition reactions from this type of experiment. The isomers involved need not be enantiomers. Thus, the fact that *cis*-2-butene treated with $KMnO_4$ gives *meso*-2,3-butanediol and not the racemic mixture is evidence that the two OH groups attack the double bond from the same side (see reaction **5-39**).

Kinetic Evidence[18]

The rate of a homogeneous reaction[19] is the rate of disappearance of a reactant or of appearance of a product. The rate nearly always changes with time, since it is usually proportional to concentration and the concentration of reactants decreases with time. However, the rate is not always proportional to the concentration of all reactants. In some cases a change in the concentration of a reactant produces no change at all in the rate, while in other cases the rate may be proportional to the concentration of a substance (a catalyst) which does not even appear in the stoichiometric equation. A study of which reactants affect the rate often tells a good deal about the mechanism.

A. Benjamin, Inc., New York, 1969; Leffler and Grunwald, "Rates and Equilibria of Organic Reactions," John Wiley & Sons, Inc., New York, 1963; Jencks, Ref. 12, pp. 555–614; and Refs. 4 and 8.

[19] A homogeneous reaction occurs in one phase. Heterogeneous kinetics have been studied much less.

If the rate is proportional to the change in concentration of only one reactant (A), the rate law (the rate of change of concentration of A with time *t*) is

$$\text{Rate} = \frac{-d[\mathrm{A}]}{dt} = k[\mathrm{A}]$$

where *k* is the *rate constant* for the reaction. There is a minus sign because the concentration of A decreases with time. A reaction which follows such a rate law is called a *first-order reaction*. The units of *k* for a first-order reaction are $\sec^{-1}$. The rate of a *second-order reaction* is proportional to the concentration of two reactants, or to the square of the concentration of one:

$$\frac{-d[\mathrm{A}]}{dt} = k[\mathrm{A}][\mathrm{B}] \qquad \text{or} \qquad \frac{-d[\mathrm{A}]}{dt} = k[\mathrm{A}]^2$$

For a second-order reaction the units are liters mol^{-1} $\sec^{-1}$ or some other units expressing the reciprocal of concentration or pressure per unit time interval.

Similar expressions can be written for third-order reactions. A reaction whose rate is proportional to [A] and to [B] is said to be first order in A and in B, second order overall. A reaction rate may be measured in terms of any reactant or product, but the rates so determined are not necessarily the same. For example, if the stoichiometry of a reaction is

$$\mathbf{2A + B \longrightarrow C + D}$$

then, on a molar basis, A must disappear twice as fast as B, so that $-d[\mathrm{A}]/dt$ and $-d[\mathrm{B}]/dt$ are not equal but the former is twice as large as the latter.

The rate law of a reaction is an experimentally determined fact. From this fact we attempt to learn the *molecularity*, which may be defined as the number of molecules which come together to form the activated complex. It is obvious that if we know how many (and which) molecules take part in the activated complex, we know a good deal about the mechanism. The experimentally determined rate order is not necessarily the same as the molecularity. Any reaction, no matter how many steps are involved, has only one rate law, but each step of the mechanism has its own molecularity. For reactions which take place in one step (reactions without an intermediate) the order is the same as the molecularity. A first-order one-step reaction is always unimolecular; a one-step reaction which is second order in A always involves two molecules of A; if it is first order in A and in B, then a molecule of A reacts with one of B, etc. For reactions which take place in more than one step, the order *for each step* is the same as the molecularity *for that step*. This fact enables us to predict the rate law for any proposed mechanism, although the calculations may at times get lengthy.[20] If any one step of a mechanism is considerably slower than all the others (this is usually the case), the rate of the overall reaction is essentially the same as that of the slow step, which is consequently called the *rate-determining* step.

For reactions which take place in two or more steps, we can distinguish between two broad cases:

1. The first step is slower than any subsequent step and is consequently rate-determining. In such cases, the rate law simply includes the reactants which participate in the slow step. For example, if the reaction

$$\mathbf{A + 2B \longrightarrow C}$$

---

[20] For a discussion of how order is related to molecularity in many complex situations, see Szabó, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 2, pp. 1–80, Elsevier Publishing Company, New York, 1969.

has the mechanism

$$\mathbf{A} + \mathbf{B} \xrightarrow{\text{slow}} \mathbf{I}$$

$$\mathbf{I} + \mathbf{B} \xrightarrow{\text{fast}} \mathbf{C}$$

where I is an intermediate, the reaction is second order, with the rate law

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k[\mathbf{A}][\mathbf{B}]$$

2. When the first step is not rate-determining, determination of the rate law is usually much more complicated. For example, consider the mechanism

Step 1 $$\mathbf{A} + \mathbf{B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{I}$$

Step 2 $$\mathbf{I} + \mathbf{B} \xrightarrow{k_2} \mathbf{C}$$

where the first step is a rapid attainment of equilibrium, followed by a slow reaction to give C. The rate of disappearance of A is

$$\frac{-d[\mathbf{A}]}{dt} = k_1[\mathbf{A}][\mathbf{B}] - k_{-1}[\mathbf{I}]$$

Both terms must be included because A is being formed by the reverse reaction as well as being used up by the forward reaction. This equation is of very little help as it stands since we cannot measure the concentration of the intermediate. However, the combined rate law for the formation and disappearance of I is

$$\frac{d[\mathbf{I}]}{dt} = k_1[\mathbf{A}][\mathbf{B}] - k_{-1}[\mathbf{I}] - k_2[\mathbf{I}][\mathbf{B}]$$

At first glance we seem to be no better off with this equation, but we may make the assumption that *the concentration of* I *does not change with time*, since it is an intermediate which is used up (going either to A + B or to C) as fast as it is formed. This assumption, called the assumption of the *steady state*, enables us to set $d[\mathrm{I}]/dt$ equal to zero and hence to solve for [I] in terms of the measurable quantities [A] and [B]:

$$[\mathbf{I}] = \frac{k_1[\mathbf{A}][\mathbf{B}]}{k_2[\mathbf{B}] + k_{-1}}$$

We now insert this value for [I] into the original rate expression to obtain

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1 k_2[\mathbf{A}][\mathbf{B}]^2}{k_2[\mathbf{B}] + k_{-1}}$$

Note that this rate law is valid whatever the values of k_1, k_{-1}, and k_2. However, our original hypothesis was that the first step was faster than the second, or that

$$k_1[\mathbf{A}][\mathbf{B}] \gg k_2[\mathbf{I}][\mathbf{B}]$$

Since the first step is an equilibrium

$$k_1[\mathbf{A}][\mathbf{B}] = k_{-1}[\mathbf{I}]$$

we have

$$k_{-1}[\mathbf{I}] \gg k_2[\mathbf{I}][\mathbf{B}]$$

Canceling [I], we get

$$k_{-1} \gg k_2[\mathbf{B}]$$

We may thus neglect $k_2[\mathrm{B}]$ in comparison with k_{-1} and obtain

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1 k_2}{k_{-1}}[\mathbf{A}][\mathbf{B}]^2$$

The overall rate is thus third order: first order in A and second order in B. Incidentally, if the first step is rate-determining (as was the case in the preceding paragraph), then

$$k_2[\mathbf{B}] \gg k_{-1} \qquad \text{and} \qquad \frac{-d[\mathbf{A}]}{dt} = k_1[\mathbf{A}][\mathbf{B}]$$

which is the same rate law we deduced from the rule that where the first step is rate-determining, the rate law includes the reactants which participate in that step.

It is possible for a reaction to involve A and B in the rate-determining step although only [A] appears in the rate law. This occurs when a large excess of B is present, say 100 times the molar quantity of A. In this case the complete reaction of A uses up only 1 mol of B, leaving 99 mol. It is not easy to measure the change in concentration of B with time in such a case, and it is seldom attempted, especially when B is also the solvent. Since [B] is, for practical purposes, unchanging with time in such a case, the reaction appears to be first order in A though actually both A and B are involved in the rate-determining step. This is often referred to as a *pseudo-first-order* reaction. Pseudo-order reactions may also come about when one reactant is a catalyst whose concentration does not change with time because it is replenished as fast as it is used up and when a reaction is conducted in a medium which keeps the concentration of a reactant constant, e.g., in a buffer solution where H^+ or OH^- is a reactant.

What is actually being measured is the change in concentration of a product or a reactant with time. Many methods have been used to make such measurements. The choice of a method depends on its convenience and on its applicability to the reaction being studied. Among the most common methods are:[21]

1. *Periodic spectral readings.* In many cases the reaction can be carried out in the cell while it is in the instrument. Then all that is necessary is that the instrument be periodically read. Among the methods used are ir and uv spectroscopy, nmr, and esr.
2. *Quenching and analyzing.* A series of reactions may be set up and each stopped in some way (perhaps by suddenly lowering the temperature or adding an inhibitor) after a different amount of time has elapsed. The materials are then analyzed, by spectral readings, titrations, gas chromatography, polarimetry (if optically active), or any other method.
3. *Removal of aliquots at intervals.* Each aliquot is then analyzed as in method 2.
4. *Dilatometry.* The change in total volume of a solution may be measured.
5. Measurement of changes in total pressure, for gas-phase reactions.[22]
6. *Calorimetric methods.* The output or absorption of heat may be measured at time intervals.

Special methods exist for very fast reactions.[23]

In any case what is usually obtained is a graph showing how a concentration varies with time. This must be interpreted[24] to obtain a rate law and a value of k. If a reaction obeys simple first- or second-order kinetics, the interpretation is generally not difficult. For example, if the concentration at the start is A_0, the first-order rate law

---

[21] For a discussion, see Batt, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 1, pp. 1–111, Elsevier Publishing Company, New York, 1969.

[22] For a review of the kinetics of reactions in solution at high pressures, see le Noble, *Prog. Phys. Org. Chem.* **5**, 207–330 (1967).

[23] For discussions, see Hague, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 1, pp. 112–179, Elsevier Publishing Company, New York, 1969; and Ref. 8, pt. 2.

[24] For discussions, much fuller than that given here, of methods for interpreting kinetic data, see Margerison, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 1, pp. 343–421, Elsevier Publishing Company, New York, 1969; Ref. 4, pp. 8–55; and Bunnett, in Ref. 8, pt. 1, pp. 367–488.

$$\frac{-d[A]}{dt} = k[A] \qquad \text{or} \qquad \frac{-d[A]}{[A]} = k\,dt$$

can be integrated between the limits $t = 0$ and $t = t$ to give

$$-\ln\frac{[A]}{A_0} = kt \qquad \text{or} \qquad \ln[A] = -kt + \ln A_0$$

Therefore, if a plot of ln [A] against t is linear, the reaction is first order and k can be obtained from the slope. For first-order reactions it is customary to express the rate not only by the rate constant k but also by the *half-life*, which is the time required for half of any given quantity of a reactant to be used up. Since the half-life $t_{1/2}$ is the time required for [A] to reach $A_0/2$, we may say that

$$\ln\frac{A_0}{2} = -kt_{1/2} + \ln A_0$$

so that

$$t_{1/2} = \frac{\ln \dfrac{A_0}{A_0/2}}{k} = \frac{\ln 2}{k} = \frac{0.693}{k}$$

For the general case of a reaction first order in A and first order in B, second order overall, integration is complicated, but it can be simplified if equimolar amounts of A and B are used, so that $A_0 = B_0$. In this case

$$\frac{-d[A]}{dt} = k[A][B]$$

is equivalent to

$$\frac{-d[A]}{dt} = k[A]^2 \qquad \text{or} \qquad \frac{-d[A]}{[A]^2} = k\,dt$$

Integrating as before gives

$$\frac{1}{[A]} - \frac{1}{A_0} = kt$$

Thus, under equimolar conditions, if a plot of $1/[A]$ against t is linear, the reaction is second order, with a slope of k. It is obvious that the same will hold true for a reaction second order in A.[25]

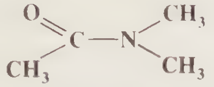
Although many reaction-rate studies do give linear plots, which can therefore be easily interpreted, the results in many other studies are not so simple. In some cases a reaction may be first order at low concentrations but second order at higher concentrations. In other cases fractional orders are obtained, and even negative orders. The interpretation of complex kinetics often requires much skill and effort. Even where the kinetics are relatively simple, there is often a problem in interpreting the data because of the difficulty of obtaining precise enough measurements.[26]

Nmr spectra can be used to obtain kinetic information in a completely different manner from that mentioned on p. 201. This method, which involves the study of nmr line shapes, depends on the fact that nmr spectra have an inherent time factor: if a proton changes its environment less rapidly than about 10^3 times per second, an nmr spectrum shows a separate peak for each position the proton assumes. For example, if the rate of rotation around the C—N bond of N,N-dimethylacetamide is slower than 10^3 rotations per second, the two N-methyl groups each

---

[25] We have given the integrated equations for simple first- and second-order kinetics. For integrated equations for a large number of kinetic types, see Margerison, Ref. 24, p. 361.

[26] See Hammett, Ref. 18, pp. 62–70.



have separate chemical shifts since they are not equivalent, one being cis to the oxygen and the other trans. However, if the environmental change takes place more rapidly than about 10^3 times per second, only one line is found, at a chemical shift which is the weighted average of the two individual positions. In many cases, two or more lines are found at low temperatures, but as the temperature is increased, the lines coalesce because the interconversion rate increases with temperature and passes the 10^3 per second mark. From studies of the way line shapes change with temperature it is often possible to calculate rates of reactions and of conformational changes.[27] The method is not limited to changes in proton line shapes but can also be used for other atoms which give nmr spectra and for esr spectra.

Several types of mechanistic information can be obtained from kinetic studies.

1. From the order of a reaction, information can be obtained about which molecules and how many take part in the rate-determining step. Such knowledge is very useful and often essential in elucidating a mechanism. Erroneous ideas about the mechanism of the benzidine rearrangement (reaction **8-44**) were accepted for many years, until it was discovered that the reaction was usually second order in H^+ (third order overall), indicating that *two* protons were required in the rate-determining step. For any mechanism which can be proposed for a given reaction, a corresponding rate law can be calculated by the methods discussed on pp. 199–201. If the experimentally obtained rate law fails to agree with this, the proposed mechanism is wrong. However, it is often difficult to relate the order of a reaction to the mechanism, especially when the order is fractional or negative. In addition, it is frequently the case that two or more proposed mechanisms for a reaction are kinetically indistinguishable; i.e., they predict the same rate law.

2. Probably the most useful data obtained kinetically are the rate constants themselves. They are important since they may tell us the effect on the rate of a reaction of changes in the structure of the reactants (see Chapter 9), the solvent, the ionic strength, the addition of catalysts, etc.

3. If the rate is measured at several temperatures, in most cases a plot of $\ln k$ against $1/T$ (T stands for absolute temperature) is nearly linear, with a negative slope, and fits the equation

$$\ln k = \frac{-E_a}{RT} + \ln A$$

where R is the gas constant and A a constant called the *frequency factor*. This permits calculation of E_a, which is the Arrhenius activation energy of the reaction. From this can be obtained $\Delta H^{\ddagger}$ by

$$E_a = \Delta H^{\ddagger} + RT$$

It is also possible to use these data to calculate $\Delta S^{\ddagger}$ by the formula[27a]

$$\frac{\Delta S^{\ddagger}}{4.576} = \log k - 10.753 - \log T + \frac{E_a}{4.576T}$$

Potential energy
Dissociation energy for a C—H bond
Dissociation energy for a C—D bond
Internuclear distance

Figure 5 A C—D bond has a lower zero-point energy than does a corresponding C—H bond; thus the dissociation energy is higher.

Isotope Effects

When a hydrogen in a reactant molecule is replaced by deuterium, there is often a change in the rate. Such changes are known as *deuterium isotope effects*[28] and are expressed by the ratio k_H/k_D. The ground-state vibrational energy (called the zero-point vibrational energy) of a bond depends on the mass of the atoms and is lower when the reduced mass is higher.[29] Therefore, D—C, D—O, D—N bonds, etc., have lower energies in the ground state than the corresponding H—C, H—O, H—N bonds, etc. Complete dissociation of a deuterium bond therefore requires more energy than that for a corresponding hydrogen bond in the same environment (Figure 5). If an H—C, H—O, or H—N bond is not broken at all in a reaction or is broken in a non-rate-determining step, substitution of deuterium for hydrogen causes no change in the rate (see below for an exception to this statement), but if the bond is broken in the rate-determining step, the rate must be lowered by the substitution.

This provides a valuable diagnostic tool for determination of mechanism. For example, in the bromination of acetone (reaction **2-4**)

$$CH_3COCH_3 + Br_2 \longrightarrow CH_3COCH_2Br$$

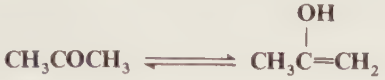
[29] The reduced mass μ of two atoms connected by a covalent bond is

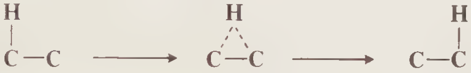
$$\mu = \frac{m_1 m_2}{m_1 + m_2}$$

the fact that the rate is independent of the bromine concentration led to the postulate that the rate-determining step was tautomerization of the acetone:



$$CH_3COCH_3 \rightleftharpoons CH_3\overset{\displaystyle OH}{\overset{|}{C}}{=}CH_2$$

In turn, the rate-determining step of the tautomerization involves cleavage of a C—H bond (see reaction **2-3**). Thus there should be a substantial isotope effect if deuterated acetone is brominated. In fact, k_H/k_D was found to be about 7.[30] Deuterium isotope effects usually range from 1 (no isotope effect at all) to about 9 or 10, though in a few cases larger[31] or smaller values have been reported. Values of k_H/k_D which are smaller than 1 are called *inverse isotope effects.* Isotope effects are greatest when, in the transition state, the hydrogen is symmetrically bonded to the atoms between which it is being transferred.[32] Also, calculations show that isotope effects are at a maximum when the hydrogen in the transition state is on the straight line connecting the two atoms between which the hydrogen is being transferred and that for sufficiently nonlinear configurations they decrease to $k_H/k_D = 1$ to 2.[33] Of course, in open systems there is no reason for the transition state to be nonlinear, but this is not the case in many intramolecular mechanisms; e.g., in a 1,2 migration of a hydrogen



Transition
state

The substitution of tritium for hydrogen gives isotope effects which are numerically larger.[34] Isotope effects have also been observed with other elements, but they are much smaller, about 1.02 to 1.10. For example, $k_{^{12}C}/k_{^{13}C}$ for

$$Ph{*}CH_2Br + CH_3O^- \xrightarrow{CH_3OH} Ph{*}CH_2OCH_3$$

is 1.053.[35] Although they are small, heavy-atom isotope effects can be measured quite accurately and are often very useful.

Deuterium isotope effects have been found even where it is certain that the C—H bond does not break at all in the reaction. Such effects are called *secondary isotope effects,*[36] the term *primary isotope effect* being reserved for the type discussed previously. Secondary isotope effects can be divided, for convenience, into α and β effects, although it is possible that they have the same cause. In a β secondary isotope effect, substitution of deuterium for hydrogen β to the position of bond breaking slows the reaction. An example is solvolysis of isopropyl bromide:

[31] For an example of a reaction with a deuterium isotope effect of 24.2, see Lewis and Funderburk, *J. Am. Chem. Soc.* **89,** 2322 (1967). The high isotope effect in this case has been ascribed to *tunneling* of the proton: because it is so small a hydrogen atom can sometimes get through a thin potential barrier without going over the top, i.e., without obtaining the usually necessary activation energy. A deuterium, with a larger mass, is less able to do this. The phenomenon of tunneling is a consequence of the uncertainty principle and is important only for electrons and hydrogen atoms. k_H/k_T for the same reaction is 79: Lewis and Robinson, *J. Am. Chem. Soc.* **90,** 4337 (1968).

[36] For reviews see Laszlo and Welvart, *Bull. Soc. Chim. Fr.* 2412–2438 (1966); Halevi, *Prog. Phys. Org. Chem.* **1,** 109–221 (1963); and Shiner, Mahler, Baker, and Hiatt, *Ann. N.Y. Acad. Sci.* **84,** 583–595 (1960).

$$(CH_3)_2CHBr + H_2O \xrightarrow{k_H} (CH_3)_2CHOH$$

$$(CD_3)_2CHBr + H_2O \xrightarrow{k_D} (CD_3)_2CHOH$$

where k_H/k_D was found to be 1.34.[37] The cause of β isotope effects has been a matter of much controversy, but they are most likely due to hyperconjugation effects in the transition state. The effects are greatest when the transition state has considerable carbonium-ion character.[38] Although the C—H bond in question is not broken in the transition state, the carbonium ion is stabilized by hyperconjugation involving this bond. Because of hyperconjugation, the difference in vibrational energy between the C—H bond and the C—D bond in the transition state is less than it is in the ground state, so that the reaction is slowed by substitution of deuterium for hydrogen.

Support for hyperconjugation as the major cause of β isotope effects is the fact that the effect is greatest when D is trans to the leaving group[39] (because of the requirement that all atoms in a resonance system be coplanar, planarity of the D—C—C—X system would most greatly increase the hyperconjugation), and the fact that secondary isotope effects can be transmitted through unsaturated systems.[40] There is evidence that at least some β isotope effects are steric in origin[41] (e.g., a CD_3 group has a smaller steric requirement than a CH_3 group), and a field-effect explanation has also been suggested (CD_3 is apparently a better electron donor than CH_3[42]), but hyperconjugation is the most probable cause in most instances.[43] Part of the difficulty in attempting to explain these effects is their small size, ranging only as high as about 1.5. Another complicating factor is that they may change with temperature. In one case[44] k_H/k_D was 1.00 ± 0.01 at 0°C, 0.90 ± 0.01 at 25°C, and 1.15 ± 0.09 at 65°C. Whatever the cause, there seems to be a good correlation between β secondary isotope effects and carbonium character in the transition state, and they are thus a useful tool for probing mechanisms.

The other type of secondary isotope effect results from a replacement of hydrogen by deuterium at the carbon containing the leaving group. These (called α *secondary isotope effects*) are varied, values so far reported ranging from 0.87 to 1.26.[45] These effects are also correlated with carbonium-ion character. Nucleophilic substitutions which do not proceed through carbonium-ion intermediates (SN2 reactions) have α isotope effects near unity.[46] Those which do involve carbonium ions (SN1 reactions) have higher α isotope effects, which depend on the nature of the leaving group.[47] The accepted explanation for α isotope effects is that one of the bending C—H vibrations is affected by the substitution of D for H more or less strongly in the transition state than in the ground state.[48] Depending on the nature of the transition state, this may increase or decrease the rate of the reaction. γ secondary isotope effects have also been reported.[49]

Another kind of isotope effect is the *solvent isotope effect*.[50] Reaction rates often change when the solvent is changed from H_2O to D_2O or from ROH to ROD. These changes may be due to any of three factors or a combination of all of them:

1. The solvent may be a reactant. If an O—H bond of the solvent is broken in the rate-determining step, there will be a primary isotope effect. If the molecules involved are D_2O or D_3O^+ there may also be a secondary effect caused by the O—D bonds which are not breaking.
2. The substrate molecules may become labeled with deuterium by rapid hydrogen exchange, and then the newly labeled molecule may become cleaved in the rate-determining step.
3. The extent or nature of solvent-solute interactions may be different in the deuterated and nondeuterated solvents; and this may change the energies of the transition state and hence the activation energy of the reaction. These are secondary isotope effects. Two physical models for this third factor have been constructed.[51] It is obvious that in many cases the first and third factors at least, and often the second, are working simultaneously. Attempts have been made to separate them.[52]

The methods described in this chapter are not the only means of determining mechanisms. In an attempt to elucidate a mechanism, the investigator is limited only by his ingenuity.

Seven
Photochemistry

Most reactions carried out in organic chemistry laboratories take place between molecules all of which are in their ground electronic states. In a *photochemical reaction*,[1] however, a reacting molecule has previously been promoted by absorption of light to an electronically excited state. A molecule in an excited state must lose its extra energy in some manner; it cannot remain in the excited condition for long. However, a chemical reaction is not the only possible means of relinquishing the extra energy. In this chapter we shall first discuss electronically excited states and the processes of promotion to these states. Then we shall examine the possible pathways open to the excited molecule, first the physical and then the chemical pathways. The subject of electronic spectra is closely related to photochemistry.

Excited States and the Ground State

In Chapter 1 it was mentioned that electrons can move from the ground-state energy level to a higher one and that outside energy is required for this. In a photochemical process this energy is in the form of light. Light of any wavelength has associated with it an energy value given by $E = h\nu$, where ν is the frequency of the light (ν = velocity of light c divided by the wavelength λ) and h is Planck's constant. Since the energy levels of a molecule are quantized, the amount of energy required to raise an electron in a given molecule from one level to a higher one is a fixed quantity. Only light with exactly the frequency corresponding to this amount of energy will cause the electron to move to the higher level. If light of another frequency is sent through a sample, it will pass out without a loss in intensity, since the molecules will not absorb it. However, if light of the correct frequency is passed in, the energy will be used by the molecules for electron promotion and hence the light that leaves the sample will be diminished in intensity or altogether gone. A *spectrophotometer* is a device which allows light of a given frequency to pass through a sample and which detects (by means of a phototube) the amount of light which has been transmitted, i.e., not absorbed. The instrument compares the intensity of the transmitted light with that of the incident light. The user of a manual spectrophotometer may select visible or uv light of any frequency, pass it through the sample, and read the amount of absorption. Automatic instruments gradually and continuously change the frequency, and an automatic recorder plots a graph of absorption versus frequency or wavelength.

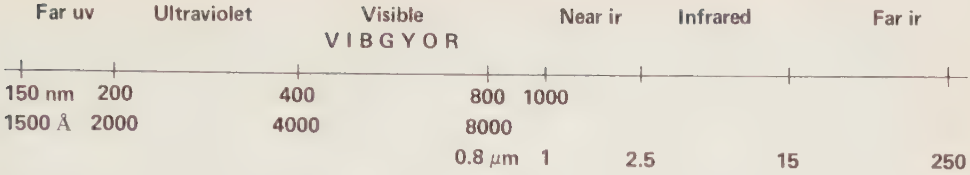

Figure 1 The uv, visible, and ir portions of the spectrum.

The energy of electronic transitions corresponds to light in the visible, uv, and far-uv regions of the spectrum (Figure 1). Absorption positions are normally expressed in wavelength units; either in angstroms (Å) or in nanometers (nm).[2] If a compound absorbs in the visible, it is colored, possessing a color complementary to that which is absorbed. Thus a compound absorbing in the violet is yellow. The far-uv region is studied by organic chemists less often than the visible or ordinary uv regions because special vacuum instruments are required owing to the fact that oxygen and nitrogen absorb in these regions.

From these considerations it would seem that an electronic spectrum should consist of one or more sharp peaks, each corresponding to the transfer of an electron from one electronic level to another. In practice the peaks are seldom sharp. In order to understand why, it is necessary to realize that molecules are constantly vibrating and rotating and that these motions are also quantized. A molecule at any time is in a given electronic state but also in a given vibrational and rotational state. The difference between two adjacent vibrational levels is much smaller than the difference between adjacent electronic levels, and the difference between adjacent rotational levels is smaller still. A typical situation is shown in Figure 2. When an electron moves from one electronic level to another, it moves from a given vibrational and rotational level within that electronic level to some vibrational and rotational level at the next electronic level. A given sample contains a large number of molecules, and even if all of them are in the ground electronic state, they are still distributed among the vibrational and rotational states (though the ground vibrational state V_0 is most heavily populated). This means that not just one wavelength of light will be absorbed but a number of them close together, with the most probable transition causing the most intense peak. But in molecules containing more than a few atoms there are so many possible transitions and these are so close together that what is observed is a relatively broad band. The height of the peak depends on the number of molecules making the transition and is proportional to log ε, where ε is the *extinction coefficient*. The extinction coefficient may be expressed by $\varepsilon = E/cl$, where c is the concentration in moles per liter, l is the cell length in centimeters, and $E = \log I_0/I$, where I_0 is the intensity of the incident light and I of the transmitted light. The wavelength is usually reported as $\lambda_{\max}$, meaning that this is the top of the peak. Purely vibrational transitions, such as between V_0 and V_1 of E_1, which require much less energy, are found in the ir region and are the basis of ir spectra. Purely rotational transitions are found in the far-ir and microwave (beyond the far-ir) regions.[3]

A uv or visible absorption peak is caused by the promotion of an electron in one orbital (usually a ground-state orbital) to a higher orbital. Normally the amount of energy necessary to make this transition depends mostly on the nature of the two orbitals involved and much less on the rest of the molecule. Therefore, a simple functional group such as the C=C double bond always causes absorption in the same general area. A group which causes absorption is called a *chromophore*.

---

[2] Formerly, millimicrons (mμ) were frequently used; numerically they are the same as nanometers.

[3] For a review of how chemical information is obtained from microwave spectra, see Lide, *Surv. Prog. Chem.* **5**, 95–127 (1969).

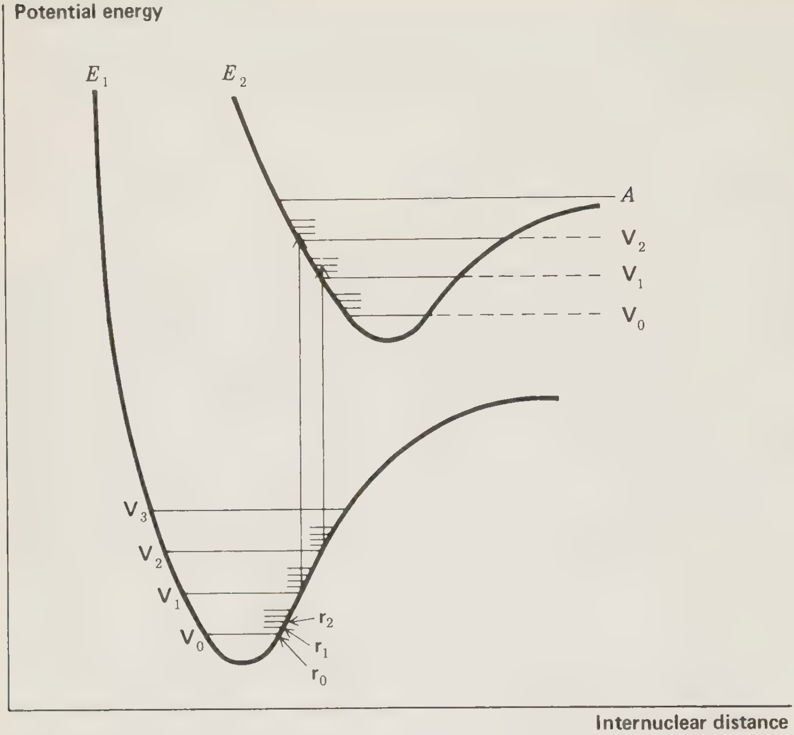

Figure 2 Energy curves for a diatomic molecule. Two possible transitions are shown. When an electron has been excited to the point marked *A*, the molecule may cleave (p. 214).

The amount of light energy necessary to raise an electron to a higher level is called a *quantum* or a *photon;* 1 mol of photons is 1 *einstein.* Obviously, an einstein of light represents a different amount of energy depending on which molecule absorbs it and which energy levels are involved.

Singlet and Triplet States. "Forbidden" Transitions

In most organic molecules all electrons in the ground state are paired, each member of a pair possessing opposite spin, as demanded by the Pauli principle. When one of a pair of electrons is promoted to an orbital of higher energy, however, the Pauli principle no longer applies because the two electrons are no longer sharing an orbital, and the promoted electron may, in principle, have the same spin as its former partner or the opposite spin. As we have seen in Chapter 5, a molecule in which two unpaired electrons have the same spin is called a *triplet*, while one in which all spins are paired is a *singlet*. Thus, at least in principle, for every excited singlet state there is a corresponding triplet state. In most cases, the triplet state has a lower energy than the corresponding singlet because of Hund's rule (p. 7). Therefore a different amount of energy and hence a different wavelength is required to promote an electron from the ground state (which is almost always a singlet) to an excited singlet than to the corresponding triplet state.

It would thus seem that promotion of a given electron in a molecule could result either in a singlet or a triplet excited state depending on the amount of energy added. However, this is often not the case because transitions between energy levels are governed by selection rules which state that certain transitions are "forbidden." There are several types of "forbidden" transitions, two of which are more important than the others.

1. *Spin-forbidden transitions.* Transitions in which the spin of an electron changes are not allowed, because a change from one spin to the opposite involves a change in angular momentum, and such a change would violate the law of conservation of angular momentum. Therefore singlet-triplet and triplet-singlet transitions are forbidden, whereas singlet-singlet and triplet-triplet transitions are allowed.
2. *Symmetry-forbidden transitions.* Among the transitions in this class are those in which a molecule has a center of symmetry. In such cases, a $g \rightarrow g$ or $u \rightarrow u$ transition (see p. 9) is "forbidden," while a $g \rightarrow u$ or $u \rightarrow g$ transition is allowed.

We have put the word "forbidden" into quotation marks because these transitions are not actually forbidden but only highly improbable. In most cases promotions from a singlet ground state to a triplet excited state are so improbable that they cannot be observed, and it is safe to state that in most molecules only singlet-singlet promotions take place. However, this rule does break down in certain cases, most often when a heavy atom (such as iodine) is present in the molecule, in which cases it can be shown from spectra that singlet-triplet promotions are occurring. Symmetry-forbidden transitions can frequently be observed, though usually with low intensity.

Types of Excitation

When an electron in a molecule is promoted (normally only one electron in any molecule), it usually goes into the lowest available vacant orbital, though promotion to higher orbitals is also possible if any are available. For most organic molecules there are consequently four types of electronic excitation:

1. $\sigma \rightarrow \sigma^*$. Alkanes, which have no n or π electrons, can be excited only in this way.[4]
2. $n \rightarrow \sigma^*$. Alcohols, amines, ethers, etc., can also be excited in this manner.
3. $\pi \rightarrow \pi^*$. This pathway is open to alkenes as well as to aldehydes, esters, etc.
4. $n \rightarrow \pi^*$. Aldehydes, ketones, esters, etc., can undergo this promotion as well as the other three.

The four excitation types above are listed in what is normally the order of decreasing energy. Thus light of the highest energy (in the far uv) is necessary for $\sigma \rightarrow \sigma^*$ excitation, while $n \rightarrow \pi^*$ promotions are caused by ordinary uv light. However, in some solvents the order may sometimes be altered.

In 1,3-butadiene (and other compounds with two conjugated double bonds) there are two π and two π^* orbitals (p. 32). The energy difference between the higher π (χ_2) and the lower π^* (χ_3) orbital is less than the difference between the π and π^* orbitals of ethylene. Therefore 1,3-butadiene requires less energy than ethylene, and thus light of a higher wavelength, to promote an electron. This is a general phenomenon, and it may be stated that, in general, *the more conjugation in a molecule, the more the absorption is displaced toward higher wavelengths* (see Table 1).[5] When a chromophore absorbs at a certain wavelength and the substitution of one group for another causes absorption at a higher wavelength, a *bathochromic shift* is said to have occurred. The opposite kind of shift is called *hypsochromic*.

---

[4] An n electron is one in an unshared pair.

[5] Bohlmann and Mannhardt, *Chem. Ber.* **89**, 1307 (1956).

TABLE 1 Ultraviolet absorption[5] of $CH_3-(CH=CH)_n-CH_3$ for some values of n

n	nm
2	227
3	263
6	352
9	413

Of the four excitation types listed above, the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ are far more important in organic photochemistry than the other two. Compounds containing C=O groups can be excited in both ways, giving rise to at least two peaks in the uv. These are often easy to distinguish, because $\pi \rightarrow \pi^*$ transitions are found farther toward the far uv and are generally much more intense (ε for $\pi \rightarrow \pi^*$ is usually about 100 to 10,000 compared with $\varepsilon = 10$ to 1000 for $n \rightarrow \pi^*$). However, there are many cases in which it is difficult to tell them apart. In such cases there are several methods which can be used,[6] one of which involves the measurement of the spectrum in different solvents. An increase in solvent polarity usually causes a hypsochromic shift in $n \rightarrow \pi^*$ transitions and a bathochromic shift in $\pi \rightarrow \pi^*$ transitions. For the $n \rightarrow \pi^*$ transition the explanation is that hydrogen bonding between a hydrogen of the solvent and the oxygen of the C=O group lowers the energy of the ground state without doing the same for the excited state,[7] so that more energy is required for excitation. Acetone, for example, has an $n \rightarrow \pi^*$ peak at 265 nm in water but 279 nm in hexane. The bathochromic shift in the case of $\pi \rightarrow \pi^*$ transitions is more difficult to explain but may be caused by the formation of charge-transfer or π complexes.[8]

As we have seen, a chromophore is a group which causes a molecule to absorb light. Examples of chromophores in the visible or uv are C=O, N=N,[9] Ph, and NO_2. Some chromophores in the far uv (beyond 200 nm) are C=C, C≡C, Cl, and OH. An *auxochrome* is a group which displaces (through resonance) and usually intensifies the absorption of a chromophore present in the same molecule. Groups such as Cl, OH, and NH_2 are generally regarded as auxochromes since they shift (usually bathochromically) the uv and visible bands of chromophores such as Ph or C=O (see Table 2).[10] Since auxochromes are themselves chromophores (to be sure, generally in the far uv), it is sometimes difficult to decide which group in a molecule is an auxochrome and which a chromophore. For example, in acetophenone (PhCOMe) is the chromophore Ph or C=O? In such cases the distinction becomes practically meaningless.

Properties and Nomenclature of Excited States

An excited state of a molecule may be regarded as a distinct chemical species, different from the ground state of the same molecule and from other excited states. It is obvious that we need some method of naming excited states. Unfortunately, there are several methods in use, depending on

---

[6] See Calvert and Pitts, Ref. 1, pp. 260–262.

[7] There is evidence that the energy of the initially formed excited state is actually *increased* by desolvation in more polar solvents: Haberfield, *J. Am. Chem. Soc.* **96,** 6526 (1974).

[8] For a discussion, see Jaffé and Orchin, "Theory and Applications of Ultraviolet Spectrosopy," John Wiley & Sons, Inc., New York, 1962, pp. 188–195.

[9] For a review of the azo group as a chromophore, see Rau, *Angew. Chem. Int. Ed. Engl.* **12,** 224–235 (1973) [*Angew. Chem.* **85,** 248–258].

[10] These values are from Ref. 8, p. 257.

TABLE 2 Some uv peaks of substituted benzenes in water, or water with a trace of methanol (for solubility)

Note how auxochromes shift and usually intensify the peaks[10]

	Primary band		Secondary band	
	λ_{max}, nm	ε_{max}	λ_{max}, nm	ε_{max}
PhH	203.5	7,400	254	204
PhCl	209.5	7,400	263.5	190
PhOH	210.5	6,200	270	1,450
PhOMe	217	6,400	269	1,480

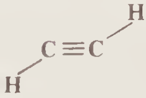
PhCHO	249.5	11,400		
$PhNO_2$	268.5	7,800		

whether one is primarily interested in photochemistry, spectroscopy, or molecular-orbital theory.[11] One of the most common methods simply designates the original and newly occupied orbitals, with or without a superscript to indicate singlet or triplet. Thus the singlet state arising from promotion of a π to a π^* orbital in ethylene would be the $^1(\pi,\pi^*)$ state or the π,π^* singlet state. Another very common method may be used even in cases where one is not certain which orbitals are involved. The lowest-energy excited state is called S_1, the next S_2, etc., and triplet states are similarly labeled T_1, T_2, T_3, etc. In this notation the ground state is S_0. In another convention, the *symmetry notation*, the H_2 $\sigma \rightarrow \sigma^*$ transition is written

$$^1\Sigma_u^+ \leftarrow {}^1\Sigma_g^+$$

Here the superscript 1 means singlet, u and g refer to ungerade and gerade, respectively (p. 9), and the + means that reflection through a plane of symmetry leaves the sign of the wave function unaltered. A Σ state is one in which net orbital angular momentum about the molecular axis is zero. The ground state of ethylene in this notation is ^1A_g. In the symmetry notation the state of higher energy is written first, whether the process is absorption or emission. The arrow shows the direction of the transition. Other notational systems exist too, but in this book we shall confine ourselves to the $^1(\pi,\pi^*)$ type and the S_0, S_1, T_1 type.

The properties of excited states are not easy to measure because of their generally short lifetimes and low concentrations, but enough work has been done for us to know that they often differ from the ground state in geometry, dipole moment, and acid or base strength.[12] For example, acetylene, which is linear in the ground state, has a trans geometry



---

[11] For discussions of excited-state notation and other terms in the photochemistry vocabulary, see Pitts, Wilkinson, and Hammond, *Adv. Photochem.* **1**, 1–21 (1963); Porter, Balzani, and Moggi, *Adv. Photochem.* **9**, 147–196 (1974).

TABLE 3 Typical energies for some covalent single bonds (see Table 6, Chapter 1) and the corresponding approximate wavelengths

Bond	E, kcal/mol	λ, nm
C—H	95	300
C—O	88	325
C—C	83	345
Cl—Cl	58	495
O—O	35	820

with approximately sp^2 carbons in the $^1(\pi,\pi^*)$ state.[13] Similarly, the $^1(\pi,\pi^*)$ and the $^3(\pi,\pi^*)$ states of ethylene have a perpendicular and not a planar geometry,[14] and the $^1(n,\pi^*)$ and $^3(n,\pi^*)$ states of formaldehyde are both pyramidal.[15] Triplet species tend to stabilize themselves by distortion, which relieves interaction between the unpaired electrons. Obviously, if the geometry is different, the dipole moment will probably differ also; and the change in geometry and electron distribution often results in a change in acid or base strength.[15a] For example, the S_1 state of 2-naphthol is a much stronger acid (pK = 3.1) than the ground state (S_0) of the same molecule (pK = 9.5).[16]

Photolytic Cleavage

We have said that when a molecule absorbs a quantum of light, it is promoted to an excited state. Actually, that is not the only possible outcome. Because the energy of visible and uv light is of the same order of magnitude as that of covalent bonds (Table 3), another possibility is that the molecule may cleave into two parts, a process known as *photolysis*. There are three situations which may lead to cleavage.

1. The promotion may bring the molecule to a vibrational level so high that it lies above the right-hand portion of the E_2 curve (line A in Fig. 2). In such a case the excited molecule cleaves at its first vibration.

2. Even where the promotion is to a lower vibrational level, one which lies wholly within the E_2 curve (such as V_1 or V_2), the molecule may still cleave. As Figure 2 shows, equilibrium distances are greater in excited states than in the ground state. The *Franck-Condon principle* states that promotion of an electron takes place much faster than a single vibration (the promotion takes about 10^{-15} sec; a vibration about 10^{-12} sec). Therefore, when an electron is suddenly promoted, even to a low vibrational level, the distance between the atoms is essentially unchanged and the bond finds itself in a compressed condition, like a pressed-in spring; this condition may be relieved by an outward surge which is sufficient to break the bond.

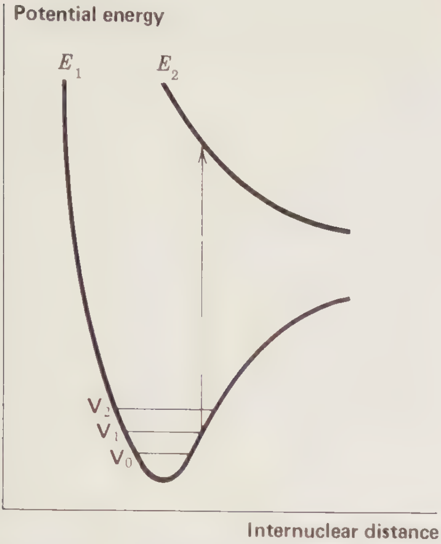

Figure 3 Promotion to a dissociative state results in bond cleavage

3. In some cases the excited state is entirely dissociative (Figure 3), i.e., there is no distance where attraction outweighs repulsion, and the bond must cleave. An example is the hydrogen molecule, where a $\sigma \rightarrow \sigma^*$ promotion always results in cleavage.

A photolytic cleavage may break the molecule into two smaller molecules or into two free radicals (see p. 220). Cleavage into two ions, though known, is much rarer. Once free radicals are produced by a photolysis, they behave like free radicals produced in any other way (Chapter 5) except that they may be in excited states, and this can cause differences in behavior.

The Fate of the Excited Molecule: Physical Processes

When a molecule has been photochemically promoted to an excited state, it does not remain there for long. Most promotions are from the S_0 to the S_1 state. As we have seen, promotions from S_0 to triplet states are "forbidden." Promotions to S_2 and higher singlet states take place, but in liquids and solids these higher states usually drop very rapidly to the S_1 state (about 10^{-13} to 10^{-11} sec). The energy which is lost when an S_2 or S_3 molecule drops to S_1 is given up in small increments to the environment by collisions with neighboring molecules. Such a process is called an *energy cascade*. In a similar manner, the initial excitation and the decay from higher singlet states initially populate many of the vibrational levels of S_1, but these also cascade, down to the lowest vibrational level of S_1. Therefore, in most cases, the lowest vibrational level of the S_1 state is the only important excited singlet state. This state can undergo various physical and chemical processes. In the following list, we shall describe the physical pathways open to molecules in the S_1 and excited triplet states. These pathways are also shown in a modified Jablonski diagram (Figure 4) and in Table 4.

1. A molecule in the S_1 state can cascade down through the vibrational levels of the S_0 state and thus return to the ground state by giving up its energy in small increments to the environment,

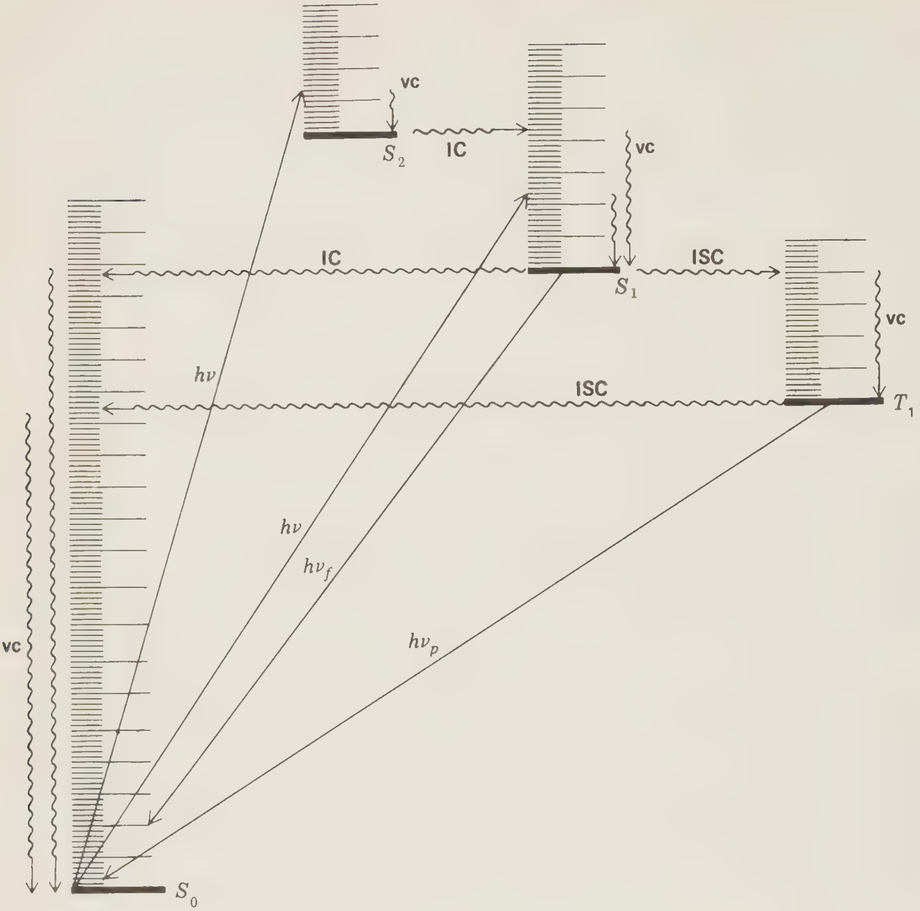

Figure 4 Modified Jablonski diagram showing transitions between excited states and the ground state. Radiative processes are shown by straight lines; radiationless processes by wavy lines. *IC* = internal conversion; *ISC* = intersystem crossing; *vc* = vibrational cascade; $h\nu_f$ = fluorescence; $h\nu_p$ = phosphorescence.

but this is generally quite slow because the amount of energy is large. The process is called *internal conversion* (IC). Because it is slow, most molecules in the S_1 state adopt other pathways.

2. A molecule in the S_1 state can drop to some low vibrational level of the S_0 state all at once by giving off the energy in the form of light. This process, which generally happens within 10^{-9} sec, is called *fluorescence*. This pathway is not very common either (because it is relatively slow) except for small molecules, e.g., diatomic, and rigid molecules, e.g., aromatic. For most other compounds fluorescence is very weak or undetectable. For compounds which do fluoresce, the fluorescence emission spectra are usually the approximate mirror images of the absorption spectra. This comes about because the fluorescing molecules all drop from the lowest vibrational level of the S_1 state to various vibrational levels of S_0, while excitation is from the lowest vibrational level of S_0 to various levels of S_1 (Figure 5). The only peak in common is the one resulting from transitions between the lowest vibrational levels of the two states. This peak is usually called the

TABLE 4 Physical processes undergone by excited molecules

The superscript v indicates vibrationally excited state: excited states higher than S_1 or T_1 are omitted

$S_0 + h\nu \rightarrow S_1{}^v$	Excitation
$S_1{}^v \rightsquigarrow S_1$ + heat	Vibrational relaxation
$S_1 \rightarrow S_0 + h\nu$	Fluorescence
$S_1 \rightsquigarrow S_0$ + heat	Internal conversion
$S_1 \rightsquigarrow T_1{}^v$	Intersystem crossing
$T_1{}^v \rightsquigarrow T_1$ + heat	Vibrational relaxation
$T_1 \rightarrow S_0 + h\nu$	Phosphorescence
$T_1 \rightsquigarrow S_0$ + heat	Intersystem crossing
$S_1 + \mathbf{A}_{(S_0)} \rightarrow S_0 + \mathbf{A}_{(S_1)}$	Singlet-singlet transfer (photosensitization)
$T_1 + \mathbf{A}_{(S_0)} \rightarrow S_0 + \mathbf{A}_{(T_1)}$	Triplet-triplet transfer (photosensitization)

0-0 peak, because the transition is from the V_0 level of one state to the V_0 level of another. In solution, even the 0-0 peak may be noncoincidental because the two states are solvated differently. Fluorescence nearly always arises from a $S_1 \rightarrow S_0$ transition, though azulene (p. 50) and its simple derivatives are exceptions,[17] emitting fluorescence from $S_2 \rightarrow S_0$ transitions.

Because of the possibility of fluorescence, any chemical reactions of the S_1 state must take place very fast, or fluorescence will occur before they can happen.

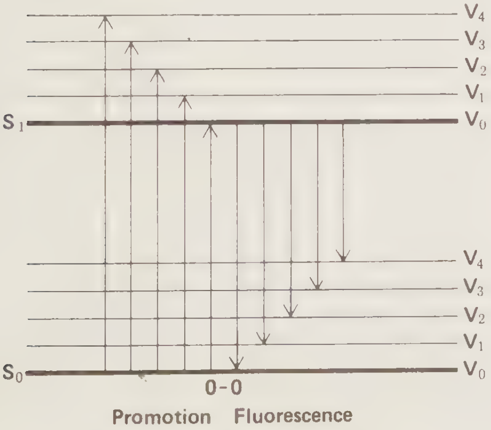
3. Most molecules (though by no means all) in the S_1 state can undergo an *intersystem crossing* (ISC) to the lowest triplet state T_1.[18] An important example is benzophenone, of which ap-

---

[17] For other exceptions see Hirayama, Gregory, and Lipsky, *J. Chem. Phys.* **58**, 4696 (1973); Gregory, Hirayama, and Lipsky, *J. Chem. Phys.* **58**, 4697 (1973); and references cited in these papers.

[18] Intersystem crossing from S_1 to T_2 and higher triplet states has also been reported in some aromatic molecules: Li and Lim, *J. Chem. Phys.* **57**, 605 (1972); Sharf and Silbey, *Chem. Phys. Lett.* **5**, 314 (1970). See also Schlag, Schneider, and Fischer, *Annu. Rev. Phys. Chem.* **22**, 465–526 (1971), pp. 490–494.

Figure 5 Promotion and fluorescence between S_1 and S_0 states.



proximately 100% of the molecules which are excited to the S_1 state cross over to the T_1.[19] Intersystem crossing from singlet to triplet is of course a "forbidden" pathway, since the angular-momentum problem (p. 211) must be taken care of, but this often takes place by compensations elsewhere in the system. Intersystem crossings take place without loss of energy. Since a singlet state usually has a higher energy than the corresponding triplet, this means that energy must be given up. One way for this to happen is for the S_1 molecule to cross to a T_1 state at a high vibrational level and then for the T_1 to cascade down to its lowest vibrational level (see Figure 4). This cascade is very rapid (10^{-12} sec). When T_2 or higher states are populated, they too rapidly cascade to the lowest vibrational level of the T_1 state.

4. A molecule in the T_1 state may return to the S_0 state by giving up heat (intersystem crossing) or light (this is called *phosphorescence*).[20] Of course the angular-momentum difficulty exists here, so that both intersystem crossing and phosphorescence are very slow ($\sim 10^{-3}$ to 10^1 sec). This means that T_1 states generally have much longer lifetimes than S_1 states. When they occur in the same molecule, phosphorescence is found at lower frequencies than fluorescence (because of the higher difference in energy between S_1 and S_0 than between T_1 and S_0) and is longer-lived (because of the longer lifetime of the T_1 state). Besides fluorescence and phosphorescence, there is a third type of emission, *slow fluorescence*. This has the same wavelength as fluorescence but occurs much more slowly. One way in which slow fluorescence is caused is when a molecule in the T_1 state acquires enough thermal energy to raise it to a higher vibrational level (equal in energy to the lowest S_1 level) and then crosses to S_1, which of course can then fluoresce. Slow fluorescence caused in this manner obviously increases with increasing temperature. Slow fluorescence can also be caused by a collision between two triplet molecules in which an excited singlet is produced.

5. If nothing else happens to it first, a molecule in an excited state (S_1 or T_1) may transfer its excess energy all at once to another molecule in the environment, in a process called *photosensitization*.[21] The excited molecule (which we shall call D for donor) thus drops to S_0 while the other molecule (A for acceptor) becomes excited:

$$\mathbf{D^* + A \longrightarrow A^* + D}$$

Thus there are *two* ways for a molecule to reach an excited state: by absorption of a quantum of light and by transfer from a previously excited molecule.[22] The donor D is also called a *photosensitizer*. This energy transfer is subject to the *Wigner spin-conservation rule*, which is actually a special case of the law of conservation of momentum we have encountered previously. According to the Wigner rule, the total electron spin does not change after the energy transfer. For example, when a triplet species interacts with a singlet the following are some allowed possibilities:[23]

$\underset{\mathbf{D^*}}{(\uparrow\uparrow)^*} + \underset{\mathbf{A}}{\uparrow\downarrow} \longrightarrow \underset{\mathbf{D}}{\uparrow\downarrow} + \underset{\mathbf{A^*}}{(\uparrow\uparrow)^*}$	singlet and triplet
$\longrightarrow \uparrow\uparrow\downarrow + \uparrow$	doublet and doublet (two free radicals)
$\longrightarrow \uparrow\uparrow + \downarrow + \uparrow$	triplet and two doublets
$\longrightarrow \uparrow\downarrow + \uparrow + \uparrow$	singlet and two doublets

For a review of physical and chemical processes of triplet states see Wagner and Hammond, *Adv. Photochem.* **5,** 21–156 (1968). For a review of phosphorescence, see Parker, *Adv. Photochem.* **2,** 305–383 (1964).

[21] For reviews, see Wilkinson, *Adv. Photochem.* **3,** 241–268 (1964); Turro, Dalton, and Weiss, *Org. Photochem.* **2,** 1–62 (1969).

[22] There is also a third way: in certain cases excited states can be produced directly in ordinary reactions. For a review, see White, Miano, Watkins, and Breaux, *Angew. Chem. Int. Ed. Engl.* **13,** 229–243 (1974) [*Angew. Chem.* **86,** 292–307].

[23] For additional tables of this kind, see Calvert and Pitts, Ref. 1, p. 89; and Cox and Kemp, Ref. 1, p. 22.

TABLE 5 Some triplet energies[25]

Compound	Energy, kcal/mol	Compound	Energy, kcal/mol
Benzene	85	Naphthalene	61
Phenol	82	Nitrobenzene	60
Aniline	77	Chrysene	57
Benzaldehyde	72	Biacetyl	55
Carbazole	70	Benzil	54
Benzophenone	69	Eosin	43
Fluorene	68	Anthracene	42
Quinoline	62	Naphthacene	29

In all these cases the products have three electrons spinning "up" and the fourth "down" (as do the starting molecules). However, formation of, say, two triplets ($\uparrow\uparrow + \downarrow\downarrow$) or two singlets ($\uparrow\downarrow + \uparrow\downarrow$), whether ground states or excited, would violate the rule.

In the two most important types of photosensitization, both of which are in accord with the Wigner rule, a triplet excited state generates another triplet, and a singlet generates a singlet:

$$\mathbf{D}_{T_1} + \mathbf{A}_{S_0} \longrightarrow \mathbf{A}_{T_1} + \mathbf{D}_{S_0} \qquad \text{triplet-triplet transfer}$$

$$\mathbf{D}_{S_1} + \mathbf{A}_{S_0} \longrightarrow \mathbf{A}_{S_1} + \mathbf{D}_{S_0} \qquad \text{singlet-singlet transfer}$$

Singlet-singlet transfer can take place over relatively long distances, e.g., 40 Å, but triplet transfer normally requires a collision between the molecules.[24] Both types of photosensitization can be useful for creating excited states when they are difficult to achieve by direct irradiation. Photosensitization is therefore an important method for carrying out photochemical reactions when a molecule cannot be brought to the desired excited state by direct absorption of light. Triplet-triplet transfer is especially important because triplet states are usually much more difficult to prepare by direct irradiation than singlet states (often impossible) and because triplet states, having longer lifetimes, are much more likely than singlets to transfer energy by photosensitization.

One way in which photosensitization can be detected is if the addition of a substance A to the original substance D quenches the fluorescence or phosphorescence of D. Another way is if A now exhibits fluorescence or phosphorescence or undergoes reactions which it would not in the absence of D.

Photosensitization is most efficient when the donor D* has a higher energy than the excited acceptor A*. The excess energy appears as kinetic energy of D and A*. Thus, before carrying out a photosensitization, one should know the energies of these states. Table 5 lists some triplet energies.[25] In choosing a photosensitizer one should avoid a compound which absorbs in the same region as the acceptor because the latter will then compete for the light.[26] For examples of the use of photosensitization to accomplish reactions, see pp. 753, 783.

It is also possible for an excited molecule D* to collide with a molecule A and for D* to drop to the ground state D, without A becoming excited, but with all the excess energy going into kinetic energy (translational, vibrational, rotational) of the recoiling A and D molecules. This, however, is relatively rare because the direct conversion of electronic to kinetic energy is a highly inefficient process.

---

[24] Long-range triplet-triplet transfer has been observed in a few cases: Bennett, Schwenker, and Kellogg, *J. Chem. Phys.* **41**, 3040 (1964); Ermolaev and Sveshnikova, *Izv. Akad. Nauk SSSR, Ser. Fiz.* **26**, 29 (1962) [*C. A.* **57**, 1688 (1962)], *Opt. Spectrosc. (USSR)* **16**, 320 (1964).

[25] These values are taken from a much longer list in Turro, Ref. 1, p. 132, See also Calvert and Pitts, Ref. 1, pp. 297–298.

[26] For a review of other complications which may take place in photosensitized reactions, see Engel and Monroe, *Adv. Photochem.* **8**, 245–313 (1971).

TABLE 6 Primary photochemical reactions of an excited molecule **A—B—C**[28]

Examples are given in the text; the most common are (1), (2), *and, in the presence of a suitable acceptor molecule,* (7)

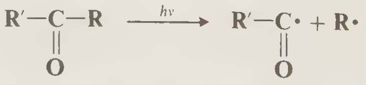
$(\mathrm{A{-}B{-}C}) \xrightarrow{\mathrm{A}} \mathrm{ABC} + \mathrm{A}^*$	Photosensitization	(7)

The Fate of the Excited Molecule: Chemical Processes

Although both excited singlet and triplet species can undergo chemical reactions, they are much more common for triplets, simply because these generally have much longer lifetimes. Excited singlet species, in most cases, have a lifetime of less than 10^{-10} sec and undergo one of the physical processes already discussed before they have a chance to react chemically. Therefore, photochemistry is largely the chemistry of triplet states.[27] Table 6[28] lists many of the possible chemical pathways which can be taken by an excited molecule.[28a] The first four of these are unimolecular reactions, and the others are bimolecular. In the case of bimolecular reactions it is rare for two excited molecules to react with each other (because the concentration of excited molecules at any one time is generally low); reactions are between an excited molecule and an unexcited molecule, either of the same or of another species. The reactions listed in Table 6 are primary processes. Secondary reactions often follow, since the primary products are frequently free radicals or carbenes; even if they are ordinary molecules, they are often in upper vibrational levels and so have excess energy. In almost all cases the primary products of photochemical reactions are in their ground states, though exceptions are known.[29] Of the reactions listed in Table 6, the most common are cleavage into free radicals (1), decomposition into molecules (2), and (in the presence of a suitable acceptor molecule) photosensitization (7), which we have already discussed. The following are some specific examples of reaction categories (1) to (6). Other examples are discussed in Part 2 of this book.

Category (1). Aldehydes and ketones absorb in the 230 to 330 nm region. This is assumed to result from an $n \rightarrow \pi^*$ singlet-singlet transition. The excited aldehyde or ketone can then cleave:[30]



$$\mathrm{R'{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R} \xrightarrow{h\nu} \mathrm{R'{-}\underset{\underset{\displaystyle O}{\|}}{C}\cdot + R\cdot}$$

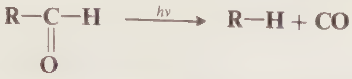
Rev.* **1,** 465–480 (1972); Pitts and Wan, in Patai, "The Chemistry of the Carbonyl Group," pp. 823–916, Wiley-Interscience, New York, 1966; Dalton and Turro, *Annu. Rev. Phys. Chem.* **21,** 499–560 (1970); Bérces, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 5, pp. 277–380, American Elsevier Publishing Company, New York, 1972; Turro, Dalton, Dawes, Farrington, Hautala, Morton, Niemczyk, and Shore, *Acc. Chem. Res.* **5,** 92–101 (1972); and Wagner and Hammond, Ref. 20, pp. 87–129. For reviews of the photochemistry of cyclic ketones, see Chapman and Weiss, *Org. Photochem.* **3,** 197–288 (1973); Morton and Turro, *Adv. Photochem.* **9,** 197–309 (1974). For reviews of the photochemistry of α-diketones, see Rubin, *Fortschr. Chem. Forsch.* **13,** 251–306 (1969); and Monroe, *Adv. Photochem.* **8,** 77–108 (1971).

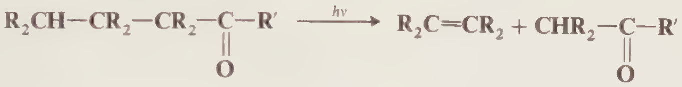
When applied to ketones, this is called *Norrish Type I cleavage* or often just *Type I cleavage*. In a secondary process, the acyl radical R′—CO• can then lose CO to give R′• radicals. Another example of a category (1) process is cleavage of Cl_2 to give two Cl atoms. Other bonds which are easily cleaved by photolysis are the O—O bonds of peroxy compounds and the C—N bonds of aliphatic azo compounds R—N=N—R. The latter is an important source of free radicals R•, since the other product is the very stable N_2.

Category (2). Aldehydes (though not generally ketones) can also cleave in this manner:



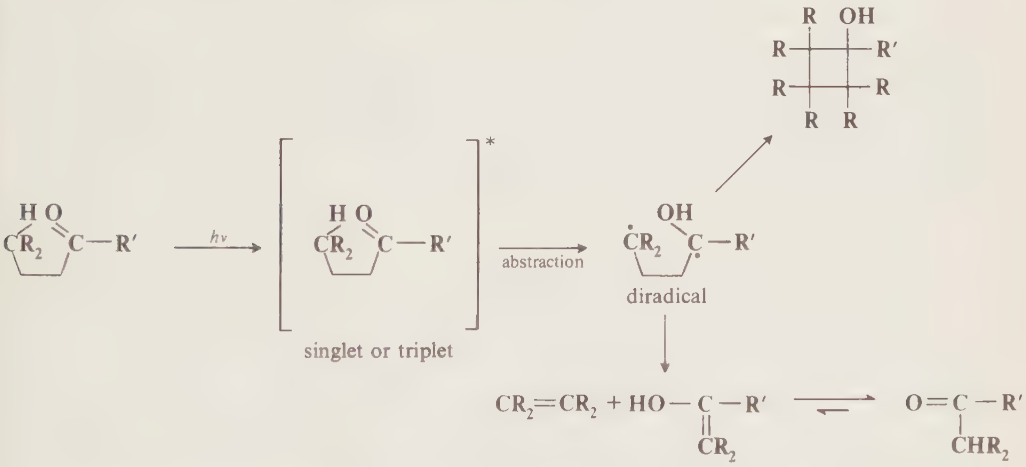
$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H} \xrightarrow{h\nu} \mathrm{R{-}H + CO}$$

This is an extrusion reaction (see Chapter 17). In another example of a process in category (2), aldehydes and ketones which have a γ-hydrogen can cleave in still another way (a β-elimination, see Chapter 17):



$$\mathrm{R_2CH{-}CR_2{-}CR_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} \xrightarrow{h\nu} \mathrm{R_2C{=}CR_2 + CHR_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}$$

This reaction, which is called *Norrish Type II cleavage*,[31] involves intramolecular abstraction of the γ-hydrogen followed by cleavage of the resulting diradical (a secondary reaction) to give an enol which tautomerizes to the aldehyde or ketone product:[32]



Both singlet and triplet n,π^* states undergo the reaction.[33] The intermediate diradical can also cyclize to a cyclobutanol, which is often a side product. Esters, anhydrides, and other carbonyl compounds can also give this reaction. The photolysis of ketene to CH_2 (p. 182) is still another example of a reaction in category (2). Both singlet and triplet CH_2 are generated, the latter in two ways:

---

[31] For thorough discussions of the mechanism, see Dalton and Turro, Ref. 30, pp. 526–538; Wagner, *Acc. Chem. Res.* **4,** 168–177 (1971).

[32] This mechanism was proposed by Yang and Yang, *J. Am. Chem. Soc.* **80,** 2913 (1958). Among the evidence for this mechanism is the fact that the diradical intermediate has been trapped by the addition of mercaptans: Wagner and Zepp, *J. Am. Chem. Soc.* **94,** 287 (1972); Wagner, Kelso, and Zepp, *J. Am. Chem. Soc* **94,** 7480 (1972). See also Zepp and Wagner, *J. Chem. Soc., Chem. Commun.* 167 (1972).

[33] Wagner and Hammond, *J. Am. Chem. Soc.* **87,** 4009 (1965); Dougherty, *J. Am. Chem. Soc.* **87,** 4011 (1965); Ausloos and Rebbert, *J. Am. Chem. Soc.* **86,** 4512 (1964); Casey and Boggs, *J. Am. Chem. Soc.* **94,** 6457 (1972).

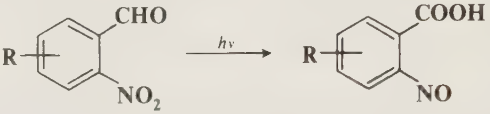
$$\begin{array}{llll} CH_2{=}C{=}O & \xrightarrow{h\nu} & CH_2{=}C{=}O\,(S_1) \rightarrow & \overline{C}H_2 + CO \\ & & \qquad\downarrow & \quad\downarrow \\ & & CH_2{=}C{=}O\,(T_1) \rightarrow & \cdot\dot{C}H_2 + CO \end{array}$$

A final example of category (2) is the irradiation of alkanes at 147 to 130 nm, whereby the predominant process is cleavage to carbenes and hydrogen:

$$RCH_3 \xrightarrow{h\nu} RCH + H_2$$

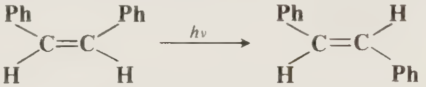
though other reactions of categories (1) and (2) also take place.

Category (3). When *o*-nitrobenzaldehydes are irradiated, *o*-nitrosobenzoic acids are products:[34]

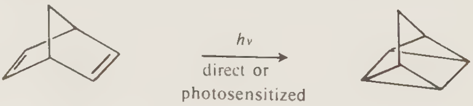


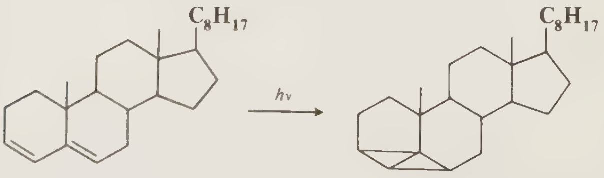
It is possible that this is not a one-step process but a cleavage from the NO_2 group of an oxygen, which then combines with the CHO group.

Category (4). The most common reaction in this category is photochemical cis-trans isomerization.[35] For example, *cis*-stilbene can be converted to the trans isomer:



The isomerization takes place because the excited states, both S_1 and T_1, of many olefins have a perpendicular instead of a planar geometry (p. 214), so that cis-trans isomerism disappears upon excitation. When the excited molecule drops back to the S_0 state, either isomer can be formed. A useful example is the photochemical conversion of *cis*-cyclooctene to the much less stable trans isomer.[36] Two other examples of category (4) reactions are[37]





Cholesta-3, 5-diene

---

[34] For a review of this and closely related reactions, see Morrison, in Feuer, "The Chemistry of the Nitro and Nitroso Groups," pt. 1, pp. 165–213, 185–191, Wiley-Interscience, New York, 1969.

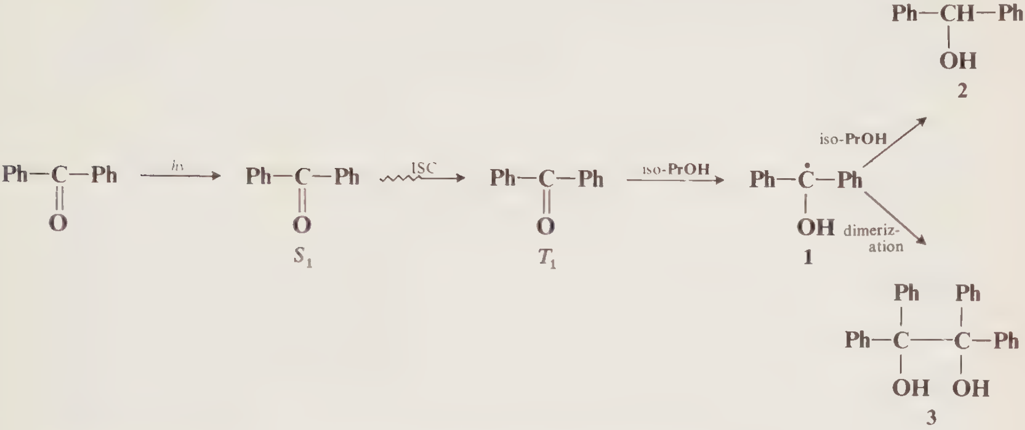
[35] For reviews, see Saltiel, Chang, Megarity, Rousseau, Shannon, Thomas, and Uriarte, *Pure Appl. Chem.* **41**, 559 579 (1975); Saltiel, D'Agostino, Megarity, Metts, Neuberger, Wrighton, and Zafiriou, *Org. Photochem.* **3**, 1–113 (1973); Saltiel, *Surv. Prog. Chem.* **2**, 239–328 (1964), pp. 254–264; and Schönberg, "Preparative Organic Photochemistry," pp. 56–64, Springer-Verlag New York Inc., New York, 1968.

[36] Deyrup and Betkouski, *J. Org. Chem.* **37**, 3561 (1972).

[37] Hammond, Turro, and Fischer, *J. Am. Chem. Soc.* **83**, 4674 (1961); Dauben and Cargill, *Tetrahedron* **15**, 197 (1961); Dauben and Willey, *Tetrahedron Lett.* 893 (1962); Dauben and Wipke, *Pure Appl. Chem.* **9**, 539 (1964).

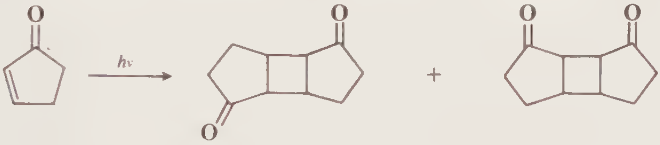
These examples illustrate that the use of photochemical reactions can make it very easy to obtain compounds which would be difficult to get in other ways. Reactions similar to these are discussed at reaction **5-52.**

Category (5). When benzophenone is irradiated in isopropyl alcohol, the initially formed S_1 state crosses to the T_1 state, which abstracts hydrogen from the solvent to give the ketyl radical **1. 1** then abstracts another hydrogen to give benzhydrol (**2**) or dimerizes to benzpinacol (**3**):



An example of intramolecular abstraction has already been given (p. 221).

Category (6). An example is dimerization of cyclopentenone:[38]



See p. 783 for a discussion of this and similar reactions.

The Determination of Photochemical Mechanisms[39]

Ideally, if one is to know a photochemical mechanism, one should know the states of all the molecules in the reaction and the energies and lifetimes of these states and all the side reactions which take place. In practice we usually know these things very imperfectly. "... to establish the exact fate of all the light-absorbing molecules and of all the free radicals formed in a photochemical system is an analytical task which to date has been nearly impossible to perform...."[40] The methods used for the determination of photochemical mechanisms are largely the same as those used for organic mechanisms in general (Chapter 6): product identification, isotopic tracing, the detection and trapping of intermediates, and kinetics, though there are a few new factors: (1) there are generally many products in a photochemical reaction, as many as 10 or 15; (2) in measuring kinetics, there are more variables, since we can study the effect on the rate of the intensity or the wavelength of light; (3) in the detection of intermediates by spectra we can use the technique of *flash photolysis*, which can detect extremely short-lived intermediates.

[38] Eaton, *J. Am. Chem. Soc.* **84,** 2344, 2454 (1962), *Acc. Chem. Res.* **1,** 50 (1968).

[39] For a review, see Calvert and Pitts, Ref. 1, pp. 580–670.

[40] Calvert and Pitts, Ref. 1, p. 581.

In addition to these methods, there are two additional techniques.

1. The use of emission (fluorescence and phosphorescence) as well as absorption spectroscopy. From these spectra the presence of as well as the energy and lifetimes of singlet and triplet excited states can often be calculated.

2. The study of quantum yields. The *quantum yield* is the fraction of absorbed light which goes to produce a particular result. There are several types. A *primary quantum yield* (usually designated φ) for a particular process is the fraction of molecules absorbing light which undergo that particular process. Thus, if 10% of all the molecules which are excited to the S_1 state cross over to the T_1 state, the primary quantum yield for that process is 0.10. However, primary quantum yields are often difficult to measure. A *product quantum yield* Φ for a product P which is formed from a photoreaction of an initially excited molecule A may be expressed as

$$\Phi = \frac{\text{number of molecules of } \mathbf{P} \text{ formed}}{\text{number of quanta absorbed by } \mathbf{A}}$$

Product quantum yields are much easier to measure. The number of quanta absorbed can be determined by an instrument called an *actinometer*, which is actually a standard photochemical system whose quantum yield is known. An example of the information which can be learned from quantum yields is the following. If the quantum yield of a product is finite and invariant with changes in experimental conditions, it is likely that the product is formed in a primary rate-determining process. Another example: in some reactions, the product quantum yields are found to be well over 1 (perhaps as high as 1000). Such a finding indicates a chain reaction (see p. 619 for a discussion of chain reactions).

Eight

Acids and Bases

Two acid-base theories are in use today in organic chemistry, the Brönsted theory and the Lewis theory.[1] These theories are quite compatible, and are used for different purposes.[2]

Brönsted Theory

According to this theory, an acid is defined as a *proton donor* and a base as a *proton acceptor* (a base must have available a pair of electrons to share with the proton; this is usually present as an unshared pair, but sometimes is in a π orbital). An acid-base reaction is simply the transfer of a proton from an acid to a base. (Protons cannot exist free in solution but must be attached to an electron pair.) When the acid gives up a proton, the species remaining still retains the electron pair to which the proton was formerly attached. Thus the new species, in theory at least, can reacquire a proton and is therefore a base. It is referred to as the *conjugate base* of the acid. All acids have a conjugate base, and all bases have a *conjugate acid*. All acid-base reactions fit the equation

$$\underset{\text{Acid}_1}{\mathrm{A{-}H}} + \underset{\text{Base}_2}{\overline{\mathrm{B}}} \rightleftharpoons \underset{\text{Base}_1}{\overline{\mathrm{A}}} + \underset{\text{Acid}_2}{\mathrm{B{-}H}}$$

No charges are shown in this equation, but an acid always has a charge which is one positive unit higher than that of its conjugate base, whether the charge on the acid is positive, negative, or neutral. Many substances can be both bases and acids. Such species are called *amphoteric*.

Acid strength may be defined as the tendency to give up a proton and *base strength* as the tendency to accept a proton. Acid-base reactions occur because acids are not equally strong. If an acid, say HCl, is placed in contact with the conjugate base of a weaker acid, say acetate ion, the proton will be transferred because the HCl has a greater tendency to lose its proton than acetic acid does. That is, the equilibrium

$$\mathrm{HCl} + \mathrm{CH_3COO^-} \rightleftharpoons \mathrm{CH_3COOH} + \mathrm{Cl^-}$$

lies well over to the right. On the other hand, treatment of acetic acid with chloride ion gives essentially no reaction, since the weaker acid already has the proton.

This is always the case for any two acids, and by measuring positions of the equilibrium the relative strengths of acids and bases can be determined.[3] Of course, if the two acids involved are close to each other in strength, a measurable reaction will occur from both sides, although the position of equilibrium will still be over to the side of the weaker acid (unless the acidities are equal within experimental limits). In this manner it is possible to construct a table in which acids are listed in order of acid strength (Table 1).[4] Next to each acid in Table 1 is shown its conjugate

[1] For a monograph on acids and bases, see Bell, "The Proton in Chemistry," 2d ed., Cornell University Press, Ithaca, N.Y., 1973. For a review, see Gillespie, in Olah, "Friedel-Crafts and Related Reactions," vol. 1, pp. 169-199, Interscience Publishers, New York, 1963.

[2] For discussion of the historical development of acid-base theory, see Bell, *Q. Rev., Chem. Soc.* **1**, 113–125 (1947); Bell, "The Proton in Chemistry," 1st ed., pp. 7–17, Cornell University Press, Ithaca, N.Y., 1959.

[3] Although in most acid-base reactions equilibrium is reached extremely rapidly (the rates of proton transfer between singly bonded oxygen and or nitrogen atoms are usually diffusion-controlled), some are slow (especially those in which the proton is given up by a carbon) and in these cases time must be allowed for the system to come to equilibrium.

[4] Table 1 is a thermodynamic acidity scale and applies only to positions of equilibria. For the distinction between thermodynamic and kinetic acidity, see p. 161.

base. It is obvious that if the acids in such a table are listed in *decreasing* order of acid strength, the bases must be listed in *increasing* order of base strength, since the stronger the acid, the weaker must be its conjugate base. The pK_a values in Table 1 are most accurate in the middle of the table. They are much harder to measure[5] for very strong and very weak acids, and these values must be regarded as approximate. Qualitatively, it can be determined that $HClO_4$ is a stronger acid than H_2SO_4, since a mixture of $HClO_4$ and H_2SO_4 in methyl isobutyl ketone may be titrated to an $HClO_4$ end point without interference by H_2SO_4.[6] Similarly, $HClO_4$ can be shown to be stronger than HNO_3 or HCl. However, this is not quantitative, and the value of -10 in the table is not much more than an educated guess. The values for RNO_2H^+, $ArNO_2H^+$, HI, $RCNH^+$, and $RSH_2{}^+$ must also be regarded as highly speculative.[7] A wide variety of pK_a values has been reported for the conjugate acids of even such simple bases as acetone (-0.24 to -7.2), diethyl ether (-0.30 to -6.2), ethanol (-0.33 to -4.8), methanol (-0.34 to -4.9), and 2-propanol (-0.35 to -5.2), depending on the method used to measure them.[8] Only for acids weaker than hydronium ion and stronger than water can very accurate values be obtained.

The bottom portion of Table 1, consisting of very weak acids[9] (pK_a above ~ 17) is known as the *MSAD scale*, in recognition of the work of McEwen, Streitwieser, Applequist, and Dessy, who made advances in this area. In most of these acids, the proton is lost from a carbon atom, and such acids are known as *carbon acids*. pK_a values for such weak acids are difficult to measure and are known only approximately. The methods used to determine the relative positions of these acids are discussed in Chapter 5.[10] The acidity of carbon acids is proportional to the stability of the carbanions which are their conjugate bases (see p. 160).

The extremely strong acids at the top of the table are known as *super acids* (see p. 161). The actual species present in the FSO_3H-SbF_5 mixture are probably $H[SbF_5(SO_3F)]$ and $H[SbF_2(SO_3F)_4]$.[11] The addition of SO_3 causes formation of the still stronger $H[SbF_4(SO_3F)_2]$, $H[SbF_3(SO_3F)_3]$, and $H[(SbF_5)_2(SO_3F)]$.[11]

By the use of tables such as Table 1, it is possible to determine whether a given acid will react with a given base. For tables in which acids are listed in order of decreasing strength, the rule is that *any acid will react with any base in the table which is below it but not with any above it.* The chart is most useful when the acid and the base are not close together, for the following reasons.

1. When an acid and a base are close together, the reaction will not be complete, though the position of equilibrium will be such that the weaker acid predominates.

2. The order can change with temperature. Thus, above 50°C the order of base strength is $BuOH > H_2O > Bu_2O$; from 1 to 50°C the order is $BuOH > Bu_2O > H_2O$; while below 1°C it becomes $Bu_2O > BuOH > H_2O$.[12] Other examples are that acetic acid is stronger than diethylacetic acid above 30°C but weaker below this temperature,[13] while propionic acid is weaker than butyric below 75 C but above 75°C the order is reversed.[14] Such inversions of acidity order with temperature are quite common when the acids are close together on the scale.

cyclo-C_6H_{12}	cyclo-$C_6H_{11}^-$	45	49

[15] In this table it has not been possible to give pK_a values for individual compounds (with a few exceptions) but only average values for functional groups. Extensive tables of pK values for many carboxylic and other acids and amines are given in Ref. 36. Kortüm, Vogel, and Andrussow, *Pure Appl. Chem.* **1,** 190–536 (1960), give values for 631 carboxylic acids and 110 phenols. Ref. 19 gives hundreds of values for very strong acids (very weak bases). Perrin, "Dissociation Constants of Organic Bases in Aqueous Solution," Butterworth & Co., Ltd., London, 1965, and Supplement, 1972, list pK values for more than 7000 amines and other bases. Collumeau, *Bull. Soc. Chim. Fr.* 5087–5112 (1968) gives pK values for about 800 acids and bases. Perrin, *Pure Appl. Chem.* **20,** 133–236 (1969) lists values for 217 inorganic acids and bases.

[16] Acids, esters, and amides are shown in this table to be protonated on the carbonyl oxygen. There has been some controversy on this point, but the weight of evidence today is in that direction. See Katritzky and Jones, *Chem. Ind. (London)* 722 (1961); Ottenheym, van Raayen, Smidt, Groenewege, and Veerkamp, *Recl. Trav. Chim. Pays-Bas* **80,** 1211 (1961); Stewart and Muenster, *Can. J. Chem.* **39,** 401 (1961); Casadevall, Cauquil, and Corriu, *Bull. Soc. Chim. Fr.* 187 (1964); Olah, O'Brien, and White, *J. Am. Chem. Soc.* **89,** 5694 (1967); Smith and Yates, *Can. J. Chem.* **50,** 771 (1972); Henriksen and Baltzer, *Tetrahedron Lett.* 2485 (1972); Martin, *J. Chem. Soc., Chem. Commun.* 793 (1972); Benderly and Rosenheck, *J. Chem. Soc., Chem. Commun.* 179 (1972); Kresge, Fitzgerald, and Chiang, *J. Am. Chem. Soc.* **96,** 4698 (1974); Homer and Johnson, in Zabicky, "The Chemistry of Amides," pp. 188–197, Interscience Publishers, New York, 1970; Ref. 7. For a review of alternative proton sites, see Liler, *Adv. Phys. Org. Chem.* **11,** 267–392 (1975).

[17] This value includes the CO_2 usually present. The value for H_2CO_3 alone is 3.9 (Ref. 20).

3. For acids stronger than hydronium ion and weaker than water, not only are the pK_a values uncertain, but in many cases so are the relative positions.

It must be emphasized that the order of acid strength in Table 1 applies when a given acid and base react without a solvent or, when possible, in water. In other solvents the order may be greatly different (see pp. 233, 243). In the gas phase, where solvation effects are completely or almost completely absent, acidity orders may also differ greatly. For example, in the gas phase, toluene is a stronger acid than water, and *t*-butoxide ion is a weaker base than methoxide ion[54] (see also pp. 243–244).

Acidic and Basic Solvents[55]

One way to determine the position of an acid in a table such as Table 1 is simply to measure the position of equilibrium with a number of appropriate bases. This method is not always easy in practice. Another way is to make use of a solvent which is itself an acid or a base. An acidic solvent (SH) may be used in the following manner: a base placed in such a solvent will take protons from the solvent if it is stronger than S^-. We may imagine two bases B_1 and B_2, which are weaker than S^-, and two others, B_3 and B_4, which are stronger. Then a list similar to Table 1 will be

HB_2^+	B_2
HB_1^+	B_1
SH	S^-
HB_3^+	B_3
HB_4^+	B_4

If the base is B_3 or B_4, the concentrations of S^- and HB_3^+ (or HB_4^+) will be greater than those of SH and B_3 (or B_4). For B_1 and B_2 the reverse will be true. Now if the $[SH]/[S^-]$ or $[HB^+]/[B]$ ratios can be measured, this is a means of telling not only whether each B is stronger or weaker than S^- but also whether B_1 is stronger or weaker than B_2. From these measurements quantitative scales can be set up.[56] When the solvent is water, this is the pK_b scale.

However, if two bases, say B_3 and B_4, are so strong that $[HB_3^+]/[B_3]$ and $[HB_4^+]/[B_4]$ are both greater than, say, 100, then all that can be said is that they are both essentially completely protonated and it is not possible to tell the difference between a ratio of, say, 10^3 and one of 10^6. This is called the *leveling effect* of the solvent, since, to the solvent SH, the bases B_3 and B_4 are equally strong, even though their actual strengths may be greatly different. Similarly, if the two bases are so weak in relation to SH that the two ratios are both less than, say, $\frac{1}{100}$, the solvent cannot distinguish between their basicities. A similar argument holds for basic solvents.

In water, which is both an acidic and a basic solvent, it is very easy to measure S^- accurately (or SH^+ for measuring acid strengths), since H_3O^+ (and consequently OH^-) can be quite accurately measured between about 10 and 10^{-15} mol/liter; hence the pK of acids stronger than water and weaker than hydronium ion can be accurately determined. But outside this range, water is useless as a solvent because of two kinds of leveling effect. When an acid is stronger than H_3O^+, then it is converted essentially completely to H_3O^+. Although 1 mol each of two strong acids will give, say, 0.9990 mol H_3O^+ and 0.9999 mol H_3O^+, it is not possible to tell the difference, since the activity is what is actually being measured and the difference between activity and concentration is greater than the difference between 0.9990 and 0.9999. The second kind of leveling effect is found with acids weaker than water, since the amount of H_3O^+ produced by the acid is less than that produced by the autoprotolysis of the water and thus cannot be measured. Another way of saying this is that the base water would rather take a proton from the acid water than from an acid weaker than water. Similarly, in water, pK_b can be measured only for bases stronger than water and weaker than OH^-.

[55] For fuller treatments, see Kolthoff, in Kolthoff and Elving, "Treatise on Analytical Chemistry," vol. 1, pt. 1, pp. 407–420, Interscience Publishers, Inc., New York, 1959; King, in Covington and Dickinson, "Physical Chemistry of Organic Solvent Systems," pp. 331–403, Plenum Press, New York, 1973; and Bykova and Petrov, *Russ. Chem. Rev.* **41,** 975–990 (1972).

[56] Actually, $[SH]/[S^-]$ cannot be accurately measured, since the amount of SH is overwhelming. But if $[S^-]$ can be accurately measured, then the value of $[BH^+]$ is known, since it must be equal to $[S^-]$. If the initial concentration B_0 of B was known, this gives the $[HB^+]/[B]$ ratio, since $B_0 = [B] + [BH^+]$.

Other amphoteric solvents may be used in a similar manner to measure other areas of the chart. In acetic acid, it is possible to distinguish acidities of acids which in water would have pK_a between about -10 and $+5$; i.e., in acetic acid, it is possible to distinguish HBr and HCl but not H_2O and phenol. Conversely, in ammonia, the carboxylic acids are as strong as HCl, while the acidities of methanol and ethanol may be differentiated. The pK_a range in this solvent, relative to water, is about 3 to 23. In solvents such as these, we must measure, not $[H_3O^+]$ or $[OH^-]$, but analogously, $[CH_3COOH_2{}^+]$ or $[CH_3COO^-]$, or $[NH_4{}^+]$ or $[NH_2{}^-]$. These are usually much more difficult to measure than pH. Therefore many methods have been devised, e.g., freezing-point depressions, ir spectra, vapor-pressure measurements, etc.; still the values obtained are seldom as accurate as values in water. Of course, values obtained in other solvents must be corrected to the water scale. As a first approximation, this can be done by simple subtraction if the pK_a of any acid is known in both water and the other solvent, since differences in pK values of two acids of the same charge type should not be greatly affected by the solvent. However, when acids of different charge types are compared, there are no simple correlations.

Solvents which are not amphoteric may also be used. For basic solvents, such as diethyl ether or pyridine, there is a limit only on the strong-acid side, since on the weak-acid side there is no autoprotolysis to supply Et_2OH^+ or $C_5H_5NH^+$ to compete with that formed from even a weak acid and the solvent. Similarly, for acidic solvents such as HCN, there is a limit only on the other side. In aprotic solvents, such as benzene or chloroform, there are no limits, since the solvent merely serves as a diluent, and it is only necessary to measure the concentrations of two of the four participants in the equilibrium. However, most acid-base systems are not very soluble in aprotic solvents, and ion-pairing and complexing often become troublesome.

Measurements of Solvent Acidity[57]

So far we have seen that acid or base strength depends on the acidity or basicity of the solvent, but other characteristics of the solvent are also important. One of these is the dielectric constant, and it is important because it is a measure of the ion-solvating ability of the solvent. Solvents with high dielectric constants (e.g., H_2O) completely solvate each ion. When the dielectric constant is lower, then ions aggregate, so that ion pairs and larger aggregations are present. This usually makes little difference when the equation has the same total charge on both sides, as in $HA^+ + B \rightleftharpoons HB^+ + A$, but when the total charge increases, as, for example, in $HA + B \rightleftharpoons HB^+ + A^-$, a solvent with high dielectric constant pushes the equilibrium farther to the right than does one with a lower constant. Even when the charge is unchanged, the dielectric constant of the solvent may still make a difference if the ion (or ions) on the left are more solvated than the ones on the right. Also the solvent may cause differential solvation in another way, quite different from the effect of dielectric constant, arising from the difference in solvation of anions by a protic solvent (which can form hydrogen bonds) and an aprotic one.[58] The effect can be extreme: in dimethylformamide, picric acid is stronger than HBr.[59] This particular result can be attributed to size. That is, the large ion $(O_2N)_3C_6H_2O^-$ is better solvated by dimethylformamide than the smaller ion Br^-; while in a protic solvent like water the solvation of an anion is by the small unshielded proton.[60]

---

[57] For fuller treatments, see Hammett, "Physical Organic Chemistry," 2d ed., pp. 263–313, McGraw-Hill Book Company, New York, 1970; Ref. 6, pp. 485–499; Deno, *Surv. Prog. Chem.* **2**, 155–187 (1964), pp. 169–178; and Arnett, *Prog. Phys. Org. Chem.* **1**, 223–403 (1963), pp. 233–258.

A measurement of solvent acidity is thus needed which takes into account factors such as dielectric constant and which applies to mixed solvents as well. The Hammett acidity function[61] is a measurement which is used for acidic solvents of high dielectric constant.[62] For any solvent, including mixtures of solvents (but the proportions of the mixture must be specified), a value H_0 is defined as

$$H_0 = \mathrm{p}K_{\mathrm{BH}_w^+} - \log \frac{[\mathbf{BH}^+]}{[\mathbf{B}]}$$

H_0 is measured by using "indicators" which are weak bases and so are partly converted in these acidic solvents. Typical indicators are *o*-nitroanilinium ion, with a pK in water of -0.29, and 2,4-dinitroanilinium ion, with a pK in water of -4.53. For a given solvent, $[BH^+]/[B]$ is measured for one indicator, usually by spectrophotometric means. Then, using the known pK in water for that indicator, H_0 can be calculated for that solvent system. In practice, several indicators are used, so that an average H_0 is taken. Once H_0 is known for a given solvent system, pK_a values in it can be calculated for any other acid-base pair.

H_0 is defined only for neutral bases, whose conjugate acids therefore have a charge of $+1$. An analogous function for bases with a charge of -1 is called H_-, but results with this function are less consistent than with H_0:

$$H_- = \mathrm{p}K_{\mathrm{BH}_w} - \log \frac{[\mathbf{BH}]}{[\mathbf{B}^-]}$$

The symbol h_0 is defined as

$$h_0 = \frac{a_{\mathrm{H}^+} f_{\mathrm{I}}}{f_{\mathrm{HI}^+}}$$

where a_{H^+} is the activity of the proton and f_{I} and f_{HI^+} are the activity coefficients of the indicator and conjugate acid of the indicator, respectively. H_0 is related to h_0 by

$$H_0 = -\log h_0$$

so that H_0 is analogous to pH, and h_0 to $[H^+]$, and indeed in dilute aqueous solution H_0 and $H_- = \mathrm{pH}$.

H_0 and H_- reflect the ability of the solvent system to donate protons, but they can be applied only to acidic solutions of high dielectric constant, mostly mixtures of water with acids like nitric, sulfuric, perchloric, etc. It is apparent that the H_0 treatment is valid only when $f_{\mathrm{I}}/f_{\mathrm{HI}^+}$ is independent of the nature of the base (the indicator). Since this is so only when the bases are structurally similar, the treatment is limited. Even when similar bases are compared, many devia-

tions are found.[63] Other acidity scales have been set up, among them H_R for aryl carbinols,[64] $H_{R'}$ for aryl olefins and other molecules whose conjugate acids are stable carbonium ions which do not form hydrogen bonds with the solvent,[65] H_C for bases which protonate on carbon,[66] H_E for aliphatic esters,[67] and H_A for unsubstituted amides.[68] It is now clear that there is no single acidity scale which can be applied to a series of solvent mixtures irrespective of the bases employed.[69]

Although most acidity functions have been applied only to acidic solutions, some work has also been done with strongly basic solutions. The H_- function, which is used for highly acidic solutions when the base has a charge of -1, can also be used for strongly basic solvents, in which case it measures the ability of these solvents to abstract a proton from a neutral acid BH.[70]

Another approach to the acidity-function problem was proposed by Bunnett and Olsen,[71] who derived the equation

$$\log \frac{[\mathrm{SH}]^+}{[\mathrm{S}]} + H_0 = \phi(H_0 + \log [\mathrm{H}^+]) + \mathrm{p}K_{\mathrm{SH}^+}$$

where S is a base which is protonated by an acidic solvent. Thus the slope of a plot of $\log([\mathrm{SH}^+]/[\mathrm{S}]) + H_0$ against $H_0 + \log[\mathrm{H}^+]$ is the parameter ϕ, while the intercept is the $\mathrm{p}K_a$ of the acid SH^+ (referred to infinite dilution in water). The value of ϕ expresses the response of the equilibrium $\mathrm{S} + \mathrm{H}^+ \rightleftharpoons \mathrm{SH}^+$ to changing acid concentration. A negative ϕ indicates that the log of the ionization ratio $[\mathrm{SH}^+]/[\mathrm{S}]$ increases, as the acid concentration increases, more rapidly than does $-H_0$. A positive ϕ value indicates the reverse. The Bunnett-Olsen equation given above is a linear free-energy relationship (see p. 254) which pertains to acid-base equilibria. A corresponding equation which applies to kinetic data is

$$\log k_\psi + H_0 = \phi(H_0 + \log [\mathrm{H}^+]) + \log k_2^\circ$$

where k_ψ is the pseudo-first-order rate constant for a reaction of a weakly basic substrate taking place in an acidic solution and k_2° is the second-order rate constant at infinite dilution in water. In this case ϕ characterizes the response of the reaction rate to changing acid concentration of the solvent. The Bunnett-Olsen treatment has also been applied to basic media, where, in a group of nine reactions in concentrated NaOMe solutions, no correlation was found between reaction rates and either H_- or stoichiometric base concentration but where the rates were successfully correlated by a linear free-energy equation similar to those given above.[72]

For a number of years it was believed that when log k (the rate constant) for an acid-catalyzed reaction was linear with $-H_0$, the transformation of the protonated substrate AH^+ to the transition state did not involve a molecule of water, but when log k was linear with log [HA], a molecule of water was required. This was known as the Zucker-Hammett hypothesis.[73] However, in most cases the rates did not follow either line, and the Zucker-Hammett hypothesis has now been shown to be invalid.[74] A new classification system has been devised by Bunnett[75] for reactions occurring in moderately concentrated acid solutions. $\log k_\psi + H_0$ is plotted against $\log a_{H_2O}$, where k_ψ is the pseudo-first-order rate constant for the protonated species and a_{H_2O} is the activity of water. Most such plots are linear or nearly so. According to Bunnett, the slope of this plot w tells something about the mechanism. Where w is between -2.5 and 0, water is not involved in the rate-determining step; where w is between 1.2 and 3.3, water is a nucleophile in the rate-determining step; and where w is between 3.3 and 7 water is a proton-transfer agent. These rules hold for acids in which the proton is attached to oxygen or nitrogen.[76]

Acid and Base Catalysis[77]

The old idea that a catalyst is something which merely increases the rate of a reaction which would proceed without the catalyst, only more slowly, has been found to be invalid for most reactions which are acid- or base-catalyzed. In these cases there is no reaction at all without at least some catalyst. Older workers were deceived because often only a trace of catalyst is necessary. The catalyst is involved in a fundamental way in the mechanism. Nearly always the first step of such a reaction is a proton transfer between the catalyst and the substrate.

Reactions may be catalyzed by acid or base in two different ways, called *general* and *specific catalysis*. If the rate of an acid-catalyzed reaction run in a solvent S is proportional to $[SH^+]$, the reaction is said to be subject to *specific acid catalysis*, the acid being SH^+. The acid which is put into the solvent may be stronger or weaker than SH^+, but the rate is proportional only to the $[SH^+]$ that is actually present in the solution (derived from $S + HA \rightleftharpoons SH^+ + A^-$) and the identity of HA makes no difference except insofar as it determines the position of equilibrium and hence the $[SH^+]$. Most measurements have been made in water, where SH^+ is H_3O^+.

In *general acid catalysis*, the rate is increased not only by an increase in $[SH^+]$ but also by an increase in the concentration of other acids (e.g., in water by phenols or carboxylic acids). These other acids increase the rate even when $[SH^+]$ is held constant. In this type of catalysis the strongest acids catalyze best, so that, in the example given, an increase in the phenol concentration would catalyze the reaction much less than a similar increase in $[H_3O^+]$. This relationship between acid strength of the catalyst and its catalytic ability may be expressed by the *Brönsted catalysis equation*[78]

$$\log k = \alpha \log K_a + C$$

where k is the rate constant for a reaction catalyzed by an acid of ionization constant K_a. According to this equation, when log k is plotted against log K_a for catalysis of a given reaction by a series of acids, a straight line should be obtained with slope α and intercept C. Although straight lines are obtained in many cases, this is not always the case. The relationship usually fails when acids of different types are being compared. For example, it is much more likely to hold for a group of substituted phenols than for a collection of acids which contains both phenols and carboxylic acids. The Brönsted equation is another linear free-energy relationship (see p. 254).

[76] The Bunnett w treatment has been criticized by Long and Bakule, *J. Am. Chem. Soc.* **85**, 2313 (1963).

[77] For reviews, see Hammett, Ref. 57, pp. 315–345; Bell, Ref. 1, pp. 159–193; Jencks, "Catalysis in Chemistry and Enzymology," pp. 163–242, McGraw-Hill Book Company, New York, 1969; and Bender, "Mechanisms of Homogeneous Catalysis from Protons to Proteins," pp. 19–144, John Wiley & Sons, Inc., New York, 1971.

[78] For a review, see Kresge, *Chem. Soc. Rev.* **2**, 475–503 (1973).

Analogously, there are *general* and *specific* (S^- from an acidic solvent SH) *base-catalyzed reactions*. The Brönsted law for bases is

$$\log k = \beta \log K_b + C$$

A knowledge of whether a reaction is subject to general or specific acid catalysis supplies information about the mechanism. For any acid-catalyzed reaction we may write

Step 1 $$\mathrm{A} \xrightleftharpoons{\mathrm{SH}^+} \mathrm{AH}^+$$

Step 2 $$\mathrm{AH}^+ \longrightarrow \text{products}$$

If the reaction is catalyzed only by the specific acid SH^+, it means that step 1 is rapid and step 2 is rate-controlling, since an equilibrium has been rapidly established between A and the strongest acid present in the solution, namely, SH^+ (since this is the strongest acid which can be present in S). On the other hand, if step 2 is faster, there is no time to establish equilibrium and the rate-determining step must be step 1. This step will be affected by all the acids present, and the rate will reflect the sum of the effects of each acid (general acid catalysis). General acid catalysis is also observed if the slow step is reaction of a hydrogen-bond complex $A \cdots\cdots HB$, since each complex will react with a base at a different rate. A comparable discussion may be used for general and specific base catalysis. Further information may be obtained from the values α and β in the Brönsted catalysis equations, since these are approximate measures of the extent of proton transfer in the transition state. In most cases values of α and β are between 1 and 0. A value of α or β near 0 is generally taken to mean that the transition state resembles the reactants; i.e., the proton has been transferred very little when the transition state has been reached. A value of α or β near 1 is taken to mean the opposite; i.e., in the transition state the proton has been almost completely transferred. However, cases are known in which these generalizations are not followed.[79] In general, the proton in the transition state lies closer to the weaker base.

Lewis Acids and Bases. Hard and Soft Acids and Bases

At about the same time that Brönsted proposed his acid-base theory, Lewis put forth a broader one. A base in the Lewis theory is the same as in the Brönsted one, namely, a compound with an available pair of electrons, either unshared or in a π orbital. A *Lewis acid*, however, is any species which has a vacant orbital. In a Lewis acid-base reaction the unshared pair of the base forms a covalent bond with the vacant orbital of the acid, as represented by the general equation

$$\mathrm{A} + \overline{\mathrm{B}} \longrightarrow \mathrm{A{-}B}$$

in which charges are not shown, since they may differ. A specific example is

$$\mathrm{BF_3} + \overline{\mathrm{N}}\mathrm{H_3} \longrightarrow \mathrm{F_3}\overset{\ominus}{\mathrm{B}}{-}\overset{\oplus}{\mathrm{N}}\mathrm{H_3}$$

In the Brönsted picture, the acid is a proton donor, but in the Lewis picture the proton itself is the acid since it has a vacant orbital. A Brönsted acid becomes, in the Lewis picture, the compound that gives up the actual acid. The advantage of the Lewis theory is that it correlates the behavior of many more processes. For example, $AlCl_3$ and BF_3 are Lewis acids because they have only six electrons in the outer shell and have room for eight. $SnCl_4$ and SO_3 have eight, but their central elements, not being in the first row of the periodic table, have room for ten or twelve. Other Lewis acids are simple cations, like Ag^+. The simple reaction $A + \overline{B} \rightarrow A{-}B$ is not very common in organic chemistry, but the scope of the Lewis picture is much larger because reactions of the types

---

[79] See for example Bordwell and Boyle, *J. Am. Chem. Soc.* **94,** 3907 (1972); Davies, *J. Chem. Soc., Perkin Trans. 2* 1018 (1974); Hanna, Jermini, Loewenschuss, and Zollinger, *J. Am. Chem. Soc.* **96,** 7222 (1974).

$$\begin{array}{rcl} \mathbf{A^1 + A^2{-}B} & \longrightarrow & \mathbf{A^1{-}B + A^2} \\ \mathbf{B^1 + A{-}B^2} & \longrightarrow & \mathbf{A{-}B^1 + B^2} \\ \mathbf{A^1{-}B^1 + A^2{-}B^2} & \longrightarrow & \mathbf{A^1{-}B^2 + A^2{-}B^1} \end{array}$$

which are very common in organic chemistry, are also Lewis acid-base reactions. In fact, all reactions in which a covalent bond is formed through one species contributing a filled and the other a vacant orbital may be regarded as Lewis acid-base reactions.

When a Lewis acid combines with a base to give a negative ion in which the central atom has a higher-than-normal valence, the resulting salt is called an *ate complex*.[79a] Examples are

$$\mathbf{Me_3B + LiMe} \longrightarrow \underset{\text{Ate complex}}{\mathbf{Me_4B^-\quad Li^+}}$$

$$\mathbf{Ph_5Sb + LiPh} \longrightarrow \underset{\text{Ate complex}}{\mathbf{Ph_6Sb^-\quad Li^+}}$$

Ate complexes are analogous to the onium salts formed when a Lewis base expands its valence; e.g.,

$$\mathbf{Me_3N + MeI} \longrightarrow \underset{\text{Onium salt}}{\mathbf{Me_4N^+\quad I^-}}$$

Far fewer quantitative measurements have been made of Lewis acid strength compared with that of Brönsted acids.[80] A simple table of Lewis acidities based on some quantitative measurement (such as that given for Brönsted acids in Table 1) is not feasible because Lewis acidity depends on the nature of the base. Qualitatively, the following approximate sequence of acidity of Lewis acids of the type MX_n has been suggested, where X is a halogen atom or an inorganic radical:[80] $BX_3 > AlX_3 > FeX_3 > GaX_3 > SbX_5 > InX_3 > SnX_4 > AsX_5 > ZnX_2 > HgX_2$.

The facility with which an acid-base reaction takes place depends of course on the strengths of the acid and of the base. But it also depends on quite another quality, called the *hardness* or *softness* of the acid or base.[81] This quality cannot be precisely measured, only qualitatively described. The characteristics are as follows:

Soft bases. The donor atoms are of low electronegativity and high polarizability and are easy to oxidize. They hold their valence electrons loosely.

Hard bases. The donor atoms are of high electronegativity and low polarizability and are hard to oxidize. They hold their valence electrons tightly.

Soft acids. The acceptor atoms are large, have low positive charge, and contain unshared pairs of electrons (*p* or *d*) in their valence shells. They have high polarizability and low electronegativity.

Hard acids. The acceptor atoms are small, have high positive charge, and do not contain unshared pairs in their valence shells. They have low polarizability and high electronegativity.

TABLE 2 Hard and soft acids and bases[82]

Hard bases	Soft bases	Borderline bases
H_2O OH^- F^-	R_2S RSH RS^-	$ArNH_2$ C_5H_5N
AcO^- SO_4^{2-} Cl^-	I^- R_3P $(RO)_3P$	N_3^- Br^-
CO_3^{2-} NO_3^- ROH	CN^- RCN CO	NO_2^-
RO^- R_2O NH_3	C_2H_4 C_6H_6	
RNH_2	H^- R^-	
Hard acids	**Soft acids**	**Borderline acids**
H^+ Li^+ Na^+	Cu^+ Ag^+ Pd^{2+}	Fe^{2+} Co^{2+} Cu^{2+}
K^+ Mg^{2+} Ca^{2+}	Pt^{2+} Hg^{2+} BH_3	Zn^{2+} Sn^{2+} Sb^{3+}
Al^{3+} Cr^{2+} Fe^{3+}	$GaCl_3$ I_2 Br_2	Bi^{3+} BMe_3 SO_2
BF_3 $B(OR)_3$ $AlMe_3$	CH_2 carbenes	R_3C^+ NO^+ GaH_3
$AlCl_3$ AlH_3 SO_3		$C_6H_5^+$
RCO^+ CO_2		
HX (hydrogen-bonding molecules)		

Acids and bases can be ranked in (approximate) order of hardness or softness (e.g., base softness decreases in the order $I^- > Br^- > Cl^- > F^-$, and in the order $CH_3^- > NH_2^- > OH^- > F^-$), but since the quality is not precisely defined, it seems more appropriate to divide them each into three groups: hard, soft, and borderline. Such a listing is found in Table 2.[82] Note that the proton, which is involved in all Brönsted acid-base reactions, is classified as a hard acid.

Once acids and bases have been classified as hard or soft, a simple rule can be given: *hard acids prefer to bond to hard bases, and soft acids prefer to bond to soft bases.* The rule has nothing to do with acid or base *strength* but merely says that the complex A—B will have extra stability if both A and B are hard or if both are soft. The rule is not a theory but a generalization based on experimental facts.

One application of the rule is found in complexes between alkenes or aromatic compounds and metal ions (p. 79). Alkenes and aromatic rings are soft bases and should prefer to complex with soft acids. Thus, Ag^+, Pt^{2+}, and Hg^{2+} complexes are common, but complexes of Na^+, Mg^{2+}, or Al^{3+} are rare. Chromium complexes are also common, but in such complexes the chromium is in a low or zero oxidation state (which softens it) or attached to other soft ligands. Another application of the rule is discussed on p. 323.

The Effects of Structure on the Strengths of Acids and Bases[83]

The structure of a molecule may affect its acidity or basicity in a number of ways. Unfortunately, in most molecules two or more of these effects (as well as solvent effects) are operating, and it is usually very difficult or impossible to say how much each effect contributes to the acid or base strength. Small differences in acidity or basicity between similar molecules are particularly difficult to interpret, and it is well to be cautious when attributing them to any particular effect.

---

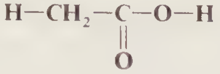
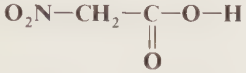
(vol. 4 of Weissberger, "Techniques of Chemistry"), pt. 1, pp. 611–676, John Wiley & Sons, Inc., New York, 1972. For discussions, see Bolton and Hepler, *Q. Rev., Chem. Soc.* **25,** 521–532 (1971); Clark and Perrin, *Q. Rev., Chem. Soc.* **18,** 295–320 (1964); Barlin and Perrin, *Q. Rev., Chem. Soc.* **20,** 75–101 (1966); Thirot, *Bull. Soc. Chim. Fr.* 3559 (1967); Liler, Ref. 8, pp. 59–144.

1. *Field effects.* These were discussed on p. 20. As an example of the influence of field effects on acidity, we may compare the acidity of acetic acid and nitroacetic acid:



$H{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}O{-}H$

$pK_a = 4.76$



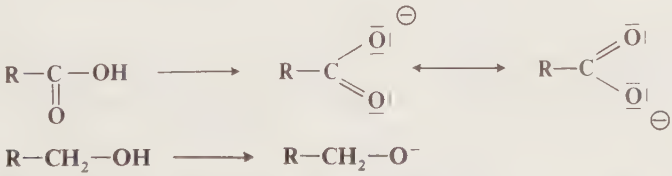
$O_2N{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}O{-}H$

$pK_a = 1.68$

The only difference in the structure of these molecules is the substitution of NO_2 for H. Since NO_2 is a strongly electron-withdrawing group, the electrons in the O—H bond of nitroacetic acid are closer to the oxygen than are the electrons in the O—H bond of acetic acid. The electron density is thus considerably greater on the oxygen (and hence lower on the hydrogen) in the former than in the latter. Since the electron cloud surrounds the hydrogen less, the proton of nitroacetic acid is more easily lost and, as the pK_a values indicate, nitroacetic acid is about 1000 times stronger than acetic.

Another way to look at it is the following: the NO_2 group in the anion of nitroacetic acid withdraws electron density from the negatively charged COO^- group (compared with the anion of acetic acid). Any effect which results in electron withdrawal from a negatively charged center is a stabilizing effect because it spreads the charge. Thus, $-I$ groups increase the acidity of uncharged acids like acetic because they spread the negative charge of the anion. However, $-I$ groups also increase the acidity of any acid, no matter what the charge. For example, if the acid has a charge of $+1$ (and its conjugate base is therefore uncharged), a $-I$ group destabilizes the positive center (by increasing and concentrating the positive charge) of the acid, a destabilization which will be relieved when the proton is lost. Similarly, if the acid has a charge of -1, then the $-I$ group stabilizes the conjugate base (with a charge of -2) more than it does the acid. In general we may say that *groups which withdraw electrons by the field effect increase acidity and decrease basicity, while electron-donating groups act in the opposite direction.* Another example is the molecule $(C_6F_5)_3CH$, with three strongly electron-withdrawing C_6F_5 groups, which has a pK_a of 16[84] compared with Ph_3CH, with a pK_a of 31.5 (Table 1), an acidity enhancement of about 10^{15}. Table 3 shows pK_a values for some acids,[85] and an approximate idea of field effects can be obtained from this table. In the case of the chlorobutyric acids note how the effect decreases with distance. It must be remembered, however, that field effects are not the sole cause of the acidity differences noted and that in fact solvation effects may be more important in many cases (see pp. 243–245).

2. *Resonance effects.* Resonance which stabilizes an acid but not its conjugate base results in the acid's having a lower acidity than otherwise expected, and vice versa. An example is found in the higher acidity of carboxylic acids compared with primary alcohols.



The $RCOO^-$ ion is stabilized by resonance not available to the RCH_2O^- ion (or to RCOOH). Note that the $RCOO^-$ is stabilized not only by the fact there are two equivalent canonical forms

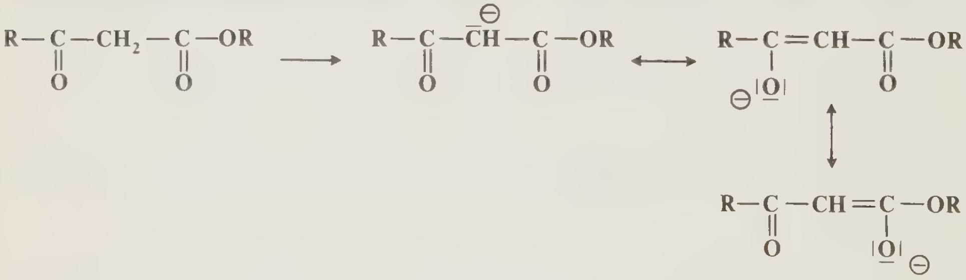
[85] These values are from Ref. 36.

TABLE 3 pK values for some acids[85]

Acid	pK	Acid	pK
HCOOH	3.77	$ClCH_2COOH$	2.86
CH_3COOH	4.76	$Cl_2CHCOOH$	1.29
CH_3CH_2COOH	4.88	Cl_3CCOOH	0.65
$CH_3(CH_2)_nCOOH$[86]	4.82–4.95		
		O_2NCH_2COOH	1.68
$(CH_3)_2CHCOOH$	4.86	$(CH_3)_3\overset{\oplus}{N}CH_2COOH$	1.83
$(CH_3)_3CCOOH$	5.05	$HOOCCH_2COOH$	2.83
		$PhCH_2COOH$	4.31
FCH_2COOH	2.66	$\overset{\ominus}{O}OCCH_2COOH$	5.69
$ClCH_2COOH$	2.86		
$BrCH_2COOH$	2.86	$\overset{\ominus}{O}_3SCH_2COOH$	4.05
ICH_2COOH	3.12	$HOCH_2COOH$	3.83
		$H_2C{=}CHCH_2COOH$	4.35
$ClCH_2CH_2CH_2COOH$	4.52		
$CH_3CHClCH_2COOH$	4.06		
$CH_3CH_2CHClCOOH$	2.84		

but also by the fact that the negative charge is spread over both oxygen atoms and is therefore less concentrated than it is in RCH_2O^-. The same effect is found in other compounds containing a C=O (or C≡N) group. Thus amides $RCONH_2$ are more acidic than amines RCH_2NH_2; esters RCH_2COOR' than ethers RCH_2CH_2OR'; and ketones RCH_2COR' than alkanes RCH_2CH_2R' (Table 1). The effect is enhanced when two carbonyl groups are attached to the same carbon (because of additional resonance and spreading of charge); and, for example, β-keto esters are more acidic than simple ketones or esters (Table 1). Extreme examples of this effect are found in

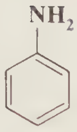


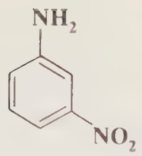
the molecules tricyanomethane $(NC)_3CH$, with a pK_a of −5, and 2-(dicyanomethylene)-1,1,3,3-tetracyanopropene $(NC)_2C{=}C[CH(CN)_2]_2$, whose first pK_a is below −8.5 and whose second pK_a is −2.5.[29]

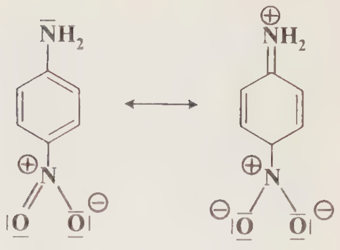
Resonance effects are also important in aromatic amines. *m*-Nitroaniline is a weaker base than aniline, a fact which can be accounted for by the −*I* effect of the nitro group. But *p*-nitroaniline is weaker still, though the −*I* effect should be less, because of the greater distance. We can explain this result by taking into account the canonical form **1**. Because **1** contributes to the resonance hybrid, the electron density of the unshared pair is lower in *p*-nitroaniline than it is in *m*-

---

[86] $n = 2$ to 7.







1

pK_a of conjugate[87] acid	4.60	2.47	1.11

nitroaniline, where a canonical form such as **1** is impossible. The basicity is lower in the para compound for two reasons, both caused by the same effect: (1) the unshared pair is less available for attack by a proton, and (2) when the conjugate acid is formed, the resonance stabilization afforded by **1** is no longer available because the previously unshared pair is now being shared by the proton. The acidity of phenols is affected by substituents in a similar manner.

In general, resonance effects act in the same direction as field effects. That is, here too, electron-withdrawing groups increase acidity and decrease basicity, and electron-donating groups act in the opposite manner. As a result of both resonance and field effects, charge dispersal leads to greater stability.

3. *Periodic-table correlations.* When comparing Brönsted acids and bases which differ in the position of an element in the periodic table:

a. Acidity increases and basicity decreases in going from left to right across a row of the periodic table. Thus acidity increases in the order $CH_4 < NH_3 < H_2O < HF$, and basicity decreases in the order $CH_3^- > NH_2^- > OH^- > F^-$. This behavior can be explained by the increase in electronegativity upon going from left to right across the table. It is this effect which is responsible for the great differences in acidity between carboxylic acids, amides, and ketones: $RCOOH \gg RCONH_2 \gg RCOCH_3$.

b. Acidity increases and basicity decreases in going down a column of the periodic table, despite the decrease in electronegativity. Thus acidity increases in the order $HF < HCl < HBr < HI$, and $H_2O < H_2S$, and basicity decreases in the order $NH_3 > PH_3 > AsH_3$. This behavior is related to the size of the species involved. Thus, for example, F^-, which is much smaller than I^-, attracts a proton much more readily because its negative charge occupies a smaller volume and is therefore more concentrated (note that F^- is also much harder than I^- and is thus more attracted to the hard proton; see p. 238).

Lewis acidity is also affected by periodic-table considerations. In comparing acid strengths of Lewis acids of the form MX_n:[80]

a. Acids which require only one electron pair to complete an outer shell are stronger than those which require two. Thus $GaCl_3$ is stronger than $ZnCl_2$. This results from the relatively smaller energy gain in adding an electron pair which does not complete an outer shell and from the buildup of negative charge if two pairs come in.

b. Other things being equal, the acidity of MX_n decreases in going down the periodic table because as the size of the molecule increases, the attraction between the positive nucleus and the incoming electron pair is weaker. Thus BCl_3 is a stronger acid than $AlCl_3$.[88]

---

[87] Smith, in Patai, "The Chemistry of the Amino Group," pp. 161–204, Interscience Publishers, New York, 1968.

[88] Note that Lewis acidity *decreases*, whereas Brönsted acidity *increases*, on going down the table. There is no contradiction here when we remember that in the Lewis picture the actual acid in all Brönsted acids is the same, namely the proton. In comparing, say, HI and HF, we are not comparing different Lewis acids but only how easily F^- and I^- give up the proton.

TABLE 4 Bases listed in increasing order of base strength when compared with certain reference acids[91]

Increasing order of base strength	Reference acid			
	H^+ or BMe_3	BMe_3	$B(CMe_3)_3$	
↓	NH_3	Et_3N	Me_3N	Et_3N
	Me_3N	NH_3	Me_2NH	Et_2NH
	$MeNH_2$	Et_2NH	NH_3	$EtNH_2$
	Me_2NH	$EtNH_2$	$MeNH_2$	NH_3

c. As has been noted, some MX_n compounds in which M already possesses an octet can still be Lewis acids by using empty *d* orbitals to bond with the incoming base (e.g., $SnCl_4$). These *d* orbitals become more readily available as we go down the periodic table, thus resulting in an increase in Lewis acidity. This factor contradicts factor **b**, to some extent, and the two effects must be added together. The Lewis acidity order given on p. 237 is in accord with these principles.

d. For cations, increased charge and decreased radius increase acidity. Thus the Lewis acids $Al(H_2O)_5{}^{3+}$, $Al(H_2O)_4Cl^{2+}$, and $Al(H_2O)_3Cl_2{}^+$ decrease steadily in acid strength. For anions, increased charge and decreased radius increase basicity, and O^{2-} is a stronger base than either OH^- or Se^{2-}.

4. *Statistical effects.* In a symmetrical dibasic acid, the first dissociation constant is twice as large as expected, since there are two equivalent ionizable hydrogens, while the second constant is only one-half as large as expected because the conjugate base can accept a proton at two equivalent sites. So K_1/K_2 should be 4, and approximately this value is found for dicarboxylic acids where the two groups are sufficiently far apart in the molecule that they do not influence each other. A similar argument holds for molecules with two equivalent basic groups.[89]

5. *Hydrogen bonding.* Internal hydrogen bonding can greatly influence acid or base strength. For example, the p*K* for *o*-hydroxybenzoic acid is 2.98, while the value for the para isomer is 4.58. Internal hydrogen bonding between the OH and COO^- groups of the conjugate base of the ortho isomer stabilizes it and results in an increased acidity.

6. *Steric effects.*[90] The proton itself is so small that direct steric hindrance is seldom encountered in proton transfers. Steric effects are much more common in Lewis acid-base reactions in which larger acids are used. Spectacular changes in the order of base strength have been demonstrated when the size of the acid was changed. Table 4 shows the order of base strength of simple amines when compared against acids of various size.[91] It may be seen that the usual order of basicity of amines (when the proton is the reference acid) may be completely inverted by using a large enough acid. The strain caused by formation of a covalent bond when the two atoms involved each have three large groups is called *face strain* or *F strain.* When the reference acids were boranes, the order of basicity was determined by measurements of dissociation pressures.

Steric effects may indirectly affect acidity or basicity by affecting the resonance (see p. 38). For example, *o-t*-butylbenzoic acid is about 10 times as strong as the para isomer, because the carboxyl group is forced out of the plane by the *t*-butyl group. Indeed, virtually all ortho benzoic acids are stronger than the corresponding para isomers, regardless of whether the group on the ring is electron-donating or electron-withdrawing.

---

[89] The effect discussed here is an example of a symmetry factor. For an extended discussion, see Eberson, in Patai, "The Chemistry of Carboxylic Acids and Esters," pp. 211–293, Interscience Publishers, New York, 1969.

[90] For a review, see Gold, *Prog. Stereochem.* **3**, 169–201 (1962).

[91] Brown, *J. Am. Chem. Soc.* **67**, 378, 1452 (1945), "Boranes in Organic Chemistry," pp. 53–64, Cornell University Press, Ithaca, N.Y., 1972.

7. *Hybridization.* An *s* orbital has a lower energy than a *p* orbital. Therefore the energy of a hybrid orbital is lower the more *s* character it contains. It follows that a carbanion at an *sp* carbon is more stable than a corresponding carbanion at an sp^2 carbon. Thus $HC{\equiv}C^-$, which has more *s* character in its unshared pair than $CH_2{=}CH^-$ or $CH_3CH_2^-$ (*sp* versus sp^2 versus sp^3, respectively), is a much weaker base. This explains the relatively high acidity of acetylenes and of HCN. Another example is that alcohol and ether oxygens, where the unshared pair is sp^3, are more strongly basic than carbonyl oxygens, where the unshared pair is sp^2 (Table 1).

The Effects of the Medium on Acid and Base Strength

Structural features are not the only factors which affect acidity or basicity. The same compound may have its acidity or basicity changed when the conditions are changed. The effects of temperature (p. 226) and some effects of solvent (p. 233) have already been discussed. Another way in which the solvent may influence acid and base strength is by differential solvation. If a base is more solvated than its conjugate acid, its stability is increased relative to the conjugate acid. For example, Table 4 shows that, toward the proton, where steric effects are absent, methylamine is a stronger base than ammonia, and dimethylamine stronger still,[92] results which are easily explainable if one assumes that methyl groups are electron-donating. However, trimethylamine, which should be even stronger, is a weaker base than dimethylamine or methylamine. This apparently anomalous behavior may be explained by differential hydration.[93] Thus, NH_4^+ is much better hydrated (by hydrogen bonding to the water solvent) than NH_3 because of its positive charge.[94] It has been estimated that this effect contributes about 11 p*K* units to the base stength of ammonia.[95] When methyl groups replace hydrogen, this difference in hydration decreases until, for trimethylamine, it contributes only about 6 p*K* units to the base strength.[95] Thus two effects act in opposite directions, the field effect increasing the basicity as the number of methyl groups increases and the hydration effect decreasing it. When the effects are added, the strongest base is dimethylamine and the weakest is ammonia. If alkyl groups are electron-donating, one would expect that in the gas phase,[96] where the solvation effect does not exist, the basicity order of amines toward the proton should be $R_3N > R_2NH > RNH_2 > NH_3$, and this has indeed been confirmed, for R = Me as well as R = Et and Pr.[97] Aniline too, in the gas phase, is a stronger base than NH_3,[98] so that its much lower basicity in aqueous solution (pK_a of $PhNH_3^+$ 4.60, compared with pK_a of 9.24 for aqueous NH_4^+), is caused by similar solution effects and not by resonance and field electron-withdrawing effects of a phenyl group, as had been generally believed. Similarly, pyridine[99] and pyrrole[100] are both much less basic than NH_3 in aqueous solution

TABLE 5 Thermodynamic values for the ionizations of acetic and chloroacetic acids in H_2O at 25°C[105]

Acid	pK_a	ΔG, kcal/mol	ΔH, kcal/mol	$T\,\Delta S$, kcal/mol
CH_3COOH	4.76	+6.5	−0.1	−6.6
$ClCH_2COOH$	2.86	+3.9	−1.1	−5.0
Cl_3CCOOH	0.65	+0.9	+1.5	+0.6

(pyrrole is neutral in aqueous solution) but *more* basic in the gas phase. These examples in particular show how careful one must be in attributing relative acidities or basicities to any particular effect.

For simple alcohols the order of gas-phase *acidity* is completely reversed from that in aqueous solution. In solution the acidity is in the order $H_2O > CH_3OH > MeCH_2OH > Me_2CHOH > Me_3COH$, but in the gas phase the order is precisely the opposite.[101] Once again solvation effects can be invoked to explain the differences. Comparing the two extremes, H_2O and Me_3COH, we see that the OH^- ion is very well solvated by water while the bulky Me_3CO^- is much more poorly solvated because the water molecules cannot get as close to the oxygen. Thus in solution H_2O gives up its proton more readily. When solvent effects are absent, however, the intrinsic acidity is revealed and Me_3COH is a stronger acid than H_2O. This result demonstrates that simple alkyl groups cannot be simply regarded as electron-donating. If methyl is an electron-donating group, then Me_3COH should be a weaker acid (intrinsically) than H_2O; yet it is stronger. The evidence in this and other cases[102] is that alkyl groups may be electron-donating when connected to unsaturated systems but in other systems may have either no effect or actually be electron-withdrawing. The explanation given for the gas-phase (intrinsic) acidity order of alcohols, as well as the basicity order of amines, is that alkyl groups, because of their polarizability, can spread both positive and negative charges.[103]

An important aspect of solvent effects is the effect on the orientation of solvent molecules when an acid or base is converted to its conjugate. For example, consider an acid RCOOH converted to $RCOO^-$ in aqueous solution. The solvent molecules, by hydrogen bonding, arrange themselves around the COO^- group in a much more orderly fashion than they had been arranged around the COOH group (because they are more strongly attracted to the negative charge). This represents a considerable loss of freedom and a decrease in entropy. Thermodynamic measurements show that for simple aliphatic and halogenated aliphatic acids in aqueous solution at room temperature, the entropy ($T\,\Delta S$) usually contributes much more to the total free-energy change ΔG than does the enthalpy ΔH.[104] Two examples are shown in Table 5.[105] Resonance and field effects of functional groups therefore affect the acidity of RCOOH in two distinct ways. They affect the enthalpy (electron-withdrawing groups increase acidity by stabilizing $RCOO^-$ by charge dispersal), but they also affect the entropy (by lowering the charge on the COO^- group and by changing the electron-density distribution in the COOH group, electron-withdrawing groups alter the solvent orientation patterns around both the acid and the ion, and consequently change ΔS).

[105] Bolton and Hepler, Ref. 83, p. 529; Hambly, Ref. 14, p. 92.

As an example, the data in Table 5 show that more than half of the acid-strengthening effect of the Cl in $ClCH_2COOH$ comes from entropy and less than half is caused by ΔH. A more extreme example is trichloroacetic acid, which is about 10,000 times stronger than acetic acid but which actually would be a weaker acid if enthalpy factors were all that mattered (Table 5). In this case it is the very large entropy change which makes the difference. Because the field effect spreads the negative charge of Cl_3CCOO^- all over the molecule, solvent molecules are less strongly attracted than they are to CH_3COO^-; they have much more freedom and consequently a higher entropy. There are other carboxylic acids in which enthalpy and entropy effects act in opposite directions, but in general, whether they act in the same or in opposite directions, entropy effects are more important.

The solvent may affect acidity or basicity even when it is aprotic. For example, the order of base strength against 2,4-dinitrophenol was $Bu_3N > Bu_2NH > BuNH_2$ in chlorobenzene; $Bu_2NH > Bu_3N > BuNH_2$ in benzene; and $Bu_2NH > BuNH_2 > Bu_3N$ in dibutyl ether.[106] The ionic strength of the solvent also influences acidity or basicity, since it has an influence on activity coefficients.

Effects of Structure on Reactivity

It is customary in writing the equation for a reaction of, say, carboxylic acids, to use the formula RCOOH, implying that all carboxylic acids undergo the reaction. Since most compounds with a given functional group do give more or less the same reactions, the custom is useful, and the practice will be used in this book. It enables a large number of individual reactions to be classified together and serves as an aid both to the memorization and the understanding of them. Organic chemistry would be a huge morass of facts without the symbol R. Nevertheless, it must be borne in mind that a given functional group does not always react the same way no matter what molecule it is a part of. The reaction at the functional group is influenced by the rest of the molecule. This influence may be so great as to stop the reaction completely or to make it take an entirely unexpected course. Even when two compounds with the same functional group undergo the same reaction, the rates and/or the positions of equilibrium are usually different, sometimes slightly, sometimes greatly, depending on the structures of the compounds. The greatest variations may be expected when functional groups are present in addition to the one reacting.

The effects of structure on reactivity can be divided into three major types: field, resonance (or mesomeric), and steric. In most cases two or all three of these are operating, and it is usually not easy to tell how much of the rate enhancement (or decrease) is caused by each of the three effects.

Resonance and Field Effects

It is often particularly difficult to separate these two, and they are frequently grouped together under the heading of *electrical effects*.[1] Field effects were discussed on pp. 20–22. Table 3 in Chapter 1 (p. 21) contains a list of some $+I$ and some $-I$ groups. As for resonance effects, on p. 38 it was shown how the electron-density distribution in aniline is not the same as it would be if there were no resonance interaction between the ring and the NH_2 group. Most groups which contain an unshared pair on an atom connected to an unsaturated system display a similar effect; i.e., the electron density on the group is less than expected, and the density on the unsaturated system is greater. Such groups are said to be electron-donating by the resonance effect ($+M$ groups).[2] Alkyl groups, which do not have an unshared pair, are also $+M$ groups, presumably because of hyperconjugation.

---

[1] On p. 20 we showed that there are two types of inductive effects: bond and field effects. Similarly, it is possible to define several types of resonance effects. Dewar and Grisdale, *J. Am. Chem. Soc.* **84,** 3539 (1962) recognize at least five distinct types of electrical effects, and Katritzky and Topsom, *J. Chem. Educ.* **48,** 427 (1971), point out at least seven. However, quantitatively (see p. 255) only two variables are necessary to account for the total electrical effects of substituents, one an overall field and one an overall resonance contribution: Hammett, "Physical Organic Chemistry," 2d ed., p. 376, McGraw-Hill Book Company, New York, 1970; Swain and Lupton, *J. Am. Chem. Soc.* **90,** 4328 (1968).

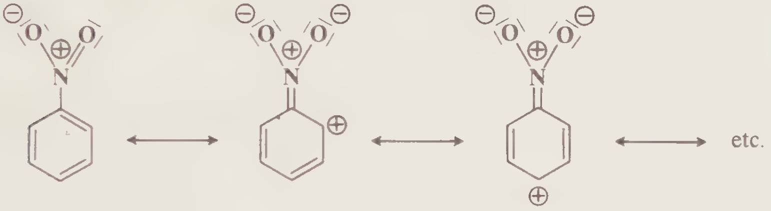
[2] The letters T and R are occasionally used instead of M.

TABLE 1 Some groups with $+M$ and $-M$ effects, not listed in order of strength of effect

Ar appears in both lists because it is capable of both kinds of effect

$+M$ groups		$-M$ groups	
O^-	SR	NO_2	CHO
S^-	SH	CN	COR
NR_2	Br	COOH[4]	SO_2R
NHR	I	COOR[4]	SO_2OR
NH_2	Cl	$CONH_2$	NO
NHCOR	F[3]	CONHR	Ar
OR	R	$CONR_2$	
OH	Ar		
OCOR			

On the other hand, groups which have a multiple-bonded electronegative atom directly connected to an unsaturated system are $-M$ groups. In such cases we can draw canonical forms in which electrons have been taken from the unsaturated system into the group; e.g.,



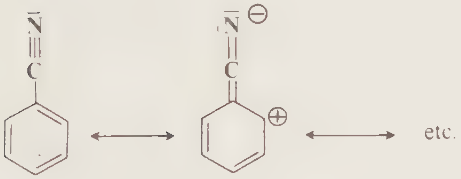


Table 1 contains a list of some $+M$ and $-M$ groups.

The resonance effect of a group, whether $+M$ or $-M$, operates only when the group is directly connected to an unsaturated system, so that, for example, in explaining the effect of the CH_3O group on the reactivity of the COOH in $CH_3OCH_2CH_2COOH$, only the field effect of the CH_3O need be considered. This is one way of separating the two effects. In *p*-methoxybenzoic acid both effects must be considered. The field effect operates through space, solvent molecules, or the σ bonds of a system, while the resonance effect operates through π electrons.

It must be emphasized once again that neither by the resonance nor by the field effect are any electrons actually being donated or withdrawn, though these terms are convenient to use (and we shall use them). As a result of both effects the electron-density distribution is not the same as it would be without the effect (see pp. 21, 38).

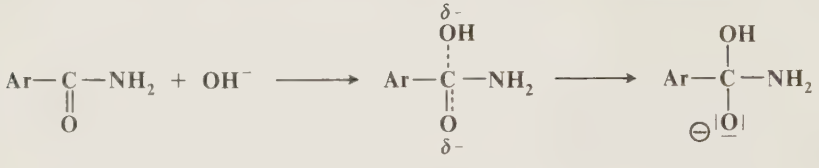
---

[3] For a review of the effects of F, see Yagupol'skii, Il'chenko, and Kondratenko, *Russ. Chem. Rev.* **43**, 32–47 (1974).

[4] For a review of the effects of the COOH, COOR, and COO^- groups, see Kohnstam and Williams, in Patai, "The Chemistry of Carboxylic Acids and Esters," pp. 765–869, Interscience Publishers, 1969.

One thing which complicates the study of these effects is that a given group may have an effect in the transition state which is considerably more or less than it has in the unreacting molecule. For example, consider a molecule $C_6H_5CH_2Y$, where Y is the reaction site. The replacement of, say, a para hydrogen by a group X gives $XC_6H_4CH_2Y$, in which the electron density at the CH_2 group is greater or less, depending on the resonance or field effects of X. However, when the molecule undergoes reaction, the bond between CH_2 and Y begins to break, causing the CH_2 to have partial carbanion, carbonium-ion, or free-radical character, depending on the nature of the reaction. The group X, which in the unreacting molecule may have donated only slightly, may now donate electron density a good deal more or a good deal less. A given group X may even be electron-donating in one reaction and electron-withdrawing in another.

An example will show the nature of electrical effects (resonance and field) on reactivity. In the alkaline hydrolysis of aromatic amides (reaction **0-12**), the rate-determining step is the attack of hydroxide ion at the carbonyl carbon:



transition state

intermediate

1

2

In the transition state, which has a structure somewhere between that of the starting amide (**1**) and the intermediate (**2**), the electron density on the carbonyl carbon has been increased. Therefore, electron-withdrawing groups ($-I$ or $-M$) on the aromatic ring will lower the free energy of the transition state (by spreading the negative charge). These groups have much less effect on the free energy of **1.** Since G is lowered for the transition state but not substantially for **1,** $\Delta G^{\ddagger}$ is lowered, and the reaction rate is increased (Chapter 6). Conversely, electron-donating groups ($+I$ or $+M$) should decrease the rate of this reaction. Of course, many groups are $-I$ and $+M$, and for these it is not always possible to predict which effect will predominate.

Steric Effects[5]

It occasionally happens that a reaction proceeds much faster or much slower than expected on the basis of electrical effects alone. Very often in these cases it can be shown that steric effects are influencing the rate. For example, Table 2 lists relative rates for the SN2 ethanolysis of certain alkyl halides (see p. 266).[5] All these compounds are primary bromides; the branching is on the second carbon, so that field-effect differences should be small. As Table 2 shows, the rate decreases with increasing β branching and reaches a very low value for neopentyl bromide. This reaction is known to involve an attack by the nucleophile from a position opposite to that of the bromine (see p. 266). The great decrease in rate may be attributed to *steric hindrance*, a sheer physical blockage to the attack of the nucleophile. Another example of steric hindrance is found in 2,6-disubstituted benzoic acids, which are difficult to esterify no matter what the resonance or field effects of the groups in the 2 or the 6 position. Similarly, once 2,6-disubstituted benzoic acids *are* esterified, the esters are difficult to hydrolyze (for another example, see p. 150).

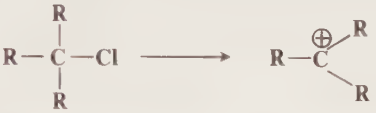
---

[5] Hughes, *Q. Rev., Chem. Soc.* **2,** 107–131 (1948).

TABLE 2 Relative rates of reaction of RBr with ethanol[5]

R	Relative rate
CH_3	17.6
CH_3CH_2	1
$CH_3CH_2CH_2$	0.28
$(CH_3)_2CHCH_2$	0.030
$(CH_3)_3CCH_2$	4.2×10^{-6}

Not all steric effects decrease reaction rates. In the hydrolysis of RCl by an SN1 mechanism (see p. 270), the first step, which is rate-determining, involves ionization of the alkyl chloride to a carbonium ion:



The central carbon in the alkyl chloride is sp^3-hybridized and thus has angles of about 109.5°, but when it is converted to the carbonium ion, the hybridization becomes sp^2 and the preferred angle is 120°. If the halide is tertiary and the three alkyl groups are large enough, they will be pushed together by the enforced tetrahedral angle, resulting in strain (see p. 148). This type of strain is called *B strain*[6] (for back strain), and it can be relieved by ionization to the carbonium ion. The rate of ionization (and hence the solvolysis rate) of a molecule in which there is B strain would therefore be expected to be larger than in cases where B strain is not present. Table 3 shows that this is so.[7] Substitution of ethyl groups for the methyl groups of *t*-butyl chloride does not cause B strain; the increase in rate is relatively small, and the rate smoothly rises with the increasing number of ethyl groups. The rise is caused by normal field and resonance (hyperconjugation) effects. Substitution by one isopropyl group is not greatly different. But with the second isopropyl group the crowding is now great enough to cause B strain, and the rate is increased tenfold. Substitution of a third isopropyl group increases the rate still more. Another example where B strain increases solvolysis rates is found with the highly crowded molecules tri-*t*-butylcarbinol, di-*t*-butylneopentylcarbinol, *t*-butyldineopentylcarbinol, and trineopentylcarbinol, where rates of solvolysis of the *p*-nitrobenzoate esters were faster than that of *t*-butyl nitrobenzoate by factors of 13,000, 19,000, 68,000, and 560, respectively.[8]

Another type of strain, which can affect rates of cyclic compounds, is called *I strain* (internal strain).[9] This type of strain results from changes in ring strain on going from a tetrahedral to a trigonal carbon or vice versa. For example, as mentioned above, SN1 solvolysis of an alkyl halide involves a change in the bond angle of the central carbon from about 109.5° to about 120°. This change is highly favored in 1-chloro-1-methylcyclopentane because it relieves eclipsing strain (p. 145); thus this compound undergoes solvolysis in 80% ethanol at 25°C 43.7 times faster than

TABLE 3 Rates of hydrolysis of tertiary alkyl chlorides at 25°C in 80% aqueous ethanol[7]

Halide	Rate	Halide	Rate
Me_3CCl	0.033	Et_3CCl	0.099
Me_2EtCCl	0.055	Me_2(iso-Pr)CCl	0.029
$MeEt_2CCl$	0.086	Me(iso-Pr)$_2$CCl	0.45

the reference compound *t*-butyl chloride.[10] In the corresponding cyclohexyl compound this factor is absent because the substrate does not have eclipsing strain (p. 144), and this compound undergoes the reaction at about one-third the rate of *t*-butyl chloride. The reasons for this small decrease in rate are not clear. Corresponding behavior is found in the other direction: in changes from a trigonal to a tetrahedral carbon. Thus cyclohexanone undergoes addition reactions faster than cyclopentanone. Similar considerations apply to larger rings. Rings of 7 to 11 members exhibit eclipsing and transannular strain, and in these systems reactions in which a tetrahedral carbon becomes trigonal generally proceed faster than in open-chain systems.

	t-BuCl		Relative solvolysis rates	1.0	43.7	0.35

Cyclopropyl substrates are extremely *unreactive* in cases where a tetrahedral carbon must become trigonal. For example, cyclopropyl tosylate solvolyzes about 10^6 times more slowly than cyclobutyl tosylate in acetic acid at 60°C.[11] The lack of reactivity here may be caused in part by I strain, since the ring bond angle cannot change much when the carbonium ion is formed. In the original compound, the preferred angle was about 109.5° and the real angle 60°, so the strain is about 50°; but in the carbonium ion the preferred angle has increased to 120°, yet the real angle is still about 60°, so the strain is now about 60°. Another factor which may contribute to the lack of reactivity in cyclopropyl substrates is the fact that the σ bonds have considerable π character (p. 141), so that we should expect cyclopropyl halides to resemble vinyl halides in reactivity. As shown on p. 317, vinyl halides are very unreactive to SN1 substitutions.

Conformational effects on reactivity may be considered under the heading of steric effects, although in these cases we are considering not the effect of a group X and that of another group X′ upon reactivity at a site Y but the effect of the conformation of the molecule. Many reactions fail entirely unless the molecules are able to assume the proper conformation. An example is the rearrangement of N-benzoylnorephedrine. The two diastereomers of this compound behave very differently when treated with alcoholic HCl. In one of the isomers nitrogen-to-oxygen migration takes place, while the other does not react at all.[12] In order for the migration to take place, the nitrogen must be near the oxygen (gauche to it). When **3** assumes this conformation, the methyl and phenyl groups are anti to each other, which is a favorable position, but when **4** has the nitrogen gauche to the oxygen, the methyl must be gauche to the phenyl, which is so unfavorable that the reaction does not occur. Other examples are electrophilic additions to C=C

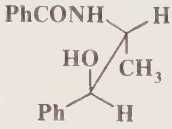
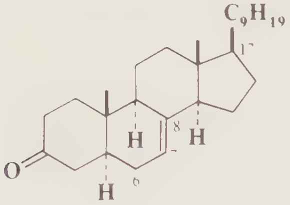
3



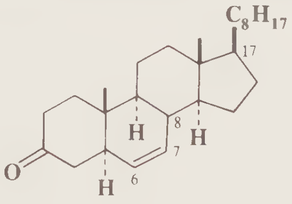
4

double bonds (see p. 673) and E2 elimination reactions (see p. 896). Also, many examples are known where axial and equatorial groups behave differently.[13]

In steroids and other rigid systems, a functional group in one part of the molecule can strongly affect the rate of a reaction taking place at a remote part of the same molecule by altering the conformation of the whole skeleton. An example of this effect, called *conformational transmission*, is found in ergost-7-en-3-one (**5**) and cholest-6-en-3-one (**6**), where **6** condenses with



5



6

benzaldehyde 15 times faster than **5**.[14] The reaction site in both cases is the carbonyl group, and the rate increases because moving the double bond from the 7 to the 6 position causes a change in conformation at the carbonyl group (the difference in the side chain at C-17 does not affect the rate).

Quantitative Treatments of the Effect of Structure on Reactivity[15]

Suppose that the substitution of a group X for H in a reaction of $XCH{=}CHCH_2Y$ (the reaction taking place at the Y group) results in a rate increase by a factor of, say, 10. We would like to be able to know just what part of the increase is due to each of the effects previously mentioned. The obvious way to approach such a problem is to try to find compounds in which one or two of the factors are absent or at least negligible. This is not easy to do acceptably because factors which seem negligible to one investigator do not always appear so to another. The first attempt to give numerical values was that of Hammett.[16] For the cases of *m*- and *p*-XC_6H_4Y, Hammett set up the equation

Chem.* **64,** 1805–1815 (1960); and Pal'm, *Russ. Chem. Rev.* **30,** 471–498 (1961). For a theoretical discussion, see Ehrenson, *Prog. Phys. Org. Chem.* **2,** 195–251 (1964).

$$\log \frac{k}{k_0} = \sigma\rho$$

where k_0 is the rate constant or equilibrium constant for X = H, k is the constant for the group X, ρ is a constant for a given reaction under a given set of conditions, and σ is a constant characteristic of the group X. The equation is called the *Hammett equation.*

The value of ρ was originally set at 1.00 for dissociation of XC_6H_4COOH at 25°C, and σ_m and σ_p values were then calculated for each group (for a group X, σ is different for the meta and para positions). Once a set of σ values was so obtained, ρ values could be obtained for other reactions from the rates of just two X-substituted compounds if the σ values of the X groups were known (in practice, at least four well-spaced values are used to calculate ρ because of experimental error and because the treatment is not exact). With the ρ value thus calculated and the known σ values for other groups, rates may be predicted for reactions which have not yet been run.

The σ values are numbers which sum up the total electrical effects (resonance plus field) of a group X when attached to a benzene ring. The treatment usually fails for the ortho position. The Hammett treatment has been applied to many reactions and to many functional groups and correlates quite well an enormous amount of data. In a review article by Jaffé[16] are listed ρ values for 204 reactions,[17] many of them having different ρ values for different conditions. Among them are reactions as disparate as the following:

Rate constants for

$$\mathbf{ArCOOMe + OH^- \longrightarrow ArCOO^-}$$

$$\mathbf{ArCH_2OCOMe + OH^- \longrightarrow ArCH_2OH}$$

$$\mathbf{ArCH_2Cl + I^- \longrightarrow ArCH_2I}$$

$$\mathbf{ArNH_2 + PhCOCl \longrightarrow ArNHCOPh}$$

$$\mathbf{ArH + NO_2{}^+ \longrightarrow ArNO_2}$$

$$\mathbf{ArCO_2OCMe_3} \longrightarrow \text{decomposition (a free-radical process)}$$

Equilibrium constants for

$$\mathbf{ArCOOH + H_2O \rightleftharpoons ArCOO^- + H_3O^+}$$

$$\mathbf{ArCHO + HCN \rightleftharpoons ArCH(CN)OH}$$

The Hammett equation has also been shown to apply to many physical measurements, including ir frequencies and nmr chemical shifts. The treatment is reasonably successful whether the substrates are attacked by electrophilic, nucleophilic, or free-radical reagents, the important thing being that the mechanism be constant *within* a given reaction series.

However, there are many reactions which do not fit the treatment. These are mostly reactions where the attack is directly on the ring and where the X group is one which can enter into direct resonance interaction with the reaction site in the transition state. For these cases, two new sets of σ values have been devised: σ^+ values (proposed by H. C. Brown) for cases in which an electron-donating group interacts with a developing positive charge in the transition state (this

---

[16] For a review, see Jaffé, *Chem. Rev.* **53,** 191 (1953).

[17] Additional ρ values are given in Wells, Ref. 15; and in van Bekkum, Verkade, and Wepster, *Recl. Trav. Chim. Pays-Bas* **78,** 821–827 (1959).

TABLE 4 σ, σ^+, and σ^- values for some common groups[19]

Group	σ_p	σ_m	$\sigma_p^{\ +}$	$\sigma_m^{\ +}$	$\sigma_p^{\ -}$

includes the important case of electrophilic aromatic substitutions; see Chapter 11) and σ^- values,[18] where electron-withdrawing groups interact with a developing negative charge. Table 4 gives σ, σ^+, and σ^- values for some common X groups.[19] As shown in the table, σ is essentially the same as σ^+ for most electron-withdrawing groups.

A positive value of σ indicates an electron-withdrawing group and a negative value an electron-donating group. The constant ρ measures the susceptibility of the reaction to electrical effects. Reactions with a positive ρ are helped by electron-withdrawing groups, and vice versa.

Similar calculations have been made for compounds with two groups X and X′ on one ring, where the σ values have been found to be sometimes additive and sometimes not,[20] for other ring systems such as naphthalene[21] and heterocyclic rings, and for ethylenic and acetylenic systems.[22]

---

[18] These were formerly called σ^* values, but this designation is now used for the field-effect values mentioned in footnote 25.

[19] σ values are taken from Jaffé, Ref. 16, except for the values for $N_2^{\ +}$, which are from Lewis and Johnson, *J. Am. Chem. Soc.* **81,** 2070 (1959), and the σ_p value for CHO, which is from Humffray, Ryan, Warren, and Yung, *Chem. Commun.* 610 (1965). σ^- values are also from Jaffé. σ^+ values are from Okamoto, Inukai, and Brown, *J. Am. Chem. Soc.* **80,** 4969 (1958), and Brown and Okamoto, *J. Am. Chem. Soc.* **80,** 4979 (1958), except for the $\sigma_m^{\ +}$ value for Me, which is from Glyde and Taylor, *J. Chem. Soc., Perkin Trans. 2* 1463 (1975). See also the extensive table in Ritchie and Sager, Ref. 15, pp. 334–337.

[20] Stone and Pearson, *J. Org. Chem.* **26,** 257 (1961).

The Hammett equation is a *linear free-energy relationship*. This can be demonstrated as follows for the case of equilibrium constants (for rate constants a similar demonstration can be made with $\Delta G^{\ddagger}$ instead of ΔG). For each reaction, where X is any group,

$$\Delta G = -RT \ln K$$

For the unsubstituted case,

$$\Delta G_0 = -RT \ln K_0$$

The Hammett equation may be rewritten

$$\log K - \log K_0 = \sigma\rho$$

so that

$$\frac{-\Delta G}{2.3RT} + \frac{\Delta G_0}{2.3RT} = \sigma\rho$$

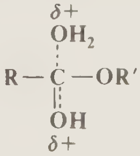
and

$$-\Delta G = \sigma\rho 2.3RT - \Delta G_0$$

For a given reaction under a given set of conditions, ρ, R, T, and ΔG_0 are all constant, so that σ is linear with ΔG.

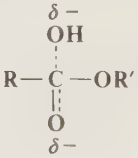
The Hammett equation is not the only linear free-energy relationship. About five or six are known at this time. Some of them, like the Hammett equation, correlate structural changes in reactants, but the Grunwald-Winstein relationship (see p. 334) correlates changes in solvent, and the Brönsted relation (see p. 235) relates acidity to catalysis. The Taft equation is a structure-reactivity equation which correlates only field effects.[23]

Taft, following Ingold,[24] assumed that for the hydrolysis of esters, steric and resonance effects will be the same whether the hydrolysis is catalyzed by acid or base (see the discussion of ester-hydrolysis mechanisms, reaction **0-11**). Rate differences would therefore be caused only by the field effects of R and R′ in RCOOR′. This is reasonable because the transition state for acid-catalyzed hydrolysis (**7**) has a greater positive charge (and is hence destabilized by $-I$ and stabilized by $+I$ substituents) than the starting ester, while the transition state for base-catalyzed hydrolysis (**8**) has a greater negative charge than the starting ester. Field effects of substituents X could therefore be determined by measuring the rates of acid- and base-catalyzed hydrolysis of a



$$R-\overset{\overset{\delta+}{OH_2}}{\underset{\underset{\delta+}{OH}}{C}}-OR'$$

7



$$R-\overset{\overset{\delta-}{OH}}{\underset{\underset{\delta-}{O}}{C}}-OR'$$

8

[24] Ingold, *J. Chem. Soc.* 1032 (1930).

series XCH_2COOR', where R′ would be held constant. From these rate constants, a value σ_I could be determined by the equation

$$\sigma_I \equiv 0.181 \left[\log \left(\frac{k}{k_0}\right)_B - \log \left(\frac{k}{k_0}\right)_A\right]$$

In this equation $(k/k_0)_B$ is the rate constant for basic hydrolysis of XCH_2COOR' divided by the rate constant for basic hydrolysis of CH_3COOR', $(k/k_0)_A$ is the similar rate-constant ratio for acid catalysis, and 0.181 is an arbitrary constant. σ_I is a substituent constant for a group X, substituted at a saturated carbon, which reflects only field effects.[25] Once a set of σ_I values was obtained, it was found that the equation

$$\log \frac{k}{k_0} = \rho_I \sigma_I$$

holds for a number of reactions, among them:[26]

$$\mathbf{RCH_2OH} \longrightarrow \mathbf{RCH_2O^-}$$

$$\mathbf{RCH_2Br + PhS^-} \longrightarrow \mathbf{RCH_2SPh + Br^-}$$

$$\text{Acetone} + \mathbf{I_2}\text{, catalyzed by } \mathbf{RCOOH} \longrightarrow$$

$$o\text{-Substituted-}\mathbf{ArNH_2 + PhCOCl} \longrightarrow \mathbf{ArNHCOPh}$$

As with the Hammett equation, ρ_I is constant for a given reaction under a given set of conditions. For very large groups the relationship may fail because of the presence of steric effects, which are not constant. The equation also fails when X enters into resonance with the reaction center to different extents in the initial and final (or transition) states. A list of some σ_I values is given in Table 5. The σ_I values are about what we would expect for pure field-effect values (see p. 21) and are additive, as field effects (but not resonance or steric effects) would be expected to be. Thus, in moving a group one carbon down the chain, there is a decrease by a factor of 2.8 ± 0.5 (compare the values of R and RCH_2 in Table 5 for R = Ph and CH_3CO).

Since σ_p values represent the sum of resonance and field effects, these values can be divided into resonance and field contributions if σ_I is taken to represent the field-effect portion.[27] The resonance contribution σ_R[28] is defined as

$$\sigma_R = \sigma_p - \sigma_I$$

As it stands, however, this equation is not very useful because the σ_R value for a given group, which should be constant if the equation is to have any meaning, is actually not constant but depends on the nature of the reaction.[29] In this respect, the σ_I values are much better. Although they vary with solvent in some cases, σ_I values are essentially invariant throughout a wide variety of reaction series. However, it is possible to overcome the problem of varying σ_R values

---

[25] There is another set of values (called σ^* values) which are also used to correlate field effects. These are related to σ_I values by $\sigma_{I(X)} = 0.45\sigma^*_{XCH_2}$. Following the suggestion by Ritchie and Sager (Ref. 15), we discuss only σ_I and not σ^* values. See also footnote 18.

NMe_3^+	0.86		

by using a special set of σ_p values, called σ_p°, for reactions which take place at some site effectively insulated from the π electrons of the benzene rings.[30] By means of these values, we can define a new set of values σ_R° as

$$\sigma_R^{\circ} = \sigma_p^{\circ} - \sigma_I$$

σ_R° vary much less with the nature of the reaction. Table 5 lists some values of σ_R° and σ_p°[31] based on this equation. According to this definition of σ_R°, both σ_I and σ_R° contribute equally to σ_p°. Exner[32] has shown that if one assumes that they do not contribute equally, the data give a better fit. His equation is

$$\sigma_p^{\circ} = 1.14\sigma_I + \sigma_R^{\circ}$$

---

[30] Taft, Ehrenson, Lewis, and Glick, *J. Am. Chem. Soc.* **81,** 5352 (1959).

[31] These values are from Wells, Ehrenson, and Taft, Ref. 28, except for the values for H, Ph, CMe_3, and NMe_3^+, which are from Ref. 30; Taft, Deno, and Skell, Ref. 27; and Seth-Paul, de Meyer–van Duyse, and Tollenaere, *J. Mol. Struct.* **19,** 811 (1973). The values for the CH_2Ph and CH_2COCH_3 groups were calculated from σ^* values by the formula given in footnote 25.

COOH	0.552	0.140	N_2^+	2.760	0.360

According to Exner, σ_I and σ_R° contribute to σ_m in the proportion

$$\sigma_m = \sigma_I + 0.33\sigma_R^\circ$$

Another attempt to divide σ values into resonance and field contributions[33] is that of Swain and Lupton, who have shown that the large number of sets of σ values (σ_m, σ_p, σ_p^-, σ_p^+, σ_I, σ_R°, etc., as well as others we have not mentioned) are not entirely independent and that linear combinations of two sets of new values $\mathfrak{F}$ (which expresses the field-effect contribution) and $\mathfrak{R}$ (the resonance contribution) satisfactorily express 43 sets of σ values.[34] Each set is expressed as

$$\sigma = f\mathfrak{F} + r\mathfrak{R}$$

where f and r are weighting factors. Some $\mathfrak{F}$ and $\mathfrak{R}$ values for common groups are given in Table 6. From the calculated values of f and r, Swain and Lupton have calculated that the importance of resonance, % $\mathfrak{R}$, is 22% for σ_m, 53% for σ_p, 66% for σ_p^+, and 92% for $\sigma_p - \sigma_m$. The Swain-Lupton approach has been extended by other workers.[35]

Another way of measuring resonance effects is by use of ^{19}F nmr of *m*- and *p*-XC_6H_4F. The chemical shift of the fluorine is taken to be a measure of the electron density around the fluorine. The field effect is regarded as the same for the meta and para positions, so that the difference in chemical shifts should be proportional to the resonance effect of X.[36] Chemical-shift differences obtained from these measurements have been converted, by a general formula, into σ_R values[37] which agree in general tendency, though not exactly, with those in Table 5. It has been shown[38] that electron density on fluorine cannot always be correlated with ^{19}F chemical shifts.

Taft was also able to isolate steric effects. For the acid-catalyzed hydrolysis of esters in aqueous acetone, log (k/k_0) was shown to be insensitive to polar effects. In cases where resonance interaction

TABLE 7 E_s values for some groups[39]

Group	E_s	Group	E_s	Group	E_s
H	1.24	ICH_2	−0.37	*t*-Bu	−1.54
Me	0	$PhOCH_2$	−0.38	Neopentyl	−1.85
Et	−0.07	iso-Pr	−0.47	Cl_3C	−2.06
$ClCH_2$	−0.24	Cyclohexyl	−0.79	Br_3C	−2.43
$BrCH_2$	−0.27	*sec*-Bu	−1.13	$(Me_3CCH_2)_2CH$	−3.18
Pr	−0.36	F_3C	−1.16	Et_3C	−3.8

was absent, this value was proportional only to steric effects (and any others which are not field or resonance). The equation is

$$\log \frac{k}{k_0} = E_s$$

The methyl group is taken as standard, with the value 0. Some E_s values are given in Table 7.[39] This treatment is more restricted than those previously discussed, since it requires more assumptions, but the E_s values are approximately in order of the size of the groups. Charton has shown that E_s values for substituents of types CH_2X, CHX_2, and CX_3 are linear functions of the van der Waals radii for these groups.[40] Another set of E_s values, called E_s^*, has been developed based on rates of hydroboration (reaction **5-15**).[41] The E_s^* scale is similar to the E_s scale except that the values are larger for tertiary systems.

An equation taking into account both field-effect and steric factors is the Pavelich-Taft equation:[42]

$$\log \frac{k}{k_0} = \rho_I \sigma_I + \delta E_s$$

where δ is analogous to ρ. However, not much work has been done on this.

Since the Hammett equation has been so successful in the treatment of the effects of groups in the meta and para positions, it is not surprising that much work has been done in attempting to apply it to ortho positions also.[43] The effect on a reaction rate or equilibrium constant of a group in the ortho position is called the *ortho effect*.[44] It has generally been believed that ortho substituents are not amenable to simple Hammett treatment because steric effects are important here. Therefore much of the work on the ortho effect has involved equations which attempt to separate steric from electrical effects. In an analysis of a vast amount of data, by means of such equations, Charton[45] reached the unexpected conclusion that the effect of ortho substituents is independent of steric effects[46] except for bulky substituents, such as I, Ph, or *t*-Bu. According to his analysis, ortho effects (except for bulky substituents and for groups which are capable of intramolecular hydrogen bonding) are linear combinations of σ_I and σ_R, and the usual Hammett treatment fails for ortho substituents because σ_I and σ_R can make vastly different contributions to the hypothetical σ_o, depending on which reaction is being studied. For some reactions, "σ_o" is completely made up of σ_I; for others only σ_R contributes; while for still others combinations of σ_I and σ_R in any proportion may be involved. Thus, according to Charton, the search for "true" ortho substituents σ_o must be fruitless because they do not exist. However, the Hammett treatment is successful for ortho compounds when the group Y in *o*-XC_6H_4Y is separated from the ring; e.g., ionization constants of *o*-$XC_6H_4OCH_2COOH$ can be successfully correlated.[47] Another way in which the ortho effect differs from σ_p or σ_m is in sensitivity to solvent changes. σ_p and σ_m do not vary when the solvent is changed, but ortho effects are sensitive to the solvent; Charton and Charton report that the relative contributions of σ_I and σ_R change when the solvent changes.[48]

[44] This is not the same as the ortho effect discussed on p. 466.

[45] Charton, *J. Am. Chem. Soc.* **91,** 615, 619, 624, 6649 (1969). See also Ref. 43.

[46] A small steric effect has been found in one reaction: Charton, *J. Org. Chem.* **40,** 407 (1975).

Linear free-energy relationships may have mechanistic implications. If $\log (k/k_0)$ is linear with the appropriate σ, it is likely that the same mechanism is operating throughout the series. If not, then a smooth curve usually indicates a gradual change in mechanism, while a pair of intersecting straight lines indicates an abrupt change,[49] though nonlinear plots can also be due to other causes, such as complications arising from side reactions. Information can also be obtained from the magnitude and sign of ρ. For example, a strongly negative value of ρ indicates a large electron demand at the reaction center, from which it may be concluded that a highly electron-deficient center, perhaps an incipient carbonium ion, is involved. Conversely, a positive value of ρ is associated with a developing negative charge in the transition state. The $\sigma\rho$ relationship even applies to free-radical reactions, because free radicals can have some polar character (p. 627), though ρ values here are usually small (less than about 1.5) whether positive or negative. Reactions involving cyclic transition states (p. 188) also exhibit very small ρ values.

PART TWO

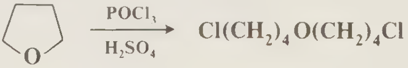
In Part 2 of this book we shall be directly concerned with organic reactions and their mechanisms. The reactions have been classified into 10 chapters, based primarily on reaction type and not on mechanism. These types are substitutions, additions to multiple bonds, eliminations, rearrangements, and oxidation-reduction reactions. Five chapters have been devoted to substitutions, and these are classified on the basis of mechanism as well as substrate. Chapters 10 and 13 include nucleophilic substitutions at aliphatic and aromatic substrates, respectively. Similarly, Chapters 12 and 11 deal with electrophilic substitutions at aliphatic and aromatic substrates, respectively. All free-radical substitutions, both aromatic and aliphatic, are discussed in Chapter 14. Additions to multiple bonds are classified not according to mechanism, but according to the type of multiple bond. Additions to carbon-carbon multiple bonds are dealt with in Chapter 15, while in Chapter 16 we treat additions to other multiple bonds. One chapter is devoted to each of the three remaining reaction types: Chapter 17, eliminations; Chapter 18, rearrangements; and Chapter 19, oxidation-reduction reactions. This last chapter considers only those oxidation-reduction reactions which could not be conveniently treated in any of the other categories (except for oxidative eliminations).

Each chapter in Part 2 consists of two main sections. The first section of each chapter (except Chapter 19) deals with mechanism and reactivity. For each reaction type there are a number of possible mechanisms. These are discussed in turn, with particular attention given to the evidence for each mechanism and to the factors which cause one mechanism rather than another to prevail in a given reaction. Following the discussion of mechanisms, there is in each chapter a section on reactivity including, where pertinent, a consideration of orientation and of the factors affecting it.

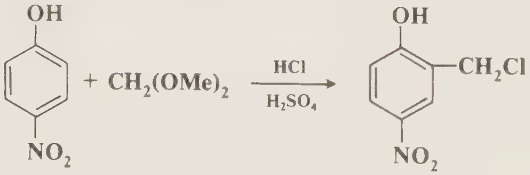
The second main section in each chapter is a treatment of reactions belonging to the category indicated by the title of the chapter. It is not possible—nor indeed would it be wise even if it were possible—to discuss in a book of this nature all or nearly all known reactions. However, an attempt has been made to include all the important reactions of standard organic chemistry which may be used to prepare relatively pure compounds in reasonable yields. In order to present a well-rounded picture and to include some reactions which are traditionally discussed in textbooks, a number of reactions which do not fit into the above category have been included. The scope of the coverage is apparent from the fact that more than 90% of the individual preparations given in *Organic Syntheses* are treated in this book. However, certain special areas have been covered only lightly or not at all. Among these are electrochemical and polymerization reactions, and the preparation and reactions of heterocyclic compounds, carbohydrates, steroids, and compounds containing phosphorus, silicon, arsenic, boron, and mercury. The basic principles involved in these areas are of course no different from those in the areas more fully treated. Even with these omissions, however, some 610 reactions are treated in this book.

Each reaction is discussed in its own numbered section.[1] These are numbered consecutively within a chapter. The *first* digit in each number is the *second* digit of the chapter number. Thus, reaction **6-1** is the first reaction of Chapter 16, and reaction **3-21** is the twenty-first reaction of Chapter 13. The second part of the reaction number has no other significance. The order in which the reactions are presented is not arbitrary but is based on an orderly outline which depends on the reaction type. The placement of each reaction in a separate numbered section serves as an aid to both memory and understanding by setting clear boundary lines between one reaction and another, even if these boundary lines must be arbitrary, and by clearly showing the relationship of each reaction to all the others. Within each section, the scope and utility of the reaction are discussed, and references are given to review articles, if any. If there are features of the mechanism which especially pertain to that reaction, these are also discussed within the section rather than in the first part of the chapter where the discussion of mechanism is more general.

At the end of each numbered section there is a list of *Organic Syntheses* references (abbreviated OS). With the exception of a few very common reactions (**2-3, 2-20, 2-21,** and **2-37**) the list includes *all Organic Syntheses* references for each reaction. The volumes of *Organic Syntheses* which have been covered are Collective Volumes **I** to **V** and individual volumes **50** to **55.** Where no *Organic Syntheses* references are listed at the end of a section, the reaction has not been reported in *Organic Syntheses* through volume **55.** These listings thus constitute a kind of index to *Organic Syntheses.*[2] Certain ground rules were followed in assembling these lists. A reaction in which two parts of a molecule independently undergo simultaneous reaction is listed under both reactions. Similarly, if two reactions happen (or might happen) rapidly in succession without the isolation of an intermediate, the reactions are listed in both places. For example, at OS **IV,** 266 is



This reaction is treated as reaction **0-68** followed by reaction **0-18** and is listed at both places. However, certain reactions are not listed because they are trivial examples. An instance of this is the reaction found at OS **III,** 468:



---

[1] The classification of reactions into sections is, of course, to some degree arbitrary. Each individual reaction (for example, $CH_3Cl + CN^- \rightarrow CH_3CN$ and $C_2H_5Cl + CN^- \rightarrow C_2H_5CN$) is different, and custom generally decides how we group them together. Individual preferences also play a part. Some chemists would say that $C_6H_5N_2^+ + CuCN \rightarrow C_6H_5CN$ and $C_6H_5N_2^+ + CuCl \rightarrow C_6H_5Cl$ are examples of the "same" reaction, and others would say that they are not, but that $C_6H_5N_2^+ + CuCl \rightarrow C_6H_5Cl$ and $C_6H_5N_2^+ + CuBr \rightarrow C_6H_5Br$ are examples of the "same" reaction. No claim is made that the classification system used in this book is more valid than any other.

[2] A comprehensive index to Collective Volumes I to V has been published as part of the series: Shriner and Shriner, "Organic Syntheses Collective Volumes I, II, III, IV, V, Cumulative Indices," John Wiley & Sons, New York, 1976. For another index to *Organic Syntheses* (through volume **45**), see Sugasawa and Nakai, "Reaction Index of Organic Syntheses," John Wiley & Sons, New York, 1967.

This is a chloromethylation reaction and is consequently listed at reaction **1-27.** However, in the course of the reaction formaldehyde is generated from the acetal. This reaction is not listed at **0-7** (hydrolysis of acetals), because it is not really a preparation of formaldehyde. Another instance comes from OS **III,** 841:

$$Ph_3COH + CH_3COCl \longrightarrow Ph_3CCl + CH_3COOH$$

In this case, an acyl halide is converted to the corresponding acid (reaction **0-9**), but the reaction is not listed at **0-9,** because it is obviously designed to prepare triphenylmethyl chloride and not acetic acid. Thus the reaction is listed only at **0-67.**

Ten

Aliphatic Nucleophilic Substitution

In nucleophilic substitution the attacking reagent (the nucleophile) brings an electron pair to the substrate, using this pair to form the new bond, and the leaving group (the nucleofuge) comes away with an electron pair:

$$\mathrm{R}\overset{\curvearrowright}{-}\mathrm{X} + \overline{\mathrm{Y}} \longrightarrow \mathrm{R{-}Y} + \overline{\mathrm{X}}$$

This equation says nothing about charges. Y may be neutral or negatively charged; RX may be neutral or positively charged; so that there are four charge types, examples of which are

$$\begin{array}{llcl}
\text{Type I} & \mathrm{R{-}I} + \mathrm{OH}^- & \longrightarrow & \mathrm{R{-}OH} + \mathrm{I}^- \\
\text{Type II} & \mathrm{R{-}I} + \mathrm{NMe_3} & \longrightarrow & \mathrm{R{-}}\overset{\oplus}{\mathrm{N}}\mathrm{Me_3} + \mathrm{I}^- \\
\text{Type III} & \mathrm{R{-}}\overset{\oplus}{\mathrm{N}}\mathrm{Me_3} + \mathrm{OH}^- & \longrightarrow & \mathrm{R{-}OH} + \mathrm{NMe_3} \\
\text{Type IV} & \mathrm{R{-}}\overset{\oplus}{\mathrm{N}}\mathrm{Me_3} + \mathrm{H_2S} & \longrightarrow & \mathrm{R{-}}\overset{\oplus}{\mathrm{S}}\mathrm{H_2} + \mathrm{NMe_3}
\end{array}$$

In all cases, Y must have an unshared pair of electrons, so that all nucleophiles are Lewis bases. When Y is the solvent, the reaction is called *solvolysis*. Nucleophilic substitution at an aromatic carbon is considered in Chapter 13.

Nucleophilic substitution at an alkyl carbon is said to *alkylate* the nucleophile. For example, the reaction above between RI and $\mathrm{NMe_3}$ is an *alkylation* of trimethylamine. Similarly, nucleophilic substitution at an acyl carbon is an *acylation* of the nucleophile.

MECHANISMS

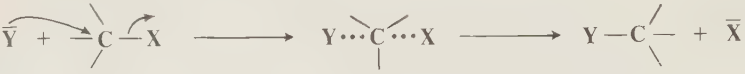
Several distinct mechanisms are possible for aliphatic nucleophilic substitution reactions, depending on the substrate, nucleophile, leaving group, and reaction conditions, but in all of them the attacking reagent carries the electron pair with it, so that the similarities are greater than the differences. Mechanisms that occur at a saturated carbon atom are considered first.[1] By far the most common are the SN1 and SN2 mechanisms.

---

[1] For monographs on this subject, see Hartshorn, "Aliphatic Nucleophilic Substitution," Cambridge University Press, Cambridge, 1973; Bunton, "Nucleophilic Substitution at a Saturated Carbon Atom," American Elsevier Publishing Company, New York, 1963; Thornton, "Solvolysis Mechanisms," The Ronald Press Company, New York, 1964. For reviews, see de la Mare and Swedlund, in Patai, "The Chemistry of the Carbon-Halogen Bond," pt. 1, pp. 409–490, John Wiley & Sons, New York, 1973; Streitwieser, *Chem. Rev.* **56,** 571–752 (1956). The latter review has been reprinted and more recent material added, in Streitwieser, "Solvolytic Displacement Reactions," McGraw-Hill Book Company, New York, 1962.

The SN2 Mechanism

SN2 stands for *substitution nucleophilic bimolecular*. In this mechanism there is *backside attack:* the nucleophile approaches the substrate from a position 180° away from the leaving group. The reaction is a one-step process with no intermediate (see, however, p. 276). The C—Y bond is formed as the C—X bond is broken:



1

The energy necessary to break the C—X bond is supplied by simultaneous formation of the C—Y bond. The position of the atoms at the top of the curve of free energy of activation can be represented as **1**. Of course the reaction does not stop here: this is the transition state. The group X must leave as the group Y comes in, because at no time can the carbon have more than eight electrons in its outer shell. In molecular-orbital terms, the transition state can be described as a point at which the previously unshared orbital of Y overlaps with the carbon orbital to about the same extent as the soon-to-be unshared orbital of X. When the transition state is reached, the central carbon atom has gone from its initial sp^3 hybridization to an sp^2 state with an approximately perpendicular p orbital. One lobe of this p orbital overlaps with the nucleophile, and the other with the leaving group. It is because of this that a frontside SN2 mechanism has never been observed. In a hypothetical frontside transition state, both the nucleophile and the leaving group would have to overlap with the same lobe of the p orbital. The backside mechanism involves the maximum amount of overlap throughout the course of the reaction.[2] During the transition state the three nonreacting groups and the central carbon are approximately coplanar. They will be exactly coplanar if both the entering and the leaving group are the same. Otherwise, they will deviate slightly from planarity, depending on whether bond making or bond breaking is more important in the transition state.

There is a large amount of evidence for the SN2 mechanism. First we consider the kinetic evidence. Since both the nucleophile and the substrate are involved in the rate-determining step (the only step, in this case), the reaction should be first order in each component, second order overall, and satisfy the rate expression

$$\text{Rate} = k[\mathbf{RX}][\mathbf{Y}] \tag{1}$$

This rate law has been found to apply in many cases. It has been noted that the 2 in SN2 stands for bimolecular. It must be remembered that this is not always the same as second order (see p. 201). If a large excess of nucleophile is present—for example, if it is the solvent—the mechanism may still be bimolecular, though the experimentally determined kinetics will be first order:

$$\text{Rate} = k[\mathbf{RX}] \tag{2}$$

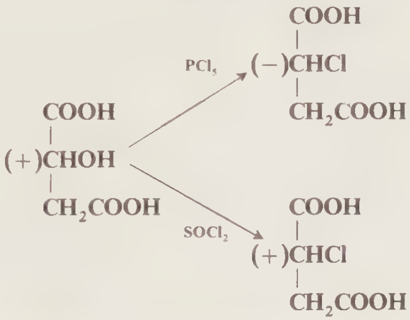
As previously mentioned (p. 201), such kinetics are called *pseudo first order*.

The kinetic evidence is a necessary but not a sufficient condition, since other mechanisms may be devised which would also be consistent with these data. Much more convincing evidence is obtained from the fact that the mechanism predicts inversion of configuration when the substrate is optically active, and this has been observed many times. This inversion of configuration (see p. 102) is called the *Walden inversion* and was observed long before the SN2 mechanism was formulated by Hughes and Ingold.[3]

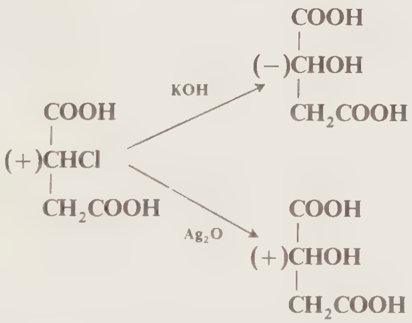
---

[2] For molecular-orbital calculations, see Allinger, Tai, and Wu, *J. Am. Chem. Soc.* **92,** 579 (1970).

At this point it is desirable for us to see just how it was originally proved that a given substitution reaction proceeds with inversion of configuration even before the mechanism was known. Walden presented a number of examples[4] in which inversion *must* have taken place. For example, (+)-malic acid could be converted to (+)-chlorosuccinic acid by thionyl chloride, and to (−)-chlorosuccinic acid by phosphorus pentachloride:



One of these must be an inversion and the other a retention of configuration, but the question is, which is which? The signs of rotation are of no help in answering this question since, as we have seen in Chapter 4 (p. 98), rotation need not be related to configuration. Another example discovered by Walden is



Once again, one reaction and only one must be an inversion, but which?[5] It may also be noticed [illustrated by the use of thionyl chloride on (+)-malic acid and treatment of the product with KOH] that it is possible to convert an optically active compound into its enantiomer.[6]

---

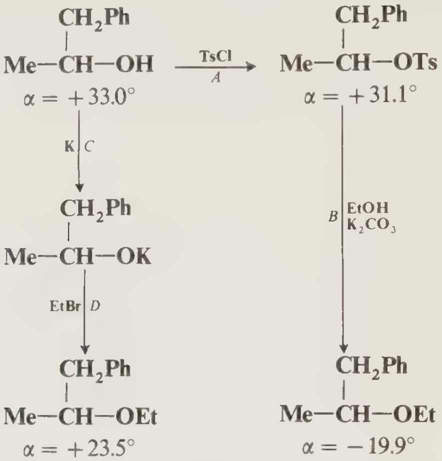
[3] Cowdrey, Hughes, Ingold, Masterman, and Scott, *J. Chem. Soc.* 1252 (1937). The idea that the addition of one group and removal of the other are simultaneous was first suggested by Lewis in "Valence and the Structure of Atoms and Molecules," p. 113, Chemical Catalog Company, New York, 1923. The idea that a one-step substitution leads to inversion was proposed by Olsen, *J. Chem. Phys.* **1**, 418 (1933).

[4] Walden, *Ber.* **26**, 210 (1893), **29**, 133 (1896), **32**, 1855 (1899).

[5] For a discussion of these cycles, see Kryger and Rasmussen, *Acta Chem. Scand.* **26**, 2349 (1972).

[6] The student may wonder just what the mechanism is in cases where retention of configuration is involved, since it certainly is not simple SN2. As we shall see later, the reaction between malic acid and thionyl chloride is an SNi process (p. 302), while a neighboring-group mechanism (p. 279) is involved in the treatment of chlorosuccinic acid with silver oxide.

A series of experiments designed to settle the matter of exactly where inversion takes place was performed by Phillips, Kenyon, and coworkers. In 1923, Phillips carried out the following cycle:[7]



In this cycle, (+)-1-phenyl-2-propanol is converted to its ethyl ether by two routes, path *AB* giving the (−) ether, and path *CD* giving the (+) ether. Therefore, at least one of the four steps must be an inversion. It is extremely unlikely that there is inversion in step *A*, *C*, or *D*, since in all these steps the C—O bond is unbroken, and in none of them could the oxygen of the bond have come from the reagent. There is therefore a high probability that *A*, *C*, and *D* proceeded with retention of configuration, leaving *B* as the step involving inversion. A number of other such cycles were carried out, always with nonconflicting results.[8] These experiments not only definitely showed that certain specific reactions proceed with inversion, but also established the configurations of many compounds.

Walden inversion has been found at a primary carbon atom by the use of an optically active substrate containing a deuterium and a hydrogen atom at the carbon bearing the leaving group.[9] Inversion of configuration has also been found for S_N2 reactions proceeding in the gas phase.[10]

Another kind of evidence for the S_N2 mechanism comes from compounds with potential leaving groups at bridgehead carbons. If the S_N2 mechanism is correct, these compounds should not be able to react by this mechanism, since the nucleophile cannot approach from the rear. Among the many known examples of unsuccessful reaction attempts at bridgeheads under S_N2 conditions[11] are treatment of the [2.2.2] system **2** with ethoxide ion[12] and treatment of the [3.3.1] system **3** with sodium iodide in acetone.[13] In these cases, open-chain analogs underwent the

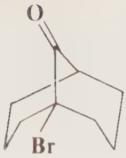
2



3

reactions readily. As a final example of evidence for the SN2 mechanism, the reaction between optically active 2-octyl iodide and radioactive iodide ion may be mentioned:

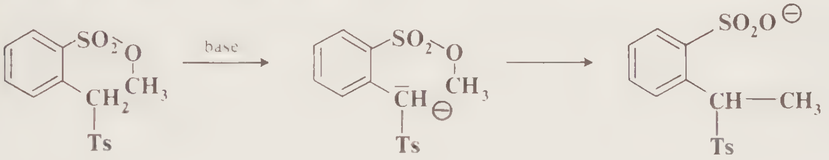
$$C_6H_{13}CHMeI + {}^*I^- \longrightarrow C_6H_{13}CHMe^*I + I^-$$

In this reaction, racemization is expected, since if we start with the pure *R* isomer, at first each exchange will produce an *S* isomer, but with increasing concentration of *S* isomer, *it* will begin to compete for I^- with the *R* isomer, until at the end a racemic mixture will be left, which will then remain at equilibrium. The point investigated was a comparison of the rate of inversion with the rate of uptake of radioactive ${}^*I^-$. It was found[14] that the rates were identical within experimental error:

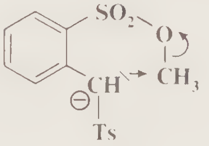
Rate of inversion	$2.88 \pm 0.03 \times 10^{-5}$
Rate of exchange	$3.00 \pm 0.25 \times 10^{-5}$

What was actually measured was the rate of racemization, which is twice the rate of inversion, since each inversion creates, in effect, two racemic molecules. The significance of this result is that it shows that every act of exchange is an act of inversion.

Eschenmoser and coworkers have provided strong evidence that the transition state in an SN2 reaction must be linear.[15] Base treatment of methyl α-tosyl-*o*-toluenesulfonate (**4**) gives the *o*-(1-tosylethyl)benzenesulfonate ion (**6**). The role of the base is to remove the α-proton to give the ion **5**. It might be supposed that the negatively charged carbon of **5** attacks the methyl group in an internal SN2 process:



4 **5** **6**



5

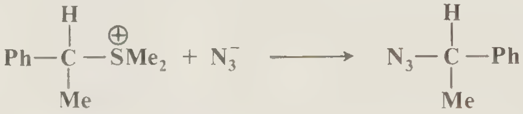
---

[14] Hughes, Juliusburger, Masterman, Topley, and Weiss, *J. Chem. Soc.* 1525 (1935).

[15] Tenud, Farooq, Seibl, and Eschenmoser, *Helv. Chim. Acta* **53**, 2059 (1970).

but this is not the case. Crossover experiments[15] (p. 506) have shown that the negatively charged carbon attacks the methyl group of another molecule rather than the nearby one in the same molecule; that is, the reaction is intermolecular and not intramolecular, despite the more favorable entropy of the latter pathway (p. 193). The obvious conclusion is that intramolecular attack does not take place because complete linearity cannot be attained. This behavior is in sharp contrast to that in cases in which the leaving group is not constrained (p. 279), where intramolecular SN2 mechanisms operate freely.

It has now been shown that the SN2 mechanism can operate in reactions of all four of the charge types shown on p. 265, even in the case of type III, where a negatively charged nucleophile must attack a positively charged substrate at a position in the molecule farthest away from the positive charge.[16] For example, the reaction between azide ion and dimethyl-1-phenylethylsulfonium chloride proceeds with complete inversion:



$$\mathrm{Ph{-}}\overset{\mathrm{H}}{\underset{\mathrm{Me}}{\mathrm{C}}}\mathrm{{-}\overset{\oplus}{S}Me_2} + \mathrm{N_3^-} \longrightarrow \mathrm{N_3{-}}\overset{\mathrm{H}}{\underset{\mathrm{Me}}{\mathrm{C}}}\mathrm{{-}Ph}$$

In reactions of type III it might have been expected that the negative nucleophile would directly attack the side occupied by the positively charged group.

The SN1 Mechanism

The most ideal version of the SN1 mechanism (*substitution nucleophilic unimolecular*) consists of two steps (once again, possible charges on the substrate and nucleophile are not shown):

Step 1 $\quad \mathrm{R{-}X} \xrightleftharpoons{\text{slow}} \mathrm{R^+ + X}$

Step 2 $\quad \mathrm{R^+ + Y} \xrightarrow{\text{fast}} \mathrm{R{-}Y}$

The first step is a slow ionization of the substrate and is the rate-determining step. The second step is a rapid reaction between the intermediate carbonium ion and the nucleophile. The ionization is always assisted by the solvent, since the energy necessary to break the bond is largely recovered by solvation of R^+ and of X. For example, the ionization of t-BuCl to $t\text{-Bu}^+$ and Cl^- in the gas phase without a solvent requires 150 kcal/mol. In the absence of a solvent such a process simply would not take place, except at very high temperatures. In water this ionization requires only 20 kcal/mol. The difference is solvation energy. In cases where the role of the solvent is solely to assist in departure of the leaving group from the frontside, that is, where there is a complete absence of backside (SN2) participation by solvent molecules, the mechanism is called *limiting SN1*, or often just *limiting*.

In looking for evidence for the SN1 reaction, the first thought is that it should be a first-order reaction following the rate law

$$\text{Rate} = k[\mathbf{RX}] \qquad (3)$$

Since the slow step involves only the substrate, the rate should be dependent only on that. Although the solvent is necessary to assist in the process of ionization, it does not enter the rate expression, since it is present in large excess. However, the simple rate law given [Eq. (3)] is not sufficient to account for all the data. Many cases are known where pure first-order kinetics are followed, but in many other cases more complicated kinetics are found. We can explain this by taking into account the reversibility of the first step of the reaction. The X formed in this step competes with Y for the substrate, and the rate law must be modified as follows (see Chapter 6):

---

[16] Harvey, Hoye, Hughes, and Ingold, *J. Chem. Soc.* 800 (1960); Hughes and Whittingham, *J. Chem. Soc.* 806 (1960); Hoffmann and Hughes, *J. Chem. Soc.* 1252, 1259 (1964).

$$\mathbf{RX} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{R}^+ + \mathbf{X}$$

$$\mathbf{R}^+ + \mathbf{Y} \xrightarrow{k_2} \mathbf{RY}$$

$$\text{Rate} = \frac{k_1 k_2[\mathbf{RX}][\mathbf{Y}]}{k_{-1}[\mathbf{X}] + k_2[\mathbf{Y}]} \tag{4}$$

At the beginning of the reaction, when the concentration of X is very small, $k_{-1}[X]$ is negligible compared with $k_2[Y]$, and the rate law is reduced to Eq. (3). Indeed, SN1 reactions generally do display simple first-order kinetics in their initial stages. Most kinetic studies of SN1 reactions have been carried out on solvolytic reactions, since most SN1 reactions fall into this category. In the later stages of SN1 solvolyses, [X] becomes large, and Eq. (4) predicts that the rate should decrease. This is found to be the case for diarylmethyl halides,[17] though not for *t*-butyl halides which follow Eq. (3) for the entire reaction.[18] An explanation for this difference is that *t*-butyl cations are more reactive than the relatively stable diarylmethyl type (p. 155) and hence less selective. Although halide ion is a much more powerful nucleophile than water, there is much more water available since it is the solvent.[19] The selective diphenylmethyl cation survives many collisions with solvent molecules before combining with a reactive halide, but the less selective *t*-butyl ion cannot wait for a reactive but relatively rare halide ion and combines with the solvent.

If the X formed during the reaction can decrease the rate, at least in some cases, it should be possible to *add* X from the outside and further decrease the rate in that way. This retardation of rate by addition of X is called the *common-ion effect* or the *mass-law effect*. Once again, addition of halide ions decreases the rate for diphenylmethyl but not for *t*-butyl halides. Evidence that the common-ion effect operates even with *t*-butyl halides is that, when *t*-butyl chloride was hydrolyzed in the presence of $^{36}\text{Cl}^-$ (which is radioactive), radioactive *t*-butyl chloride was detected.[20]

One factor which complicates the kinetic picture is the *salt effect*. An increase in ionic strength of the solution usually increases the rate of an SN1 reaction (p. 333). But when the reaction is of charge type II, where both Y and RX are neutral, so that X is negatively charged (and most solvolyses are of this charge type), then the ionic strength increases as the reaction proceeds and this increases the rate. This effect must be taken into account in studying the kinetics. Incidentally, the fact that the addition of outside ions *increases* the rate of most SN1 reactions makes especially impressive the *decrease* in rate caused by the common ion.

It may be noted that the pseudo-first-order rate law for an SN2 reaction in the presence of a large excess of Y [Eq. (2)] is the same as that for an ordinary SN1 reaction [Eq. (3)]. It is thus not possible to tell these cases apart by simple kinetic measurements. However, we can often distinguish between them by the common-ion effect, mentioned above. Addition of a common ion will not markedly affect the rate of an SN2 reaction beyond the effect caused by other ions. Unfortunately, as we have seen above, not all SN1 reactions show the common-ion effect, and this test fails for *t*-butyl and similar cases.

[17] Benfey, Hughes, and Ingold, *J. Chem. Soc.* 2488 (1952).

[18] Bateman, Hughes, and Ingold, *J. Chem. Soc.* 960 (1940).

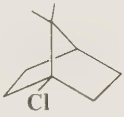
[19] Actually, in the experiments mentioned the solvent was "70%" or "80%" aqueous acetone. "80%" aqueous acetone consists of 4 vol of dry acetone and 1 vol of water.

[20] Bunton and Nayak, *J. Chem. Soc.* 3854 (1959).

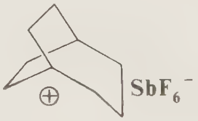
The role of the solvent in assisting the ionization of the substrate may be illustrated by experiments involving ethanolysis of benzhydryl chloride to give benzhydryl ethyl ether. The addition of small amounts of water linearly increases the rate of the reaction, but the product is still almost entirely the ether.[21] The added water clearly cannot be attacking the substrate from the rear (or a proportionate amount of benzhydrol would be found in the product). It must be helping the chloride ion to leave and obviously performs this task better than does ethanol.

Kinetic studies also provide other evidence for the SN1 mechanism. If this mechanism operates essentially as shown on p. 270 then the rate should be the same for a given substrate under a given set of conditions, *regardless of the identity of the nucleophile or of its concentration.* One experiment which demonstrated this was carried out by Bateman, Hughes, and Ingold.[22] In this experiment benzhydryl chloride was treated in SO_2 with the nucleophiles fluoride ion, pyridine, and triethylamine at several concentrations of each nucleophile. In each case the initial rate of the reaction was approximately the same when corrections were made for the salt effect. The same type of behavior has been shown in a number of other cases, even when the reagents are as different in their nucleophilicities (see p. 322) as H_2O and OH^-.

Further evidence for the SN1 mechanism is that reactions run under SN1 conditions fail, or proceed very slowly, at bridgehead positions.[23] SN2 reactions also fail with these substrates (p. 268), though for a different reason. If SN1 reactions require carbonium ions and if carbonium ions must be planar or nearly planar, then it is no surprise that bridgehead carbon atoms, which cannot assume planarity, do not become the seat of carbonium ions. As an example, 1-chloroapocamphane (**7**) boiled 21 hr with 30% KOH in 80% ethanol, or 48 hr with aqueous ethanolic silver nitrate, gave no reaction in either case,[24] although analogous open-chain systems reacted readily. According to this theory, if the rings are large enough, SN1 reactions should be possible, since near-planar carbonium ions might be expected there. This turns out to be the case. For example, [2.2.2] bicyclic systems undergo SN1 reactions much faster than smaller bicyclic systems, though the reaction is still slower than with open-chain systems. Proceeding to a still larger system, the bridgehead 1-bicyclo[3.2.2]nonyl cation (**8**) is actually stable enough to be kept in solution in SbF_5–SO_2ClF at temperatures below −50°C.[25]



7



8

Certain nucleophilic substitution reactions which normally involve carbonium ions can take place at [2.2.1] bridgeheads[26] (though it is not certain that carbonium ions are actually involved in all cases) if the leaving group used is of the type which cannot function as a nucleophile (and thus come back) once it has gone, e.g.,

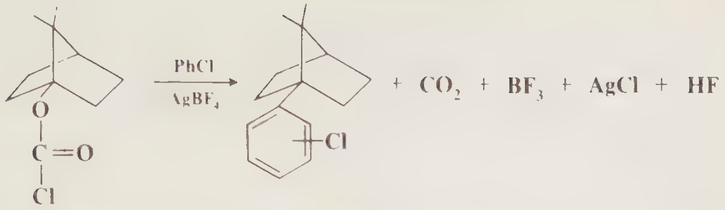
[25] Olah, Liang, Wiseman, and Chong, *J. Am. Chem. Soc.* **74,** 4927 (1972).

[26] Ref. 24; Beak and Trancik, *J. Am. Chem. Soc.* **90,** 2714 (1968); White, Tiwari, and Todd, *J. Am. Chem. Soc.* **90,** 4734 (1968); Clive and Denyer, *Chem. Commun.* 1112 (1971); White, McGirk, Aufdermarsh, Tiwari, and Todd, *J. Am. Chem. Soc.* **95,** 8107 (1973); Beak and Harris, *J. Am. Chem. Soc.* **96,** 6363 (1974).



In this example, chlorobenzene is the nucleophile (see reaction **1-13**). Halogen exchange at a bridgehead [2.2.1] position has also been reported.[27]

In certain reactions where an SN1 mechanism would seem to be obviously indicated, it has been shown (by esr detection of the intermediate) that free radicals are actually involved.[28] These are cases where a carbonium ion is a good electron acceptor and the nucleophile a good electron donor. An example is the reaction between the triphenylmethyl cation and the *t*-butoxide ion, which proceeds in this manner:[29]

$$\mathrm{Ph_3C^+} + t\text{-}\mathrm{BuO^-} \longrightarrow \mathrm{Ph_3C\cdot} + t\text{-}\mathrm{BuO\cdot} \longrightarrow t\text{-}\mathrm{BuOCPh_3}$$

Ion Pairs in the SN1 Mechanism[30]

Like the kinetic evidence, the stereochemical evidence for the SN1 mechanism is also less clear-cut than it is for the SN2 mechanism. If there is a free carbonium ion, it is planar (p. 157), and the nucleophile should attack with equal facility from either side of the plane, resulting in complete racemization. Although many first-order substitutions do give complete racemization, many others do not. Typically there is 5 to 20% inversion, though in a few cases a small amount of retention of configuration has been found. These and other results have led to the conclusion that in many SN1 reactions at least some of the products are not formed from free carbonium ions but rather from *ion pairs*. According to this concept,[31] SN1 reactions proceed in this manner:

$$\mathrm{R{-}X} \rightleftharpoons \underset{\mathbf{9}}{\mathrm{R^+\,X^-}} \rightleftharpoons \underset{\mathbf{10}}{\mathrm{R^+\,\|\,X^-}} \rightleftharpoons \underset{\mathbf{11}}{\mathrm{R^+ + X^-}}$$

where **9** is an *intimate, contact*, or *tight* ion pair, **10** a solvent-separated ion pair, and **11** the dissociated ions (each surrounded by molecules of solvent). In **9** and **10**, X^- is called the *counterion*. The reaction in which the intimate ion pair recombines to give the original substrate is referred to as *internal return*. The reaction products can result from attack by the nucleophile at any stage. In the intimate ion pair **9**, R^+ does not behave like the free cation of **11**. There is probably significant bonding between R^+ and X^-, and asymmetry can well be maintained.[32] X^- "solvates" the cation on the side from which it departed, while solvent molecules near **9** can only solvate it from the opposite side. Nucleophilic attack by a solvent molecule on **9** will thus lead to inversion.

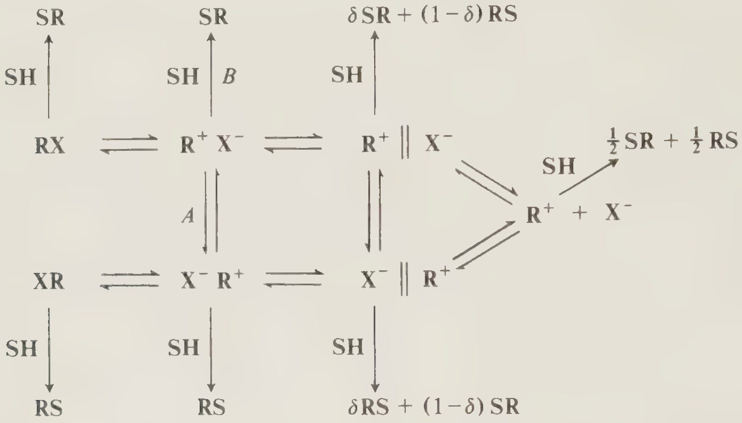
[32] Fry, Lancelot, Lam, Harris, Bingham, Raber, Hall, and Schleyer, *J. Am. Chem. Soc.* **92**, 2538 (1970).

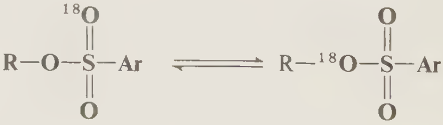
A complete picture of the possibilities for solvolysis reactions in a solvent SH (ignoring, however, the possibilities of elimination or rearrangement—see Chapters 17, 18) is the following,[33] though in any particular case it is unlikely that all these reactions occur:



In this scheme RS and SR represent enantiomers, etc., and δ represents some fraction. The following are the possibilities: (1) Direct attack by SH on RX gives SR (complete inversion) in a straight SN2 process. (2) If the intimate ion pair $R^+ X^-$ is formed, then the solvent can attack at this stage. This can lead to total inversion if reaction *A* does not take place, or to a combination of inversion and racemization if there is competition between *A* and *B*. (3) If the solvent-separated ion pair is formed, SH can attack here. The stereochemistry is not maintained as tightly, and more racemization (perhaps total) is expected. (4) Finally, if free R^+ is formed, it is planar, and attack by SH gives complete racemization.

The ion-pair concept thus predicts that SN1 reactions can display either complete racemization or partial inversion, and the fact that this behavior is generally found is evidence that ion pairs are involved in many SN1 reactions. There is much other evidence for the intervention of ion pairs:[34]

1. The compound 2-octyl brosylate was labeled at the sulfone oxygen with ^{18}O and solvolyzed. The unreacted brosylate recovered at various stages of solvolysis was shown to have the ^{18}O considerably, though not completely, scrambled:[35]



$$R{-}O{-}\overset{\overset{^{18}O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar \rightleftharpoons R{-}{}^{18}O{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Ar$$

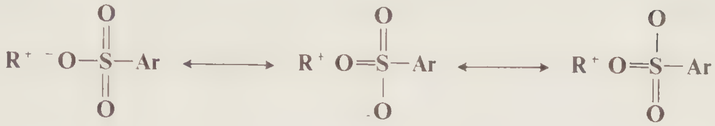
[35] Diaz, Lazdins, and Winstein, *J. Am. Chem. Soc.* **90,** 1904 (1968).

In an intimate ion pair the three oxygens may become equivalent:



$$R^+\ {}^-O-\overset{O}{\underset{O}{S}}-Ar \longleftrightarrow R^+\ O{=}\overset{O}{\underset{{}^-O}{S}}-Ar \longleftrightarrow R^+\ O{=}\overset{O}{\underset{O}{S}}-Ar$$

Similar results were obtained with several other sulfonate esters.[36] The possibility must be considered that the scrambling resulted from ionization of one molecule of $ROSO_2Ar$ to R^+ and $ArSO_2O^-$ followed by attack by the $ArSO_2O^-$ ion on *another* carbonium ion (or perhaps on a molecule of $ROSO_2Ar$ in an SN2 process). However, this was ruled out by solvolyzing unlabeled substrate in the presence of labeled $HOSO_2Ar$. These experiments showed that there was some intermolecular exchange (3 to 20%), but not nearly enough to account for the amount of scrambling found in the original experiments. Similar scrambling was found in solvolysis of labeled esters $R{-}^{18}O{-}COR'$, where the leaving group is $R'COO^-$.[37] In this case also, the external addition of $RCOO^-$ did not result in significant exchange. Since the oxygen atoms of the intimate ion pair are not always completely equivalent (R^+ may remain closer to the oxygen from which it cleaved), such experiments provide a lower limit for ion-pair formation and internal return. In any given case, they could be a good deal higher.[37a]

2. The *special salt effect*. The addition of $LiClO_4$ or LiBr in the acetolysis of certain tosylates produced an initial steep rate acceleration which then decreased to the normal linear acceleration (caused by the ordinary salt effect).[38] This is interpreted as follows: the ClO_4^- (or Br^-) traps the solvent-separated ion pair to give $R^+\ \ ClO_4^-$ which, being unstable under these conditions, goes to product. Hence, the amount of solvent-separated ion pair which would have returned to the starting material is reduced, and the rate of the overall reaction is increased. This is an example of shifting the position of the equilibrium by removing a product.

3. We have previously discussed the possibilities of racemization or inversion of the *product* RS of a solvolysis reaction. However, the formation of an ion pair followed by internal return may also affect the stereochemistry of the *substrate* molecule RX. Cases have been found where internal return racemizes an original optically active RX, an example being solvolysis in aqueous acetone of α-*p*-anisylethyl *p*-nitrobenzoate,[39] while in other cases partial or complete retention is found, for example, solvolysis in aqueous acetone of *p*-chlorobenzhydryl *p*-nitrobenzoate.[40] Racemization of RX is presumably caused by the pathway: $RX \rightleftharpoons R^+\ X^- \rightleftharpoons X^-\ R^+ \rightleftharpoons XR$. Evidence for ion pairs is that, in some cases where internal return involves racemization, it has been shown that such racemization is *faster* than solvolysis. For example, optically active *p*-chlorobenzhydryl chloride racemizes about 30 times faster than it solvolyzes in acetic acid.[41]

In a few cases, SN1 reactions have been found to proceed with partial retention (20 to 50%)

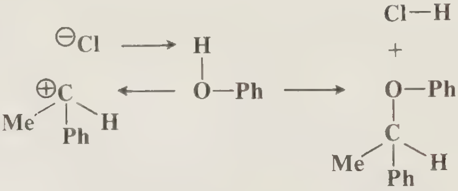
of configuration. Ion pairs have been invoked to explain some of these.[42] For example, it has been proposed that the phenolysis of optically active α-phenylethyl chloride, in which the ether of net retained configuration is obtained, involves a four-center mechanism:



This conclusion is strengthened by the fact that partial retention was obtained in this system only with chloride or other neutral leaving groups; but with leaving groups bearing a positive charge, which are much less likely to hydrogen-bond with the solvent, no retention was found.[43] Partial retention can also arise when the ion pair is shielded at the backside by an additive such as acetonitrile or acetone.[44]

The difference between the SN1 and SN2 mechanisms is in the timing of the steps. In the SN1 mechanism, first X leaves, then Y attacks. In the SN2 case, the two things happen simultaneously. One could imagine a third possibility: first the attack of Y, and then the removal of X. This is not possible at a saturated carbon, since it would mean more than eight electrons in the outer shell of carbon. However, this type of mechanism is possible and indeed occurs at other types of substrate (p. 307; Chapter 13).

Mixed SN1 and SN2 Mechanisms

Some reactions of a given substrate under a given set of conditions display all the characteristics of SN2 mechanisms; other reactions seem to proceed by SN1 mechanisms, but often cases are found which cannot be characterized so easily. There seems to be something in between, a mechanistic "borderline" region. At least two broad theories have been devised to explain these phenomena. One theory holds that intermediate behavior is caused by a mechanism which is neither "pure" SN1 nor "pure" SN2, but some "in-between" type. According to the second theory, there is no intermediate mechanism at all, and borderline behavior is caused by simultaneous operation, in the same flask, of both the SN1 and SN2 mechanisms; that is, some molecules react by the SN1, while others react by the SN2 mechanism.

One formulation of the intermediate-mechanism theory is that of Sneen.[45] The formulation is in fact very broad and applies not only to borderline behavior but to all nucleophilic substitution at a saturated carbon.[46] According to Sneen, all SN1 and SN2 reactions can be accommodated by one basic mechanism (the *ion-pair mechanism*). The substrate first ionizes to an intermediate ion pair which is then converted to products:

$$\mathrm{RX} \underset{}{\overset{k_1}{\rightleftharpoons}} \mathrm{R^+\,X^-} \overset{k_2}{\rightleftharpoons} \text{products}$$

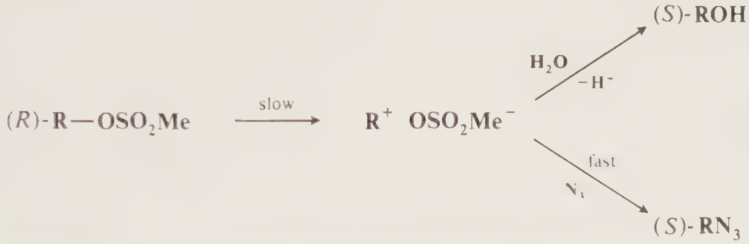
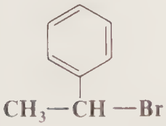
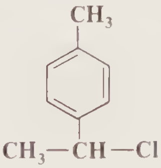
The difference between the SN1 and SN2 mechanisms is that in the former case the *formation* of the ion pair (k_1) is rate-determining, while in the SN2 mechanism its *destruction* (k_2) is rate-determining. Borderline behavior is found where the rates of formation and destruction of the ion pair are of the same order of magnitude. Evidence that ion pairs intervene in at least some reactions which would generally be called SN2 reactions is the following: solvolysis of optically active 2-octyl methanesulfonate in 25% aqueous dioxane gave 2-octanol with about 95% inversion of configuration. From this fact the mechanism is regarded as SN2, though it cannot be shown to be second order, because the nucleophile is present in large excess. Addition of 0.0462 *M* azide ions had no effect on the rate of solvolysis (the rate of disappearance of the starting sulfonate), even though 31% of the product was now 2-octyl azide (the other 69% was inverted alcohol).[47] This means that azide ion is not involved in the rate-determining step, so it would seem that the mechanism of azide formation could not be SN2. *Yet the configuration of the 2-octyl azide was about 81% inverted.* It may be concluded that the rate-determining step is formation of the ion pair, which in this case maintains its configuration, and that this is what is attacked either by azide or by the solvent water. Consequently, not only is azide absent from the transition state, but so is water:



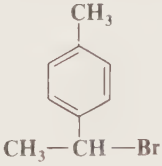
Other evidence for the ion-pair mechanism comes from a linear free-energy relationship which was discovered to hold between the stability of a carbonium ion and its selectivity.[48] The stability of R^+ was measured by the rate of $RX \rightarrow R^+$ hydrolysis in the absence of an added nucleophile. The selectivity of R^+ was measured by adding the nucleophile N_3^- and measuring the ratio of ROH to RN_3 produced. As might be expected, there is a direct relationship between the stability of R^+ and its selectivity, but this relationship holds only where free carbonium ions are present[49] and breaks down in the case of compounds for which borderline behavior is found. Further evidence was obtained in a study of the reactions of **12**, **13**, and **14** with solvent and



12



13



14

added nucleophiles. In these three molecules only small changes in structure have been made, and yet in going from **12** to **13** to **14** the mechanism shifts not abruptly, but gradually, from SN2-like, to borderline, to SN1-like.[50] Linear free-energy relationships have also been used to support the contention that the ion-pair mechanism operates not only on secondary but also on primary substrates,[51] which have traditionally been regarded as showing "pure" SN2 behavior.[52] A number of investigators have raised objections to the ion-pair mechanism of Sneen and have asserted that these results could also be explained in other ways.[53]

[47] Weiner and Sneen, Ref. 45.

[48] Sneen, Carter, and Kay, *J. Am. Chem. Soc.* **88**, 2594 (1966); Raber, Harris, Hall, and Schleyer, *J. Am. Chem. Soc.* **93**, 4821 (1971).

[49] Kovačević, Majerski, Borčić, and Sunko, *Tetrahedron* **28**, 2469 (1972).

Among the experiments that have been cited for the viewpoint that borderline behavior results from simultaneous SN1 and SN2 mechanisms is the behavior of 4-methoxybenzyl chloride in 70% aqueous acetone.[54] In this solvent, hydrolysis (that is, conversion to 4-methoxybenzyl alcohol) occurs by an SN1 mechanism. When azide ions are added, the alcohol is still a product, but now 4-methoxybenzyl azide is another product. Addition of azide ions increases the rate of ionization (by the salt effect) but *decreases* the rate of hydrolysis. If more carbonium ions are produced but fewer go to the alcohol, then some azide must be formed by reaction with carbonium ions—an SN1 process. However, the rate of ionization is always *less* than the total rate of reaction, so that some azide must also form by an SN2 mechanism.[54] Thus, the conclusion is that SN1 and SN2 mechanisms operate simultaneously.[55]

Some nucleophilic substitution reactions which seem to involve a "borderline" mechanism actually do not. Thus, one of the principal indications that a "borderline" mechanism is taking place has been the finding of partial racemization and partial inversion. However, Weiner and Sneen have demonstrated that this type of stereochemical behavior is quite consistent with a strictly SN2 process. These workers studied the reaction of optically active 2-octyl brosylate in 75% aqueous dioxane, under which conditions inverted 2-octanol was obtained in 77% optical purity.[56] When sodium azide was added, 2-octyl azide was obtained along with the 2-octanol, *but the latter was now 100% inverted.* It is apparent that, in the original case, 2-octanol was produced by two different processes, an SN2 reaction leading to inverted product, and another process in which some intermediate leads to racemization or retention. When azide ions were added, they scavenged this intermediate, so that the entire second process now went to produce azide, while the SN2 reaction, unaffected by addition of azide, still went on to give inverted 2-octanol. What is the nature of the intermediate in the second process? At first thought we might suppose that it is a carbonium ion, so that this would be another example of simultaneous SN1 and SN2 reactions. However, solvolysis of 2-octyl brosylate in pure methanol, or of 2-octyl methanesulfonate in pure water, in the absence of azide ions, gave methyl 2-octyl ether, or 2-octanol, respectively, *with 100% inversion of configuration,* indicating that the mechanism in these solvents was pure SN2. Since methanol and water are more polar than 75% aqueous dioxane and since an increase in polarity of solvent increases the rate of SN1 reactions at the expense of SN2 (p. 331), it is extremely unlikely that any SN1 process could occur in 75% aqueous dioxane. The intermediate in the second process is thus not a carbonium ion. What it is, is suggested by the fact that, in the absence of azide ions, the amount of inverted 2-octanol decreased with an increasing percentage of dioxane in the solvent. Thus the intermediate is an oxonium ion formed by an SN2 attack *by dioxane*. This ion is not a stable product but reacts with water in another SN2 process to produce 2-octanol with retained configuration. The entire process may be shown as follows:

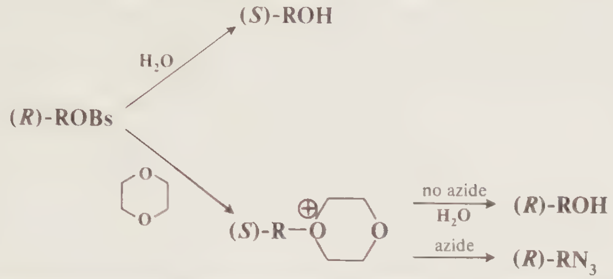
[55] These data have also been explained as being in accord with the ion-pair mechanism: Sneen and Larsen, *J. Am. Chem. Soc.* **91,** 6031 (1969).

[56] Weiner and Sneen, *J. Am. Chem. Soc.* **87,** 287 (1965).



That part of the original reaction which resulted in retention of configuration is thus seen to stem from two successive SN2 reactions and not from any "borderline" behavior.[57] In another investigation, Streitwieser, Walsh, and Wolfe showed that the racemization accompanying inversion in the acetolysis of optically active 2-octyl tosylate stems from processes other than the actual solvolytic displacement: from reaction of the product 2-octyl tosylate with the *p*-toluenesulfonic acid also formed, from addition of acetic acid to 2-octene (formed from the substrate by a competing elimination reaction), and from racemization of the starting tosylate.[58] The actual nucleophilic substitution

$$\mathrm{ROTs + HOAc \longrightarrow ROAc}$$

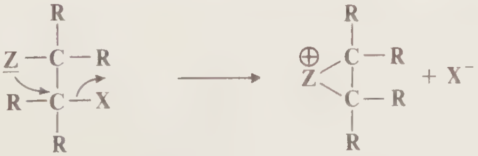
proceeds with essentially complete inversion of configuration.

The mechanisms so far considered can, in theory at least, operate on any type of saturated (or for that matter unsaturated) substrate. There are other mechanisms which are more limited in scope.

The Neighboring-Group Mechanism[59]

It is occasionally found with certain substrates that (1) the rate of reaction is greater than expected, and (2) the configuration at a chiral carbon is *retained* and not inverted or racemized. In these cases there is usually a group with an unshared pair of electrons β to the leaving group (or sometimes farther away). The mechanism operating in such cases is called the *neighboring-group mechanism* and consists essentially of two SN2 substitutions, each causing an inversion, so that the net result is retention of configuration. In the first step of this reaction the neighboring group acts as a nucleophile, pushing out the leaving group but still retaining attachment to the molecule. In the second step the external nucleophile pushes out the neighboring group:

Step 1



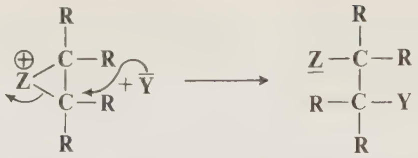
---

[57] According to this scheme, the configuration of the isolated RN$_3$ should be retained. It was, however, largely inverted, owing to a competing SN2 reaction where N$_3^-$ directly attacks ROBs.

[58] Streitwieser, Walsh, and Wolfe, *J. Am. Chem. Soc.* **87**, 3682 (1965); Streitwieser and Walsh, *J. Am. Chem. Soc.* **87**, 3686 (1965). For another example, see Beronius, Nilsson, and Holmgren, *Acta Chem. Scand.* **26**, 3173 (1972).

[59] For a review, see Capon, *Q. Rev., Chem. Soc.* **18**, 45–111 (1964).

Step 2

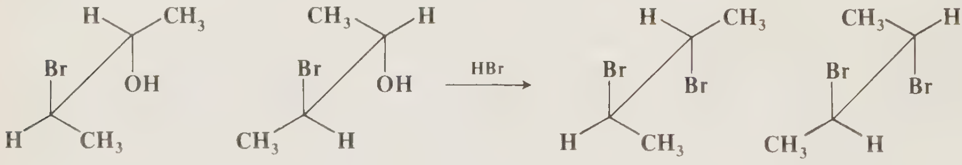


The reaction obviously must go faster than if Y were attacking directly, since if the latter process were faster, *it* would be happening. The neighboring group Z is said to be lending *anchimeric assistance*. The rate law followed in the neighboring-group mechanism is the first-order law shown in Eq. (2) or (3); that is, Y does not take part in the rate-determining step.

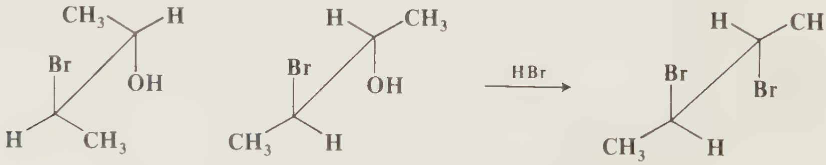
The question may be asked as to why attack by Z is faster than that by Y. The answer is that the group Z is more available. In order for Y to react, it must collide with the substrate, but Z is immediately available by virtue of its position. A reaction between the substrate and Y involves a large decrease in entropy of activation ($\Delta S^\ddagger$), since the reactants are far less free in the transition state than before. Reaction of Z involves a much smaller loss of $\Delta S^\ddagger$ (see p. 193).[60]

It is not always easy to determine when a reaction rate has been increased by anchimeric assistance. In order to be certain, it is necessary to know what the rate would be without participation by the neighboring group. The obvious way to examine this question is to compare the rates of the reaction with and without the neighboring group, for example, $HOCH_2CH_2Br$ versus CH_3CH_2Br. However, this will certainly not give an accurate determination of the extent of participation, since the steric and field effects of H and OH are not the same. Furthermore, no matter what the solvent, the shell of solvent molecules which surrounds the polar protic OH group must differ greatly from that which surrounds the nonpolar H. Because of these considerations, it is desirable to have a large increase in the rate, preferably more than fiftyfold, before a rate increase is attributed to neighboring-group participation.

The first important evidence for the existence of this mechanism was the demonstration that retention of configuration can occur if the substrate is suitable. It was shown that the threo DL pair of 3-bromo-2-butanol when treated with HBr gave DL-2,3-dibromobutane, while the erythro pair gave the meso isomer:[61]



threo DL pair DL pair



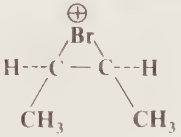
erythro DL pair meso

---

[60] For a review of the energetics of neighboring-group participation, see Page, *Chem. Soc. Rev.* **2**, 295–323 (1973).

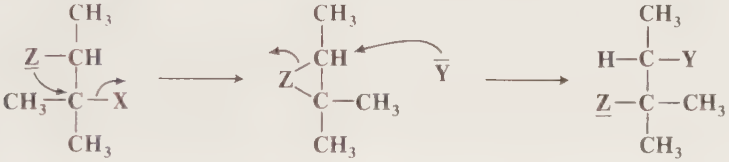
[61] Winstein and Lucas, *J. Am. Chem. Soc.* **61**, 1576, 2845 (1939).

This indicated that retention had taken place. Note that both products are optically inactive and so cannot be told apart by differences in rotation. The meso and DL dibromides have different boiling points and indexes of refraction and were identified by these properties. Even more convincing evidence was that either of the two threo isomers alone gave not just one of the enantiomeric dibromides, but the DL pair. The reason for this is that the intermediate present after the attack by the neighboring group (**15**) is symmetrical, so that the external nucleophile, Br$^-$, could equally well attack both carbon atoms. **15** is a bromonium ion, the existence of which has been demonstrated in several types of reactions.[62]



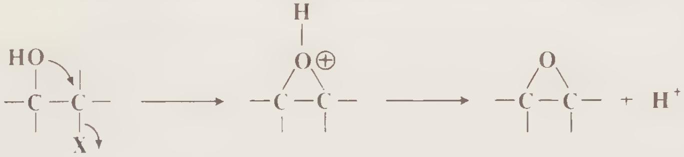
15

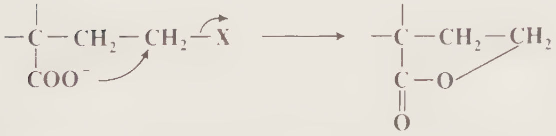
Although **15** is symmetrical, intermediates in most neighboring-group mechanisms are not, and it is therefore possible to get not a simple substitution product but a rearrangement. This will happen if Y attacks not the carbon atom from which X left, but the one to which Z was originally attached:



In such cases substitution and rearrangement products are often produced together. For a discussion of rearrangements, see Chapter 18.

Another possibility is that the intermediate may be stable or may find some other way to stabilize itself. In such cases, Y never attacks at all, and the product is cyclic. These are simple internal SN2 reactions. Two examples are formation of epoxides and lactones:



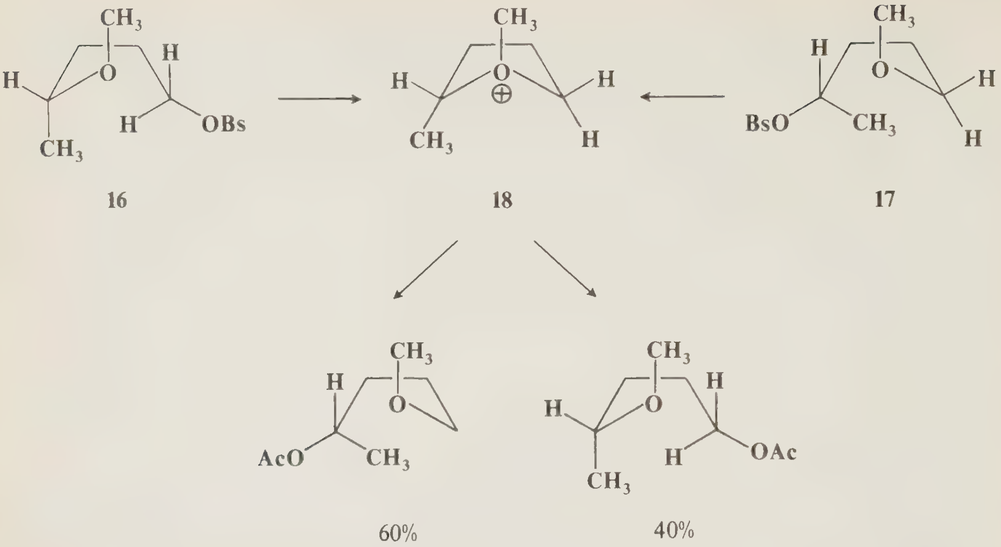


The fact that acetolysis of both 4-methoxy-1-pentyl brosylate (**16**) and 5-methoxy-2-pentyl brosylate (**17**) gave the same mixture of products is further evidence for participation by a neighboring group.[63] In this case the intermediate **18** is common to both substrates. Evidence has

---

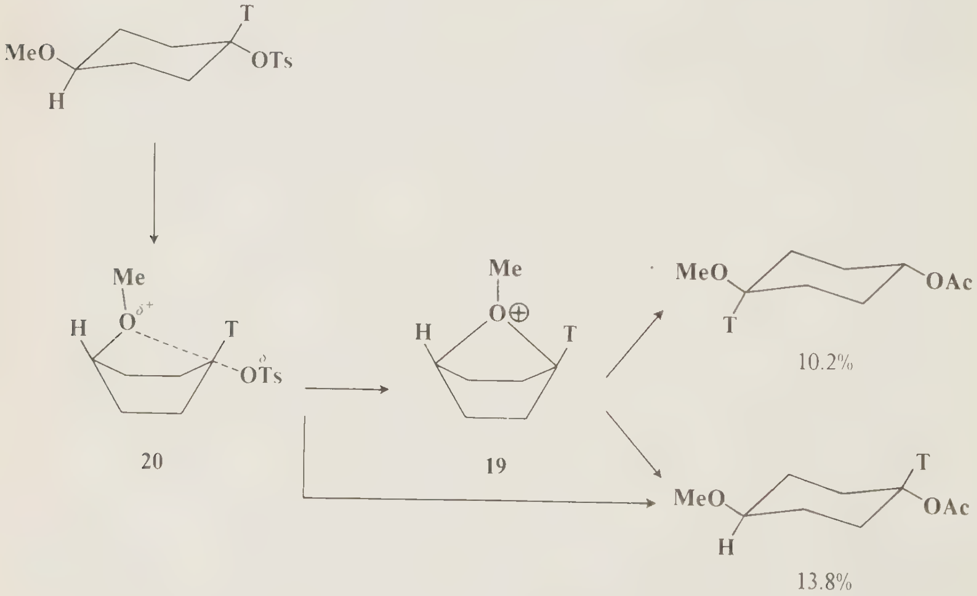
[62] See Traynham, *J. Chem. Educ.* **40**, 392 (1963).

[63] Allred and Winstein, *J. Am. Chem. Soc.* **89**, 3991, 3998 (1967).



been obtained from special salt effects that **18** is present both as the free ion and as ion pairs (with OBs$^-$ as the counterion).[63]

There is evidence that a neighboring group need not form a completely covalent bond with the substrate carbon in order to lend anchimeric assistance. Thus Noyce and coworkers showed that *trans*-4-methoxy-1-^{3}H-cyclohexyl tosylate when subjected to acetolysis gave 24% *trans*-4-methoxycyclohexyl acetate with 35% more tritium in the 1 position than in the 4 position.[64]



---

[64] Noyce, Thomas, and Bastian, *J. Am. Chem. Soc.* **82**, 885 (1960); Noyce and Bastian, *J. Am. Chem. Soc.* **82**, 1246 (1960).

If all the trans product came from the intermediate **19**, which is fully covalently bonded, then the tritium would have been equally distributed between the 1 and the 4 positions, except for the small isotope effect by which, if anything, more tritium would be expected in the 4 position. The excess 1-tritiated acetate could not have come from an ordinary SN2 reaction, since in that case the configuration would have been inverted. Indeed, 9.6% of *cis*-4-methoxycyclohexyl acetate (all labeled in the 1 position) was isolated in this reaction, formed by a concurrent SN2 reaction. Noyce and coworkers were thus led to postulate the intermediacy of an ion pair (**20**) which could go to **19** or directly to the substitution product. Similarly, in the hydrolysis of the anions of several α-bromoarylacetic and β-bromoarylpropionic acids, it was concluded that the action of the COO$^-$ group in assisting the departure of the Br is through electrostatic repulsion only, and that a covalent O—C bond is not being formed in the transition state.[65]

The neighboring-group mechanism operates only when the ring size is right for a particular type of Z. For example, for MeO(CH$_2$)$_n$OBs, neighboring-group participation was important for $n = 4$ or 5 (corresponding to a five- or six-membered intermediate) but not for $n = 2$, 3, or 6.[66] However, optimum ring size is not the same for all reactions, even with a particular Z. In general, the most rapid reactions occur when the ring size is three, five, or six, depending on the reaction type.

The following are some of the more important neighboring groups: COO$^-$ (but not COOH), OCOR, COOR, COAr,[67] OR, OH, O$^-$,[68] NH$_2$, NHR, NR$_2$, NHCOR, SH, SR, S$^-$,[69] I, Br, and Cl. The effectiveness of halogens as neighboring groups decreases in the order I > Br > Cl.[70] Cl is a very weak neighboring group and can be shown to act in this way only when the solvent does not interfere. For example, when 5-chloro-2-hexyl tosylate is solvolyzed in acetic acid, there is little participation by the Cl; but when the solvent is changed to trifluoroacetic acid, which is much less nucleophilic, neighboring-group participation by the Cl becomes the major reaction pathway.[71] Thus, Cl acts a neighboring group *only when there is need for it* (for other examples of this principle, see pp. 284, 288).

A number of intermediates of halogen participation (halonium ions),[71a] e.g., **21** and **22**, have been prepared as stable salts in SbF$_5$–SO$_2$ or SbF$_5$–SO$_2$ClF solutions.[72] Some of them have even

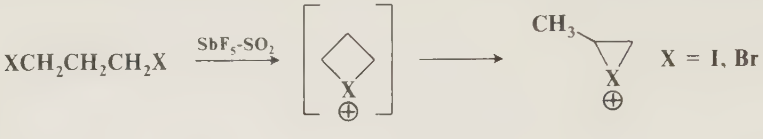
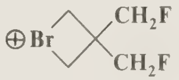
been crystallized. Attempts to prepare four-membered homologs of **21** and **22** did not bear fruit, as only three- or five-membered rings were obtained,[73] presumably by rearrangement, e.g.,

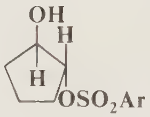


23

The fact that **23** (X = I or Br) forms in this reaction, but not the corresponding chloro analog, is further evidence for the low effectiveness of Cl as a neighboring group. In the case of 1,3-dichloropropane, the nmr spectrum of the product indicated the presence of an equilibrating mixture of **23** (X = Cl) and the open-chain ions $CH_3CH_2\overset{+}{C}HCl$ and $CH_3\overset{+}{C}HCH_2Cl$.[73] However, the four-membered bromonium ion **24** has been prepared.[74] There is no evidence that F can act as a neighboring group.[70]



24



25

The principle that a neighboring group lends assistance in proportion to the need for such assistance also applies to differences in leaving-group ability. Thus, *p*-$NO_2C_6H_4SO_2O$ (the nosylate group) is a better leaving group than *p*-$MeC_6H_4SO_2O$ (the tosylate group). Experiments have shown that the OH group in *trans*-2-hydroxycyclopentyl arenesulfonates (**25**) acts as a neighboring group when the leaving group is tosylate but not when it is nosylate, apparently because the nosylate group leaves so rapidly that it does not require assistance.[75]

Neighboring-Group Participation by π and σ Bonds. Nonclassical Carbonium Ions[76]

For all the neighboring groups listed in the preceding section, the internal nucleophilic attack is made by an atom with an unshared pair of electrons. In this section we shall consider neighboring-group participation by C=C π bonds and C—C and C—H σ bonds. There has been a great deal of controversy over whether such bonds can act as neighboring groups and about the existence and structure of the intermediates involved. These intermediates are called *nonclassical* (or *bridged*) carbonium ions. In classical carbonium ions (Chapter 5) the positive charge is localized on one carbon atom, or delocalized by resonance involving an unshared pair of electrons or a double or triple bond in the allylic position. In a nonclassical carbonium ion the positive charge is delocalized by a double or triple bond which is not in the allylic position, or by a

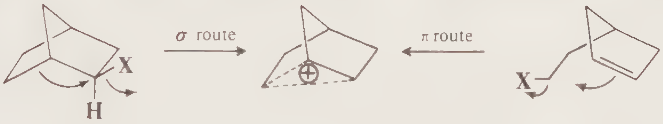
single bond. Examples are the 7-norbornenyl cation (**26**),[77] the norbornyl cation (**27**), and the cyclopropylmethyl cation (**28**). **26** is called a *homoallylic* carbonium ion, because in **26a** there is one carbon atom between the positively charged carbon and the double bond. Many nonclassical carbonium ions can be produced in more than one way if the proper substrates are chosen. For example, **27** can be generated by departure of a leaving group from **29** or from **30**.[78] The first of



29 **27** **30**

these pathways is called the σ route to a nonclassical carbonium ion, because participation of a σ bond is involved. The second is called the π route.[79] The argument against the existence of nonclassical carbonium ions is essentially that the structures **26a**, **26b**, **26c** (or **27a**, **27b**, etc.) are not canonical forms but real structures, and that there is rapid equilibration among them.

In the arguments for and against nonclassical carbonium ions, the distinction between neighboring-group participation and the existence of nonclassical carbonium ions has not always been kept clear.[80] If a nonclassical carbonium ion exists in any reaction, then an ion with electron delocalization, as shown in the above examples, is a discrete reaction intermediate. If a carbon-carbon double or single bond participates in the departure of the leaving group to form a carbonium ion, it may be that a nonclassical carbonium ion is involved, but there is no necessary relation. There are four possibilities:

---

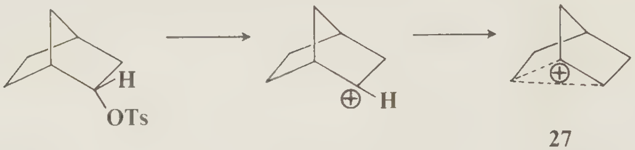
[77] There is evidence that **26d** is not the best representation of this ion. See p. 297.

[78] Lawton, *J. Am. Chem. Soc.* **83**, 2399 (1961); Bartlett, Bank, Crawford, and Schmid, *J. Am. Chem. Soc.* **87**, 1288 (1965).

[79] Winstein and Carter, *J. Am. Chem. Soc.* **83**, 4485 (1961).

[80] This has been pointed out by Cram, *J. Am. Chem. Soc.* **86**, 3767 (1964).

1. The leaving group may depart without assistance, and *then* a nonclassical ion may form, e.g.,



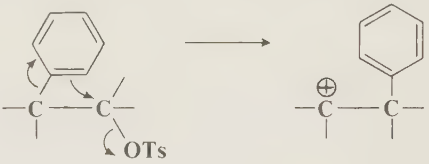
27

Classical carbonium ion

Nonclassical carbonium ion

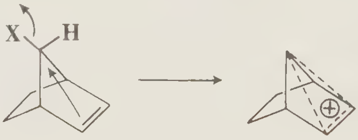
In this case there is no rate enhancement (compared, say, to the same reaction run on cyclopentyl tosylate, where no nonclassical ion is involved at any time).

2. A carbon-carbon double or single bond may lend assistance but may nonetheless give a classical open carbonium ion, e.g.,



In this case the rate *would* be enhanced, though no bridged ion is involved.

3. Both assistance and a nonclassical ion may be involved, e.g.,



31 **26d**

4. And, of course, there may be unassisted ionization to a classical carbonium ion.

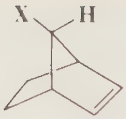
Enhanced rates are usually evidence for neighboring-group assistance but are not *always* evidence for the existence of nonclassical carbonium ions.

In the following pages we shall consider some of the evidence bearing on the questions of the participation of π and σ bonds and on the existence of nonclassical carbonium ions,[81] though a thorough discussion would be beyond the scope of this book.[76]

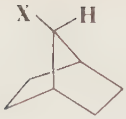
1. C=C *as a neighboring group*.[82] The most striking evidence that C=C can act as a neighboring group is that acetolysis of **31**-OTs is 10^{11} times faster than that of **32**-OTs and *proceeds with*

[81] For summaries of the arguments for nonclassical carbonium ions, see Winstein, *Aromaticity, Chem. Soc. Spec. Publ.* no. 21, 5–45 (1967), *Q. Rev., Chem. Soc.* **23,** 141–176 (1969). [The latter article is reprinted in Olah and Schleyer, Ref. 76, vol. 3, pp. 965–1005, 1972.] For summaries of the arguments against them, see Brown, *Chem. Br.* **2,** 199–208 (1966), "Boranes in Organic Chemistry," pp. 131–205, Cornell University Press, Ithaca, N.Y., 1972, *Acc. Chem. Res.* **6,** 377–386 (1973), *Tetrahedron* **32,** 179–204 (1976); Hückel, *Justus Liebigs Ann. Chem.* **711,** 1–18 (1968).

[82] For reviews, see Story and Clark, in Olah and Schleyer, Ref. 76, vol. 3, pp. 1007–1060, 1972; Richey, in Zabicky, "The Chemistry of Alkenes," vol. 2, pp. 77–101, Interscience Publishers, New York, 1970.

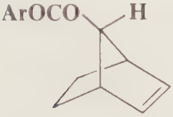


31

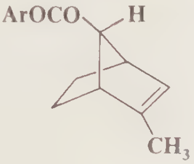


32

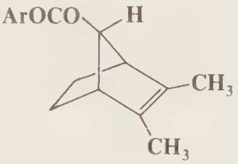
retention of configuration.[83] The rate data alone do not necessarily prove that acetolysis of **31**-OTs involves a nonclassical intermediate (**26d**), but it is certainly strong evidence that the C=C group assists in the departure of the OTs. It had been suggested that a pair of rapidly equilibrating classical carbonium ions (**26b** and **26c**) could also account for the results.[84] However, evidence against this view was obtained by a comparison of the rates of acetolysis of **33, 34,** and **35** at 140°C, which were found to be 1 : 13.3 : 148.[85] This ratio is in accord with the intermediate **26d,**



33



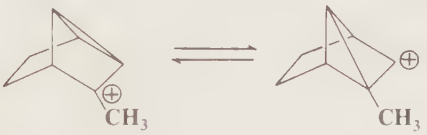
34



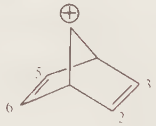
35

Ar = p-$NO_2C_6H_4$

since this intermediate has a partial positive charge at both carbons and should be stabilized by the first methyl group and then further stabilized by the second. If, however, an equilibrium between **26b** and **26c** were involved, then each of these ions would have a positive charge at only one carbon. Introduction of one methyl group would increase the rate, because the charge would then be at a tertiary carbon, but this would mean that **36** would be greatly favored at the



36 **37**



38

expense of **37**. The introduction of a second methyl group should have little effect on the rate, since it has to be located on a carbon atom which bears no charge.

Further evidence that **26** is indeed a nonclassical ion comes from an nmr study of the relatively stable norbornadienyl cation (**38**). The spectrum shows that the 2 and 3 protons are not equivalent to the 5 and 6 protons.[86] Thus there is interaction between the charged carbon and one double bond, which is evidence for the existence of **26d.**[87] In the case of **31** the double bond is geometrically fixed in an especially favorable position for backside attack on the carbon bearing the leaving group (hence the very large rate enhancement), but there is much evidence that other double bonds in the homoallylic position,[88] as well as in positions farther away,[89] can also lend anchimeric assistance, though generally with much lower rate ratios. One example of the latter is the compound β-(*syn*-7-norbornenyl)ethyl brosylate (**39**) which undergoes acetolysis at 25°C about 140,000 times faster than the saturated analog **40**.[90] Triple bonds[91] and allenes[92] can also act as neighboring groups.

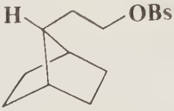
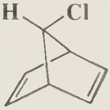
39

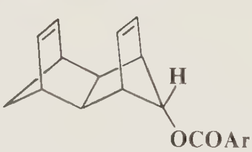


40

An interesting fact is that a second double bond, suitably placed, can increase solvolysis rates still further. Thus, solvolysis of 7-chloronorbornadiene (**41**) was 10^3 times faster than that of **31**-Cl,[93] while **42** (which has a [2.2.1] bicyclic system fused to a 7-norbornenyl system) solvolyzed about 10^3 times faster than the *p*-nitrobenzoate ester of **31**-OH.[94] Thus both these systems solvolyze about 10^{14} times faster than the saturated 7-norbornyl system.



41



Ar = p-$NO_2C_6H_4$

42

We have already seen evidence that participation by a potential neighboring group can be reduced or eliminated if an outside nucleophile is present which is more effective than the neighboring group in attacking the central carbon (p. 283), or if a sufficiently good leaving group is present (p. 284). In another example of this principle, Gassman and coworkers have shown that neighboring-group participation can also be reduced if the stability of the potential carbonium ion is increased. They found that the presence of a *p*-anisyl group at the 7 position of **31** and **32** exerts a powerful leveling effect on the rate differences. Thus, solvolysis in acetone-water at 85°C of *syn*-7-*p*-anisyl-*anti*-7-norborn-2-enyl *p*-nitrobenzoate (**43**) was only about 2.5 times faster than

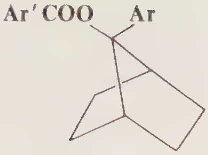
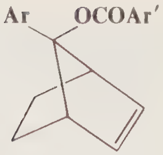
43



44



45

$\mathrm{Ar} = p\text{-}\mathrm{MeOC_6H_4}$
$\mathrm{Ar'} = p\text{-}\mathrm{NO_2C_6H_4}$

that of the saturated compound **44**.[95] Furthermore, both **43** and its stereoisomer **45** gave the same mixture of solvolysis products, showing that the stereoselectivity in the solvolysis of **31** is not present here. The difference between **43** and **31** is that in the case of **43** the positive charge generated at the 7 position in the transition state is greatly stabilized by the *p*-anisyl group. Apparently the stabilization by the *p*-anisyl group is so great that further stabilization which would come from participation by the C═C bond is not needed. The use of a phenyl instead of a *p*-anisyl group is not sufficient to stop participation by the double bond completely, though it does reduce it.[96] These results permit us to emphasize our previous conclusion, that *a neighboring group lends anchimeric assistance only when there is sufficient demand for it.*

2. *Cyclopropyl*[97] *as a neighboring group.*[98] On p. 141 we saw that the properties of a cyclopropane ring are in some ways similar to those of a double bond. Therefore it is not surprising that a suitably placed cyclopropyl ring can also be a neighboring group. Thus *endo-anti*-tricyclo-[3.2.1.0^{2,4}]octan-8-yl *p*-nitrobenzoate (**46**) solvolyzed about 10^{14} times faster than the *p*-nitrobenzoate of **32**-OH.[99] Obviously, a suitably placed cyclopropyl ring can be even more effective[100] as a neighboring group than a double bond.[101] The need for suitable placement is emphasized by the fact that **48** solvolyzed only about five times faster than **32**-OBs,[102] while **47** solvolyzed three

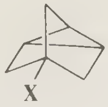
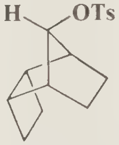
[102] Battiste, Deyrup, Pincock, and Haywood-Farmer, Ref. 99; Haywood-Farmer and Pincock, *J. Am. Chem. Soc.* **91**, 3020 (1969).

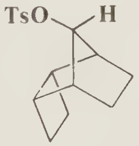
times *slower* than **32**-OBs.[103] In the case of **46** and of all other cases known where cyclopropyl lends considerable anchimeric assistance, the developing *p* orbital of the carbonium ion is orthogonal to the participating bond of the cyclopropane ring.[104] An experiment designed to test whether a developing *p* orbital which would be parallel to the participating bond would be assisted by that bond showed no rate enhancement.[104] This is in contrast to the behavior of cyclopropane rings directly attached to positively charged carbons, where the *p* orbital is parallel to the plane of the ring (pp. 155, 299). Another geometrical situation in which rate enhancement is not found is where the developing *p* orbital is directly over the face of a cyclopropane ring, as in **49**.[105]



49



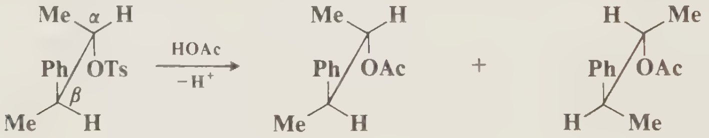
50



51

Rate enhancements, though considerably smaller, have also been reported for suitably placed cyclobutyl rings. For example, acetolysis of **50** was about 2×10^4 times faster than that of **32**-OTs.[106] Suitable placement is essential in this case also, as shown by the fact that there was essentially no rate enhancement at all in acetolysis of **51**, compared with that of **32**-OTs.

3. *Aromatic rings as neighboring groups.*[107] There is a great deal of evidence that aromatic rings in the *β*-position can function as neighboring groups. Stereochemical evidence was obtained by solvolysis of L-*threo*-3-phenyl-2-butyl tosylate (**52**) in acetic acid.[108] Of the acetate product 96%



52 **53** **54**

was the threo isomer and only about 4% was erythro. Moreover, both the D and L threo isomers (**53** and **54**) were produced in approximately equal amounts (a racemic mixture). When solvolysis was conducted in formic acid, even less erythro isomer was obtained. This result is similar to that found on reaction of 3-bromo-2-butanol with HBr (p. 280) and leads to the conclusion that configuration is retained because phenyl acts as a neighboring group. However, evidence from rate studies is not so simple. If β-aryl groups assist the departure of the leaving group, then solvolysis rates should be enhanced. In general they are not. However, solvolysis rate studies in 2-arylethyl systems are complicated by the fact that, for primary and secondary systems, two pathways can exist.[109] In one of these (designated k_Δ), the aryl, behaving as a neighboring group, pushes out the leaving group to give a bridged carbonium ion, called a *phenonium ion* (**55**), and is in turn pushed out by the solvent SOH, so that the net result is substitution with retention of configuration (or rearrangement, if **55** is opened from the other side). The other pathway (k_s) is simple S$_N$2 attack by the solvent at the leaving-group carbon. The net result here is substitution with inversion and no possibility of rearrangement. Whether the leaving group is located at a primary or a secondary carbon,[110] there is no crossover between these pathways; they are completely independent.[111] The overall rate constant k_t (which is determined by titration of the departed leaving group) is then given by

55

$$k_t = Fk_\Delta + k_s$$

where F is the fraction of **55** which goes to product. This factor is needed because **55** may be present as an ion pair and consequently may undergo partial internal return to the starting compound. Which of the two pathways predominates in any given case depends on the solvent and on the nature of the aryl group. As expected from the results we have seen for Cl as a neighboring group (p. 283), the k_Δ/k_s ratio is highest for solvents which are poor nucleophiles and so compete very poorly with the aryl group. For several common solvents the k_Δ/k_s ratio increases in the order EtOH < CH_3COOH < HCOOH < CF_3COOH.[112] In accord with this, the following percentages of retention were obtained in solvolysis of 1-phenyl-2-propyl tosylate at 50°C: solvolysis in EtOH 7%, CH_3COOH 35%, HCOOH 85%.[112] This indicates that k_s predominates in EtOH (phenyl participates very little), while k_Δ predominates in HCOOH. Trifluoroacetic acid is a solvent of particularly low nucleophilic power, and in this solvent the reaction proceeds entirely by k_Δ;[113] deuterium labeling showed 100% retention.[114] This case provides a clear example of neighboring-group rate enhancement by phenyl: the rate of solvolysis of $PhCH_2CH_2OTs$ at 75°C in CF_3COOH is 3040 times the rate for CH_3CH_2OTs.[113] The presence of special salt effects

during solvolysis of $PhCH_2CH_2OTs$ in CF_3COOH shows that under these conditions **55** and its counterion exist as intimate ion pairs, as solvent-separated ion pairs, and as dissociated ions.[115]

With respect to the aromatic ring, the k_Δ pathway is an electrophilic aromatic substitution (Chapter 11), and we would predict that groups on the ring which activate that reaction (p. 459) will increase, and deactivating groups will decrease, the rate of this pathway. This prediction has been borne out by several investigations. The p-nitro derivative of L-*threo*-**52** solvolyzed in acetic acid 190 times slower than **52**, and there was much less retention of configuration: the acetate produced was only 7% threo and 93% erythro.[116] At 90°C, acetolysis of p-$ZC_6H_4CH_2CH_2OTs$ gave the rate ratios shown in Table 1.[117] Throughout this series k_s is fairly constant, as it should be since it is affected only by the rather remote field effect of Z. It is k_Δ which changes substantially as Z is changed from activating to deactivating. The evidence is thus fairly clear that participation by aryl groups depends greatly on the nature of the group, and that for some groups, e.g., p-nitrophenyl, in some solvents, e.g., acetic acid, there is essentially no neighboring-group participation at all,[118] while for others, e.g., p-methoxyphenyl, neighboring-group participation is substantial. The combined effect of solvent and structure is shown in Table 2, where the figures shown were derived by three different methods.[119]

For some years there was controversy about the structure of phenonium ions **55**,[120] but several

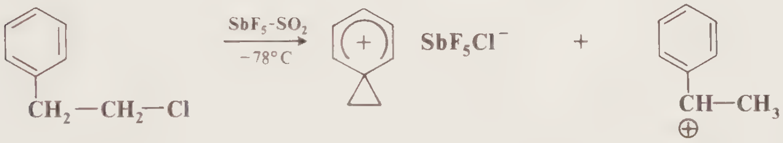
57 **58** **59**

of these have now been prepared as stable ions in solution where they can be studied by nmr, among them **56**,[121] **57**,[122] and the unsubstituted **55**.[123] These were prepared by the method shown for **55**: treatment of the corresponding β-arylethyl chloride with SbF_6–SO_2 at low temperatures. These conditions are even more extreme than the solvolysis in CF_3COOH mentioned earlier. The absence of any nucleophile at all eliminates not only the k_s pathway but also nucleophilic



55 **60**

attack on **55**. The 1-phenylethyl cation (**60**) is formed along with **55**, but the two ions are formed by separate pathways and do not interconvert. **60** is produced by a hydride shift. Although **55** is not in equilibrium with the open-chain ion $PhCH_2CH_2^+$ (which is primary and hence unstable), **57** is in equilibrium with the open-chain tertiary ions **58** and **59**, though only **57** is present in appreciable concentration. Proton and ^{13}C nmr show that **55**, **56**, and **57** are classical carbonium ions where the only resonance is in the six-membered ring. The three-membered ring is a normal cyclopropane ring which is influenced only to a relatively small extent by the positive charge on

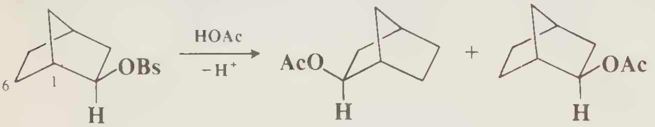
61

the adjacent ring. Nmr spectra show that the six-membered rings have no aromatic character but are similar in structure to those carbonium ions, e.g., **61**, which are intermediates in electrophilic aromatic substitution (Chapter 11). These ions can be quenched with an added nucleophile to give normal nucleophilic substitution products. For example, the addition of K_2CO_3-buffered ice in SO_2ClF to solutions containing mixtures of **55** and **60** gave a mixture of α- and β-phenylethyl alcohols.[123]

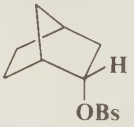
It is thus clear that β-aryl groups can function as neighboring groups.[124] Much less work has been done on aryl groups located in positions farther away from the leaving group, but there is evidence that these too can lend anchimeric assistance.[125]

4. *The carbon-carbon single bond as a neighboring group.*[126]

a. *The 2-norbornyl system.* In the investigations to determine whether a C—C σ bond can act as a neighboring group, by far the greatest attention has been paid to the 2-norbornyl system.[127] Winstein and Trifan found that solvolysis in acetic acid of optically active *exo*-2-norbornyl brosylate (**62**) gave a racemic mixture of the two exo acetates;[128] no endo isomers were formed:[129]



62 **63** **64**



65

Furthermore, **62** solvolyzed about 350 times faster than its endo isomer **65**. Similar high exo/endo rate ratios have been found in many other 2.2.1 systems. These two results, (1) that solvolysis of an optically active exo isomer gave only racemic exo isomers and (2) the high exo/endo rate ratio, were interpreted by Winstein and Trifan as indicating that the 1,6 bond assists in the departure of the leaving group and that a nonclassical intermediate (**66**) is involved. They reasoned that

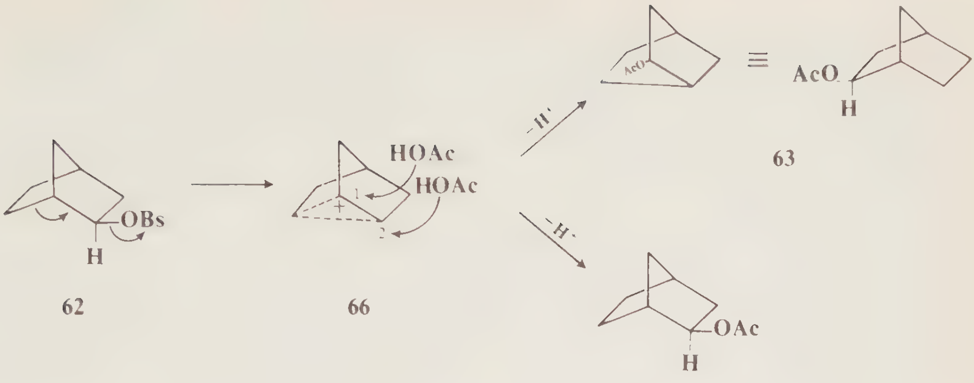
[128] Winstein and Trifan, *J. Am. Chem. Soc.* **74,** 1147, 1154 (1952).

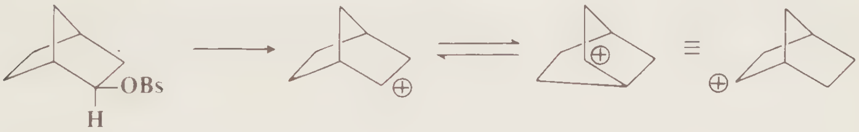
[129] It has been shown that the endo content is definitely less than 0.02%: Winstein, Clippinger, Howe, and Vogelfanger, *J. Am. Chem. Soc.* **87,** 376 (1965).



62 66 63 64

solvolysis of the endo isomer **65** is not assisted by the 1,6 bond because it is not in a favorable position for backside attack, and that consequently solvolysis of **65** takes place at a "normal" rate. Therefore the much faster rate for the solvolysis of **62** must be caused by anchimeric assistance. The stereochemistry of the product is also explained by the intermediacy of **66**, since in **66** the 1 and 2 positions are equivalent and would be attacked by the nucleophile with equal facility, but only from the exo direction in either case. There is the possibility that the 1,6 bond assists (accounting for the rate increase), but that **66** is not an intermediate. However, if this were the case, then every act of assistance would be an act of rearrangement (case 2, p. 286), and an optically active product would have been obtained. Incidentally, acetolysis of **65** also leads exclusively to the exo acetates (**63** and **64**), so that in this case Winstein and Trifan postulated that a classical ion (**67**) is first formed and then converted to the more stable **66**. Evidence for this interpretation is that the product from solvolysis of **65** is not racemic but contains somewhat more **64** than **63** (corresponding to 3 to 13% inversion, depending on the solvent),[129] suggesting that, when **67** is formed, some of it goes to give **64** before it can collapse to **66**.

The concepts of σ participation and of the nonclassical ion **66** have been challenged by H. C. Brown,[81] who has suggested that the two results can also be explained by postulating that **62** solvolyzes without participation of the 1,6 bond to give the classical ion **67** which is in rapid equilibrium with **68**. This rapid interconversion has been likened to the action of a windshield wiper. Obviously, in going from **67** to **68** and back again, **66** must be present, but in Brown's view it is only a transition state and not an intermediate. Brown's explanation for the stereochemical result is that exclusive exo attack is a property to be expected from any 2-norbornyl system, not only for the cation but even for reactions not involving cations, because of steric hindrance to attack from the endo side, and there is a large body of data which shows that exo attack on norbornyl systems is fairly general in many reactions. As for the obtention of a racemic mixture, this will obviously happen if **67** and **68** are present in equal amounts, since they are equivalent and exo attack on **67** and **68** gives, respectively, **64** and **63**. Brown explains the high



62 67 68

exo/endo rate ratios by contending that it is not the endo rate which is normal and the exo rate abnormally high, but the exo rate which is normal and the endo rate abnormally *low*, because of steric hindrance to removal of the leaving group in that direction. Schleyer has proposed that *torsional effects* are at least partly responsible for the high exo/endo rate ratios.[130] That is, when an exo leaving group departs, eclipsing and other nonbonded interactions decrease but, when an endo group departs, these interactions increase. However, there is evidence that torsional effects in this system are minor.[131]

A vast amount of work has been done[132] on solvolysis of the 2-norbornyl system in efforts to determine whether the 1,6 bond participates and whether **66** is an intermediate, but the question is still not settled.[133] However, there is general agreement on two points: (1) *endo*-2-norbornyl substrates solvolyze without participation (though some workers believe that formation of **66** may follow), and (2) substituents in the 2 position which stabilize a positive charge (e.g., methyl or phenyl) either entirely eliminate σ participation or at least greatly decrease it[134] (by the principle that the extent of neighboring-group participation depends on the need for it). The fact that high exo/endo rate and product ratios are also found in these systems[135] lends support to the statement that these phenomena are not caused by σ participation.

Though the intermediacy of **66** under solvolysis conditions remains to be proven or disproven, it has been stated that a nonclassical 2-norbornyl cation does exist under some conditions. Olah and coworkers have prepared the 2-norbornyl cation in stable solutions at temperatures below −150°C in SbF_5–SO_2 and FSO_3H–SbF_5–SO_2, where the structure is static and hydride shifts are absent.[136] Studies by proton and ^{13}C nmr, as well as by laser Raman spectra and x-ray electron spectroscopy,[137] led to the conclusion that under these conditions the ion is definitely nonclassical,[138] though this conclusion has been challenged.[138a] Olah and coworkers represented the structure as a corner-protonated nortricyclane (**69**); the symmetry is better seen when the

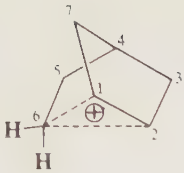
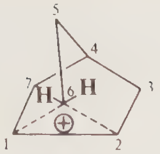
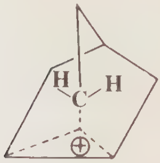
Nortricyclane



69

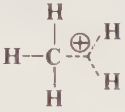


70

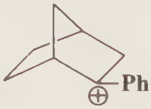


71

ion is drawn as in **70**. Almost all the positive charge resides on C-1 and C-2 and very little on the bridging carbon C-6. Because this means that C-6 is essentially tetrahedral, Olah has suggested[139] that a still better representation is **71**, which involves a two-electron, three-center



72



73

bond similar to the bonding found in the methanonium ion CH_5^+ (**72**)[140] (see p. 532). By measuring the rate of reaction of the stable (at low temperatures) 2-norbornyl cation with H_2 and

$$R^+ + H_2 \longrightarrow RH + H^+$$

comparing this with the rate for other cations, Hogeveen has concluded that the 2-norbornyl cation (which is of course a secondary cation) is almost as stable as typical tertiary cations (e.g., *t*-butyl, methylcyclohexyl) and much more stable than typical secondary cations (e.g., cyclopentyl, isopropyl).[141]

The spectra of other norbornyl cations have also been investigated under these conditions. Spectra of the tertiary 2-methyl- and 2-ethylnorbornyl cations show less delocalization,[142] and the 2-phenylnorbornyl cation (**73**) is essentially classical,[143] as are the 2-methoxy-[144] and 2-chloronorbornyl cations.[145] We may recall (p. 156) that methoxy and halo groups also stabilize a positive charge.

Note that in the 7-norbornenyl cation (**26**) there is also a corner-protonated cyclopropane ring. The similarity of the nmr spectra of **26** and **70** shows that in **26** also there is very little charge on the bridging carbon, which means that **26a** contributes very little to the hybrid; thus the structure is better represented as **74** rather than as **26d**.[145a]

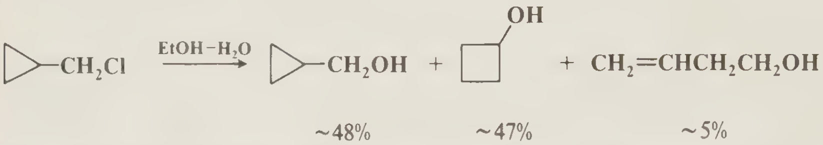
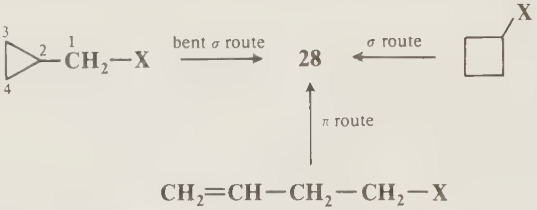
b. *The cyclopropylmethyl system.* Apart from the 2-norbornyl system, the greatest amount of effort in the search for C—C participation has been devoted to the cyclopropylmethyl system.[146] It has long been known that cyclopropylmethyl substrates solvolyze with abnormally high rates, and that the products often include not only unrearranged cyclopropylmethyl but also cyclobutyl and homoallylic compounds. An example is:[147]

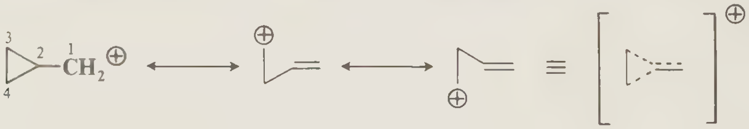


Cyclobutyl substrates also solvolyze abnormally rapidly and give similar products. Furthermore, when the reactions are carried out with labeled substrates, considerable, though not complete, scrambling is observed. For these reasons it has been suggested that a common intermediate (some kind of nonclassical intermediate, e.g., **28**, p. 285) is present in these cases. This could then be obtained by three routes:



In recent years much work has been devoted to the study of these systems, and it is apparent that matters are not so simple. Though there is much that is still not completely understood, some conclusions can be drawn.

i. In solvolysis of simple primary cyclopropylmethyl systems the rate is enhanced because of participation by the σ bonds of the ring. The ion which forms initially is an unrearranged cyclopropylmethyl cation[148] which is *symmetrically* stabilized; that is, both the 2,3 and the 2,4 σ bonds help to stabilize the positive charge. We have already seen (p. 155) that a cyclopropyl group stabilizes an adjacent positive charge even better than a phenyl group. One way of representing the structure of this cation is as shown in **75**. Among the evidence that **75** is a symmetrical



75

ion is that substitution of one or more methyl groups in the 3 and 4 positions increases the rate of solvolysis of cyclopropylcarbinyl 3,5-dinitrobenzoates by approximately a factor of 10 for *each* methyl group.[149] As we saw on p. 287, if only one of the σ bonds (say the 2,3 bond) stabilizes the cation, then methyl substitution at the 3 position should increase the rate, and a second methyl group at the 3 position should increase it still more, but a second methyl group at the 4 position should have little effect.[150] However, in bicyclic systems where there may be geometrical constraints, there is evidence that the cyclopropylmethyl cations formed are stabilized by the 2,3 or the 2,4 bond but not by both.

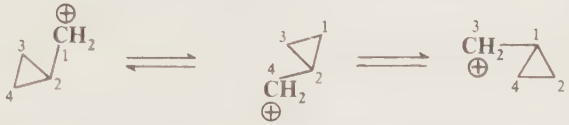
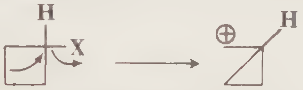
ii. The most stable geometry of simple cyclopropylmethyl cations is the bisected one shown on p. 156. There is much evidence that in systems where this geometry cannot be obtained, solvolysis is greatly slowed.[151]

iii. Once a cyclopropylmethyl cation is formed, it can rearrange to two other cyclopropylmethyl cations:



This rearrangement, which accounts for the scrambling found, is completely stereospecific.[152] The rearrangements probably take place through a nonplanar cyclobutyl cation intermediate or transition state. The formation of cyclobutyl and homoallylic products from a cyclopropylmethyl cation is also completely stereospecific. These products may arise by direct attack of the nucleophile on **75**, or on the cyclobutyl cation intermediate or transition state.[152] A planar cyclobutyl cation is ruled out in both cases, because it would be symmetrical and the stereospecificity would be lost.

iv. The rate enhancement in the solvolysis of secondary cyclobutyl substrates is probably caused by participation by a σ bond leading directly to **75**, which accounts for the fact that solvolysis of



cyclobutyl and of cyclopropylmethyl substrates often gives similar product mixtures. There is no evidence which requires that cyclobutyl cations be intermediates in most secondary systems. An exception is the 3-ethoxycyclobutyl cation which does form in solvolysis of 3-ethoxycyclobutyl tosylates and in deamination of the corresponding amine.[153] In this case there may be participation by the ethoxy group. However, tertiary cyclobutyl cations can be solvolysis intermediates.

v. The unsubstituted cyclopropylmethyl cation has been generated in super-acid solutions at low temperatures, where it has been represented as existing as an equilibrium mixture of three equivalent unsymmetrical cations, shown as **76**, **77**, and **78**.[154] In **76** there is a two-electron, three-center bond (p. 297) in which C-1 bridges the C-2, C-4 bond (or, equivalently, C-4 bridges the

[153] Lillien, *Chem. Commun.* 1009 (1968); Wiberg and Nelson, *Tetrahedron Lett.* 4385 (1969).

[154] Olah, Jeuell, Kelly, and Porter, *J. Am. Chem. Soc.* **94**, 146 (1972). See, however, Hehre and Hiberty, *J. Am. Chem. Soc.* **96**, 302 (1974); Kelly and Brown, *J. Am. Chem. Soc.* **97**, 3897 (1975).

C-1, C-2 bond); in **77** and **78** there is analogous bridging. Evidence for this structure comes from proton and ^{13}C nmr spectra which show that C-1, C-3, and C-4 are completely equivalent (^{13}C chemical shift, 138; for C-2 it is 85), and that the six protons connected to these three atoms exist as two sets. One set is made up of the three equivalent protons at $\delta = 4.21$, and the other of the three equivalent protons at $\delta = 4.64$. The fact that the same mixture of cyclopropylmethyl cations is generated whether one starts with cyclopropylmethyl or cyclobutyl substrates is evidence that secondary cyclobutyl cations are much less stable than primary cyclopropylmethyl cations, which was also implicit in the results of the solvolytic studies. However, the tertiary cation 1-phenylcyclobutyl is stable at low temperatures in super-acid solutions.[154]

c. *Methyl as a neighboring group.* Both the 2-norbornyl and cyclopropylmethyl systems contain a σ bond which is geometrically constrained to be in a particularly favorable position for participation as a neighboring group. However, there have been a number of investigations to determine whether a C—C bond can lend anchimeric assistance even in a simple open-chain compound such as neopentyl tosylate (**79**). On solvolysis, neopentyl systems undergo almost exclusive rearrangement, and **80** must lie on the reaction path, but the two questions which have been asked are: (1) Is the departure of the leaving group concerted with the formation of the CH_3—C bond (that is, does the methyl participate)? (2) Is **80** an intermediate or only a transition state? There is no clear answer to the first question. Though evidence has been presented that under some conditions the methyl group in the neopentyl system does indeed participate,[155] other investigations have failed to find such participation.[156] As to the second question, evidence that **80** is an intermediate is that small amounts of cyclopropanes (10 to 15%) can be isolated in these reactions.[157] **80** is a protonated cyclopropane and would give a cyclopropane on loss of a proton.[158] This of course does not answer question 1 since even if **80** is an intermediate, it is possible that the leaving group departs first and then the CH_3—C bond forms. In an effort to isolate a species which would have the structure **80**, the dimethyl-*t*-butylcarbonium ion was prepared in super-acid solutions at low temperatures.[159] However, proton and ^{13}C nmr, as well as Raman spectra, showed this to be a pair of rapidly equilibrating open ions. Of course, **81** must

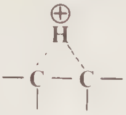
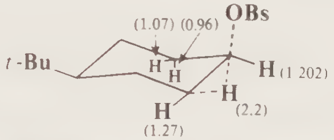
lie on the reaction path connecting the two open ions, but it is evidently only a transition state.

5. *Hydrogen as a neighboring group.* The questions relating to hydrogen are similar to those relating to methyl. There is no question that hydride can migrate, but the two questions are: (1) Does the hydrogen participate in the departure of the leaving group? (2) Is **82** an intermediate or only a transition state? Evidence that a β-hydrogen can participate comes from isotope-effect studies.[160] Solvolysis was carried out on *cis*-4-*t*-butylcyclohexyl brosylate substituted with deuterium in the α-position or in one or more of the β-positions.[161] In this compound, the large *t*-butyl group forces the brosylate group to be in the axial position. The isotope effect of one of the β-hydrogens, an axial one, was much greater than that of a hydrogen at any other position, even the other axial β-hydrogen. This indicates that this hydrogen participates in the transition state:

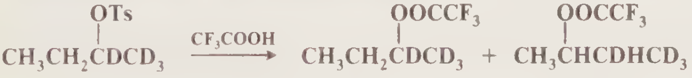


82



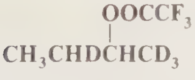
The two axial β-hydrogens are equivalent, but only one gives rise to a large isotope effect when substituted for by deuterium. This was determined by calculations using isotope-effect data from mono- and polydeuterated substrates. The isotope effect (k_H/k_D) at each position is indicated on the diagram.[162] There is also evidence that a hydrogen can participate from a more distant position if the geometry is suitable.[163]

Evidence that **82** can be an intermediate in solvolysis reactions comes from a study of the solvolysis in trifluoroacetic acid of deuterated *sec*-butyl tosylate **83**. In this solvent of very low nucleophilic power, the products were an equimolar mixture of **84** and **85**,[164] but *no* **86** or **87** was found. If this reaction did not involve neighboring hydrogen at all (pure S_N2 or S_N1), the



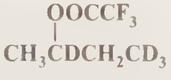
$$\underset{\textbf{83}}{CH_3CH_2\overset{OTs}{\overset{|}{C}}DCD_3} \xrightarrow{CF_3COOH} \underset{\textbf{84}}{CH_3CH_2\overset{OOCCF_3}{\overset{|}{C}}DCD_3} + \underset{\textbf{85}}{CH_3\overset{OOCCF_3}{\overset{|}{C}}HCDHCD_3}$$

83 **84** **85**



$$CH_3CHD\overset{OOCCF_3}{\overset{|}{C}}HCD_3$$

86



$$CH_3\overset{OOCCF_3}{\overset{|}{C}}DCH_2CD_3$$

[160] For a discussion, see Scheppele, Ref. 124, pp. 531–532.

[161] Shiner and Jewett, *J. Am. Chem. Soc.* **87,** 1382 (1965).

[162] For other evidence for participation by β-hydrogen, see Pánková, Sicher, Tichý, and Whiting, *J. Chem. Soc. B* 365 (1968); Tichý, Hapala, and Sicher, *Tetrahedron Lett.* 3739 (1969); Myhre and Evans, *J. Am. Chem. Soc.* **91,** 5641 (1969); Inomoto, Robertson, and Sarkis, *Can. J. Chem* **47,** 4599 (1969); Shiner and Stoffer, *J. Am. Chem. Soc.* **92,** 3191 (1970); Krapcho and Johanson, *J. Org. Chem.* **36,** 146 (1971); Chuit, Felkin, Le Ny, Lion, and Prunier, *Tetrahedron* **28,** 4787 (1972).

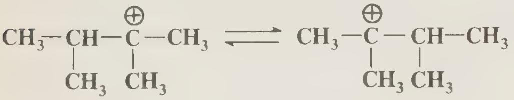
[163] Stéhelin, Lhomme, and Ourisson, *J. Am. Chem. Soc.* **93,** 1650 (1971); Stéhelin, Kanellias, and Ourisson, *J. Org. Chem.* **38,** 847, 851 (1973).

[164] Dannenberg, Weinwurzel, Dill, and Goldberg, *Tetrahedron Lett.* 1241 (1972).

product would be only **84**. On the other hand, if hydrogen does migrate, but only open cations are involved, then there should be an equilibrium among these four cations:

$$CH_3CH_2\overset{\oplus}{C}DCD_3 \rightleftharpoons CH_3\overset{\oplus}{C}HCDHCD_3 \rightleftharpoons CH_3CD\overset{\oplus}{C}HCD_3 \rightleftharpoons CH_3\overset{\oplus}{C}DCH_2CD_3$$

leading not only to **84** and **85**, but also to **86** and **87**. The results are most easily compatible with the intermediacy of the bridged ion **88** which can then be attacked by the solvent equally at the 2 and 3 positions. Attempts to prepare **82** as a stable ion in super-acid solutions at low temperatures have not been successful. Spectral results indicate that both the dimethylisopropylcarbonium ion (**89**) and the 2-butyl cation (**90**) exist under these conditions as equilibrating pairs of ions,[159] where **82** is only a transition state.



$$CH_3-\underset{CH_3}{CH}-\overset{\oplus}{\underset{CH_3}{C}}-CH_3 \rightleftharpoons CH_3-\overset{\oplus}{\underset{CH_3}{C}}-\underset{CH_3}{CH}-CH_3$$

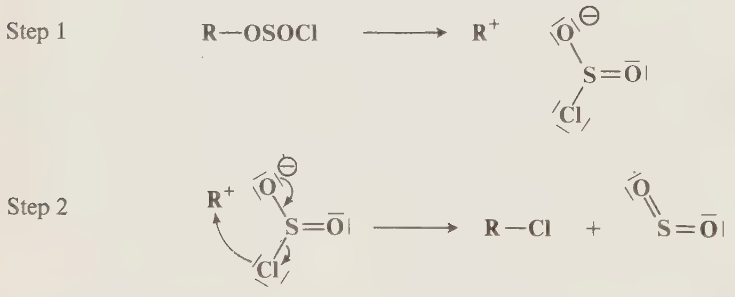
89

$$CH_3CH_2\overset{\oplus}{C}HCH_3 \rightleftharpoons CH_3\overset{\oplus}{C}HCH_2CH_3$$

90

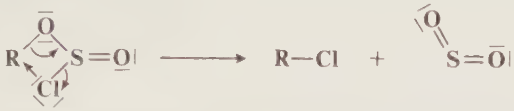
The SNi Mechanism

In a few reactions, nucleophilic substitution proceeds with retention of configuration even where there is no possibility of a neighboring-group effect. In the SNi mechanism (*substitution nucleophilic internal*) part of the leaving group must be able to attack the substrate, detaching itself from the rest of the leaving group in the process. The first step is the same as the very first step of the SN1 mechanism: dissociation into an intimate ion pair. But in the second step part of the leaving group attacks, necessarily from the front, since it is unable to get to the rear. This results in retention of configuration:

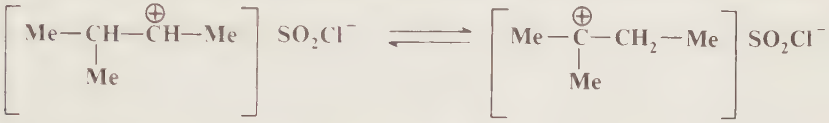


The example shown is the most important case of this mechanism yet discovered, since the reaction of alcohols with thionyl chloride to give alkyl halides usually proceeds in this way, with the first step in this case being $ROH + SOCl_2 \rightarrow ROSOCl$ (these alkyl chlorosulfites can be isolated).

Evidence for this mechanism is as follows: the addition of pyridine to the mixture of alcohol and thionyl chloride results in the formation of alkyl halide with *inverted* configuration. Inversion results because the pyridine reacts with ROSOCl to give $ROSO\overset{\oplus}{N}C_5H_5$ before anything further can take place. The Cl^- freed in this process now attacks from the rear. The reaction between alcohols and thionyl chloride is second order, which is predicted by this mechanism, but the decomposition by simple heating of ROSOCl is first order.[165] It was previously believed that the reaction was a one-step process:



However, the fact that $Me_2CHCHMeOSOCl$ gave, on heating, Me_2CClCH_2Me[166] indicated that an ion pair must have been present, since there is no other way to account for the rearrangement:

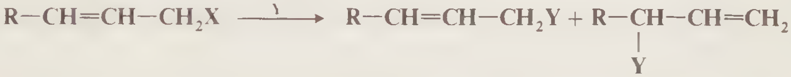


$$\left[\underset{\displaystyle Me}{\mathrm{Me{-}\underset{|}{C}H{-}\overset{\oplus}{C}H{-}Me}}\right] SO_2Cl^- \rightleftharpoons \left[\mathrm{Me{-}\underset{\underset{\displaystyle Me}{|}}{\overset{\oplus}{C}}{-}CH_2{-}Me}\right] SO_2Cl^-$$

The SNi mechanism is relatively rare, another example of it being the decomposition of ROCOCl (alkyl chloroformates) into RCl and CO_2.[167]

Nucleophilic Substitution at an Allylic Carbon. Allylic Rearrangements[168]

Allylic substrates undergo nucleophilic substitution reactions especially rapidly (see p. 318), but we discuss them in a separate section because they are usually accompanied by a certain kind of rearrangement known as an *allylic rearrangement* or an *allylic shift*. When allylic substrates are treated with nucleophiles under SN1 conditions, two products are usually obtained: the normal one and a rearranged one.



$$R{-}CH{=}CH{-}CH_2X \xrightarrow{Y} R{-}CH{=}CH{-}CH_2Y + R{-}\underset{\underset{\displaystyle Y}{|}}{CH}{-}CH{=}CH_2$$

Two products are formed because an allylic type of carbonium ion is a resonance hybrid

$$R{-}CH{=}CH{-}CH_2^{\oplus} \longleftrightarrow R{-}\overset{\oplus}{C}H{-}CH{=}CH_2$$

so that C-1 and C-3 each carry a partial positive charge, and both are attacked by Y. Of course an allylic rearrangement is undetectable in the case of symmetrical allylic carbonium ions, as in the case where R = H, unless isotopic labeling is used. This mechanism has been called the SN1′ mechanism.

[168] For reviews, see DeWolfe, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 9, pp. 417–437, American Elsevier Publishing Company, New York, 1973; DeWolfe and Young, *Chem. Rev.* **56**, 753–901 (1956); Young, *J. Chem. Educ.* **39**, 455–460 (1962); de la Mare, in Mayo, "Molecular Rearrangements," vol. 1, pp. 27–110, Interscience Publishers, New York, 1963; in Patai, "The Chemistry of Alkenes," Interscience Publishers, New York, 1964, the sections by Mackenzie, pp. 436–453, and DeWolfe and Young, pp. 681–738.

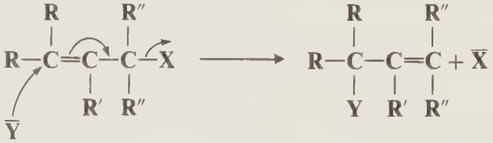
As with other SN1 reactions, there is clear evidence that SN1′ reactions may involve ion pairs. If the intermediate attacked by the nucleophile is a completely free carbonium ion, then, say,

$$\underset{\textbf{91}}{CH_3CH{=}CHCH_2Cl} \qquad \text{and} \qquad \underset{\textbf{92}}{CH_3CHClCH{=}CH_2}$$

should give the same mixture of alcohols when reacting with hydroxide ion, since the carbonium ion from each should be the same. When treated with 0.8 *N* aqueous NaOH at 25°C, **91** gave 60% $CH_3CH{=}CHCH_2OH$ and 40% $CH_3CHOHCH{=}CH_2$, while **92** gave these products in yields of 38% and 62%, respectively.[169] This phenomenon is called the *product spread.* In this case, and in most others, the product spread is in the direction of the starting compound. With increasing polarity of solvent, the product spread decreases and in some cases is entirely absent. It is evident that in such cases the high polarity of the solvent stabilizes completely free carbonium ions. There is other evidence for the intervention of ion pairs in many of these reactions. When $H_2C{=}CHCMe_2Cl$ was treated with acetic acid, both acetates were obtained, but also some $ClCH_2CH{=}CMe_2$,[170] and the isomerization was faster than the acetate formation. This could not have arisen from a completely free Cl^- returning to the carbonium ion, since the rate of formation of the rearranged chloride was unaffected by the addition of external Cl^-. All these facts indicate that the first step in these reactions is the formation of an unsymmetrical intimate ion pair which undergoes a considerable amount of internal return and in which the counterion remains close to the carbon from which it departed. Thus, **91** and **92,** for example, give rise to two *different* intimate ion pairs. The field of the anion polarizes the allylic cation, making the nearby carbon atom more electrophilic, so that it has a greater chance of attracting the nucleophile.[171] In fact, the first published suggestion[170] that ion pairs are involved in any nucleophilic substitution arose from work done on an allylic system.

Nucleophilic substitution at an allylic carbon may also take place by an SN2 mechanism, in which case *no allylic rearrangement usually takes place.* However, allylic rearrangements can also take place under SN2 conditions, and the following mechanism has been proposed, in which the nucleophile attacks at the γ-carbon rather than at the usual position:

SN2′ mechanism



This mechanism is an allylic rearrangement which is second order; it usually comes about where SN2 conditions hold but where α substitution sterically retards the normal SN2 mechanism. There are thus few well-established cases of the SN2′ mechanism on substrates of the type $C{=}C{-}CH_2X$, while compounds of the form $C{=}C{-}CR_2X$ give the SN2′ rearrangement almost exclusively when they give bimolecular reactions at all.[172] The SN2′ mechanism as shown above involves the simultaneous movement of three pairs of electrons. Bordwell has contended that there is no evidence that requires that this bond making and bond breaking be in fact concerted,[173] and that a true SN2′ mechanism is a myth. However, questions involving the timing of bond-making and bond-breaking steps can be studied by isotope effects. Evidence for a true SN2′ mechanism in the reaction between diethylamine and 3-chloro-1-butene was obtained by the principle of successive-labeling isotope effects.[174] According to this principle, isotope effects should be observed for the molecule successively labeled at each position which undergoes a bond change in going from the reactants to the transition state. If the SN2′ mechanism is correct in this case,

---

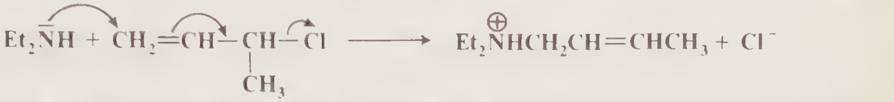
[169] DeWolfe and Young, Ref. 168, give several dozen such examples.

[170] Young, Winstein, and Goering, *J. Am. Chem. Soc.* **73,** 1958 (1951).

[171] For additional evidence for the involvement of ion pairs in SN1′ reactions, see Goering and Linsay, *J. Am. Chem. Soc.* **91,** 7435 (1969); Goering, Koermer, and Linsay, *J. Am. Chem. Soc.* **93,** 1230 (1971); d'Incan and Viout, *Bull. Soc. Chim. Fr.* 3312 (1971); Ref. 46.

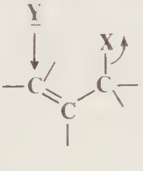
[172] For a discussion of this mechanism, with examples, see DeWolfe and Young, Ref. 168, pp. 769–784.

[173] Bordwell and Schexnayder, *J. Org. Chem.* **33,** 3240 (1968); Bordwell and Mecca, *J. Am. Chem. Soc.* **94,** 5829 (1972); Bordwell, *Acc. Chem. Res.* **3,** 281–290 (1970), pp. 282–285. See also de la Mare and Vernon, *J. Chem. Soc. B* 1699 (1971).

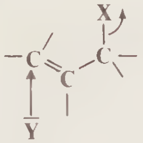


$$Et_2\overline{N}H + CH_2{=}CH{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}Cl \longrightarrow Et_2\overset{\oplus}{N}HCH_2CH{=}CHCH_3 + Cl^-$$

then labeling at the nitrogen, the 1, 2, and 3 carbons, and the chlorine should all produce isotope effects. The nitrogen isotope effect was not studied, but labeling at the three carbons and at the chlorine produced an isotope effect in each instance. The stereochemistry of reactions generally



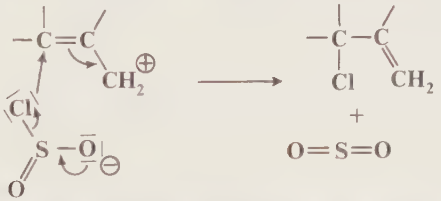
synfacial



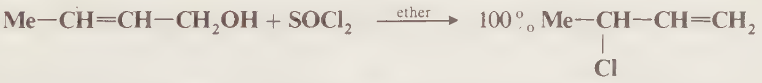
apofacial

considered to have SN2′ mechanisms has been investigated and is most often *synfacial*;[175] that is, the nucleophile enters from the same side as the leaving group departs.[176] However, *apofacial* reactions have also been reported.[177]

When a molecule has in an allylic position a leaving group capable of giving the SNi reaction, then it is possible for the nucleophile to attack at the γ-position instead of the α-position. This



is called the SNi′ mechanism and has been demonstrated on 2-buten-1-ol and 3-buten-2-ol.[178]



$$Me{-}CH{=}CH{-}CH_2OH + SOCl_2 \xrightarrow{\text{ether}} 100\%\ Me{-}CH{-}\underset{\displaystyle Cl}{\underset{|}{CH}}{-}CH{=}CH_2$$

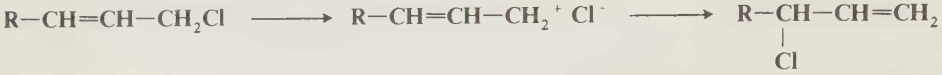
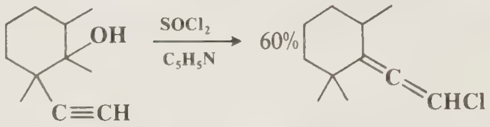
Ordinary allylic rearrangements (SN1′) or SN2′ mechanisms could not be expected to give 100% rearrangement in *both* cases. In the case shown, the nucleophile is only part of the leaving group, not the whole. But it is also possible to have reactions in which a simple leaving group, such as Cl, comes off to form an ion pair and then returns not to the position from whence it came but to the allylic position:



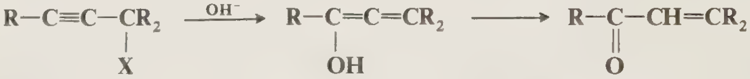
$$R{-}CH{=}CH{-}CH_2Cl \longrightarrow R{-}CH{=}CH{-}CH_2^{+}\ Cl^{-} \longrightarrow R{-}\underset{\displaystyle Cl}{\underset{|}{C}H}{-}CH{=}CH_2$$

Most SNi′ reactions are of this type.

Allylic rearrangements have also been demonstrated in propargyl systems, for example,[179]

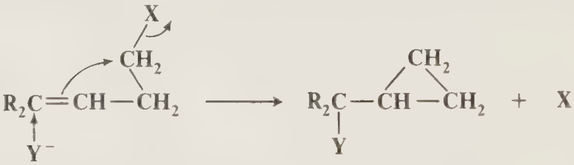


The product in this case is an allene,[180] but such shifts may also give triple-bond compounds or, if Y = OH, an enol will be obtained which will tautomerize to an α,β-unsaturated aldehyde or ketone.



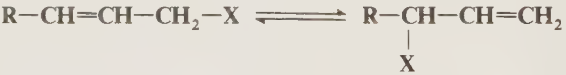
$$R{-}C{\equiv}C{-}\underset{\displaystyle X}{\underset{|}{C}}R_2 \xrightarrow{OH^-} R{-}C{=}C{=}\underset{\displaystyle OH}{\underset{|}{C}}R_2 \longrightarrow R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}CH{=}CR_2$$

When X = OH, this conversion of acetylenic alcohols to unsaturated aldehydes or ketones is called the *Meyer-Schuster rearrangement*.[181] An unusual type of "allylic shift" can occur in homoallylic systems where cyclopropyl rings may be formed, perhaps by an SN2′ type of mechanism:[182]



$$\underset{\displaystyle Y^-}{\underset{\uparrow}{R_2C}}{=}CH{-}CH_2{-}CH_2{-}X \longrightarrow \underset{\displaystyle Y}{\underset{|}{R_2C}}{-}\overset{CH_2}{CH{-}CH_2} + X^-$$

An allylic rearrangement in which the nucleophile is the same as the leaving group is an isomerization:[183]



$$R{-}CH{=}CH{-}CH_2{-}X \rightleftharpoons R{-}\underset{\displaystyle X}{\underset{|}{C}H}{-}CH{=}CH_2$$

This type of isomerization may proceed by any of the three mechanisms mentioned: SN1′, SN2′, or, as we have seen, SNi′. Examples are known where X = halide, OCOR, and OH (actually OH_2^+, the protonated OH group). It is of interest to examine the question of the direction of such isomerizations. When the reaction is permitted to proceed to equilibrium, the product will be thermodynamically controlled: the isomer of lower energy will predominate. Olefin stability increases with increasing alkyl substitution, so that where only alkyl groups are involved the more stable isomer will have the X on the less highly substituted carbon, e.g.,[184]

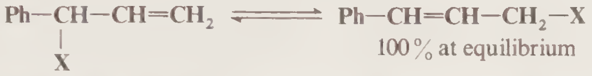
$$CH_3-\overset{CH_3}{\underset{X}{C}}-CH=CH_2 \rightleftharpoons CH_3-\overset{CH_3}{C}=CH-CH_2-X$$

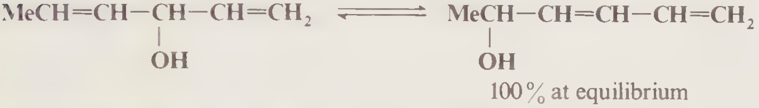
100% at equilibrium

If the double bond in one isomer can be in conjugation with an aromatic ring, a triple bond, another double bond, or a carbonyl group, then that isomer is more stable and will predominate at equilibrium, e.g.,[185]



$$Ph-\underset{X}{CH}-CH=CH_2 \rightleftharpoons Ph-CH=CH-CH_2-X$$

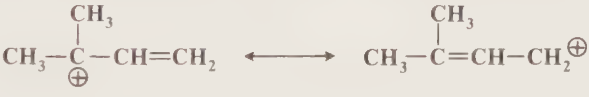
100% at equilibrium



$$MeCH=CH-\underset{OH}{CH}-CH=CH_2 \rightleftharpoons \underset{OH}{MeCH}-CH=CH-CH=CH_2$$

100% at equilibrium

It might be expected from this that, say, in an SN1′ reaction of $Me_2C{=}CHCH_2Cl$ with water, the predominant product would be the unrearranged $Me_2C{=}CHCH_2OH$ with only a smaller amount of the rearranged $Me_2COHCH{=}CH_2$. However, the main product here (85%) is the tertiary alcohol, although thermodynamically it is the less stable isomer. Equilibrium is not reached, and the product is kinetically controlled (see p. 194). In SN1′ reactions the thermodynamically less stable product is almost always formed in greater than the equilibrium proportion, because the relative rates of the two reactions are determined by the relative magnitudes of the positive charges on the two carbons. For example, in the case mentioned, **A** contributes more to the



$$CH_3-\overset{CH_3}{\underset{\oplus}{C}}-CH=CH_2 \longleftrightarrow CH_3-\overset{CH_3}{C}=CH-CH_2^{\oplus}$$

A **B**

resonance hybrid than **B** (because tertiary carbons are more stable than primary carbons), so that the charge on the tertiary carbon is greater than that on the primary carbon. However, whether one isomer or the other will predominate is usually not easy to predict in a given case. The solvent exerts a great effect. For example, the substrate mentioned gave 85% of the tertiary product when water was the solvent, but only 45% in acetic acid containing silver acetate. Increasing solvent polarity favors the formation of product resulting from attack at the more positive carbon. The existence of the product spread further complicates the picture.

Nucleophilic Substitution at an Aliphatic Trigonal Carbon.[186] The Tetrahedral Mechanism

All the mechanisms so far discussed take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double-bonded to an oxygen, a sulfur, or a nitrogen. Nucleophilic substitution at vinyl carbons is considered in the next section; at aromatic carbons in Chapter 13.

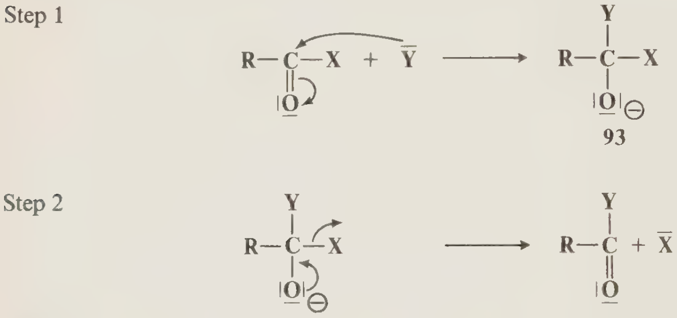
[185] Pocker, *J. Chem. Soc.* 4318 (1958); Braude and Timmons, *J. Chem. Soc.* 2000, 2007 (1950).

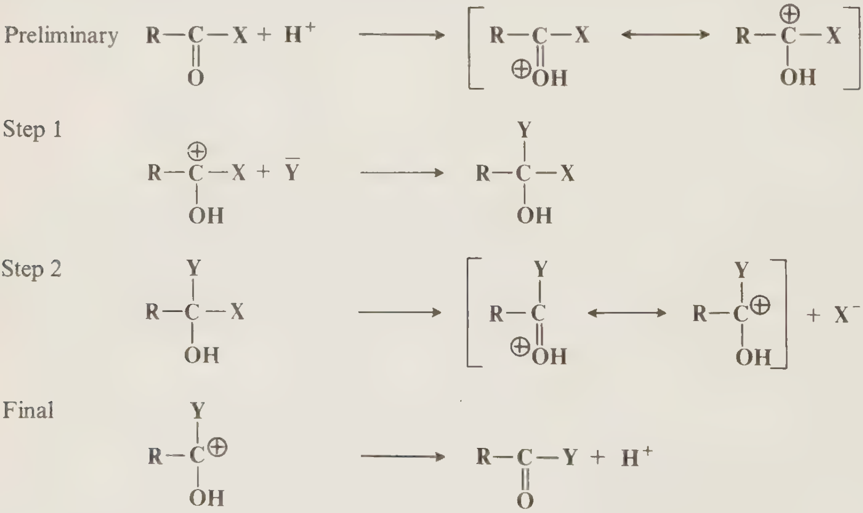
[186] For a review, see Satchell, *Q. Rev., Chem. Soc.* **17**, 160–203 (1963).

At a carbonyl group (or the corresponding nitrogen and sulfur analogs) substitution most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*[187] *mechanism.*[188] SN1 mechanisms, involving carbonium ions, are sometimes found with these substrates, especially with essentially ionic compounds such as $RCO^+ \ \ BF_4^-$, but the tetrahedral mechanism is far more prevalent. Although this mechanism displays second-order kinetics, it is not the same as the SN2 mechanism previously discussed. Simple SN2 mechanisms have seldom if ever been demonstrated for carbonyl substrates[189] (see, however, p. 355). In the tetrahedral mechanism, first Y attacks to give an intermediate containing both X and Y, and then X leaves. This sequence, impossible at a saturated carbon, is possible at an unsaturated one because the central carbon can release a pair of electrons to the oxygen and so preserve its octet:



93

When reactions are carried out in acid solution, there may be in addition a preliminary and a final step:



---

[187] This mechanism has also been called the "addition-elimination mechanism," but in this book we limit this term to the type of mechanism shown on p. 311.

[188] For reviews of this mechanism, see Talbot, in Bamford and Tipper, Ref. 168, vol. 10, pp. 209-223, 1972; Jencks, "Catalysis in Chemistry and Enzymology," pp. 463-554, McGraw-Hill Book Company, New York, 1969; Satchell and Satchell, in Patai, "The Chemistry of Carboxylic Acids and Esters," pp. 375-452, Interscience Publishers, New York, 1969; Johnson, *Adv. Phys. Org. Chem.* **5**, 237-330 (1967); Bender, *Chem. Rev.* **60**, 53-113 (1960).

[189] For example, see Kevill and Foss, *J. Am. Chem. Soc.* **91,** 5054 (1969); Haberfield and Trattner, *Chem. Commun.* 1481 (1971); Kevill, Daum, and Sapre, *J. Chem. Soc., Perkin Trans. 2* 963 (1975).

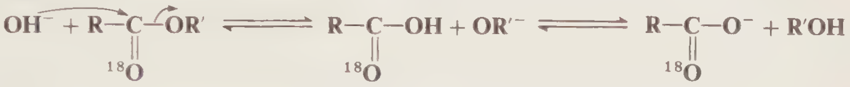
The hydrogen ion is a catalyst. The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.[190]

Evidence for the existence of the tetrahedral mechanism is as follows:

1. The kinetics are first order each in the substrate and in the nucleophile, as predicted by the mechanism.

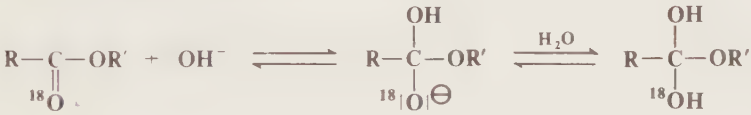
2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate "constant" for the reaction between acetamide and hydroxylamine is not constant but decreases with increasing hydroxylamine concentration.[191] This is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, this cannot happen if there is only one step: there must be two steps, and hence an intermediate. Similar kinetic behavior has been found in other cases as well,[192] in particular, plots of rate against pH are often bell-shaped.

3. Basic hydrolysis has been carried out on esters labeled with ^{18}O in the carbonyl group.[193] If this reaction proceeded by the normal SN2 mechanism, then all the ^{18}O would remain in the carbonyl group, even if, in an equilibrium process, some of the acid formed went back to the starting material:



$$\mathrm{OH^- + R{-}\underset{\overset{\|}{^{18}O}}{C}{-}OR' \rightleftharpoons R{-}\underset{\overset{\|}{^{18}O}}{C}{-}OH + OR'^- \rightleftharpoons R{-}\underset{\overset{\|}{^{18}O}}{C}{-}O^- + R'OH}$$

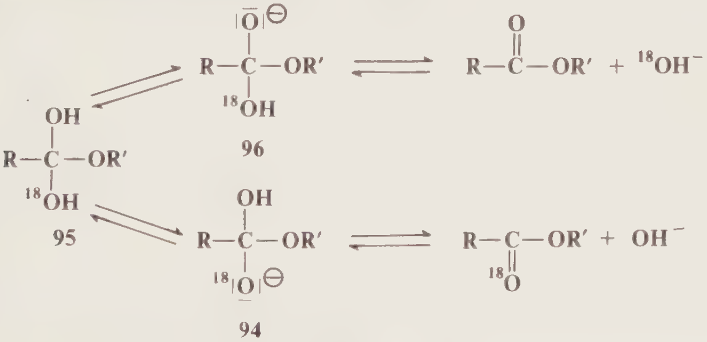
On the other hand, if the tetrahedral mechanism operates,



$$\mathrm{R{-}\underset{\overset{\|}{^{18}O}}{C}{-}OR' + OH^- \rightleftharpoons R{-}\overset{OH}{\underset{^{18}O^{\ominus}}{C}}{-}OR' \xrightarrow{H_2O} R{-}\overset{OH}{\underset{^{18}OH}{C}}{-}OR'}$$

94 95

then the intermediate **94**, by picking up a proton, becomes converted to the symmetrical intermediate **95**. In this intermediate the OH groups are equivalent, and (except for the small $^{18}O/^{16}O$ isotope effect) either one can lose a proton with equal facility:



---

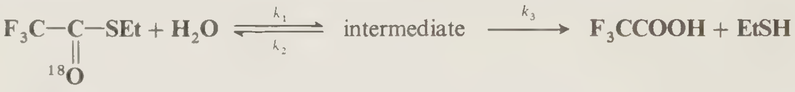
[191] Jencks and Gilchrist, *J. Am. Chem. Soc.* **86**, 5616 (1964).

[192] Hand and Jencks, *J. Am. Chem. Soc.* **84**, 3505 (1962); Bruice and Fedor, *J. Am. Chem. Soc.* **86**, 4886 (1964); Johnson, *J. Am. Chem. Soc.* **86**, 3819 (1964); Fedor and Bruice, *J. Am. Chem. Soc.* **86**, 5697 (1964), **87**, 4138 (1965); Kevill and Johnson, *J. Am. Chem. Soc.* **87**, 928 (1965); Leinhard and Jencks, *J. Am. Chem. Soc.* **87**, 3855 (1965); Schowen, Jayaraman, and Kershner, *J. Am. Chem. Soc.* **88**, 3373 (1966).

[193] Bender, *J. Am. Chem. Soc.* **73**, 1626 (1951); Bender and Thomas, *J. Am. Chem. Soc.* **83**, 4183, 4189 (1961).

The intermediates **94** and **96** can now lose OR′ to give the acid (not shown in the equations given), or they can lose OH to regenerate the ester. If **94** goes back to ester, the ester will still be labeled, but if **96** reverts to ester, the ^{18}O will be lost. A test of the two possible mechanisms then is to stop the reaction before completion and to analyze the recovered ester for ^{18}O. This is just what was done by Bender, who found that, in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost ^{18}O. A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that here too the ester lost ^{18}O. However, alkaline hydrolysis of substituted benzyl benzoates showed *no* ^{18}O loss.[194] This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If **94** and **96** do not revert to ester, but go entirely to acid, then no ^{18}O loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates this may very well be happening, because formation of the acid relieves steric strain. Even the experiments which *do* show ^{18}O loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that ^{18}O is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck[195] measured the rate of ^{18}O loss in the hydrolysis of ethyl trifluorothioloacetate-^{18}O (**97**). This reaction had previously been shown[196] to involve an intermediate by the kinetic methods mentioned on p. 309. Bender and Heck showed that the rate of ^{18}O loss and the value of the partitioning ratio k_2/k_3 as determined by the oxygen exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original ^{18}O-exchange measurements showed that there is a tetrahedral species present, though not necessarily on the reaction path; while the kinetic experiments showed that there is some intermediate present, though not necessarily tetrahedral. However, the results of Bender and Heck demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

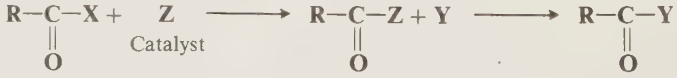


$$\mathrm{F_3C{-}\underset{\underset{^{18}O}{\|}}{C}{-}SEt + H_2O} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{intermediate} \xrightarrow{k_3} \mathrm{F_3CCOOH + EtSH}$$

97

4. In a few cases, tetrahedral intermediates have been isolated[197] or detected spectrally.[198]

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.[199] There occur, in effect, two tetrahedral mechanisms:



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}X} + \underset{\text{Catalyst}}{\mathrm{Z}} \longrightarrow \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}Z + Y} \longrightarrow \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}Y}$$

For an example, see page 348. When this happens internally, we have an example of a neighboring-group mechanism at a carbonyl carbon.[200] For example, the hydrolysis of phthalamic acid takes place as follows:

---

[194] Bender, Matsui, Thomas, and Tobey, *J. Am. Chem. Soc.* **83**, 4193 (1961). See also Shain and Kirsch, *J. Am. Chem. Soc.* **90**, 5848 (1968).

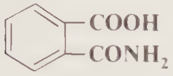
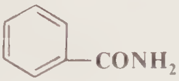
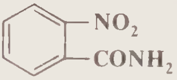
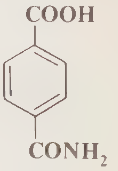
Phthalamic acid

Evidence comes from comparative rate studies.[201] Thus phthalamic acid was hydrolyzed about 10^5 times faster than benzamide ($PhCONH_2$) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of COOH (an electron-withdrawing group) was shown by the fact that both *o*-nitrobenzamide and terephthalamic acid were hydrolyzed more slowly than benzamide:









Rate ratio: 10^5 1 0.1 Less than 1

Many other examples of neighboring-group participation at a carbonyl carbon have been reported.[202] It is likely that nucleophilic catalysis is involved in enzyme catalysis of ester hydrolysis.

The attack of a nucleophile on a carbonyl group may result in substitution or addition (Chapter 16), though the first step of each mechanism is the same. The principal factor which determines the product is the identity of the group X in RCOX. When X is alkyl or hydrogen, addition usually takes place. When X is halogen, OH, OCOR, NH_2, etc., the usual reaction is substitution.

Nucleophilic Substitution at a Vinyl Carbon[203]

Nucleophilic substitution at a vinyl carbon is difficult (see p. 317), but many examples are known. The most common mechanisms are the tetrahedral mechanism and the closely related *addition-elimination mechanism*. Both of these mechanisms are impossible at a saturated substrate. The addition-elimination mechanism has been demonstrated for the reaction between 1,1-dichloroethylene (**98**) and ArS^-, catalyzed by EtO^-.[204] The product was not the 1,1-dithiophenoxy compound **99**, but the "rearranged" compound **100**. Isolation of **101** and **102** showed that an addition-elimination mechanism had taken place. In the first step ArSH adds to the double bond (nucleophilic addition, p. 678) to give the saturated **101**. The second step is an E2 elimination

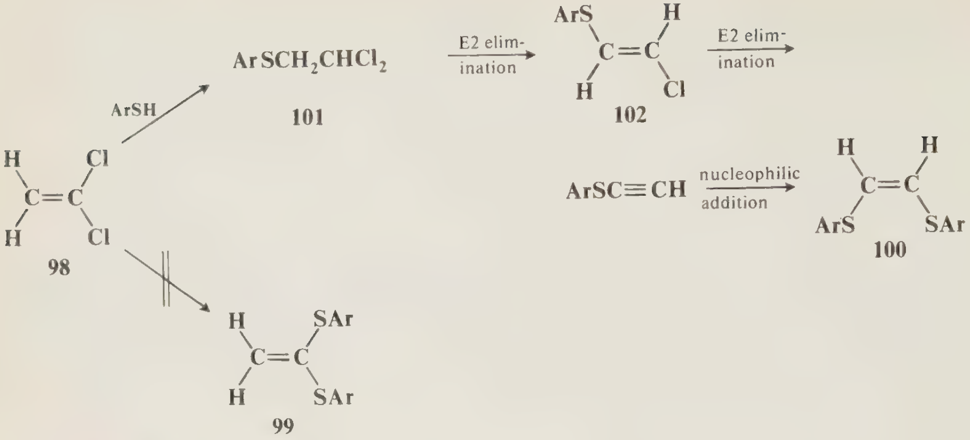
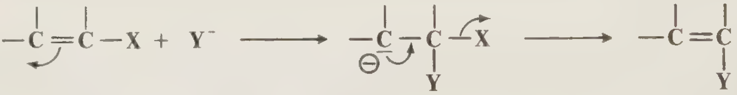
Soc.* **89,** 6728 (1967); Burrows and Topping, *Chem. Commun.* 904 (1969), 1389 (1970); Kirby and Meyer, *J. Chem. Soc., Perkin Trans. 2* 1446 (1972); Kirby, McDonald, and Smith, *J. Chem. Soc., Perkin Trans. 2* 1495 (1974); Martin, Skovron, and Yiu, *J. Chem. Soc., Perkin Trans. 2* 125 (1974); Martin and Tan, *J. Chem. Soc., Perkin Trans. 2* 129 (1974).

[203] For reviews, see Rappoport, *Adv. Phys. Org. Chem.* **7,** 1–114 (1969); Modena, *Acc. Chem. Res.* **4,** 73–80 (1971); Patai and Rappoport, in Patai, "The Chemistry of Alkenes," pp. 525–546, Interscience Publishers, New York, 1964. The nomenclature in the first and third of these reviews differs from that used in this book. Rappoport and Patai use the term "addition-elimination" to refer to three mechanisms: those we call tetrahedral, SN2, and addition-elimination.

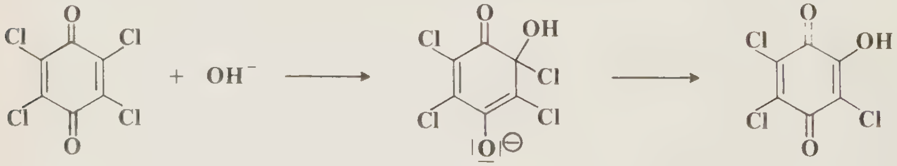
[204] Truce and Boudakian, *J. Am. Chem. Soc.* **78,** 2748 (1956).



reaction (p. 896) to give the alkene **102.** A second elimination and addition follow to give **100.** The tetrahedral mechanism, often also called addition-elimination (*Ad*N-*E*), takes place with much less facility than with carbonyl groups, since the negative charge of the intermediate must be borne by a carbon, which is less electronegative than oxygen, sulfur, or nitrogen:



Such an intermediate can also stabilize itself by combining with a positive species, and when it does, the reaction is nucleophilic addition to a C=C double bond (see Chapter 15). It is not surprising that with vinyl substrates addition and substitution often compete. For chloroquinones, where the charge is spread by resonance, tetrahedral intermediates have been isolated:[205]



Isolated

Since both the tetrahedral and addition-elimination mechanisms begin in the same way, it is usually difficult to tell them apart, and often no attempt is made to do so. The strongest kind of evidence for the addition-elimination sequence is the occurrence of a "rearrangement" (as in the conversion of **98** to **100**), but of course the mechanism could still take place even if no rearrangement is found. Evidence that a tetrahedral or an addition-elimination mechanism takes place in certain cases (as opposed, for example, to an SN1 or SN2 mechanism) is that the reaction rate increases when the leaving group is changed from Br or Cl to F (this is called the *element effect*).[206] This clearly demonstrates that the carbon-halogen bond does not break in the rate-determining step (as it would have to in both the SN1 and SN2 mechanisms), because fluorine is by far the poorest leaving group among the halogens in both the SN1 and SN2 reactions (p. 325). The rate is faster with fluorides in the cases cited, because the superior electron-withdrawing character of the fluorine makes the carbon of the C—F bond more positive and thus more susceptible to nucleophilic attack. However, there is evidence that the tetrahedral mechanism at a vinyl substrate can also take place with the second step being rate-determining.[207]

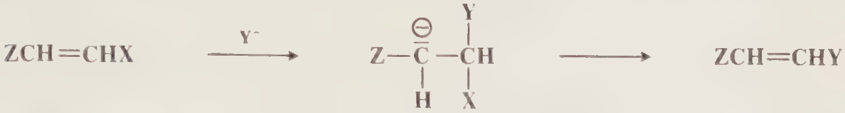
[206] Beltrame, Favini, Cattania, and Guella, *Gazz. Chim. Ital.* **98,** 380 (1968).

Ordinary vinylic substrates react very poorly if at all by these mechanisms, but substitution is greatly enhanced in substrates of the type ZCH=CHX, where Z is an electron-withdrawing group such as HCO, RCO,[208] EtOOC, $ArSO_2$, NC, F,[209] etc., since these β-groups stabilize the carbanion:



$$\mathrm{ZCH{=}CHX} \xrightarrow{Y^-} \mathrm{Z}-\underset{\mathrm{H}}{\overset{\ominus}{\bar{\mathrm{C}}}}-\underset{\mathrm{X}}{\overset{\mathrm{Y}}{\mathrm{C}}}\mathrm{H} \longrightarrow \mathrm{ZCH{=}CHY}$$

Many such examples are known. In most cases where the stereochemistry has been investigated, retention of configuration is observed.[210]

Vinyl substrates are in general very reluctant to undergo SN1 reactions, but they can be made to do so in two ways:[211] (1) By the use of an α-group which stabilizes the vinyl cation. For example, α-aryl vinyl halides $ArCBr{=}CR'_2$ have often been shown to give SN1 reactions.[212] SN1 reactions have also been demonstrated with other stabilizing groups: cyclopropyl,[213] vinyl,[214] and an adjacent double bond ($R_2C{=}C{=}CR'X$).[215] (2) Even without α stabilization, by the use of a very good leaving group, e.g., OSO_2CF_3 (triflate).[216] The stereochemical outcome of SN1 reactions at a vinyl substrate is often randomization;[217] that is, either a cis or a trans substrate gives a 1 : 1 mixture of cis and trans products, indicating that the vinyl cation is linear. Another indication that vinyl cations prefer to be linear is the fact that reactivity in cycloalkenyl systems decreases with decreasing ring size.[218] However, a linear vinyl cation need not give random

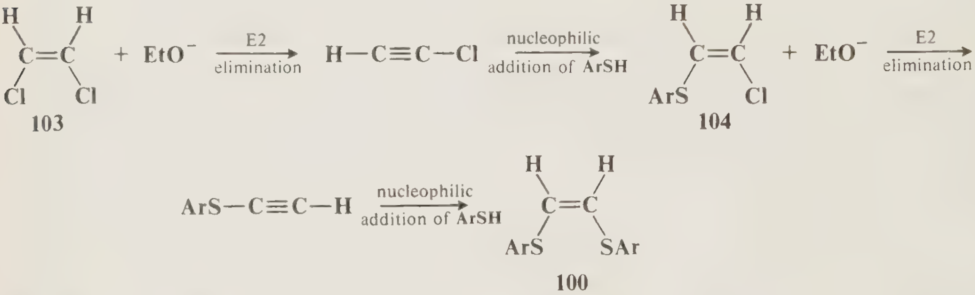
products.[219] The empty *p* orbital lies in the plane of the double bond, so entry of the nucleophile can be and often is influenced by the relative size of R^1 and R^2.[220] It must be emphasized that even where vinyl substrates do give S_N1 reactions, the rates are generally lower than those of the corresponding saturated compounds.

Besides the mechanisms already discussed, another mechanism, involving an *elimination-addition* sequence, has also been observed in vinyl systems (a similar mechanism is known for aromatic substrates, p. 588). An example of a reaction involving this mechanism is the reaction of 1,2-dichloroethane (**103**) with ArS^- and OEt^- to produce **100.** The mechanism may be formulated as:



The steps are the same as in the addition-elimination mechanism, but are in the reverse order. In the first step ethoxide ion causes E2 elimination to produce chloroacetylene. The E2 mechanism is stereoselective and proceeds rapidly when the hydrogen and halogen are trans, as they are in this case. In the second step the thiol adds to the acetylene by a nucleophilic addition mechanism to give **104.** This reaction is also stereoselective, with ArS and H adding from opposite sides (anti addition). Thus **104** still has a hydrogen trans to a halogen, and the two steps are repeated to give the cis product **100.** Evidence for this sequence[221] is as follows: (1) The reaction does not proceed without ethoxide ion, and the rate is dependent on the concentration of this ion and not on that of ArS^-. (2) *trans*-1,2-Dichloroethylene does not react under these conditions. There is no hydrogen trans to either chlorine, so that the rate of an E2 reaction is greatly reduced (**102** underwent elimination, though slowly, because strong conditions were used). (3) Under the same reaction conditions, chloroacetylene gave **104** and **100.** (4) **104** treated with ArS^- gave no reaction but, when EtO^- was added, **100** was obtained. It is interesting that the elimination-addition mechanism has even been shown to occur in five- and six-membered cyclic systems, where triple bonds are greatly strained.[222] Note that both the addition-elimination and elimination-addition sequences, as shown above, lead to overall retention of configuration, since in each case both addition and elimination are anti.

---

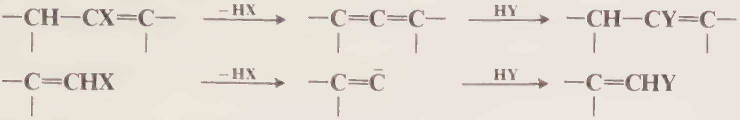
[220] Maroni, Melloni, and Modena, *J. Chem. Soc., Chem. Commun.* 857 (1972).

[221] Truce, Boudakian, Heine, and McManimie, *J. Am. Chem. Soc.* **78,** 2743 (1956); Flynn, Badiger, and Truce, *J. Org. Chem.* **28,** 2298 (1963).

[222] Montgomery, Scardiglia, and Roberts, *J. Am. Chem. Soc.* **87,** 1917 (1965); Montgomery and Applegate, *J. Am. Chem. Soc.* **89,** 2952 (1967); Montgomery, Clouse, Crelier, and Applegate, *J. Am. Chem. Soc.* **89,** 3453 (1967); Caubere and Brunet, *Tetrahedron* **27,** 3515 (1971); Bottini, Corson, Fitzgerald, and Frost, *Tetrahedron* **28,** 4883 (1972).

We have shown the elimination-addition sequence as operating through an acetylenic intermediate, but in some cases it can also take place with an allene- or a carbene-type intermediate:[223]



$$-\underset{|}{\text{CH}}-\text{CX}=\underset{|}{\text{C}}- \xrightarrow{-\text{HX}} -\underset{|}{\text{C}}=\text{C}=\underset{|}{\text{C}}- \xrightarrow{\text{HY}} -\underset{|}{\text{CH}}-\text{CY}=\underset{|}{\text{C}}-$$

$$-\underset{|}{\text{C}}=\text{CHX} \xrightarrow{-\text{HX}} -\underset{|}{\text{C}}=\bar{\text{C}} \xrightarrow{\text{HY}} -\underset{|}{\text{C}}=\text{CHY}$$

The elimination-addition sequence has also been demonstrated for certain reactions of saturated substrates, for example, $ArSO_2CH_2CH_2SO_2Ar$.[224] Treatment of this with ethoxide proceeds as follows:

$$\text{ArSO}_2\text{CH}_2\text{CH}_2\text{SO}_2\text{Ar} \xrightarrow[\text{E2 elimination}]{\text{EtO}} \text{ArSO}_2\text{CH}=\text{CH}_2 \xrightarrow[\text{addition}]{\text{EtO}} \text{ArSO}_2\text{CH}_2\text{CH}_2\text{OEt}$$

Mannich bases (see reaction **6-17**) of the type $RCOCH_2CH_2NR_2$ similarly undergo nucleophilic substitution by the elimination-addition mechanism.[225] The nucleophile replaces the NR_2 group.

The simple SN2 mechanism has never been demonstrated for vinyl substrates.[226]

REACTIVITY

A large amount of work has been done on this subject. Many small effects have been examined. However, though a great deal is known, much is still poorly understood, and many results are anomalous and hard to explain. In this section only approximate generalizations are attempted.

The Effect of Substrate Structure

The effect on the reactivity of a change in substrate structure depends on the mechanism.

1. *Branching at the α- and β- carbons.* For the SN2 mechanism, branching at either the α- or the β-carbon decreases the rate. Tertiary systems seldom[227] react by the SN2 mechanism, and neopentyl systems react so slowly as to make such reactions, in general, synthetically useless.[228] Table 3 shows average relative rates for some alkyl substrates.[229] The reason for these low rates is almost certainly steric.[230] The transition state **1** is more crowded when larger groups are close to the central carbon. It was pointed out on page 304 that allylic substrates undergo SN2′ reactions only when there is branching at the α-position. Ordinary SN2 reactions are so slowed by this α branching that the nucleophile attacks the allylic position.

[226] For a report of an "SN2" reaction at a vinyl carbon with retention of configuration, see Klein and Levene, *J. Am. Chem. Soc.* **94**, 2520 (1972). See also Stohrer, *Tetrahedron Lett.* 207 (1975).

[227] For a reported example, see Edwards and Grieco, *Can. J. Chem.* **52**, 3561 (1974).

[228] SN2 reactions on neopentyl tosylates have been conveniently carried out in the solvents hexamethylphosphoric triamide (HMPT) and dimethyl sulfoxide: Lewis, Gustafson, and Erman, *Tetrahedron Lett.* 401 (1967). Paquette and Phillips, *Tetrahedron Lett.* 4645 (1967); Stephenson, Solladié, and Mosher, *J. Am. Chem. Soc.* **94**, 4184 (1972); Anderson, Stephenson, and Mosher, *J. Am. Chem. Soc.* **96**, 3171 (1974).

[229] This table is from Streitwieser, Ref. 1, p. 13. Also see Table 2, Chapter 9 (p. 249).

[230] For a review on this point, see Ingold, *Q. Rev., Chem. Soc.* **11**, 1–14 (1957).

TABLE 3 Average relative SN2 rates for some alkyl substrates[229]

R	Relative rate
Methyl	30
Ethyl	1
Propyl	0.4
Butyl	0.4
Isopropyl	0.025
Isobutyl	0.03
Neopentyl	10^{-5}
Allyl	40
Benzyl	120

The tetrahedral mechanism for substitution at a carbonyl carbon is also slowed or blocked completely by α or β branching for similar reasons. For example, esters of the formula R_3CCOOR' cannot generally be hydrolyzed by the tetrahedral mechanism (see reaction **0-11**), nor can acids R_3CCOOH be easily esterified. Synthetic advantage can be taken of this fact, for example, when in a molecule containing two ester groups only the less hindered one is hydrolyzed.

For the SN1 mechanism, α branching increases the rate, as shown in Table 4.[231] We may explain this by the stability order of carbonium ions (tertiary > secondary > primary). Of course, the rates are not actually dependent on the stability of the carbonium ions, but on the difference in free energy between the starting compounds and the transition states, but we may use the Hammond postulate (p. 194) to make the assumption that the transition states resemble the carbonium ions and that anything (such as α branching) which lowers the free energy of the carbonium ions also lowers it for the transition states. For simple alkyl groups, the SN1 mechanism is important under all conditions only for tertiary substrates. As previously indicated (p. 279), secondary substrates generally react by the SN2 mechanism,[232] except that the SN1 mechanism may become important at high solvent polarities. Table 4 shows that isopropyl bromide reacts less than twice as fast as ethyl bromide in the relatively nonpolar 60% ethanol (compare this with the 10^4 ratio for *t*-butyl bromide, where the mechanism is certainly SN1), but in the more polar water the rate ratio is 11.6. The 2-adamantyl system is an exception: this is a secondary system which reacts by the SN1 mechanism because backside attack is hindered for steric reasons.[233] Because there is no SN2 component, this system provides an opportunity for comparing the pure SN1 reactivity of secondary and tertiary substrates. It has been found that substitution of a methyl group for the 2 α-hydrogen of 2-adamantyl substrates (thus changing a secondary to a tertiary system) increases solvolysis rates by a factor of about 10^8.[234] Simple primary substrates react by the SN2 mechanism (or with participation by neighboring alkyl or hydrogen)

---

[231] These values are from Streitwieser, Ref. 1, p. 43, where values are also given for other conditions. Methyl bromide reacts faster than ethyl bromide (and in the case of 60% ethanol, isopropyl bromide) because some of it (probably most of it) reacts by the SN2 mechanism.

TABLE 4 Relative rates of solvolysis of RBr in two solvents[231]

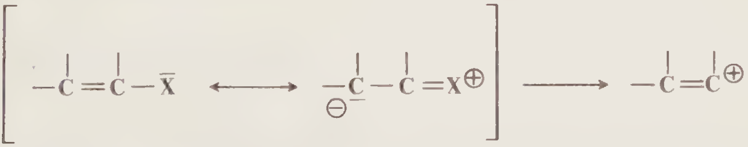
RBr substrate	In 60% ethanol at 55°C	In water at 50°C
MeBr	2.08	1.05
EtBr	1.00	1.00
iso-**PrBr**	1.78	11.6
t-**BuBr**	2.41×10^4	1.2×10^6

but not by the SN1 mechanism, even when solvolyzed in solvents of very low nucleophilicity, e.g., trifluoroacetic acid or trifluoroethanol.[235]

For some tertiary substrates, the rate of SN1 reaction is greatly increased by the relief of B strain in the formation of the carbonium ion (see p. 249). Except where B strain is involved, β branching has little effect on the SN1 mechanism, except that carbonium ions with β branching undergo rearrangements readily. Of course, isobutyl and neopentyl are primary substrates, and for this reason react very slowly by the SN1 mechanism, but not more slowly than the corresponding ethyl or propyl compounds.

To sum up, primary and secondary substrates generally react by the SN2 mechanism, and tertiary by the SN1 mechanism. However, tertiary substrates seldom undergo nucleophilic substitution at all. Elimination is always a possible side reaction of nucleophilic substitutions (wherever a β-hydrogen is present), and with tertiary substrates it usually predominates. With a few exceptions, nucleophilic substitutions at a tertiary carbon have little or no preparative value.

2. *Unsaturation at the α-carbon.* Vinyl, acetylenic,[236] and aryl substrates are very unreactive toward nucleophilic substitutions. For these systems both the SN1 and SN2 mechanisms are greatly slowed or stopped altogether. This may be attributed to several factors. The first of these is that sp^2 (and even more, sp) carbons have a higher electronegativity than sp^3 carbons and thus have a greater attraction for the electrons of the bond. As we have seen (p. 243), an sp—H bond has a higher acidity than an sp^3—H bond, with that of an sp^2—H bond in between. This is reasonable: the carbon retains the electrons when the proton is lost, and an sp carbon, which has the greatest hold on the electrons, loses the proton most easily. But in nucleophilic substitution, the leaving group *carries off* the electron pair, so that the situation is reversed, and it is the sp^3 carbon which loses the leaving group and the electron pair most easily. Another factor holds only where the leaving group has one or more unshared pairs (of course, most of them do) and applies only to SN1 reactions. When X has an unshared pair, the *molecule* is stabilized by resonance in which some of the electron density of the leaving group is transferred into the C—X bond, greatly strengthening it:



$$\left[-\overset{|}{C}=\overset{|}{C}-\bar{X} \longleftrightarrow \underset{\ominus}{-\overset{|}{C}}-\overset{|}{C}=X^{\oplus} \right] \longrightarrow -\overset{|}{C}=\overset{|}{C}^{\oplus}$$

This resonance is lost on going to the carbonium ion, and there is no resonance there for a compensating gain. It may be recalled (p. 23) that bond distances decrease with increasing *s*

---

[235] Dafforn and Streitwieser, *Tetrahedron Lett.* 3159 (1970).

[236] For a summary of SN reactions which have been reported for acetylenic substrates, see Dickstein and Miller, *J. Org. Chem.* **37**, 2168, 2175 (1972).

TABLE 5 Relative rates for the SN1 reaction between ROTs and ethanol at 25°C[237]

Group	Relative rate
Et	0.26
iso-Pr	0.69
$CH_2{=}CHCH_2$	8.6
$PhCH_2$	100
Ph_2CH	$\sim 10^5$
Ph_3C	$\sim 10^{10}$

character. Thus the bond length for a vinyl or aryl C—Cl bond is 1.73 Å, as compared with 1.78 Å for a saturated C—Cl bond. Other things being equal, a shorter bond is a stronger bond.

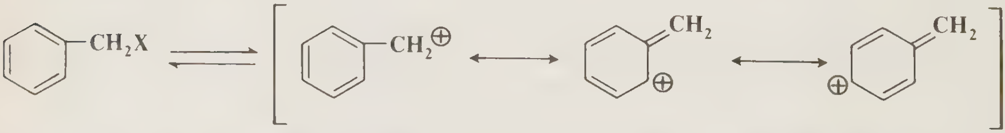
Both of the explanations given above relate to the stability of the original substrate. It is now known that vinyl cations are about as stable as simple alkyl cations (p. 157), so that lack of stability of vinyl cations cannot be the main reason for the greatly decreased SN1 reactivity of vinyl substrates. Of course we have seen (p. 313) that SN1 reactions at vinyl substrates can be accelerated by α-substituents which stabilize the cation, and that reactions by the tetrahedral mechanism can be accelerated by β-substituents which stabilize the carbanion. Also, reactions at vinyl substrates may in certain cases proceed by addition-elimination or elimination-addition sequences (pp. 311, 314).

In contrast to such systems, substrates of the type RCOX are usually much *more* reactive than the corresponding RCH_2X. Of course, the mechanism here is almost always the tetrahedral one, and there are three reasons for the enhanced reactivity of RCOX: (1) The carbonyl carbon has a sizable partial positive charge which makes it very attractive to nucleophiles. (2) In an SN2 reaction a σ bond must break in the rate-determining step, which requires more energy than the shift of a pair of π electrons, which is what happens in a tetrahedral mechanism. (3) A trigonal carbon offers less steric hindrance to a nucleophile than a tetrahedral carbon.

For reactivity in aryl systems, see Chapter 13.

3. *Unsaturation at the β-carbon.* SN1 rates are greatly increased when there is a double bond in the β-position, so that allylic and benzylic substrates react rapidly (Table 5).[237] This is because the carbonium ion is stabilized by resonance:

$$CH_2{=}CH{-}CH_2{-}X \rightleftharpoons \left[CH_2{=}CH{-}CH_2^{\oplus} \longleftrightarrow \overset{\oplus}{C}H_2{-}CH{=}CH_2\right]$$



In sharp contrast to the case of α unsaturation, where there was resonance stabilization of the molecule but not of the ion, here there is resonance stabilization of the ion but not of the molecule, since in the molecule the X group and the unsaturation are too far apart for resonance interaction. As shown in Table 5, a second and a third phenyl group increase the rate still more, because these carbonium ions are more stable yet. It should be remembered that, with allylic systems, allylic rearrangements are possible.

---

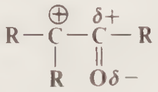
[237] Streitwieser, Ref. 1, p. 75. Actually, the figures for Ph_2CHOTs and Ph_3COTs are estimated from the general reactivity of these substrates. Solvolysis rates in ethanol have not been measured for these compounds.

In general, SN1 rates at an allylic substrate are increased by any substituent in the 1 or 3 position which can stabilize the carbonium ion by resonance or hyperconjugation.[238] Among these are alkyl, aryl, and halo groups.

SN2 rates for allylic and benzylic systems are also increased (see Table 3), probably owing to resonance possibilities in the transition state. Triple bonds in the β position (in propargyl systems) have about the same effect as double bonds.[239] Alkyl, aryl, halo, and cyano groups, among others, in the 3 position of allylic substrates increase SN2 rates, owing to increased resonance in the transition state, but alkyl and halo groups in the 1 position decrease the rates, because of steric hindrance.

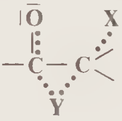
4. *α substitution.* Compounds of the formula ZCH_2X, where Z = RO, RS, or R_2N, undergo SN1 reactions very rapidly,[240] because of the increased resonance in the carbonium ion. These groups have an unshared pair on an atom directly attached to the positive carbon, which greatly stabilizes the carbonium ion (p. 156). The field effects of these groups would be expected to decrease SN1 rates (see section 6, p. 320), so that the resonance effect is far more important.

When Z in ZCH_2X is RCO, HCO, ROCO, NH_2CO, or NC, SN1 rates are decreased compared to CH_3X, owing to the electron-withdrawing effects of these groups. Furthermore, carbonium ions with an α-CO or CN group[241] are greatly destabilized because of the partial positive charge on the adjacent carbon (**105**). However, the presence in the α-position of one of these groups *increases* SN2 rates, an example being α-chloroacetophenone which reacts with KI in acetone at 75 C about 32,000 times faster than *n*-butyl chloride.[242] A number of reasons[243] have been suggested for this, among them that the transition state is stabilized by simultaneous overlap of the nucleophile with the central carbon and the carbonyl carbon (**106**), and that the CO group polarizes the nucleophile as it approaches, making the incoming end of the nucleophile more negative and hence more nucleophilic. Another possibility is that the CO oxygen or CN nitrogen lends anchimeric assistance.[244] When Z is SOR or SO_2R (e.g., α-halo sulfoxides and sulfones), nucleophilic substitution is retarded.[245] The SN1 mechanism is slowed by the electron-withdrawing effect of the SOR or SO_2R group, and the SN2 mechanism presumably by the steric effect.



$$\mathrm{R}-\underset{\mathrm{R}}{\overset{\oplus}{\mathrm{C}}}-\underset{\mathrm{O}\delta-}{\overset{\delta+}{\mathrm{C}}}-\mathrm{R}$$

105



106

5. *β substitution.* For compounds of the type ZCH_2CH_2X, where Z is any of the groups listed in the previous section as well as halogen or phenyl, SN1 rates are lower than for unsubstituted systems, because the resonance effects mentioned in section 4 are absent, but the field effects are still there, though smaller. These groups in the β-position do not have much effect on SN2 rates unless they behave as neighboring groups and enhance the rate through anchimeric assistance, or unless their size causes the rates to decrease for steric reasons.[246]

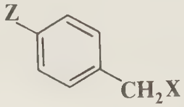
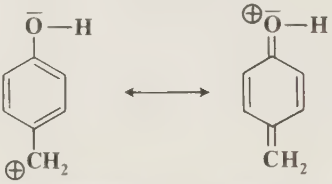
6. *The effect of electron-donating and -withdrawing groups.* If substitution rates of a series of compounds



are measured, it is possible to study the electronic effects of groups Z on the reaction. Steric effects of Z are minimized or eliminated, because Z is so far from the reaction site. For SN1 reactions electron-withdrawing Z decrease the rate and electron-donating Z increase it, because the latter decrease the energy of the transition state (and of the carbonium ion) by spreading the positive charge, e.g.,

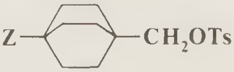


while electron-withdrawing groups concentrate the charge. The Hammett σ-ρ relationship (see p. 252) correlates fairly successfully the rates of many of these reactions (with σ^+ instead of σ). ρ values are generally about -4, which is to be expected for a reaction where a positive charge is created in the transition state.

For SN2 reactions no such simple correlations are found.[247] In this mechanism bond breaking is about as important as bond making in the rate-determining step, and substituents have an effect on both processes, often in opposite directions.

For Z = alkyl, the Baker-Nathan order (p. 70) is usually observed both for SN1 and SN2 reactions.

In para-substituted benzyl systems, steric effects have been removed, but resonance and field effects are still present. However, Holtz and Stock studied a system which removes not only steric effects but also resonance effects. This is the 4-substituted bicyclo[2.2.2]octylmethyl tosylate system (**107**).[248] In this system steric effects are completely absent, owing to the rigidity of the molecules, and only field effects operate. By this means Holtz and Stock showed that electron-withdrawing groups increase the rate of SN2 reactions. This can be ascribed to stabilization of the transition state by withdrawal of some of the electron density.



107

For substrates which react by the tetrahedral mechanism, electron-withdrawing groups increase the rate and electron-donating groups decrease it.

TABLE 6 List of groups in approximately descending order of reactivity toward SN1 and SN2 reactions

Z is RCO, HCO, ROCO, NH_2CO, NC, or a similar group

SN1 reactivity	SN2 reactivity
Ar_3CX	Ar_3CX
Ar_2CHX	Ar_2CHX
$ROCH_2X$, $RSCH_2X$, R_2NCH_2X	$ArCH_2X$
R_3CX	ZCH_2X
$ArCH_2X$	$-\overset{\vert}{C}=\overset{\vert}{C}CH_2X$
$-\overset{\vert}{C}=\overset{\vert}{C}CH_2X$	$RCH_2X \approx RCHDX \approx RCHDCH_2X$
R_2CHX	R_2CHX
$RCH_2X \approx R_3CCH_2X$	R_3CX
$RCHDX$	ZCH_2CH_2X
$RCHDCH_2X$	R_3CCH_2X
ZCH_2X	$-\overset{\vert}{C}=\overset{\vert}{C}X$
ZCH_2CH_2X	ArX
$-\overset{\vert}{C}=\overset{\vert}{C}X$	ArX	
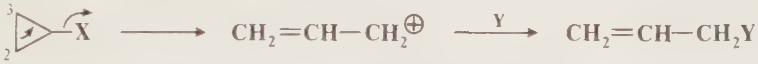
	

7. *Cyclic substrates.* Cyclopropyl substrates are extremely resistant to nucleophilic attack (p. 250). When such attack does take place, the result is generally not normal substitution (though exceptions are known[249]) but ring opening:[250]



There is much evidence that the ring opening is concerted with the departure of the leaving group[251] (as in the similar case of cyclobutyl substrates, p. 299), from which we can conclude that, if the 2,3 bond of the cyclopropane ring did not assist, the rates would be lower still. It has been estimated[252] that without this assistance the rates of these already slow reactions would be further reduced by a factor of 10^4 to 10^7. For a discussion of the stereochemistry of the ring opening, see p. 1034. For larger rings, we have seen (p. 250) that, because of I strain, cyclohexyl substrates solvolyze slower than analogous compounds in which the leaving group is attached to a ring of 5 or of from 7 to 11 members.

8. *Bridgeheads.* Nucleophilic substitution at bridgeheads is impossible or very slow, except that SN1 reactions can take place readily when the rings are large enough (pp. 268, 272).

9. *Deuterium substitution.* α and β secondary isotope effects affect the rate in various ways (p. 206). The measurement of α secondary isotope effects provides a means of distinguishing between SN1 and SN2 mechanisms, since for SN2 reactions the values range from 0.95 to 1.06 per α-D, while for SN1 reactions the values are higher.[33] This method is especially good, because it provides the minimum of perturbation of the system under study: changing from α-H to α-D hardly affects the reaction, while other probes, such as changing a substituent or the polarity of the solvent, may have a much more complex effect.

Table 6 is an approximate listing of groups in order of SN1 and SN2 reactivity.

The Effect of the Attacking Nucleophile[253]

Any species which has an unshared pair (i.e., any Lewis base) may be a nucleophile, whether it is neutral or has a negative charge. The rates of SN1 reactions are independent of the identity of the nucleophile, since it does not appear in the rate-determining step.[254] This may be illustrated by the effect of changing the nucleophile from H_2O to OH^- for a primary and a tertiary substrate. For methyl bromide, which reacts by an SN2 mechanism, the rate is multiplied by more than 5000 by the change to the more powerful nucleophile OH^-, but for *t*-butyl bromide, which reacts by an SN1 mechanism, the rate is unaffected.[255] A change in nucleophile may, however, change the *product* of an SN1 reaction. Thus solvolysis of benzyl tosylate in methanol gives benzyl methyl ether (the nucleophile is the solvent methanol). If the more powerful nucleophile Br^- is added, the rate is unchanged, but the product is now benzyl bromide.

For SN2 reactions there are four main principles which govern the effect of the nucleophile on the rate, though the nucleophilicity order is not invariant but depends on substrate, solvent, leaving group, etc.

1. A nucleophile with a negative charge is always a more powerful nucleophile than its conjugate acid (assuming the latter is also a nucleophile). Thus OH^- is more powerful than H_2O, NH_2^- more powerful than NH_3, etc. See the example given above.

2. In comparing nucleophiles whose attacking atom is in the same row of the periodic table, nucleophilicity is roughly in order of basicity, though basicity is thermodynamically controlled and nucleophilicity is kinetically controlled. So an approximate order of nucleophilicity is $NH_2^- > RO^- > OH^- > R_2NH > ArO^- > NH_3 >$ pyridine $> F^- > H_2O > ClO_4^-$, and another is $R_3C^- > R_2N^- > RO^- > F^-$ (see Table 1 in Chapter 8, p. 227). This type of correlation works best when the structures of the nucleophiles being compared are similar, as with a set of substituted phenoxides.[256]

3. Going down the periodic table, nucleophilicity increases, though basicity decreases. Thus the usual order of halide nucleophilicity is $I^- > Br^- > Cl^- > F^-$ (though as we shall see below, this order is solvent-dependent). Similarly, any sulfur nucleophile is more powerful than its oxygen analog, and the same is true for phosphorus versus nitrogen. The principal reason for this distinction between basicity and nucleophilic power is that the smaller negatively charged nucleophiles are more solvated by the usual polar solvents; that is, because the negative charge of Cl^- is more concentrated than the charge of I^-, the former is more tightly surrounded by a shell of solvent molecules which constitute a barrier between it and the substrate. This is most important for protic polar solvents in which the solvent may hydrogen-bond to small nucleophiles. Evidence for this is that many nucleophilic substitutions with small negatively charged nucleophiles are much more rapid in aprotic polar solvents than in protic ones[257] and that, in dimethylformamide, an aprotic solvent, the order of nucleophilicity was $Cl^- > Br^- > I^-$.[258] Another experiment was the use of $Bu_4N^+\ X^-$ and LiX as nucleophiles in acetone, where X^- was a halide ion. The halide ion in the former salt is much less associated than in LiX. The relative rates with LiX were Cl^-, 1; Br^-, 5.7; I^-, 6.2, which is in the normal order, while with $Bu_4N^+\ X^-$, where X^- is much freer, the relative rates were Cl^-, 68; Br^-, 18; I^-, 3.7.[259] In a further experiment halide ions were allowed to react with the molten salt $(n\text{-}C_5H_{11})_4N^+\ X^-$ at 180°C in the absence of a solvent.[260] Under these conditions, where the ions are unsolvated and unassociated, the relative rates were Cl^-, 620; Br^-, 7.7; I^-, 1. Further evidence that differences in the solvation of the nucleophile is the major cause of the nucleophilicity order comes from a study of ^{37}Cl ^{35}Cl isotope effects in reactions of RCl with nucleophiles RO^- and RS^-.[261]

---

[253] For reviews, see Hudson, in Klopman, "Chemical Reactivity and Reaction Paths," pp. 167–252, John Wiley & Sons, New York, 1974; Bunnett, *Annu. Rev. Phys. Chem.* **14**, 271–290 (1963); and Edwards and Pearson, *J. Am. Chem. Soc.* **84**, 16 (1962).

[254] It is, however, possible to measure the rates of reaction of nucleophiles with fairly stable carbonium ions: see Ritchie, *Acc. Chem. Res.* **5**, 348–354 (1972); Ritchie and Virtanen, *J. Am. Chem. Soc.* **95**, 1882 (1973).

[255] Bateman, Cooper, Hughes, and Ingold, *J. Chem. Soc.* 925 (1940).

[256] Within such a series, linear relationships can often be established between nucleophilic rates and p*K* values: see for example, Jokinen, Luukkonen, Ruostesuo, Virtanen, and Koskikallio, *Acta Chem. Scand.* **25**, 3367 (1971).

However, solvation is not the entire answer since, even for *uncharged* nucleophiles, nucleophilicity increases going down a column in the periodic table, These nucleophiles are not so greatly solvated, and changes in solvent do not greatly affect their nucleophilicity.[262] Even with the charged nucleophiles ArO^- and ArS^-, changes in solvent did not affect the order. To explain these cases we may use the principle of hard and soft acids and bases (p. 237).[263] The proton is a hard acid, but an alkyl substrate (which may be considered to act as a Lewis acid toward the nucleophile considered as a base) is a good deal softer. According to the principle given on p. 238, we may then expect the alkyl group to prefer softer nucleophiles than the proton does. Thus the larger, more polarizable (softer) nucleophiles have a greater (relative) attraction toward an alkyl carbon than toward a proton. Another way of looking at this is that the more polarizable the nucleophile, the more easily the electron cloud is distorted, and thus large nucleophiles can actually bring a greater degree of electron density to the substrate than the small nucleophiles whose electron clouds are more tightly held.

4. The freer the nucleophile, the greater the rate.[263a] We have already seen one instance of this.[259] Another is that the rate of attack by $(EtOOC)_2CBu^-\ Na^+$ in benzene was increased by the addition of substances (for example, 1,2-dimethoxyethane, adipamide) which specifically solvated the Na^+ and thus left the anion freer.[264] In a nonpolar solvent such as benzene, salts such as $(EtOOC)_2CBu^-\ Na^+$ usually exist as ion-pair aggregations of molecular weights of at least 10,000.

[257] Parker, *J. Chem. Soc.* 1328 (1961), has a list of about 20 such reactions.

[258] Weaver and Hutchison, *J. Am. Chem. Soc.* **86**, 261 (1964). See also Rodewald, Mahendran, Bear, and Fuchs, *J. Am. Chem. Soc.* **90**, 6698 (1968); Fuchs and Mahendran, *J. Org. Chem* **36**, 730 (1971); Müller and Siegfried, *Helv. Chim. Acta* **54**, 2675 (1971); Liotta, Grisdale, and Hopkins, *Tetrahedron Lett.* 4205 (1975). [264] Zaugg, Horrom, and Borgwardt, *J. Am. Chem. Soc.* **82**, 2895 (1960); Zaugg, *J. Am. Chem. Soc.* **82**, 2903 (1960); Barlow and Zaugg, *J. Org. Chem.* **37**, 2246 (1972); Zaugg, Ratajczyk, Leonard, and Schaefer, *J. Org. Chem.* **37**, 2249 (1972); Zaugg and Leonard, *J. Org. Chem.* **37**, 2253 (1972). See also Chastrette and Gauthier-Countani, *Bull. Soc. Chim. Fr.* 363 (1973).

Similarly, it was shown that the half-life of the reaction between $C_6H_5COCHEt^-$ and ethyl bromide depended on the positive ion; K^+, 4.5×10^{-3}; Na^+, 3.9×10^{-5}; Li^+, 3.1×10^{-7}.[265] Presumably, the potassium ion leaves the negative ion most free to attack most rapidly. In Chapter 3 we saw that crown ethers specifically solvate the alkali metal portion of salts like KF, KBr, KI, KOAc, and KCN, leaving the negative ions much freer. This has been turned to synthetic use, where suitable crown ethers have been used to increase greatly the rates of reactions where F^-, Br^-, I^-, OAc^-, and CN^- are nucleophiles.[266]

In the gas phase, where nucleophilic ions are totally free, without solvation or counterions, the ions F^-, OH^-, and NH_2^- were all equally reactive toward CH_3Cl.[267] This does not mean that these ions have intrinsic nucleophilicities of about equal magnitude. The rates were about equal because nearly every collision led to nucleophilic substitution. This is a kind of leveling effect, similar to diffusion control in solution.

However, the four rules given above do not always hold. One reason is that steric influences often play a part. For example, the *t*-butoxide ion Me_3CO^- is a stronger base than OH^- or OEt^-, but a much poorer nucleophile because its large bulk hinders it from closely approaching a substrate. Another example was given on p. 150, where it was shown that 2,6-di-*t*-butylpyridine is a poorer nucleophile than 2,6-dimethylpyridine.

The following overall nucleophilicity order for S_N2 mechanisms (in protic solvents) was given by Edwards and Pearson:[253] $RS^- > ArS^- > I^- > CN^- > OH^- > N_3^- > Br^- > ArO^- > Cl^- >$ pyridine $> AcO^- > H_2O$. A quantitative relationship has been worked out by Swain and Scott[268] similar to the linear free-energy equations considered in Chapter 9:[269]

$$\log \frac{k}{k_0} = sn$$

where n is the nucleophilicity of a given group, s is the sensitivity of a substrate to nucleophilic attack, and k_0 is the rate for H_2O, which is taken as the standard and for which n is assigned a value of zero. s is defined as 1.0 for methyl bromide. Table 7 contains values of n for some common nucleophiles.[270] The order is similar to that of Edwards and Pearson.

For substitution at a carbonyl carbon, the nucleophilicity order is not the same but follows the basicity order more closely. This is presumably because the carbonyl carbon, with its partial positive charge, resembles a proton more than does the carbon at a saturated center. That is, a carbonyl carbon is a much harder acid than a saturated carbon. The following nucleophilicity order for these substrates has been determined:[271] $Me_2C{=}NO^- > EtO^- > MeO^- > OH^- > OAr^- > N_3^- > F^- > H_2O > Br^- \sim I^-$. Soft bases are quite ineffective at a carbonyl carbon.

If adjacent to the attacking atom on the nucleophile there is an atom containing one or more unshared pairs, the nucleophilicity is enhanced. Examples of such nucleophiles are HO_2^-,

TABLE 7 Nucleophilicities of some common reagents[270]

Nucleophile	n	Nucleophile	n
SH^-	5.1	Br^-	3.5
CN^-	5.1	PhO^-	3.5
I^-	5.0	AcO^-	2.7
$PhNH_2$	4.5	Cl^-	2.7
OH^-	4.2	NO_3^-	1.0
N_3^-	4.0	H_2O	0.0
Pyridine	3.6		

$Me_2C{=}NO^-$, NH_2NH_2, etc. This is called the *alpha effect*,[272] and the reasons for it are not completely understood,[273] though it is likely that the effect is caused not by one factor alone but by the sum of several factors,[274] one of which is repulsion between the adjacent pairs of electrons.[275] The alpha effect is substantial for substitution at a carbonyl or other unsaturated carbon, at some inorganic atoms,[276] and for reactions of a nucleophile with a carbonium ion,[277] but is generally smaller or absent entirely for substitution at a saturated carbon.[278] The magnitude of the alpha effect correlates with β in the Brönsted equation (p. 236).[274] β is dependent on the position of the transition state (p. 236); hence the alpha effect is greatest where considerable bond formation has taken place in the transition state.[279]

The Effect of the Leaving Group

1. *At a saturated carbon.* The leaving group comes off more easily the more stable it is as a free entity. This is usually inverse to its basicity, and the best leaving groups are the weakest bases. Thus iodide is the best leaving group among the halides, and fluoride the poorest.[280] Since XH is always a weaker base than X^-, nucleophilic substitution is always easier at a substrate RXH^+ than at RX. An example of this effect is that OH and OR are not leaving groups from ordinary alcohols and ethers but can come off when the groups are protonated, that is, converted to ROH_2^+ or $RORH^+$.[281] Reactions in which the leaving group does not come off until it has been protonated are called SN1cA or SN2cA, depending on whether the reaction, after protonation, is an SN1 or SN2 process (sometimes these designations are shortened to A1 and A2). The cA stands for conjugate acid, since the substitution takes place on the conjugate acid of the substrate. The ions ROH_2^+ and $RORH^+$ can be observed as stable entities at low temperatures in super-acid solutions.[282] At higher temperatures they cleave to give carbonium ions. It is obvious that many of the best nucleophiles (e.g., NH_2^-, OH^-) cannot take part in SN1cA or SN2cA processes, because they would be converted to their conjugate acids under the acidic conditions necessary to protonate the leaving groups. Because SN1 reactions do not require powerful nucleophiles but do require good leaving groups, most of them take place under acidic conditions. In contrast, SN2 reactions, which do require powerful nucleophiles (which are generally strong bases), most often take place under basic conditions.

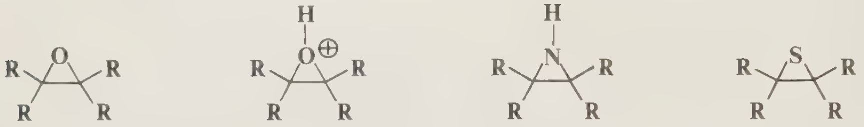
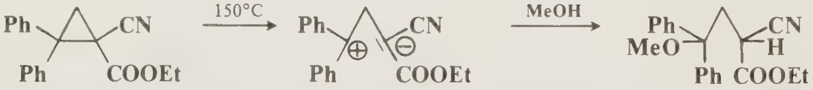
[279] See also Klopman, Tsuda, Louis, and Davis, *Tetrahedron* **26**, 4549 (1970).

[280] For a discussion of F as a leaving group, see Parker, *Adv. Fluorine Chem.* **3**, 63–91 (1963).

[281] For a review of ORH^+ as a leaving group, see Staude and Patat, in Patai, "The Chemistry of the Ether Linkage," pp. 22–46, Interscience Publishers, New York, 1967.

Another circumstance that increases leaving-group power is ring strain. Ordinary ethers do not cleave at all, and protonated ethers only under strenuous conditions, but epoxides are cleaved quite easily, and protonated epoxides even more easily. Aziridines and episulfides, three-membered rings containing, respectively, nitrogen and sulfur, are also easily cleaved (see p. 340). Even cyclopropane rings can be cleaved in a similar manner if they contain groups which can stabilize the positive and negative charges.[282a] An example is found in the treatment of ethyl 1-cyano-2,2-diphenylcyclopropanecarboxylate with methanol at 150°C for 3 days.[283] Similar reactions have been carried out photochemically.[284]





Although halides are the most common leaving groups in nucleophilic substitution for synthetic purposes, it is often more convenient to use alcohols. Since OH does not leave from ordinary alcohols, it must be converted to a group which does leave. One way is protonation, mentioned above. Another is conversion to a reactive ester, most commonly a sulfonic ester. The sulfonic ester groups *tosylate*, *brosylate*, *nosylate*, and *mesylate* are better leaving groups than halides and are frequently used. In recent years still better leaving groups have been found, and compounds containing these groups make powerful alkylating agents. Among them are oxonium ions

(ROR_2^+),[285] alkyl perchlorates ($ROClO_3$),[286] alkyl fluorosulfonates ($ROSO_2F$),[287] and the fluorinated compounds *triflates*[288] and *nonaflates*.[289] *Tresylates* are about 400 times less reactive

$R{-}OSO_2CF_3$	**$R{-}OSO_2C_4F_9$**	**$R{-}OSO_2CH_2CF_3$**
Trifluoromethanesulfonates	Nonafluorobutanesulfonates	2,2,2-Trifluoroethanesulfonates
Triflates	Nonaflates	Tresylates

than triflates, but still about 100 times more reactive than tosylates.[290] Halonium ions ($RClR^+$, $RBrR^+$, RIR^+), which can be prepared in super-acid solutions (p. 283) and isolated as solid SbF_6^- salts, are also extremely reactive in nucleophilic substitution.[291] NH_2, NHR, and NR_2 are extremely poor leaving groups, but the leaving-group ability of NH_2 can be greatly improved by converting a primary amine RNH_2 to the ditosylate $RNTs_2$. The NTs_2 group has been successfully replaced by a number of nucleophiles.[292] Ordinary NR_2 groups are very good leaving groups when the substrate is a Mannich base (these are compounds of the form $RCOCH_2CH_2NR_2$; see reaction **6-17**).[293] The elimination-addition mechanism applies in this case.

Probably the best leaving group is N_2 from the species RN_2^+, which can be generated in several ways,[294] of which the two most important are the treatment of primary amines with nitrous acid (see p. 578 for this reaction)

$$\mathbf{RNH_2 + HONO \longrightarrow RN_2^+}$$

and the protonation of diazo compounds[295]

$$\mathbf{R_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{N} + H^+ \longrightarrow R_2CHN_2^+}$$

No matter how produced, RN_2^+ are too unstable to be isolable,[296] reacting presumably by the SN1 or SN2 mechanism.[297] Actually, the exact mechanisms are in doubt because the rate laws, stereochemistry, and products have proved difficult to interpret.[298] If there are free carbonium ions, they should give the same ratio of substitution to elimination to rearrangements, etc., as carbonium ions generated in other SN1 reactions, but they often do not. "Hot" carbonium ions (unsolvated and/or chemically activated) which can hold their configuration have been postulated,[299] as have ion pairs, in which OH^- (or OAc^-, etc., depending on how the diazonium ion is generated) is the counterion.[300] Many of these carbonium ions have very short lifetimes, even when compared to what are formally the same carbonium ions generated in other ways, and the products are determined not by the same factors but largely by the conformation of the original molecule. A series of experiments which demonstrated this was carried out by Chérest and coworkers.[301] They showed, by the use of conformationally rigid molecules, that deamination is highly stereoselective. The four isomeric 4-*t*-butyl-2-aminocyclohexanols were treated with nitrous acid, and in each case only one product was obtained:

Soc.* **97**, 2148 (1975).

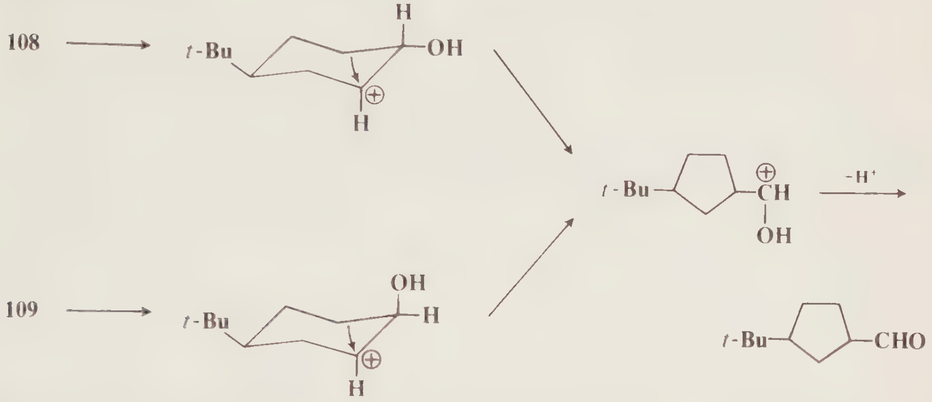
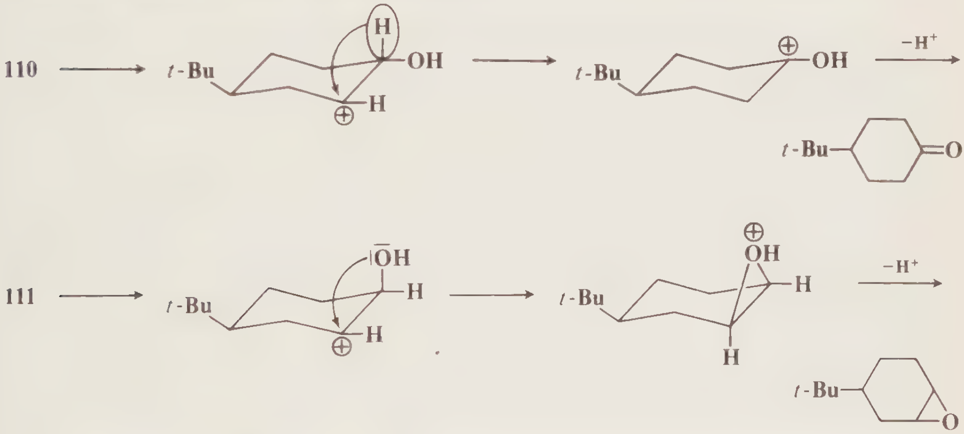
[301] Chérest, Felkin, Sicher, Šipoš, and Tichý, *J. Chem. Soc.* 2513 (1965).

For **108** and **109** the 2 hydrogen of the carbonium ion remains axial, and the different positions of the hydroxyl group and of the 1 hydrogen do not affect the product:



For **110** and **111** the 2 hydrogen remains equatorial and prevents ring contraction. In each of these cases, the axial group at the 1 position forms a bond with the carbonium-ion carbon:



It is obvious that the carbonium ion does not reach its maximum stability before the product-determining step occurs.

Diazonium ions generated from ordinary aliphatic primary amines are usually useless for preparative purposes, since they lead to a mixture of products giving not only substitution by any nucleophile present, but also elimination and rearrangements if the substrate permits. For example, diazotization of *n*-butylamine gave 25% 1-butanol, 5.2% 1-chlorobutane, 13.2% 2-butanol, 36.5% butenes (consisting of 71% 1-butene, 20% *trans*-2-butene, and 9% *cis*-2-butene), and traces of butyl nitrites.[302]

It has been suggested[303] that the reaction between aliphatic amines and nitrous acid may lead to carbonium ions *without* the intermediacy of diazonium ions. This could happen if the

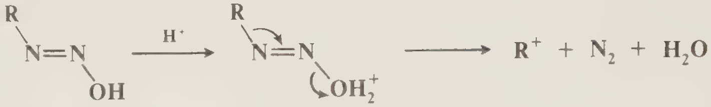
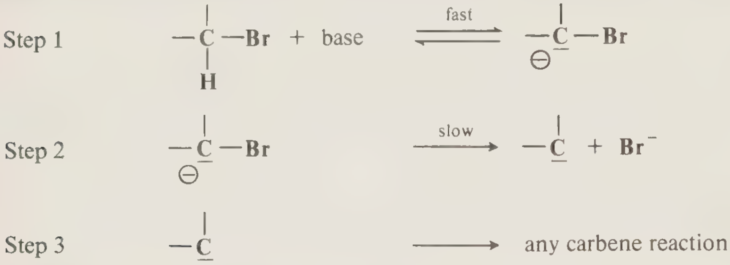
C—N bond of the diazohydroxide (see p. 579 for the mechanism of diazonium-ion formation) is cleaved at the same time as the N—O bond:



In the SN1cA and SN2cA mechanisms (p. 325) there is a preliminary step, the addition of a proton, before the normal SN1 or SN2 process occurs. There are also reactions in which the substrate *loses* a proton in a preliminary step. In these reactions there is a carbene intermediate:



Once formed by this process, the carbene may give any of the normal carbene reactions (see p. 182). When the net result is substitution, this mechanism may be called the SN1cB (for conjugate base) mechanism.[304] Though the slow step is an SN1 step, the reaction is second order: first order in substrate and first order in base.

Table 8 lists some leaving groups in approximate order of ability to leave. The order of leaving-group ability is about the same for SN1 and SN2 reactions.

2. *At a carbonyl carbon.* In both the SN1 and SN2 mechanisms the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways: (1) By altering the electron density of the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X, the greater the partial positive charge on C, and the more rapid the attack by a nucleophile. (2) The nature of the leaving group affects the *position of equilibrium.* In the intermediate **93** (p. 308) there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y, then Y will preferentially leave and **93** will revert to the starting compounds. Thus there is a partitioning factor between **93** going on to product (loss of X) or back to starting compound (loss of Y). The sum of these two factors causes the sequence of reactivity to be $RCOCl > RCOOCOR' > RCOOAr > RCOOR' > RCONH_2 > RCONR'_2 > RCOO^-$.[305] Note that this order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

---

[304] Pearson and Edgington, *J. Am. Chem. Soc.* **84,** 4607 (1962).

[305] RCOOH would belong in this sequence just after RCOOAr, but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the C=O group, are basic enough to take a proton from the acid, converting it to the unreactive $RCOO^-$.

[306] ROTs, etc., includes esters of sulfuric and sulfonic acids in general, for example, $ROSO_2OH$, $ROSO_2OR$, $ROSO_2R$, etc. $RONO_2$, etc., includes inorganic-ester leaving groups, such as $ROPO(OH)_2$, $ROB(OH)_2$, etc.

[307] Nitro substitution increases the leaving-group ability of ArO groups, and alkyl picrates [2,4,6-$ROC_6H_2(NO_2)_3$] react at rates comparable to tosylates: Sinnott and Whiting, *J. Chem. Soc. B* 965 (1971). See also Page, Pritt, and Whiting, *J. Chem. Soc., Perkin Trans. 2* 906 (1972).

The Effect of the Reaction Medium

The effect of solvent polarity on the rate of SN1 reactions depends on whether the substrate is neutral or positively charged. For neutral substrates, which constitute the majority of cases, the more polar the solvent, the faster the reaction, since there is a greater charge in the transition state than in the starting compound (Table 9) and the energy of an ionic transition state is reduced by polar solvents. However, when the substrate is positively charged, then the charge is more spread out in the transition state than in the starting ion, and a greater solvent polarity slows the reaction. Even for solvents with about the same polarity, there is a difference between protic and aprotic solvents. SN1 reactions of un-ionized substrates are more rapid in protic solvents, which can hydrogen-bond with the leaving group. Examples of protic solvents are

TABLE 9 Transition states for SN1 reactions of charged and uncharged substrates, and for SN2 reactions of the four charge types[308]

	Reactants and transition states	Change in the transition state relative to starting materials	How an increase in solvent polarity affects the rate
SN2	Type I $RX + Y^- \longrightarrow Y^{\delta-}\cdots\cdots R\cdots\cdots X^{\delta-}$	Dispersed	Small decrease
	Type II $RX + Y \longrightarrow Y^{\delta+}\cdots\cdots R\cdots\cdots X^{\delta-}$	Increased	Large increase
	Type III $RX^+ + Y^- \longrightarrow Y^{\delta-}\cdots\cdots R\cdots\cdots X^{\delta+}$	Decreased	Large decrease
	Type IV $RX^+ + Y \longrightarrow Y^{\delta+}\cdots\cdots R\cdots\cdots X^{\delta+}$	Dispersed	Small decrease
SN1	$RX \longrightarrow R^{\delta+}\cdots\cdots X^{\delta-}$	Increased	Large increase
	$RX^+ \longrightarrow R^{\delta+}\cdots\cdots X^{\delta+}$	Dispersed	Small decrease

water, alcohols, and carboxylic acids, while some polar aprotic solvents are dimethylformamide, dimethyl sulfoxide,[309] acetonitrile, acetone, nitrobenzene, sulfur dioxide, and hexamethylphosphoric triamide [$(Me_2N)_3PO$, HMPT, also called hexamethylphosphoramide, HMPA].[310]

For SN2 reactions, the effect of the solvent depends on which of the four charge types the reaction belongs to (p. 265). In types I and IV, an initial charge is dispersed in the transition state, so that the reaction is hindered by polar solvents. In type III initial charges are *decreased* in the transition state, so that the reaction is even more hindered by polar solvents. Only type II, where the reactants are uncharged but the transition state has built up a charge, is aided by polar solvents. These effects are summarized in Table 9.[308] For SN2 reactions also, the difference between protic and aprotic solvents must be considered.[311] For reactions of types I and III the transition state is more solvated in polar aprotic solvents than in protic ones, while (as we saw on p. 323) the original charged nucleophile is less solvated in aprotic solvents[312] (the second factor is generally much greater than the first[313]). So the change from, say, methanol to dimethyl sulfoxide should greatly increase the rate. As an example, the relative rates at 25°C for the reaction between methyl iodide and Cl^- were[257] in MeOH, 1; in $HCONH_2$ (still protic though a weaker acid), 12.5; in HCONHMe, 45.3; and in $HCONMe_2$, 1.2×10^6. The change in rate in going from a protic to an aprotic solvent is also related to the *size* of the attacking anion. Small ions are solvated best in protic solvents, since hydrogen bonding is most important for them, while large anions are solvated best in aprotic solvents (protic solvents have highly developed structures held together by hydrogen bonds; aprotic solvents have much looser structures, and it is easier for a large anion to be fitted in). So the rate of attack by small anions is most greatly increased by the change from a protic to an aprotic solvent. This may have preparative significance. The review articles in Ref. 311 have lists of several dozen reactions of charge types I and III in which yields are improved and reaction times reduced in polar

Octanoic acid	0.043	Benzene	
MeCN	0.036	Alkanes	
$HCONMe_2$	0.029		

aprotic solvents.[314] Reaction types II and IV are much less susceptible to the difference between protic and aprotic solvents. In these cases the original nucleophile is about equally solvated by protic and polar aprotic solvents, though the transition state is still solvated better by polar aprotic solvents.[315] Even for types I and III, there is a difference in susceptibility between primary and secondary substrates. Primary substrates are more greatly accelerated by the change from a protic to an aprotic solvent than secondary substrates. This has been attributed to a "looser" transition state for secondary substrates than for primary, "looser" meaning that bond forming lags behind bond breaking.[316]

Since for most reactions SN1 rates go up and SN2 rates go down in solvents of increasing polarity, it is quite possible for the same reaction to go by the SN1 mechanism in one solvent and the SN2 in another.

Table 10 is a list of solvents in order of ionizing power;[317] a solvent high on the list is a good solvent for SN1 reactions. Trifluoroacetic acid, which was not studied by Smith, Fainberg, and Winstein, has greater ionizing power than any solvent listed in Table 10.[318] Because it also has very low nucleophilicity, it is an excellent solvent for SN1 solvolyses. Other good solvents for this purpose are 1,1,1-trifluoroethanol CF_3CH_2OH, and 1,1,1,3,3,3-hexafluoro-2-propanol $(F_3C)_2CHOH$.[319]

We have seen how the polarity of the solvent influences the rates of SN1 and SN2 reactions. The ionic strength of the medium has similar effects. In general, the addition of an external salt affects the rates of SN1 and SN2 reactions in the same way as an increase in solvent polarity, though this is not quantitative: different salts have different effects.[320] However, there are exceptions: although the rates of SN1 reactions are usually increased by the addition of salts (this is called the *salt effect*), addition of the leaving-group ion often decreases the rate (the common-ion effect, p. 271). Also, there is the special salt effect of $LiClO_4$, mentioned on p. 275. In addition to these effects, SN1 rates are also greatly accelerated when there are ions present which specifically help in pulling off the leaving group. Especially important are Ag^+, Hg^{2+}, and $Hg_2{}^{2+}$, but H^+ helps to pull off F (hydrogen bonding).[321] This does not mean, however, that reactions in the presence of metallic ions invariably proceed by the SN1 mechanism. It has been shown that alkyl halides can react with $AgNO_2$ and $AgNO_3$ by the SN1 or SN2 mechanism, depending on the reaction conditions.[322]

The effect of solvent has been treated quantitatively (for SN1 mechanisms, in which the solvent pulls off the leaving group) by a linear free-energy relationship[323]

$$\log \frac{k}{k_0} = mY$$

where m is characteristic of the substrate (defined as 1.00 for *t*-BuCl) and is usually near unity, Y is characteristic of the solvent and measures its "ionizing power," and k_0 is the rate in a standard solvent, 80% aqueous ethanol at 25°C. This is known as the Grunwald-Winstein equation, and its utility is at best limited. Y values can of course be measured for solvent *mixtures* too, and this is one of the principal advantages of the treatment, since it is not easy otherwise to assign a polarity arbitrarily to a given mixture of solvents. The treatment is most satisfactory for different proportions of a given solvent pair. For wider comparisons the treatment is not so good quantitatively, although the Y values do give a reasonably good idea of solvolyzing power. Table 11 contains a list of some Y values.[324] At least in some cases, even where the Grunwald-Winstein equation holds, it is the result of a fortuitous combination of effects. Thus, if the substrate (and hence m) is held constant, the equation holds if $\Delta G^‡$ is proportional to the Y value of the solvent (p. 254). But $\Delta G^‡$ is the sum of $\Delta H^‡$ and $-T\Delta S^‡$, and it has been shown that in the solvolysis of *t*-butyl chloride in ethanol-water mixtures, $\Delta H^‡$ and $-T\Delta S^‡$ fluctuate wildly, though their sum (fortuitously) does vary linearly with Y.[325]

In order to include a wider range of solvents than those in which Y values can be conveniently measured, other attempts have been made at correlating solvent polarities.[326] Kosower found that the position of the charge-transfer peak (see p. 79) in the uv spectrum of the complex (**112**)

between iodide ion and 1-methyl- or 1-ethyl-4-carbomethoxypyridinium ion was dependent on the polarity of the solvent.[327] From these peaks, which are very easy to measure, Kosower calculated transition energies which he called *Z* values. *Z* values are thus measures of solvent polarity analogous to *Y* values. Another scale is based on the position of electronic spectra peaks of the pyridinium-*N*-phenolbetaine **113** in various solvents.[328] Solvent polarity values on this scale are called E_T values. E_T values are related to *Z* values by the expression[329]

$$Z = 1.41E_T + 6.92$$

Table 11 shows that *Z* and E_T values are generally in the same order as *Y* values.

[329] Reichardt and Dimroth, Ref. 324, p. 32.

The effect of solvent on nucleophilicity has already been discussed (p. 323).

It has been proposed[268] that if the Grunwald-Winstein equation, which applies only to removal of the leaving group, is combined with the nucleophilicity relationship (p. 324), which applies only to pushing by the nucleophile, an equation can be obtained which correlates both effects:

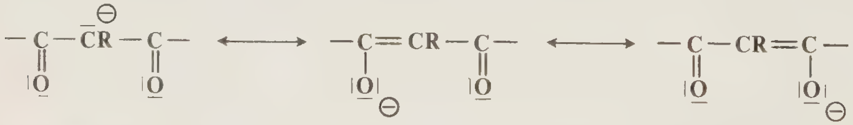
$$\log\frac{k}{k_0} = sn + s'e$$

In this equation, s and n are as defined on page 324, s' is analogous to m, and e is analogous to Y. In solvolysis reactions, the solvent may be both pushing and pulling, so that n and e are different functions of the same compound. This equation has not proved very satisfactory, and numerous attempts have been made to improve it.[330]

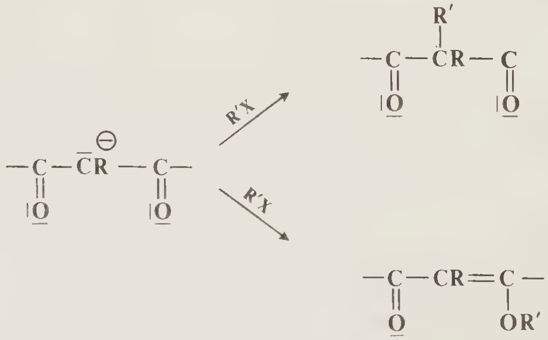
Ambident Nucleophiles. Regiospecificity

Some nucleophiles have a pair of electrons on each of two or more atoms, or canonical forms may be drawn in which two or more atoms bear an unshared pair. In these cases the nucleophile may attack in two or more different ways to give different products. Such reagents are called *ambident nucleophiles.* In most cases a nucleophile with two potentially attacking atoms can attack with either of them, depending on conditions, and mixtures are often obtained, though this is not always the case. For example, the nucleophile NCO^- usually gives only isocyanates RNCO and not the isomeric cyanates ROCN.[331] When a reaction can potentially give rise to two or more structural isomers (e.g., ROCN or RNCO) but actually produces only one, the reaction is said to be *regiospecific*[332] (compare the definition of stereospecific, p. 123). Some important ambident nucleophiles are:

1. *Ions of the type* $-\text{CO}-\overset{-\ominus}{\text{C}}\text{R}-\text{CO}-$. These ions, which are derived by removal of a proton from malonic esters, β-keto esters, β-diketones, etc., are resonance hybrids:



They can thus attack a saturated carbon with their carbon atoms (C-alkylation) or with their oxygen atoms (O-alkylation):



---

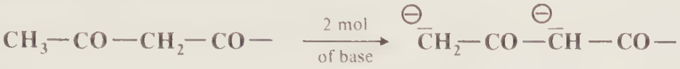
[330] See for example, Bentley, Schadt, Schleyer, Peterson, and Waller, *J. Am. Chem. Soc.* **94,** 991 (1972).

[331] Both cyanates and isocyanates have been isolated in treatment of secondary alkyl iodides with NCO^-: Holm and Wentrup, *Acta Chem. Scand.* **20,** 2123 (1966).

[332] This term was introduced by Hassner, *J. Org. Chem.* **33,** 2684 (1968).

With unsymmetrical ions, three products are possible, since either oxygen may attack. With a carbonyl substrate the ion may analogously undergo C-acylation or O-acylation.

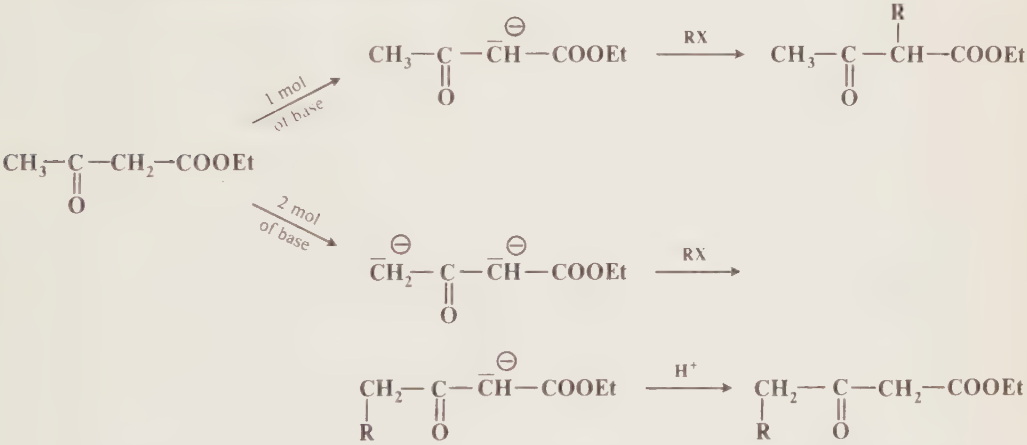
2. Compounds of the type $CH_3CO{-}CH_2{-}CO{-}$ can give up two protons, if treated with 2 moles of a strong enough base, to give dicarbanions:



$$CH_3{-}CO{-}CH_2{-}CO{-} \xrightarrow[\text{of base}]{\text{2 mol}} \overset{\ominus}{\bar{C}}H_2{-}CO{-}\overset{\ominus}{\bar{C}}H{-}CO{-}$$

114

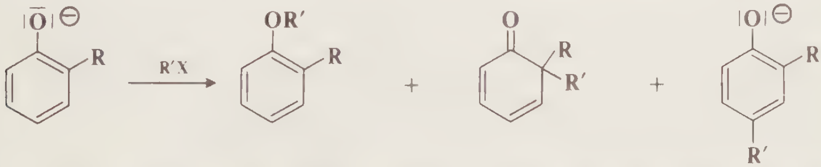
Such ions are ambident nucleophiles, since they have two possible attacking carbon atoms, aside from the possibility of attack by oxygen. In such cases, the attack is always by the more basic carbon. Since the hydrogen of a carbon bonded to two carbonyl groups is more acidic than that of a carbon bonded to just one (see Chapter 8), the CH group of **114** is less basic than the CH_2 group, so that the latter attacks the substrate. This gives rise to a useful general principle: whenever it is desired to remove a proton at a given position for use as a nucleophile, but there is a stronger acidic group in the molecule, it may be possible to take off both protons; if it is, then attack is always by the desired position, since it is the ion of the weaker acid. On the other hand, if it is desired to attack with the more acidic position, all that is necessary is to remove just one proton.[333] For example, ethyl acetoacetate may be alkylated at will, either at the methyl or at the methylene group (reaction **0-96**):



3. *The* CN⁻ *ion.* This nucleophile may give nitriles RCN (reaction **0-103**) or isonitriles RN≡C.

4. *The nitrite ion.* This ion may give nitrite esters R—O—N=O (reaction **0-33**) or nitro compounds RNO_2 (reaction **0-62**), which are not esters.

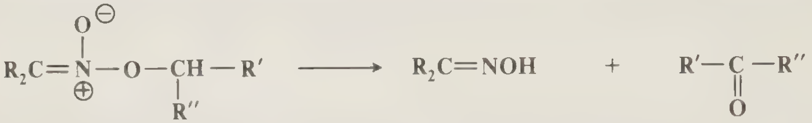
5. Phenoxide ions (which are analogous to enolate ions) may undergo C-alkylation or O-alkylation:



---

[333] The use of this principle was first reported by Hauser and Harris, *J. Am. Chem. Soc.* **80**, 6360 (1958). It has since been applied many times by Hauser, Harris, and coworkers. For a review, see Harris and Harris, *Org. React.* **17**, 155–211 (1969).

6. Removal of a proton from an aliphatic nitro compound gives a carbanion ($R_2C^{\ominus}{-}NO_2$) which can be alkylated at oxygen or carbon.[334] O-Alkylation gives nitronic esters, which are generally unstable to heat but break down to give an oxime and an aldehyde or ketone.



$$R_2C{=}\overset{\overset{\displaystyle O^{\ominus}}{|}}{\underset{\oplus}{N}}{-}O{-}\underset{\underset{\displaystyle R''}{|}}{CH}{-}R' \longrightarrow R_2C{=}NOH + R'{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R''$$

There are many other ambident nucleophiles. An interesting case is that of β-amino-α, β-unsaturated ketones, which may be alkylated on a carbon, oxygen, or nitrogen atom.[335]

It would be useful to have general rules as to which atom of an ambident nucleophile will attack a given substrate under a given set of conditions.[336] Unfortunately, the situation is complicated by the large number of variables which must be considered. It might be expected that the more electronegative atom would always attack, but this is often not the case. Where the products are determined by thermodynamic control (p. 194), the principal product is usually the one in which the atom of higher basicity has attacked (i.e., $C > N > O > S$). However, in most reactions the products are kinetically controlled and matters are much less simple. Nevertheless, the following generalizations can be made, while recognizing that there are many exceptions and unexplained results. As in the discussion of nucleophilicity in general (p. 323), there are two major factors: the polarizability (hard-soft character) of the nucleophile and solvation effects.

1. The principle of hard and soft acids and bases states that hard acids prefer hard bases and soft acids prefer soft bases (p. 238). In an SN1 mechanism the nucleophile attacks a carbonium ion, which is a hard acid. In an SN2 mechanism the nucleophile attacks the carbon atom of a molecule, which is a softer acid. The more electronegative atom of an ambident nucleophile is a harder base than the less electronegative atom. We may thus make the statement: As the character of a given reaction changes from SN1-like to SN2-like, an ambident nucleophile becomes more likely to attack with its less electronegative atom.[337] Therefore, changing from SN1 to SN2 conditions should favor C attack by CN^-, N attack by NO_2^-, C attack by enolate or phenoxide ions, etc. As an example, primary alkyl halides are attacked (in protic solvents) by the carbon atom of the anion of CH_3COCH_2COOEt, while α-chloro ethers, which react by the SN1 mechanism, are attacked by the oxygen atom. However, this does not mean that attack is by the less electronegative atom in all SN2 reactions and by the more electronegative atom in all SN1 reactions. The position of attack also depends on the nature of the nucleophile, the solvent, the leaving group, and other conditions. The rule merely states that increasing the SN2 character of the transition state makes attack by the less electronegative atom more likely.

2. All negatively charged nucleophiles must of course have a positive counterion. If this ion is Ag^+ (or some other ion which specifically helps in removing the leaving group, p. 334), rather than the more usual Na^+ or K^+, then the transition state is more SN1-like. Therefore the use of Ag^+ promotes attack at the more electronegative atom. For example, alkyl halides treated with NaCN generally give mostly RCN, but the use of AgCN increases the yield of isonitriles RNC.[338]

[334] For a review, see Erashko, Shevelev, and Fainzil'berg, *Russ. Chem. Rev.* **35**, 719–732 (1966).

[335] Leonard and Adamcik, *J. Am. Chem. Soc.* **81**, 595 (1959).

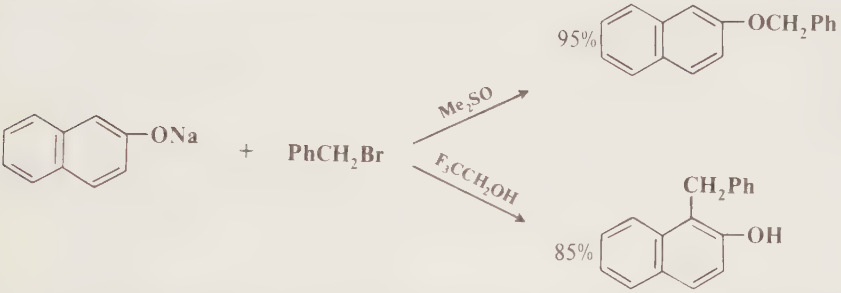
[336] For reviews, see Shevelev, *Russ. Chem. Rev.* **39**, 844–858 (1970); Gompper, *Angew. Chem. Int. Ed. Engl.* **3**, 560–570 (1964) [*Angew. Chem.* **76**, 412–423]. For discussions, see Kornblum, Smiley, Blackwood, and Iffland, *J. Am. Chem. Soc.* **77**, 6269 (1955); Kurts and Beletskaya, *Bull. Acad. Sci. USSR, Div. Chem. Sci.* 781 (1970).

[337] This principle, sometimes called *Kornblum's rule*, was first stated by Kornblum, Smiley, Blackwood, and Iffland, Ref. 336.

[338] Actually, this reaction is more complicated than it seems on the surface; see Austad, Songstad, and Stangeland, *Acta Chem. Scand.* **25**, 2327 (1971).

3. An increase in the electron-withdrawing character of the X in RX gives the carbon atom a higher partial positive charge, making it a harder acid. Thus such a change increases the extent of attack by the more electronegative atom of the nucleophile. For example, the O/C ratio increased in the order RI < RBr < RCl < ROTs (R and other conditions held constant) for a series of alkylations of the sodium salt of acetylacetone $CH_3COCH_2COCH_3$.[339]

4. In many cases the solvent influences the position of attack. The freer the nucleophile, the more likely it is to attack with its more electronegative atom, but the more this atom is encumbered by either solvent molecules or by positive counterions, the more likely is attack by the less electronegative atom. In protic solvents, the more electronegative atom is better solvated by hydrogen bonds than the less electronegative atom. In polar aprotic solvents, neither atom of the nucleophile is greatly solvated, but these solvents are very effective in solvating cations. Thus in a polar aprotic solvent the more electronegative end of the nucleophile is freer from entanglement by both the solvent and the cation, so that a change from a protic to a polar aprotic solvent often increases the extent of attack by the more electronegative atom. An example is attack by sodium β-naphthoxide on benzyl bromide, which resulted in 95% O-alkylation in dimethyl sulfoxide and 85% C-alkylation in 2,2,2-trifluoroethanol.[340] However, all polar aprotic solvents are not equal in their effects; for example, in alkylation of the anion of $CH_3COCH_2COCH_3$ with ethyl tosylate, the O/C alkylation ratio varied greatly with the identity of the dipolar aprotic solvent; ranging from 90 : 10 in $MePO(NMe_2)_2$ to 11 : 77 in sulfolane.[341] Changing the cation from Li^+ to Na^+ to K^+ (in nonpolar solvents) also favors O- over C-alkylation[342] for similar reasons (K^+ leaves the nucleophile much freer than does Li^+), as does the use of crown ethers, which are good at solvating cations (p. 82).[343]



5. In some cases steric influences control. Thus the 2,6-di-*t*-butylphenoxide ion gave 88% O-alkylation and 6% C-alkylation with methyl iodide, 11% O- and 59% C-alkylation with ethyl iodide, and 100% C-alkylation with isopropyl iodide:

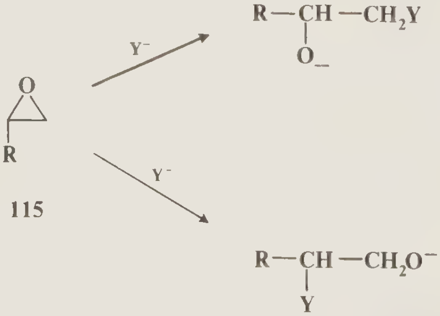
though the unsubstituted phenoxide ion gave only O-alkylation with all three alkyl halides.[344]

Ambident Substrates

Some substrates (for example, 1,3-dichlorobutane) may be attacked at two or more positions. We may call these *ambident substrates*. In the example given, there happen to be two leaving groups in the molecule, but there are two kinds of substrates which are inherently ambident (unless symmetrical). One of these, the allylic type, has already been discussed (p. 303). The other is the epoxy (or the similar aziridine[345] or episulfide) substrate.[346]



115

---

[344] Kornblum and Seltzer, *J. Am. Chem. Soc.* **83**, 3668 (1961).

[345] For a review of SN reactions at an aziridine substrate, see Dermer and Ham, "Ethylenimine and Other Aziridines," pp. 206–273, Academic Press, Inc., New York, 1969.

[346] For reviews of substitution at this type of substrate, see Wohl, *Chimia* **28**, 1–5 (1974); Kirk, *Chem. Ind.* (*London*) 109–116 (1973); Buchanan and Sable, *Sel. Org. Transform.* **2**, 1 95 (1972); Akhrem, Moiseenkov, and Dobrynin, *Russ. Chem. Rev.* **37**, 448–462 (1968); Gritter, in Patai, Ref. 281, pp. 390–400; Parker and Isaacs, *Chem. Rev.* **59**, 737–799 (1959).

Substitution of the free epoxide, which generally occurs under basic or neutral conditions, usually involves an SN2 mechanism. Since primary substrates undergo SN2 attack more readily than secondary, compounds of the type **115** are attacked in neutral or basic solution at the less highly substituted carbon, and stereospecifically, with inversion at that carbon. Under acidic conditions, it is the protonated epoxide which undergoes the reaction. Under these conditions the mechanism may be either SN1 or SN2. In SN1 mechanisms, which favor tertiary carbons, we might expect that attack would be at the more highly substituted carbon, and this is indeed the case. However, even when protonated epoxides react by the SN2 mechanism, attack is usually at the more highly substituted position.[347] Thus, it is often possible to change the direction of ring opening by changing the conditions from basic to acidic, or vice versa. When an epoxide ring is fused to a cyclohexane ring, SN2 ring opening invariably gives diaxial rather than diequatorial ring opening.[348]

REACTIONS

The reactions in this chapter are classified according to the attacking atom of the nucleophile in the order O, S, N, halogen, H, C. For a given nucleophile, reactions are classified by the substrate and leaving group, with alkyl substrates usually considered before acyl ones. Nucleophilic substitutions at a sulfur atom are treated at the end.

Not all the reactions in this chapter are actually nucleophilic substitutions. In some cases the mechanisms are not known with enough certainty even to decide whether a nucleophile, an electrophile, or a free radical is attacking. In other cases (such as **0-77**) conversion of one compound to another may occur by two or even all three of these possibilities, depending on the reagent and on the reaction conditions. However, one or more of the nucleophilic mechanisms previously discussed do hold for the overwhelming majority of the reactions in this chapter.

Oxygen Nucleophiles

A. Attack by OH at an Alkyl Carbon

0-1 Hydrolysis of Alkyl Halides

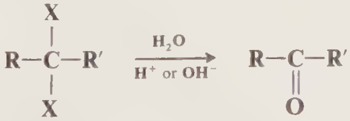
$$\mathrm{RX + H_2O \longrightarrow ROH_2^+ \xrightarrow{-H^+} ROH + H^+}$$

$$\mathrm{RX + OH^- \longrightarrow ROH}$$

Alkyl halides can be hydrolyzed to alcohols. Hydroxide ion is usually required, except that especially active substrates, such as allylic or benzylic types, may be hydrolyzed by water. In contrast to most nucleophilic substitutions at saturated carbons, this reaction can be performed on tertiary substrates without significant interference from elimination side reactions. The reaction is not frequently used for synthetic purposes, because alkyl halides are usually obtained from alcohols.

OS **II,** 408; **III,** 434; **IV,** 128; **51,** 60.

0-2 Hydrolysis of *gem*-Dihalides



$$\mathrm{R{-}\overset{X}{\underset{X}{C}}{-}R' \xrightarrow[H^+\ \text{or}\ OH^-]{H_2O} R{-}\underset{\|}{\overset{}{C}}{-}R'}\quad(\mathrm{C{=}O})$$

---

[347] Addy and Parker, *J. Chem. Soc.* 915 (1963); Biggs, Chapman, Finch, and Wray, *J. Chem. Soc. B* 55 (1971).

[348] Murphy, Alumbaugh, and Rickborn, *J. Am. Chem. Soc.* **91,** 2649 (1969).

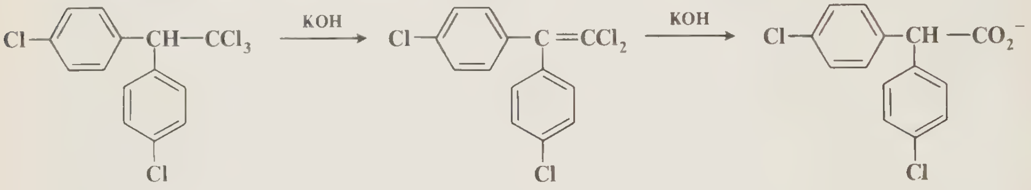
gem-Dihalides can be hydrolyzed, with either acid or basic catalysis, to give aldehydes or ketones.[349] Formally, the reaction may be regarded as first giving R—C(OH)XR′, which is unstable and loses HX to give the carbonyl compound. This is a very good reaction for the preparation of aromatic aldehydes, but for ketones and aliphatic aldehydes the starting dihalides are less easy to prepare. For aldehydes, strong bases cannot be used, because the product undergoes the aldol condensation (**6-40**) or the Cannizzaro reaction (**9-74**).

OS **I,** 95; **II,** 89, 133, 244, 549; **III,** 538, 788; **IV,** 110, 423, 807. Also see OS **III,** 737.

0-3 Hydrolysis of 1,1,1-Trihalides

$$RCX_3 + H_2O \longrightarrow RCOOH$$

This reaction is similar to the previous one. Formally, $RC(OH)X_2$ may be regarded as an intermediate which loses HX to give RCOX, which is easily hydrolyzed to the acid under the reaction conditions. However, in at least one case, that of treatment of DDT with KOH, elimination takes place first, since **116** can be isolated (OS **III,** 270):

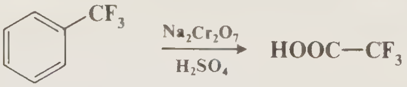


DDT

116

The utility of the method is limited by lack of availability of trihalides, though these compounds can be prepared by addition of CCl_4 and similar compounds to double bonds (reaction **5-37**), and by free-radical halogenation of methyl groups on aromatic rings (reaction **4-1**). When the hydrolysis is carried out in the presence of an alcohol, an ester can be obtained directly.[350] 1,1-Dichloroalkenes can also be hydrolyzed to carboxylic acids, by treatment with H_2SO_4.

In general 1,1,1-trifluorides do not undergo this reaction.[351] As an example of the remarkable stability of the C—F bond to nucleophilic substitution, α,α,α-trifluorotoluene, treated for 2 weeks with sodium dichromate and sulfuric acid, gave trifluoroacetic acid. However, some CF_3 groups



can be hydrolyzed to COOH groups, either by the α-proton mechanism shown above for DDT, or by strong acids[352] which assist in the removal of F by hydrogen bonding.

Chloroform is more rapidly hydrolyzed with base than is dichloromethane or carbon tetrachloride and gives not only formic acid but also carbon monoxide.[353] Hine[354] has shown that the mechanism of chloroform hydrolysis is quite different from that of dichloromethane or carbon tetrachloride, though superficially the three reactions appear similar. The first step is the loss of a proton to give CCl_3 which then loses Cl to give dichlorocarbene CCl_2, which is hydrolyzed to formic acid or carbon monoxide:

This is an example of an SN1cB mechanism (p. 330). The other two compounds react by the normal mechanisms. Carbon tetrachloride cannot give up a proton, and dichloromethane is not acidic enough.

OS **III,** 270; **V,** 93. Also see OS **I,** 327.

0-4 Hydrolysis of Alkyl Esters of Inorganic Acids

$$\left.\begin{array}{l} R{-}OSO_2OH \\ R{-}OSO_2OR' \\ R{-}OSO_2R' \\ R{-}OSOOH \\ R{-}OSOOR' \\ R{-}OSOR' \\ R{-}ONO_2 \\ R{-}ONO \\ R{-}OPO(OH)_2 \\ R{-}OPO(OR')_2 \\ R{-}OB(OH)_2 \\ \text{and others} \end{array}\right\} \xrightarrow{H_2O} R{-}OH$$

Esters of inorganic acids, including those given above and others, can be hydrolyzed to alcohols. The reactions are most successful when the ester is that of a strong acid, but it can be done for esters of weaker acids by the use of hydroxide ion (a more powerful nucleophile) or acid conditions (which make the leaving group come off more easily). When vinyl substrates are hydrolyzed (p. 313), the products are aldehydes or ketones.

$$R_2C{=}CH{-}X \xrightarrow{H_2O} R_2C{=}CH{-}OH \rightleftharpoons R_2CH{-}CHO$$

These reactions are all considered at one place because they are formally similar, but though some of them involve R—O cleavage and are thus nucleophilic substitutions at a saturated carbon, others involve cleavage of the bond between the inorganic atom and oxygen and are thus nucleophilic substitutions at a sulfur, nitrogen, etc. It is even possible for the same ester to be cleaved at either position, depending on the conditions. Thus benzhydryl *p*-toluenesulfinate ($Ph_2CHOSOC_6H_4CH_3$) was found to undergo C—O cleavage in $HClO_4$ solutions and S—O cleavage in alkaline media.[355] In general, the weaker the corresponding acid, the less likely is C—O cleavage. Thus, sulfonic acid esters $ROSO_2R'$ generally give C—O cleavage,[356] while nitrous acid esters RONO usually give N—O cleavage.[357] Esters of sulfonic acids which are frequently hydrolyzed are mentioned on p. 326. For hydrolysis of sulfonic acid esters, see also reaction **0-118.**

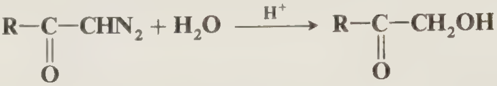
0-5 Diazotization of Primary Aliphatic Amines

$$RNH_2 + HONO \rightarrow [RN_2{}^+] \xrightarrow{H_2O} N_2 + ROH + \text{other products}$$

The diazotization of primary amines is not usually a good method for the preparation of alcohols, since it leads to a mixture of products (see p. 329). The reaction can be used, however, to measure the amount of NH_2 present in a sample, since nitrogen is evolved quantitatively.

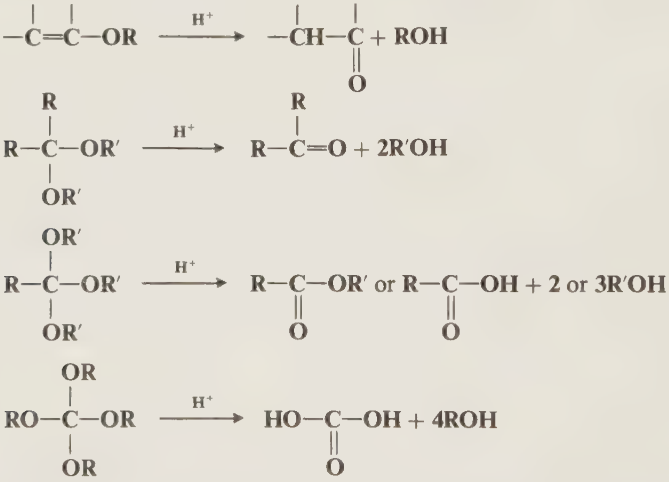
0-6 Hydrolysis of Diazo Ketones



$$R-\underset{\underset{O}{\|}}{C}-CHN_2 + H_2O \xrightarrow{H^+} R-\underset{\underset{O}{\|}}{C}-CH_2OH$$

Diazo ketones are relatively easy to prepare (see reaction **0-116**). When treated with acid, they add a proton to give diazonium salts, which are hydrolyzed to the alcohols by the SN1 or SN2 mechanism.[358] Relatively good yields of α-hydroxy ketones may be prepared in this way, since the diazonium ion is somewhat stabilized by the presence of the carbonyl group, which discourages N_2 from leaving since that would result in an unstable α-carbonyl carbonium ion.

0-7 Hydrolysis of Vinyl Ethers, Acetals, and Similar Compounds[359]



$$-\overset{|}{C}=\overset{|}{C}-OR \xrightarrow{H^+} -\overset{|}{CH}-\underset{\underset{O}{\|}}{\overset{|}{C}} + ROH$$

$$R-\overset{\overset{R}{|}}{\underset{\underset{OR'}{|}}{C}}-OR' \xrightarrow{H^+} R-\overset{\overset{R}{|}}{C}=O + 2R'OH$$

$$R-\overset{\overset{OR'}{|}}{\underset{\underset{OR'}{|}}{C}}-OR' \xrightarrow{H^+} R-\underset{\underset{O}{\|}}{C}-OR' \text{ or } R-\underset{\underset{O}{\|}}{C}-OH + 2 \text{ or } 3R'OH$$

$$RO-\overset{\overset{OR}{|}}{\underset{\underset{OR}{|}}{C}}-OR \xrightarrow{H^+} HO-\underset{\underset{O}{\|}}{C}-OH + 4ROH$$

The alkoxyl group OR is not a leaving group, and so these compounds must be converted to the conjugate acids before they can be hydrolyzed. Although 100% sulfuric acid and other concentrated strong acids readily cleave simple ethers,[360] the only acids used preparatively for this purpose are HBr and HI (reaction **0-68**). However, acetals, ketals, and ortho esters are easily cleaved by dilute acids. These compounds are hydrolyzed with greater facility because carbonium ions of the type $\mathrm{RO{-}\overset{\oplus}{\underset{|}{C}}{-}}$ are greatly stabilized by resonance (p. 156). The reactions therefore proceed by the SN1 mechanism, as shown for acetals:[361]

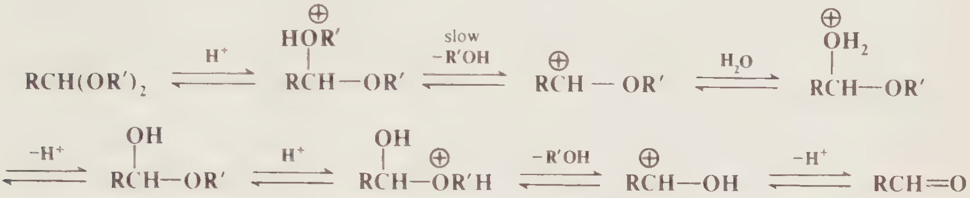
[360] Jaques and Leisten, *J. Chem. Soc.* 2683 (1964). See also Olah and O'Brien, *J. Am. Chem. Soc.* **89,** 1725 (1967).



$$\mathrm{RCH(OR')_2} \xrightleftharpoons{\mathrm{H^+}} \overset{\overset{\oplus}{\mathrm{HOR'}}}{\mathrm{RCH{-}OR'}} \xrightleftharpoons[\mathrm{-R'OH}]{\text{slow}} \mathrm{R\overset{\oplus}{C}H-OR'} \xrightleftharpoons{\mathrm{H_2O}} \overset{\overset{\oplus}{\mathrm{OH_2}}}{\mathrm{RCH{-}OR'}}$$

$$\xrightleftharpoons{\mathrm{-H^+}} \overset{\mathrm{OH}}{\mathrm{RCH{-}OR'}} \xrightleftharpoons{\mathrm{H^+}} \overset{\mathrm{OH}\quad\oplus}{\mathrm{RCH{-}OR'H}} \xrightleftharpoons{\mathrm{-R'OH}} \mathrm{R\overset{\oplus}{C}H{-}OH} \xrightleftharpoons{\mathrm{-H^+}} \mathrm{RCH{=}O}$$

This mechanism (which is an SN1cA or A1 mechanism) is the reverse of that for acetal formation by reaction of an aldehyde and an alcohol (reaction **6-6**). Among the facts supporting the mechanism are:[362] (1) The reaction proceeds with *specific* H_3O^+ catalysis (see p. 236). (2) It is faster in D_2O. (3) Optically active ROH are not racemized. (4) Even with *t*-butyl alcohol the R—O bond does not cleave, as shown by ^{18}O labeling.[363] (5) Hydrolysis rates greatly increase in the order $CH_2(OR')_2 < RCH(OR')_2 < R_2C(OR')_2 < RC(OR')_3$, as would be expected for a carbonium-ion intermediate.

While the A1 mechanism shown above operates in most acetal hydrolyses, it has been shown that at least two other mechanisms can also take place with suitable substrates.[364] In one of these mechanisms the second and third of the above steps are concerted, so that the mechanism is SN2cA (or A2). This mechanism has been demonstrated for hydrolysis of 2-(*p*-methoxyphenyl)-4,4,5,5-tetramethyl-1,3-dioxolane.[365] In the second mechanism, the first and second steps are concerted. In the case of hydrolysis of 2-(*p*-nitrophenoxy)tetrahydropyran, *general* acid catalysis was shown,[366] demonstrating that the substrate is protonated in the rate-determining step (p. 236). Reactions in which a substrate is protonated in the rate-determining step are called A-SE2 reactions.[367] However, if protonation of the substrate were all that happens in the slow step, then the proton in the transition state would be expected to lie closer to the weaker base (p. 236). Because the substrate is a much weaker base than water, the proton should be largely transferred. Since

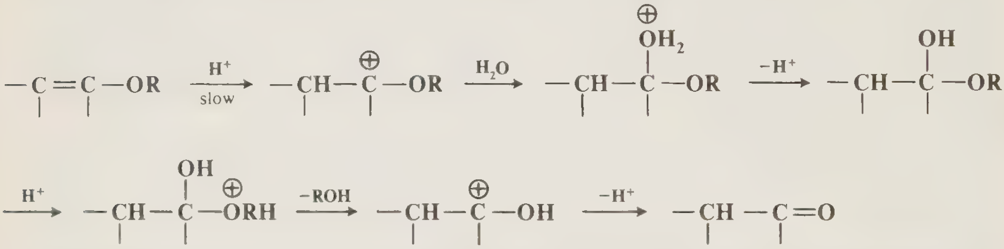
[367] For a review of A-SE2 reactions, see Williams and Kreevoy, *Adv. Phys. Org. Chem.* **6,** 63–101 (1968).

the Brönsted coefficient was found to be 0.5, the proton was actually transferred only about halfway (p. 236). This can be explained if the basicity of the substrate were increased by partial breaking of the C—O bond. The conclusion is thus drawn that steps 1 and 2 are concerted. The hydrolysis of ortho esters is also subject to general acid catalysis.

Although acetals, ketals, and ortho esters are easily hydrolyzed by acids, they are extremely resistant to hydrolyis by bases. An aldehyde or ketone can therefore be protected from attack by a base by conversion to the acetal or ketal (reaction **6-6**), and then can be later cleaved with acid. Thioacetals, thioketals, *gem*-diamines, and other compounds which contain any two of the groups OR, OCOR, NR_2, NHCOR, SR, and halogen on the same carbon can also be hydrolyzed to aldehydes or ketones, in most cases by acid treatment, though with some substrates this is insufficient and other catalysts must be used. For example, thioacetals $RCHSR'_2$ and thioketals $R_2CSR'_2$ have been converted to aldehydes and ketones, respectively, by treatment with $HgCl_2$,[368] with HgO-BF_3,[369] and with certain other reagents.[370]

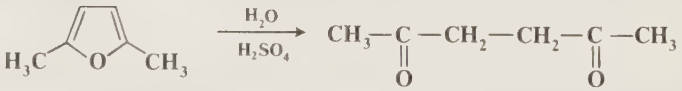
Vinyl ethers are readily hydrolyzed by acids; the rate-determining step is protonation of the substrate. However, protonation does not take place at the oxygen, but at the β-carbon.[371] After that the mechanism is similar to the A1 mechanism given above for the hydrolysis of acetals.



$$-\underset{|}{C}=\underset{|}{C}-OR \xrightarrow[\text{slow}]{H^+} -\underset{|}{CH}-\overset{\oplus}{\underset{|}{C}}-OR \xrightarrow{H_2O} -\underset{|}{CH}-\overset{\overset{\oplus}{OH_2}}{\underset{|}{C}}-OR \xrightarrow{-H^+} -\underset{|}{CH}-\overset{OH}{\underset{|}{C}}-OR$$

$$\xrightarrow{H^+} -\underset{|}{CH}-\overset{OH}{\underset{|}{C}}-\overset{\oplus}{O}RH \xrightarrow{-ROH} -\underset{|}{CH}-\overset{\oplus}{\underset{|}{C}}-OH \xrightarrow{-H^+} -\underset{|}{CH}-\underset{|}{C}=O$$

Among the facts supporting this mechanism (which is an A-SE2 mechanism because the substrate is protonated in the rate-determining step) are: (1) ^{18}O labeling shows that in $ROCH{=}CH_2$ it is the vinyl-oxygen bond and not the RO bond which cleaves;[372] (2) the reaction is subject to general acid catalysis;[373] and (3) there is a solvent isotope effect when D_2O is used.[373] Enamines are also hydrolyzed by acids (see reaction **6-2**); the mechanism is similar. Furans represent a special case of vinyl ethers which are cleaved by acid to give 1,4 diones. Thus



$$\xrightarrow[H_2SO_4]{H_2O} CH_3-\underset{\underset{O}{\|}}{C}-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-CH_3$$

Mixed aryl alkyl ethers have been cleaved in 99.6% H_2SO_4 by a simple SN1 mechanism. Dialkyl ethers have also been cleaved in this medium, but in this case the ether first reacts with SO_3 to give **117**, so that the leaving group is $ROSO_2OH$.[374] *t*-Butyl ethers are readily cleaved with

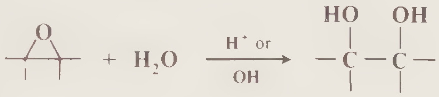
0-8 Hydrolysis of Epoxides



The hydrolysis of epoxides is a convenient method for the preparation of *vic*-glycols. The reaction is catalyzed by acids or bases (see discussion of the mechanism on p. 341). Among acid catalysts the reagent of choice is perchloric acid, since side reactions are minimized with this reagent.[376] Dimethyl sulfoxide is a superior solvent for the alkaline hydrolysis of epoxides.[377]

OS **V**, 414.

B. Attack by OH at an Acyl Carbon

0-9 Hydrolysis of Acyl Halides

$$RCOCl + H_2O \longrightarrow RCOOH$$

Acyl halides are so reactive that hydrolysis is easily carried out.[378] In fact, most simple acyl halides must be stored under anhydrous conditions lest they react with water in the air. Consequently, water is usually a strong enough nucleophile for the reaction, though in difficult cases hydroxide ion may be required. The reaction is seldom synthetically useful, because acyl halides are normally prepared from acids. The reactivity order is $F < Cl < Br < I$.[379] If a carboxylic acid is used as the nucleophile, an exchange reaction may take place (see reaction **0-75**). The mechanism[379] of hydrolysis may be either SN1 or tetrahedral, the former occurring in highly polar solvents and in the absence of strong nucleophiles.[380] The tetrahedral mechanism in this case may be formulated as

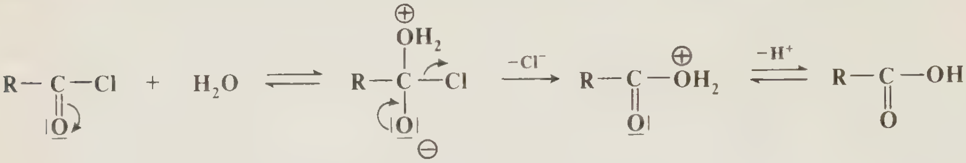
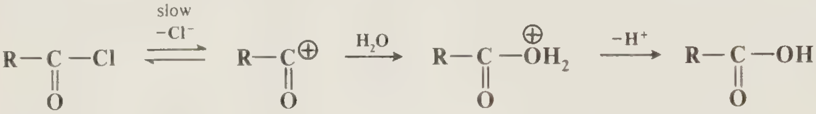
[378] For a review, see Sonntag, *Chem. Rev.* **52**, 237–416 (1953), pp. 251–258.

[379] For a review, see Talbot, Ref. 188, pp. 226–257. For a review of the mechanisms of reactions of acyl halides with water, alcohols, and amines, see Kivinen, in Patai, "The Chemistry of Acyl Halides," pp. 177–230, Interscience Publishers, New York, 1972.

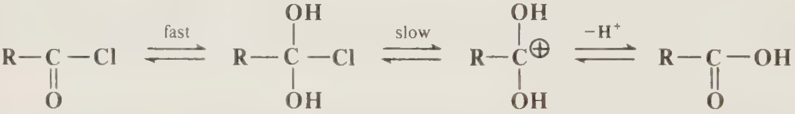


There are two possible paths for the SN1 mechanism:

Path 1



Path 2

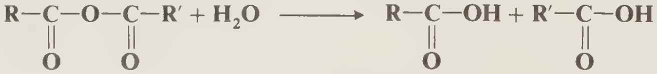


It is not easy to distinguish path 2 (which involves preliminary hydration) from path 1, but most evidence favors path 2.[381]

Hydrolysis of acyl halides is not usually catalyzed by acids, except for acyl fluorides, where hydrogen bonding can assist in the removal of F.[382]

OS **II**, 74.

0-10 Hydrolysis of Anhydrides



$$R-\underset{\underset{O}{\|}}{C}-O-\underset{\underset{O}{\|}}{C}-R' + H_2O \longrightarrow R-\underset{\underset{O}{\|}}{C}-OH + R'-\underset{\underset{O}{\|}}{C}-OH$$

Anhydrides are somewhat more difficult to hydrolyze than acyl halides, but here too water is usually a strong enough nucleophile. The mechanism is usually tetrahedral. Only under acid catalysis does the SN1 mechanism occur, and seldom even then.[383] Anhydride hydrolysis can also be catalyzed by bases. Of course, OH^- attacks more readily than water, but other bases can also catalyze the reaction. This phenomenon, called *nucleophilic catalysis* (p. 310), is actually the result of *two* successive tetrahedral mechanisms. For example, pyridine catalyzes the hydrolysis of acetic anhydride in this manner:[384]

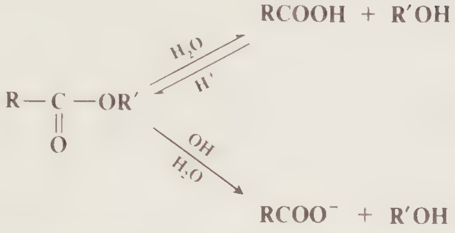
0-11 Hydrolysis of Esters



Ester hydrolysis is usually catalyzed by acids or bases. Since OR is a much poorer leaving group than halide or OCOR, water alone does not hydrolyze most esters. When bases catalyze the reaction, the attacking species is the more powerful nucleophile OH^-. This reaction is called *saponification* and gives the salt of the acid. Acids catalyze the reaction by making the carbonyl carbon more positive and therefore more susceptible to attack by the nucleophile. Both reactions are equilibrium reactions, so that they are practicable only when there is a way of shifting the equilibrium to the right. Since formation of the salt does just this, ester hydrolysis is almost always done for preparative purposes in basic solution, unless the compound is base-sensitive. Ester hydrolysis may also be catalyzed by metal ions, by enzymes, and by nucleophiles (see reaction **0-10**).[188] Methanesulfonic acid is also a good catalyst,[385] as is potassium superoxide KO_2 in benzene in the presence of 18-crown-6 (p. 82).[385a] Phenolic esters may be similarly cleaved; in fact the reaction is usually faster for these compounds. Lactones also undergo the reaction (though if the lactone is five- or six-membered, the hydroxy acid often spontaneously relactonizes); and thiol esters (RCOSR′) give mercaptans R′SH. Sterically hindered esters are hydrolyzed with difficulty (p. 316).

Ingold[386] has classified the acid- and base-catalyzed hydrolyses of esters (and the formation of esters, since these are reversible reactions and thus have the same mechanisms) into eight possible mechanisms (Table 12) depending on the following conditions: (1) acid- or base-catalyzed, (2) unimolecular or bimolecular, and (3) acyl cleavage or alkyl cleavage.[387] All eight of these are SN1, SN2, or tetrahedral mechanisms. The acid-catalyzed mechanisms are shown with reversible arrows. They are not only reversible but symmetrical; that is, the mechanisms for ester formation are exactly the same as for hydrolysis, except that H replaces R. Internal proton transfers, such as shown for **A** and **B** and for **C** and **D**, may not actually be direct but may take place through the solvent. There is much physical evidence to show that esters are initially protonated on the carbonyl and not on the alkyl oxygen (Chapter 8, Ref. 16). We have nevertheless shown the AAC1 mechanism as proceeding through the ether-protonated intermediate **A**, since it is difficult to envision OR′ as a leaving group here. It is of course possible for a reaction to proceed through an intermediate even if only a tiny concentration is present. The designations AAC1, etc., are those of Ingold. The AAC2 and AAC1 mechanisms are also called A2 and A1, respectively. It may be noted that the AAC1 mechanism is actually the same as the SN1cA mechanism for this type of substrate, and that AAL2 is analogous to SN2cA. Some authors use A1 and A2 to refer to all types

TABLE 12 Classification of the eight mechanisms for ester hydrolysis and formation[386]

		Name	Type	
Acid catalysis	Acyl cleavage	AAC1	SN1			AAC2	Tetra-hedral		Alkyl cleavage	AAL1	SN1			AAL2	SN2	Basic catalysis	Acyl cleavage	BAC1	SN1			BAC2	Tetra-hedral		Alkyl cleavage	BAL1	SN1			BAL2	SN2	
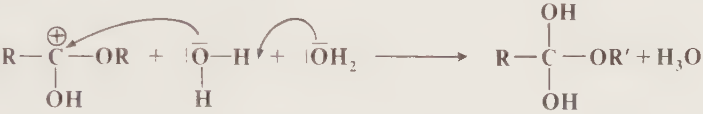
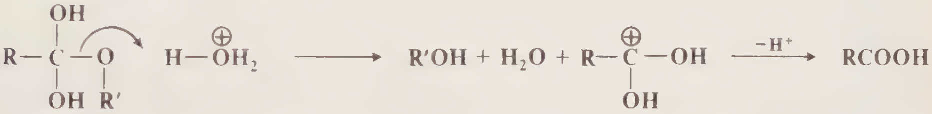
of nucleophilic substitution in which the leaving group first acquires a proton. The base-catalyzed reactions are not shown with reversible arrows, since they are reversible only in theory and not in practice. Hydrolyses taking place under neutral conditions are classified as B mechanisms.

Of the eight mechanisms, only six have actually been observed in hydrolysis of carboxylic esters. The two which have not been observed are the BAC1 and the AAL2 mechanisms. The BAC1 is an SN1 mechanism with OR′ as the leaving group, which does not happen, while the AAL2 requires water to be a nucleophile in an SN2 process.[387a] The most common mechanisms are the BAC2 for basic catalysis and the AAC2[388] for acid catalysis, that is, the two tetrahedral mechanisms. Both of these involve acyl-oxygen cleavage. Evidence for this is: (1) hydrolysis with $H_2{}^{18}O$ results in the ^{18}O appearing in the acid and not in the alcohol;[389] (2) esters with chiral R′ groups give alcohols with *retention* of configuration;[390] (3) allylic R′ gives no allylic rearrangement;[391] and (4) neopentyl R′ gives no rearrangement;[392] all these facts indicating that the O—R′ bond is not broken. It has been concluded that in the AAC2 mechanism two molecules of water are required.



If this is so, the protonated derivatives **C** and **D** would not appear at all. This conclusion stems from a value of *w* (see p. 235) of about 5, indicating that water acts as a proton donor here as well as a nucleophile.[393] Termolecular processes are rare, but in this case the two water molecules are already connected by a hydrogen bond. To maintain the symmetry of the process, the reaction would then continue as follows:



The other mechanism involving acyl cleavage is the AAC1 mechanism. This is rare, being found only where R is very bulky, so that bimolecular attack is sterically hindered, and only in ionizing solvents. The mechanism has been demonstrated for esters of 2,4,6-trimethylbenzoic acid (mesitoic acid). This acid depresses the freezing point of sulfuric acid four times as much as would be predicted from its molecular weight, which is evidence for the equilibrium

$$\mathrm{ArCOOH} + 2\mathrm{H_2SO_4} \rightleftharpoons \mathrm{ArCO}^{\oplus} + \mathrm{H_3O^+} + 2\mathrm{HSO_4^-}$$

In a comparable solution of benzoic acid the freezing point is depressed only twice the predicted amount, indicating only a normal acid-base reaction. Further, a sulfuric acid solution of methyl mesitoate when poured into water gave mesitoic acid, while a similar solution of methyl benzoate similarly treated did not.[394] The AAC1 mechanism is also found when acetates of phenols or of primary alcohols are hydrolyzed in concentrated (more than 90%) H_2SO_4 (the mechanism under the more usual dilute acid conditions is the normal AAC2).[395] This conclusion stems from kinetic investigations similar to those used in determining w values. Synthetic advantage can be taken of this: many aliphatic esters are conveniently hydrolyzed in concentrated H_2SO_4.[396]

[387a] There is evidence that the AAL2 mechanism can take place in the hydrolysis of imino esters RC(OR′)=NR″: McClelland, *J. Am. Chem. Soc.* **97**, 3177 (1975).

[388] For a discussion of this mechanism with specific attention to the proton transfers involved, see Zimmerman and Rudolph, *Angew. Chem. Int. Ed. Engl.* **4**, 40–49 (1965) [*Angew. Chem.* **77**, 65–74].

[393] Martin, *J. Am. Chem. Soc.* **84**, 4130 (1962). See also Lane, *J. Am. Chem. Soc.* **86**, 2521 (1964); Lane, Cheung, and Dorsey, *J. Am. Chem. Soc.* **90**, 6492 (1968); Yates and McClelland, *J. Am. Chem. Soc.* **89**, 2686 (1967); Yates, *Acc. Chem. Res.* **6**, 136–144 (1971).

[394] Treffers and Hammett, *J. Am. Chem. Soc.* **59**, 1708 (1937). For other evidence for this mechanism, see Bender and Chen, *J. Am. Chem. Soc.* **85**, 37 (1963).

The mechanisms involving alkyl-oxygen cleavage[397] are ordinary SN1 and SN2 mechanisms in which OCOR (an acyloxy group) or its conjugate acid is the leaving group. Two of the three mechanisms, the BAL1 and AAL1 mechanisms, occur most readily when R′ comes off as a stable carbonium ion, that is, when R′ is tertiary alkyl, allyl, benzyl, etc. For acid catalysis, most esters with this type of alkyl group (especially tertiary alkyl) cleave by this mechanism, but even for these substrates, the BAL1 mechanism occurs only in neutral or weakly basic solution, where the rate of attack by OH^- is so slowed that the normally slow (by comparison) unimolecular cleavage takes over. These two mechanisms have been established by kinetic studies. ^{18}O labeling, and isomerization of R′.[398] Secondary and benzylic acetates hydrolyze by the AAC2 mechanism in dilute H_2SO_4, but in concentrated acid the mechanism changes to AAL1.[395] The remaining mechanism, BAL2, is very rare, because it requires OH^- to attack an alkyl carbon when an acyl carbon is also available, but it has been observed in the hydrolysis of β-lactones under neutral conditions[399] (because cleavage of the C—O bond in the transition state opens the four-membered ring and relieves strain), the alkaline hydrolysis of methyl 2,4,6-tri-*t*-butyl benzoate,[400] and in the unusual reaction[401]

$$\text{ArCOOMe} + \text{RO}^- \longrightarrow \text{ArCOO}^- + \text{ROMe}$$

When it does occur, the BAL2 mechanism is easy to detect, since it is the only one of the six observed mechanisms which requires inversion at R′. However, in the last example given, the mechanism is evident from the nature of the product, since the ether could have been formed in no other way.

To sum up the acid-catalysis mechanisms, AAC2 and AAL1 are the common mechanisms, the latter for R′ which give stable carbonium ions, the former for practically all the rest. AAC1 is rare, being found mostly with strong acids and sterically hindered R. AAL2 has not been observed. For basic catalysis, BAC2 is almost universal; BAL1 occurs only with R′ which give stable carbonium ions, and then only in weakly basic or neutral solution; BAL2 is very rare; and BAC1 has never been observed.

In the special case of alkaline hydrolysis of N-substituted aryl carbamates, there is another mechanism,[401a] involving elimination-addition:[402]

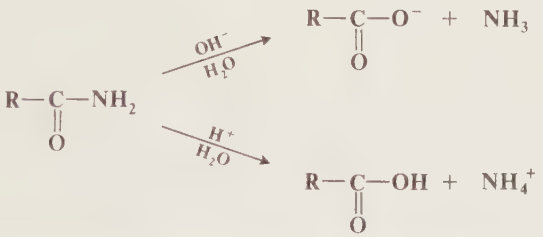
This mechanism does not apply to unsubstituted or N,N-disubstituted aryl carbamates, which hydrolyze by the normal mechanisms. Carboxylic esters substituted in the α-position by an electron-withdrawing group (e.g., CN or COOEt) can also hydrolyze by a similar mechanism, involving a ketene intermediate.[403]

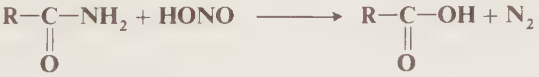
The acid-catalyzed hydrolysis of enol esters $RCOOCR'{=}CR''_2$ can take place either by the normal AAC2 mechanism or by a mechanism involving initial protonation on the double-bond carbon, similar to the mechanism for the hydrolysis of vinyl ethers given in reaction **0-7**, depending on reaction conditions.[404] In either case, the products are the carboxylic acid RCOOH and the aldehyde or ketone R''_2CHOR'.

Ester hydrolyses with concomitant decarboxylation are listed at reaction **2-39**.

0-12 Hydrolysis of Amides



Unsubstituted amides ($RCONH_2$) can be hydrolyzed with either acidic or basic catalysis, the products being, respectively, the free acid and the ammonium ion, or the salt of the acid and ammonia. N-Substituted (RCONHR′) and N,N-disubstituted ($RCONR'_2$) amides can be hydrolyzed analogously, with the primary or secondary amine, respectively (or their salts), being obtained instead of ammonia. Lactams, imides, cyclic imides, hydrazides, etc., also undergo the reaction. Water alone is not sufficient to hydrolyze most amides, since NH_2 is even a poorer leaving group than OR. Often prolonged heating is required even with acid or basic catalysts. In difficult cases, nitrous acid can be used (unsubstituted amides only) in a reaction similar to **0-5**:



$$R{-}\underset{\Large O}{\underset{\|}{C}}{-}NH_2 + HONO \longrightarrow R{-}\underset{\Large O}{\underset{\|}{C}}{-}OH + N_2$$

In contrast to reaction **0-5**, side reactions are not a problem here, and this reaction is much faster than ordinary hydrolysis: for benzamide the rate ratio was 2.5×10^7.[405] Another procedure for difficult cases involves treatment with aqueous sodium peroxide.[405a] Imidazolides (**118**) are particularly easy to hydrolyze,[406] and these are often used in synthesis (for an example, see p. 365).

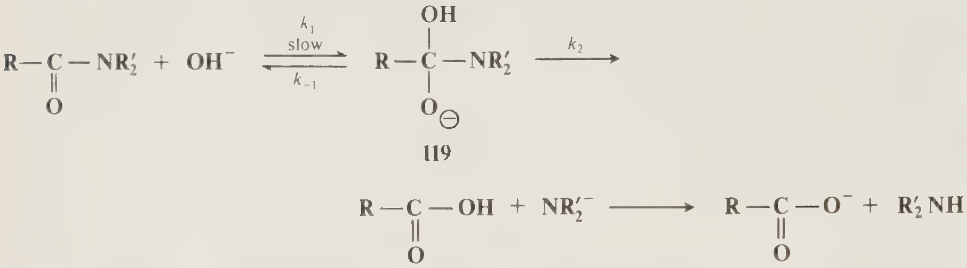
118

Amide hydrolysis can also be catalyzed by nucleophiles (see p. 310).

The same framework of eight possible mechanisms which were discussed for ester hydrolysis can also be applied to amide hydrolysis.[407] Both the acid- and base-catalyzed hydrolyses are essentially irreversible, since in both cases salts are formed. For basic catalysis[408] the mechanism is BAC2.

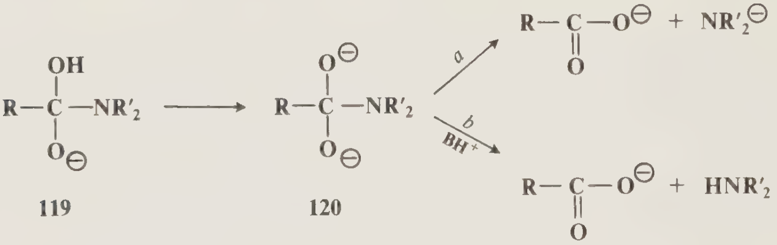


$$R-\underset{\underset{O}{\|}}{C}-NR'_2 + OH^- \underset{k_{-1}}{\overset{k_1\text{ slow}}{\rightleftharpoons}} R-\underset{\underset{O^{\ominus}}{|}}{\overset{\overset{OH}{|}}{C}}-NR'_2 \xrightarrow{k_2}$$

119

$$R-\underset{\underset{O}{\|}}{C}-OH + NR'^-_2 \longrightarrow R-\underset{\underset{O}{\|}}{C}-O^- + R'_2NH$$

There is much evidence for this mechanism, similar to that discussed for ester hydrolysis. In certain cases, kinetic studies have shown that the reaction is second order in OH^-, indicating that **119** can lose a proton to give **120**.[409] Depending on the nature of R′, **120** can cleave directly to give the two negative ions (path *a*) or become N-protonated prior to or during the act of cleavage (path *b*), in which case the products are obtained directly and a final proton transfer is not necessary.[410] Studies of the effect, on the rate of hydrolysis and on the ratio k_{-1}/k_2, of substituents on the atomatic rings in a series of amides $CH_3CONHAr$ led to the conclusion that path *a* is taken when Ar contains electron-withdrawing substituents, and path *b* when electron-donating groups are present.[411] The presence of electron-withdrawing groups helps to stabilize



119 **120**

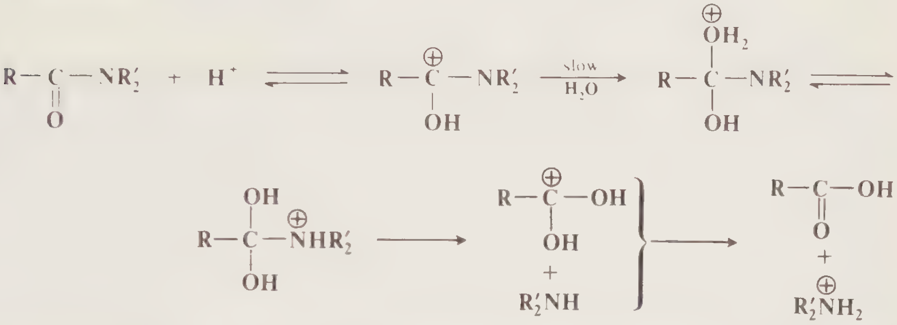
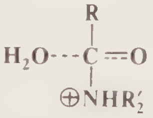
the negative charge on the nitrogen, so that NR'_2 can be a leaving group (path *a*). Otherwise, the C—N bond does not cleave until the nitrogen is protonated (either prior to or in the act of cleavage), so that the leaving group, *even in the base-catalyzed reaction*, is not NR'^-_2 but the conjugate NHR'_2 (path *b*). Though we have shown formation of **119** as the rate-determining step in the BAC2 mechanism, this is true only at high base concentrations. At lower concentrations of base, the cleavage of **119** or **120** becomes rate-determining.[412]

For acid catalysis, matters are less clear. The reaction is generally second order, and it is known that amides are primarily protonated on the oxygen (Chapter 8, Ref. 16). Because of these facts it has been generally agreed that most acid-catalyzed amide hydrolysis takes place by the AAC2 mechanism.



Further evidence for this mechanism is that a small but detectable amount of ^{18}O exchange (see p. 310) has been found in the acid-catalyzed hydrolysis of benzamide[413] (^{18}O exchange has also been detected for the base-catalyzed process,[414] in accord with the BAC2 mechanism). However, on the basis of certain kinetic results, it has been suggested[415] that acid-catalyzed amide hydrolysis in at least some cases takes place partially or exclusively on the small amount of N-protonated amide,[416] either with the transition state **121** or by simultaneous attack by H_2O



121

and departure of NHR'_2. The latter, if true, would be a rare example of an SN2 mechanism at a carbonyl carbon. Kinetic data have shown that three molecules of water are involved in the rate-determining step,[417] suggesting that, as in the AAC2 mechanism for ester hydrolysis (**0-11**), additional water molecules take part in a process such as

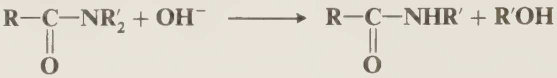
The four mechanisms involving alkyl—N cleavage (the AL mechanisms) do not apply to this reaction. They are not possible for unsubstituted amides, since the only N—C bond is the acyl bond. They are possible for N-substituted and N,N-disubstituted amides, but in these cases they give entirely different products and are not amide hydrolyses at all.

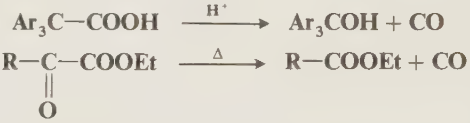


$$R-\underset{\underset{O}{\|}}{C}-NR'_2 + OH^- \longrightarrow R-\underset{\underset{O}{\|}}{C}-NHR' + R'OH$$

This reaction, while rare, has been observed for various N-*t*-butyl amides in 98% sulfuric acid, where the mechanism was the AAL1 mechanism,[418] and for certain amides containing an azo group, where a BAL1 mechanism was postulated.[419] Of the two first-order acyl cleavage mechanisms, only the AAC1 has been observed, in concentrated sulfuric acid solutions.[420] Of course, the diazotization of unsubstituted amides might be expected to follow this mechanism, and there is evidence that this is true.[405]

OS **I,** 14, 111, 194, 201, 286; **II,** 19, 25, 28, 49, 76, 208, 330, 374, 384, 457, 462, 491, 503, 519, 612; **III,** 66, 88, 154, 256, 410, 456, 586, 591, 661, 735, 768, 813; **IV,** 39, 42, 55, 58, 420, 441, 496, 664; **V,** 27, 96, 341, 471, 612, 627; **51,** 53; **55,** 114.

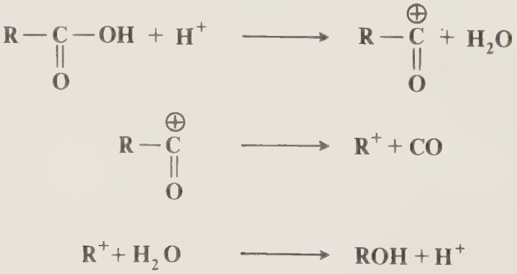
0-13 Decarbonylation of Esters and Acids



$$Ar_3C-COOH \xrightarrow{H^+} Ar_3COH + CO$$

$$R-\underset{\underset{O}{\|}}{C}-COOEt \xrightarrow{\Delta} R-COOEt + CO$$

Decarbonylations of esters and acids are not general reactions. Only certain acids can be decarbonylated in this manner: formic, oxalic, triarylacetic, α-hydroxy, and α-keto acids. Most but not all α-keto esters can be decarbonylated simply by heating. The mechanisms are little known,[421] and the reactions are included in this chapter because at least in some cases this mechanism has been demonstrated:[422]



$$R-\underset{\underset{O}{\|}}{C}-OH + H^+ \longrightarrow R-\overset{\oplus}{\underset{\underset{O}{\|}}{C}} + H_2O$$

$$R-\overset{\oplus}{\underset{\underset{O}{\|}}{C}} \longrightarrow R^+ + CO$$

$$R^+ + H_2O \longrightarrow ROH + H^+$$

This is an SN1 mechanism. The cleavage of the acyl cation is analogous to the cleavage of the diazonium ion RN_2^+.

OS **I,** 10; **II,** 279, 288, 531; **IV,** 141.

The oxidation of aldehydes to carboxylic acids can proceed by a nucleophilic mechanism, but more often it does not. The reaction is considered in Chapter 14 (reaction **4-6**). Basic cleavage of β-keto esters and the haloform reaction could be considered at this point, but they are also electrophilic substitutions and are treated in Chapter 12 (reactions **2-42** and **2-43**).

C. Attack by OR at an Alkyl Carbon

0-14 Alkylation with Alkyl Halides. The Williamson Reaction

$$\mathbf{RX + OR'^- \longrightarrow ROR'}$$

The *Williamson reaction*, discovered in 1850, is still the best general method for the preparation of unsymmetrical ethers or, for that matter, symmetrical ones.[423] The reaction can also be carried out with aromatic R′, though C-alkylation is sometimes a side reaction (see p. 337). The method is not successful for tertiary R (because of elimination), and low yields are obtained with secondary R. Many other functional groups may be present in the molecule without interference. Ethers in which one group is tertiary *can* be prepared by treatment of an alkyl halide or sulfate ester (reaction **0-16**) with a tertiary alkoxide $R'O^-$, which is prepared by removal of a proton from a tertiary alcohol with methylsulfinyl carbanion;[424] or with a copper(I) tertiary alkoxide.[425] Di-*t*-butyl ether was prepared in high yield by direct attack by *t*-BuOH on the *t*-butyl cation (at −80 C in SO_2ClF).[425a] Active halides such as Ar_3CX may react directly with the alcohol without need for the more powerful nucleophile alkoxide ion.[426] Even tertiary halides have been converted to ethers in this way, with no elimination.[427] The mechanism in these cases is of course SN1. *gem*-Dihalides react with alkoxides to give acetals, and 1,1,1-trihalides give ortho esters.[428]

Hydroxy groups may be protected by reaction of their salts with chloromethyl methyl ether.

$$\mathbf{RO^- + CH_3OCH_2Cl \longrightarrow ROCH_2OCH_3}$$

The resulting acetals are stable to bases and are easily cleaved with mild acid treatment (**0-7**).[429] Phenacyl bromides ($ArCOCH_2Br$) have also been used for this purpose.[430] The resulting ethers can easily be hydrolyzed with zinc and acetic acid. Aryl cyanates[431] can be prepared by reaction of phenols with cyanogen halides in the presence of a base: $ArO^- + ClCN \rightarrow ArOCN + Cl^-$.[432] This reaction has also been applied to certain alkyl cyanates.[433]

An efficient procedure for the synthesis of phenolic ethers by the Williamson reaction makes use of *phase-transfer catalysis*.[434] The phenol ArOH is added to a two-phase system consisting of water, CH_2Cl_2, a quaternary ammonium hydroxide $R'_4N^+\ \ OH^-$,[435] and the alkyl halide RX. The alkyl halide is soluble only in the CH_2Cl_2, and the $R'_4N^+\ \ OH^-$ only in the water. The phenol is soluble in both phases, but in the water it is converted by the base to ArO which has a small solubility in CH_2Cl_2. Once in this solvent it is quickly converted to the ether ArOR.[435] Phase-transfer-catalyzed Williamson reactions have also been used to prepare dialkyl ethers.[435a]

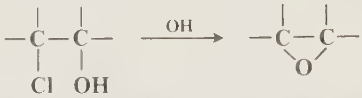
0-15 Epoxide Formation



This is a special case of reaction **0-14.** Many epoxides have been made in this way.[436] The method can also be used to prepare larger cyclic ethers: five- and six-membered rings. Additional treatment with base yields the glycol (reaction **0-8**). The base removes the proton from the OH group, and the epoxide then attacks in an internal SN2 reaction. There is much evidence for this mechanism.[437]

OS **I,** 185, 233; **II,** 256; **III,** 835.

0-16 Alkylation with Inorganic Esters

$$\mathbf{R{-}OSO_2OR'' + R'O^- \longrightarrow ROR'}$$

The reaction of alkyl sulfates with alkoxide ions is quite similar to reaction **0-14** in mechanism and scope. Other inorganic esters may also be used. However, the most common usage of this reaction is the formation of methyl ethers of alcohols and phenols by treatment of alkoxides or aroxides with methyl sulfate. Organic esters sometimes give ethers when treated with alkoxides (BAL2 mechanism, p. 352) in a very similar process (also see reaction **0-25**).

OS **I,** 58, 537; **II,** 387, 619; **III,** 127, 564, 800; **IV,** 588; **53,** 90. Also see OS **V,** 431.

0-17 Alkylation with Diazo Compounds[438]

$$\mathbf{R_2CN_2 + ArOH \longrightarrow R_2CHOAr}$$

$$\mathbf{CH_2N_2 + ROH \xrightarrow{HBF_4} CH_3OR}$$

Reaction with alcohols is general for diazo compounds, but it is most often performed with diazomethane to produce methyl ethers, or with diazo ketones to produce α-keto ethers, since these kinds of diazo compounds are most readily available. With diazomethane the method is expensive and requires great caution. It is used chiefly to methylate alcohols and phenols which are expensive or available in small amounts, since the conditions are mild and high yields are obtained. Hydroxy compounds react better as their acidity increases, and ordinary alcohols do not react at all unless HBF_4[439] or $AlCl_3$[440] is present as a catalyst. The more acidic phenols react very well in the absence of a catalyst. Oximes, and ketones which have substantial enolic contributions, give O-alkylation to form, respectively, O-alkyl oximes and enol ethers. The mechanism is as in reaction **0-6**:

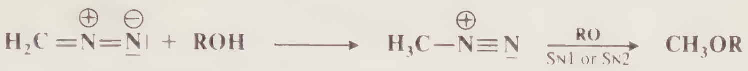
[438] For reviews, see Zollinger, "Azo and Diazo Chemistry," pp. 68–71, 102–108, Interscience Publishers, Inc., New York, 1961; Ref. 423, pp. 478–484.



$$H_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}| + ROH \longrightarrow H_3C{-}\overset{\oplus}{N}{\equiv}\underline{N} \xrightarrow[\text{SN1 or SN2}]{RO} CH_3OR$$

Diazoalkanes can also be converted to ethers by thermal or photochemical cleavage in the presence of an alcohol. In such cases there is a carbene intermediate and the mechanism is SN1cB (p. 330).[441] A carbene intermediate is also involved when diazoalkanes react with alcohols in the presence of *t*-BuOCl to give acetals:[442]

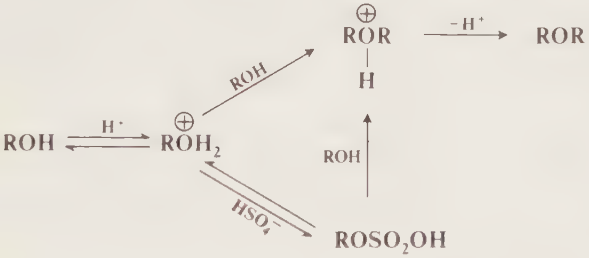
$$R_2CN_2 + 2R'OH \xrightarrow{t\text{-BuOCl}} R_2C(OR')_2$$

OS V, 245. Also see OS V, 1099.

0-18 Dehydration of Alcohols

$$2ROH \xrightarrow{H_2SO_4} ROR + H_2O$$

The dehydration of alcohols to form ethers[443] is analogous to reactions **0-14** and **0-16**, but the species from which the leaving group departs is ROH_2^+ or $ROSO_2OH$. The former is obtained directly on treatment of alcohols with sulfuric acid and may go, by an SN1 or SN2 pathway, directly to the ether if attacked by another molecule of alcohol. On the other hand, it may, again by either an SN1 or SN2 route, be attacked by the nucleophile HSO_4^-, in which case it is converted to $ROSO_2OH$, which in turn may be attacked by an alcohol molecule to give ROR. These processes are summarized:



Elimination is always a side reaction and, in the case of tertiary alkyl substrates, completely predominates.

The ether prepared is symmetrical. Mixed ethers can be prepared if one group is tertiary alkyl and the other primary or secondary, since the latter group is not likely to compete with the tertiary group in the formation of the carbonium ion, while a tertiary alcohol is a very poor nucleophile. If one group is not tertiary, then the reaction of a mixture of two alcohols leads to all three possible ethers. Glycols can be converted to cyclic ethers, though the reaction is most successful for five-membered rings. Thus, 1,6-hexanediol gives mostly 2-ethyltetrahydrofuran. This reaction is also important in preparing furfural derivatives from aldoses, with concurrent elimination:

Phenols and primary alcohols form ethers when heated with dicyclohexylcarbodiimide[444] (see reaction **0-24**). 1,2-Glycols can be converted to epoxides by treatment with dimethylformamide dimethyl acetal $[(MeO)_2CHNMe_2]$,[445] or with the diaryldialkoxysulfurane $Ph_2S[OCPh(CF_3)_2]_2$.[446]

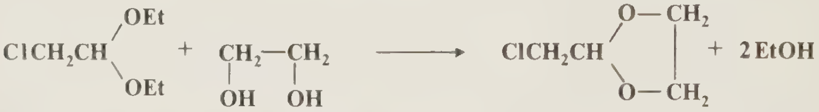
0-19 Transetherification

$$ROR' + R''OH \longrightarrow ROR'' + R'OH$$

The exchange of one alkoxyl group for another is very rare for *ethers*, though it has been accomplished with reactive R, for example, diphenylmethyl, with *p*-toluenesulfonic acid as a catalyst,[447] and by treatment of alkyl aryl ethers with alkoxide ions: $ROAr + R'O^- \rightarrow ROR' + ArO^-$.[448] However, acetals and ortho esters undergo transetherification readily,[449] for example,[450]



because, as we have seen (reaction **0-7**), departure of the leaving group from an acetal gives a particularly stable carbonium ion. These are equilibrium reactions, and most often the equilibrium is shifted by removing the lower-boiling alcohol by distillation. Enol ethers can be prepared by treating an alcohol with an enol ester or a different enol ether, with mercuric acetate as a catalyst,[451] e.g.,

$$ROCH{=}CH_2 + R'OH \xrightarrow{Hg(OAc)_2} R'OCH{=}CH_2 + ROH$$

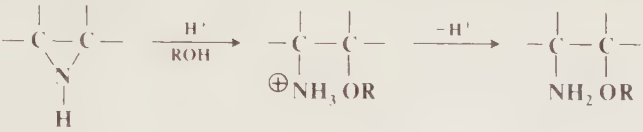
This reaction is analogous to reaction **0-8**. It may be acid- or base-catalyzed and may occur by either an SN1 or SN2 mechanism. Many of the β-hydroxy ethers produced in this way are valuable solvents, for example, diethylene glycol, Cellosolve, etc. Aziridines may similarly be converted to β-amino ethers.[452]



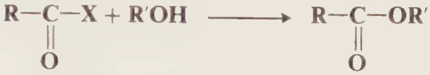
0-21 Alkylation with Onium Salts

$$R_3O^+ + R'OH \longrightarrow ROR' + R_2O$$

Oxonium ions are excellent alkylating agents, and ethers can be conveniently prepared by treating them with alcohols or phenols.[453] Quaternary ammonium salts can sometimes also be used.[454]

D. Attack by OR at an Acyl Carbon

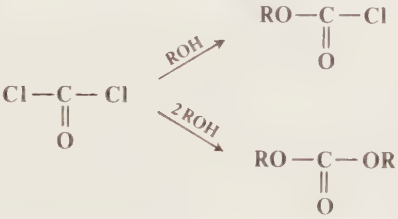
0-22 Alcoholysis of Acyl Halides



$$R-\underset{\underset{O}{\|}}{C}-X + R'OH \longrightarrow R-\underset{\underset{O}{\|}}{C}-OR'$$

The reaction between acyl halides and alcohols is the best general method for the preparation of esters.[455] The reaction is of wide scope, and many functional groups do not interfere. A base is frequently added to combine with the HX which is formed. When aqueous alkali is used, this is called the *Schotten-Baumann procedure*, but pyridine is also frequently used. Both R and R′ may be primary, secondary, or tertiary alkyl, or aryl. Enolic esters can also be prepared by this method, although C-acylation competes in these cases. In difficult cases, especially with hindered acids, or for tertiary R′, the alkoxide may be used instead of the alcohol.[456] Thallium salts of phenols give very high yields of phenolic esters.[457]

When phosgene is the acyl halide, haloformic esters[458] or carbonates may be obtained.



An important example is the preparation of carbobenzoxy chloride ($PhCH_2OCOCl$) from phosgene and benzyl alcohol. This compound is widely used for protection of amino groups during peptide synthesis (see reaction **0-54**).

[455] For a review, see Sonntag, *Chem. Rev.* **52**, 237–416 (1953), pp. 312–324.

[456] For an example, see Kaiser and Woodruff, *J. Org. Chem.* **35**, 1198 (1970).

[457] Taylor, McLay, and McKillop, *J. Am. Chem. Soc.* **90**, 2422 (1968).

[458] For a review of this method as applied to the synthesis of chloroformates, see Matzner, Kurkjy, and Cotter, *Chem. Rev.* **64**, 645–687 (1964).

As with reaction **0-9**, the mechanism may be S_N1 or tetrahedral.[379] In the tetrahedral mechanism there is evidence (the reaction is second order or higher in ROH) that the OH proton is lost or partially lost in the rate-determining step.[459] Pyridine catalyzes the reaction by the nucleophilic catalysis route (see reaction **0-10**).

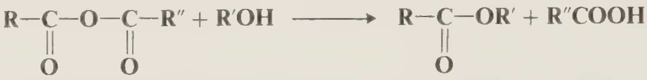
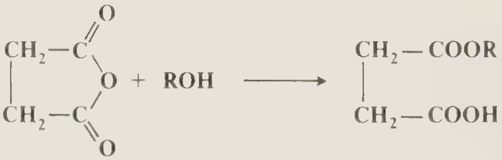
0-23 Alcoholysis of Anhydrides



$$\underset{\overset{\|}{O}}{R-C}-O-\underset{\overset{\|}{O}}{C}-R'' + R'OH \longrightarrow \underset{\overset{\|}{O}}{R-C}-OR' + R''COOH$$

The scope of this reaction is similar to that of reaction **0-22**. Though anhydrides are somewhat less reactive than acyl halides, they are often used to prepare esters. Acids, Lewis acids, and bases are often used as catalysts—most often, pyridine. Catalysis by pyridine is of the nucleophilic type; that is, there are two tetrahedral mechanisms (see reaction **0-10**). 4-(N,N-Dimethylamino)pyridine is a better catalyst than pyridine and can be used in cases where pyridine fails.[460] Formic anhydride is not a stable compound (see p. 493), but esters of formic acid can be prepared by treating alcohols[461] or phenols[462] with acetic-formic anhydride. Cyclic anhydrides give mono-esterified dicarboxylic acids, for example,



Alcohols can also be acylated by mixed organic-inorganic anhydrides, such as acetic-phosphoric anhydride $MeCOOPO(OH)_2$[463] (see reaction **0-34**).

Certain mixed anhydrides can be converted to esters simply by heating. An example is the mixed anhydride of levulinic and methylcarbonic acids, which gives pseudomethyl levulinate (**122**).[464] This reason takes place by a [3.2.1] bicyclic mechanism.

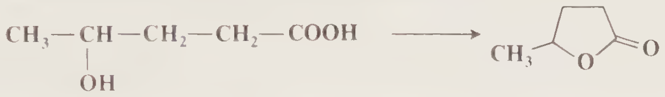
0-24 Esterification of Acids

$$\mathrm{RCOOH + R'OH \xrightleftharpoons{H} RCOOR' + H_2O}$$

The esterification of acids with alcohols is the reverse of reaction **0-12** and can be accomplished only if a means is available to drive the equilibrium to the right. There are many ways of doing this, among which are: (1) addition of an excess of one of the reactants, usually the alcohol; (2) removal of the ester or the water by distillation; and (3) removal of water by use of a dehydrating agent or a molecular sieve.[465] When R′ is methyl, the most common way of driving the equilibrium is by adding excess MeOH; when R′ is ethyl, it is preferable to remove water by distillation.[466] The most common catalysts are H_2SO_4 and TsOH, though some reactive acids (e.g., formic) do not require a catalyst. Besides methyl and ethyl, R′ may be other primary or secondary alkyl groups, but tertiary alcohols usually give carbonium ions and elimination. Phenols can sometimes be used to prepare phenolic esters, but yields are generally very low.

γ- and δ-hydroxy acids are easily lactonized by treatment with acids, or often simply on standing, but larger and smaller lactone rings cannot generally be made in this manner, because



polyester formation occurs more readily. However, sometimes the polyester can be converted to the lactone. Often the conversion of a group such as keto or halogen, γ or δ to a carboxyl group, to a hydroxyl group gives the lactone directly, since the hydroxy acid cyclizes too rapidly for isolation. β-Substituted β-hydroxy acids can be converted to β-lactones by treatment with benzenesulfonyl chloride in pyridine at 0 to 5 C.[467] ε-Lactones (seven-membered rings) have been made by cyclization of ε-hydroxy acids at high dilution.[468] Macrocyclic lactones can be prepared indirectly in very good yields by conversion of the hydroxy acids to 2-pyridinethiol esters and adding these to refluxing xylene.[469]

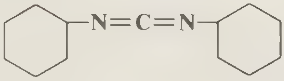
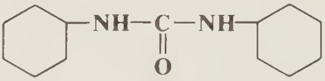
[469] Corey and Nicolaou, *J. Am. Chem. Soc.* **96,** 5614 (1974); Corey, Nicolaou, and Melvin, *J. Am. Chem. Soc.* **97,** 653, 655 (1975); Gerlach and Thalmann, *Helv. Chim. Acta* **57,** 2661 (1974).

Esterification is catalyzed by acids (not bases) in ways that were discussed on p. 349.[387] The mechanisms are usually AAC2, but AAC1 and AAL1 have also been observed.[470] Certain acids, such as 2,6-di-ortho-substituted benzoic acids, cannot be esterified by the AAC2 mechanism, because of steric hindrance (p. 316). In such cases, esterification may be accomplished by dissolving the acid in 100% H_2SO_4 (forming the ion RCO^+) and pouring the solution into the alcohol (AAC1 mechanism). The reluctance of hindered acids to undergo the normal AAC2 mechanism can sometimes be put to advantage when, in a molecule containing two COOH groups, only the less hindered one is esterified. The AAC1 pathway cannot be applied to unhindered carboxylic acids.

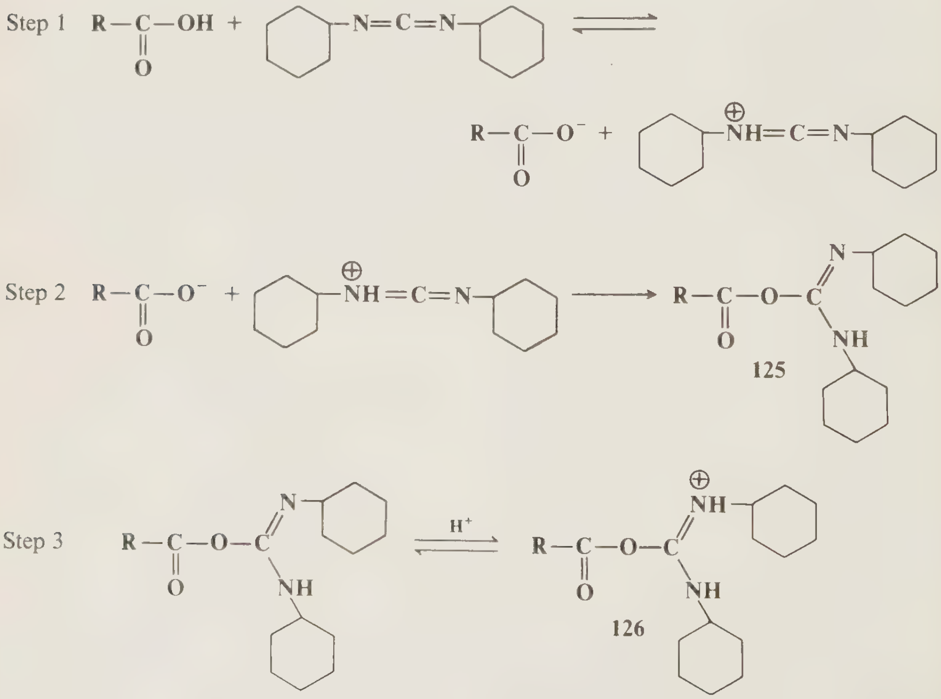
Another way to esterify an acid is to treat it with an alcohol in the presence of a dehydrating agent. One of the most common of these is dicyclohexylcarbodiimide (**123**), which is converted in the process to dicyclohexylurea (**124**). The mechanism[471] has much in common with the nucleophilic catalysis mechanism: the acid is converted to a compound with a better leaving group. However, the conversion is not by a tetrahedral mechanism (as it is in nucleophilic catalysis), since the C—O bond remains intact during this step:



123



124



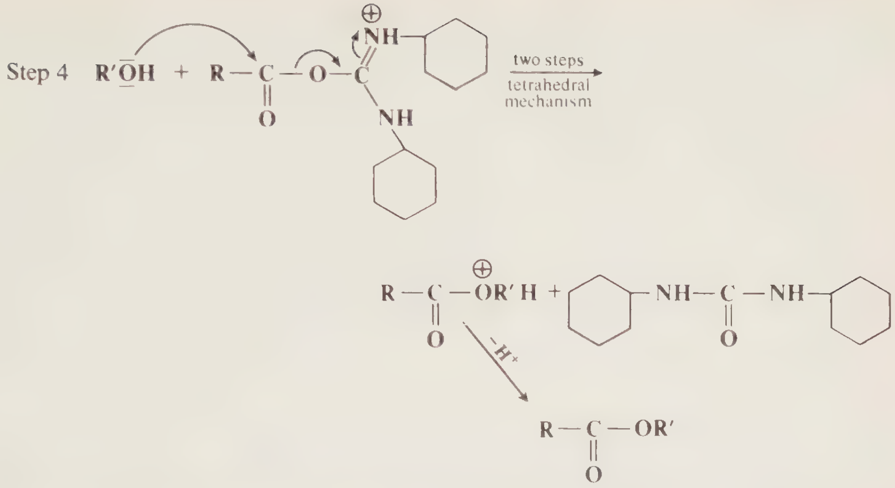
125

126

---

[470] For a review of aspects of the mechanism, see Ref. 426, pp. 466–481.

[471] Smith, Moffat, and Khorana, *J. Am. Chem. Soc.* **80**, 6204 (1958).



Evidence for this mechanism was the preparation of O-acylureas similar to **125** and the finding that when catalyzed by acids they react with alcohols to give esters.[472] Other reagents which promote the reaction are trifluoroacetic anhydride,[473] H_3BO_3–H_2SO_4,[474] polymer-protected $AlCl_3$,[475] pyridinium salts-Bu_3N,[475a] and N,N'-carbonyldiimidazole (**127**).[406] In the latter case easily alcoholyzed imidazolides (**118**) are intermediates. BF_3 promotes the esterification by converting the acid to RCO^+ BF_3OH^-, so that the reaction proceeds by an AAC1 type of mechanism. The use of BF_3-etherate is simple and gives high yields.[476] Carboxylic esters may also be prepared by treating carboxylic acids with *t*-butyl ethers and acid catalysts:[477]

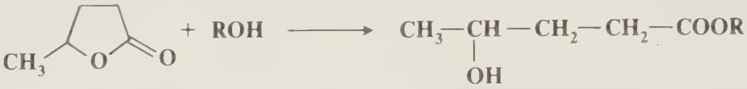
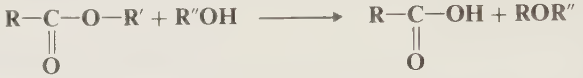
[477] Derevitskaya, Klimov, and Kochetkov, *Tetrahedron Lett.* 4269 (1970).

Transesterification is catalyzed by acids or bases. It is an equilibrium reaction and must be shifted in the desired direction. In many cases low-boiling esters may be converted to higher ones by distillation of the lower-boiling alcohol as fast as it is formed. Lactones are easily opened by treatment with alcohols to give open-chain hydroxy esters:



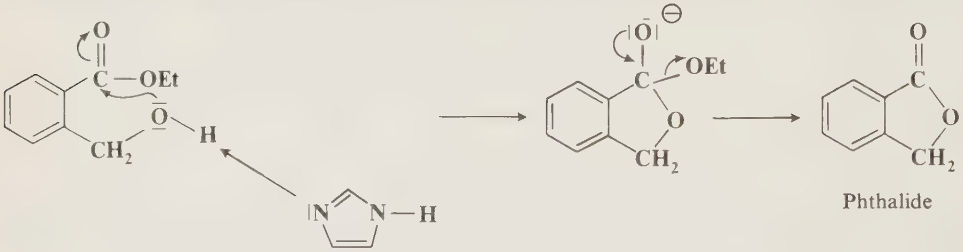
Transesterification occurs by mechanisms[478] which are identical with those of ester hydrolysis—except that ROH replaces HOH that is, by the acyl-oxygen fission mechanisms. When alkyl fission takes place, the products are the *acid* and the *ether*:



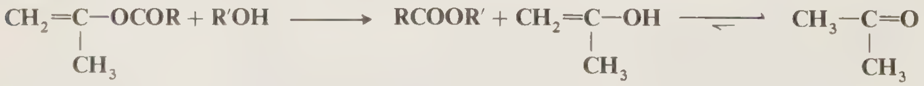
$$\mathrm{R-\underset{\overset{\|}{O}}{C}-O-R' + R''OH \longrightarrow R-\underset{\overset{\|}{O}}{C}-OH + ROR''}$$

Therefore, transesterification reactions frequently fail when R′ is tertiary, since this type of substrate most often reacts by alkyl-oxygen cleavage. In such cases, the reaction is of the Williamson type with OCOR as the leaving group (see reaction **0-16**).

It has been shown that intramolecular transesterification of ethyl 2-hydroxymethylbenzoate to give phthalide can be catalyzed by imidazole and other bases.[479] It is likely that the catalyst functions by assisting removal of the O—H proton in the rate-determining step (general base catalysis). Similar catalysis has been shown in the conversion of 2-hydroxymethylbenzamide to phthalide.[480] These reactions serve as a model for hydrolysis of esters and amides by α-chymotrypsin. This enzyme has a serine group [—NHCH(CH_2OH)CO—] in position 195. The OH group of the serine reacts with the ester or amide, releasing the alcohol or amine portion. This reaction is catalyzed by a histidine residue in the 57 position of the enzyme. Histidine contains an imidazole ring, and the catalysis is believed to follow the model shown above. Following this reaction, the acylated serine residue is deacylated to regenerate the active enzyme. Transesterification can also be catalyzed by CO_2.[481]



With enol esters, the free alcohol is the enol of a ketone, so such esters easily undergo the reaction



$$\mathrm{CH_2{=}\underset{CH_3}{\underset{|}{C}}-OCOR + R'OH \longrightarrow RCOOR' + CH_2{=}\underset{CH_3}{\underset{|}{C}}-OH \rightleftharpoons CH_3-\underset{CH_3}{\underset{|}{C}}{=}O}$$

---

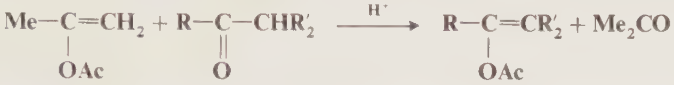
[478] For a review, see Koskikallio, in Patai, Ref. 188, pp. 103–136.

[479] Fife and Benjamin, *J. Am. Chem. Soc.* **95,** 2059 (1973). See also Kirby and Lloyd, *J. Am. Chem. Soc., Perkin Trans. 2* 637 (1974); Fife and Benjamin, *J. Chem. Soc., Chem. Commun.* 525 (1974); Pollack and Dumsha, *J. Am. Chem. Soc.* **97,** 377 (1975); Chiong, Lewis, and Shafer, *J. Am. Chem. Soc.* **97,** 418 (1975).

[480] Belke, Su, and Shafer, *J. Am. Chem. Soc.* **93,** 4552 (1971).

[481] Otsuji, Matsumura, and Imoto, *Bull. Chem. Soc. Jpn.* **44,** 852 (1971).

Hence, enol esters such as isopropenyl acetate are good acylating agents for alcohols.[482] Isopropenyl acetate can also be used to convert other ketones to the corresponding enol acetates in an exchange reaction:[483]



$$\underset{\text{OAc}}{\text{Me—C}}\text{=CH}_2 + \underset{\text{O}}{\underset{\|}{\text{R—C}}}\text{—CHR}'_2 \xrightarrow{\text{H}^+} \underset{\text{OAc}}{\text{R—C}}\text{=CR}'_2 + \text{Me}_2\text{CO}$$

Enol esters can also be prepared in the opposite type of exchange reaction, catalyzed by mercuric acetate[484] or by Pd(II) chloride,[485] e.g.,

$$\text{RCOOH} + \text{R}'\text{COOCH=CH}_2 \xrightleftharpoons[\text{H}_2\text{SO}_4]{\text{Hg(OAc)}_2} \text{RCOOCH=CH}_2 + \text{R}'\text{COOH}$$

A closely related reaction is equilibration of a dicarboxylic acid and its diester to produce monoesters:

$$\text{ROCO(CH}_2)_n\text{COOR} + \text{HOOC(CH}_2)_n\text{COOH} \rightleftharpoons 2\text{ROCO(CH}_2)_n\text{COOH}$$

OS **II**, 5, 122, 360; **III**, 123, 146, 165, 231, 281, 581, 605; **IV**, 10, 549, 630; 977; **V**, 155, 545, 863; **55**, 39.

Alcoholysis of amides is possible but is seldom performed, except for the imidazolide type of amide (p. 353).

E. Attack by OCOR at an Alkyl Carbon

0-26 Alkylation of Acid Salts

$$\text{RX} + \text{R}'\text{COO}^- \xrightarrow{\text{HMPT}} \text{R}'\text{COOR}$$

Sodium salts of carboxylic acids, including hindered acids such as mesitoic, rapidly react with primary and secondary bromides and iodides at room temperature in dipolar aprotic solvents, especially HMPT, to give high yields of carboxylic esters.[486] The mechanism is SN2. Another method uses potassium carboxylates in acetonitrile or benzene in the presence of a crown ether such as 18-crown-6 (p. 82). With this method good yields of esters are obtained from primary, secondary, benzylic, and phenacyl bromides.[487] When the reaction is carried out without crown ethers and in protic solvents, it is useful only for fairly active R, such as benzyl, allyl, etc. (SN1 mechanism), but not for tertiary alkyl, since elimination occurs instead. The salts used are often sodium, but potassium, silver, and substituted ammonium salts have also been used Lactones can be prepared from γ- and δ-halo acids by treatment with base (see reaction **0-24**).

Copper(I) carboxylates give esters with primary (including neopentyl without rearrangement), secondary, and tertiary alkyl, allylic, and vinylic halides.[488] A simple SN mechanism is obviously precluded in this case. Primary and secondary halides also give esters when treated directly with carboxylic acids in the presence of Cu_2O and an isonitrile.[489] A copper carboxylate is an intermediate here. Vinyl halides can be converted to vinyl acetates by treatment with sodium acetate if palladium(II) chloride is present.[490] A COOH group can be conveniently protected by reaction of its ion with a phenacyl bromide ($ArCOCH_2Br$).[430] The resulting ester is easily cleaved when desired with zinc and acetic acid.

Other leaving groups may also be replaced by OCOR. Alkyl chlorosulfites (ROSOCl) and other derivatives of sulfuric, sulfonic, and other inorganic acids can be treated with carboxylate ions to give the corresponding esters. The use of dimethyl sulfate[491] or trimethyl phosphate[492] allows sterically hindered COOH groups to be methylated. With certain substrates, carboxylic acids are strong enough nucleophiles for the reaction. Examples of such substrates are trialkyl phosphites $P(OR)_3$[493] and acetals of dimethylformamide:[494]

$$(RO)_2CHNMe_2 + R'COOH \longrightarrow R'COOR + ROH + HCONMe_2$$

This is an SN2 process, since inversion is found at R. Tertiary amines containing one group which forms a stable carbonium ion (e.g., benzyl, *t*-butyl, triphenylmethyl) can be cleaved by acetic anhydride,[495] e.g.,

$$PhCH_2NMe_2 + Ac_2O \longrightarrow PhCH_2OAc + Me_2NCOCH_3$$

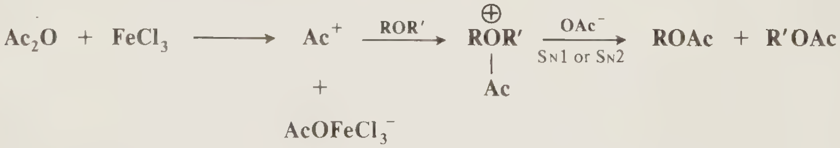
Amines which do not contain such groups do not react. Another good leaving group is NTs_2, and ditosylamines react quite well with acetate ion in dipolar aprotic solvents:[496] $RNTs_2 + OAc^- \rightarrow ROAc$. Quaternary ammonium salts can be cleaved by heating with AcO^- in an aprotic solvent.[497] Oxonium ions may also be used as substrates:[498] $R_3O^+ + R'COO^- \rightarrow R'COOR + R_2O$.

OS **II**, 5; **III**, 650; **IV**, 582; **V**, 580.

0-27 Cleavage of Ethers with Acetic Anhydride

$$R{-}O{-}R' + Ac_2O \xrightarrow{FeCl_3} ROAc + R'OAc$$

Dialkyl ethers can be cleaved by treatment with anhydrous ferric chloride in acetic anhydride.[499] In this reaction both R groups are converted to acetates. Yields are moderate to high. The mechanism has been formulated as



$$Ac_2O + FeCl_3 \longrightarrow \underset{\displaystyle AcOFeCl_3^-}{\underset{+}{Ac^+}} \xrightarrow{ROR'} \underset{\displaystyle Ac}{\overset{\oplus}{ROR'}} \xrightarrow[\text{SN1 or SN2}]{OAc^-} ROAc + R'OAc$$

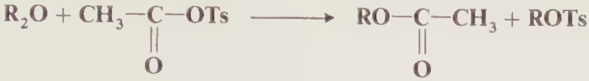
Ethers can also be cleaved by the mixed anhydride acetyl tosylate:[500]



$$R_2O + CH_3{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}OTs \longrightarrow RO{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}CH_3 + ROTs$$

0-28 Alkylation of Acids with Diazo Compounds

$$R_2CN_2 + R'COOH \longrightarrow R'COOCHR_2$$

Acids can be converted to esters with diazo compounds in a reaction which is essentially the same as reaction **0-17**. In contrast to alcohols, carboxylic acids undergo the reaction quite well at room temperature, since the reactivity of the reagent increases with acidity. The reaction is used where high yields are important or where the acid is sensitive to higher temperatures. Because of availability, the diazo compounds most often used are diazomethane (for methyl esters)

$$CH_2N_2 + RCOOH \longrightarrow RCOOCH_3$$

and diazo ketones. The mechanism is as shown in reaction **0-17**.

OS **V**, 797.

F. Attack by OCOR at an Acyl Carbon

0-29 Acylation of Acids with Acyl Halides

$$RCOCl + R'COO^- \longrightarrow RCOOCOR'$$

Unsymmetrical as well as symmetrical anhydrides are often prepared by the treatment of an acyl halide with an acid salt. If a metallic salt is used, then Na^+, K^+, or Ag^+ are the most common cations, but more often pyridine or another tertiary amine is added to the free acid, and the salt thus formed is treated with the acyl halide. Thallium(I) salts are particularly effective and react with acyl halides to give anhydrides in high yield.[457] Anhydrides which are unaffected by cold water may be made in high yield by shaking an aqueous solution of the sodium salt of an acid with an acyl halide at room temperature in the presence of a tertiary amine.[501] Acyl halides may also be converted to anhydrides by treatment with esters (with a $ZnCl_2$ catalyst) or with anhydrides (an exchange reaction), but these methods are seldom used. Symmetrical anhydrides can be prepared by treatment of acyl halides with dry N_2O_4.[502] The mixed anhydride $RCOONO_2$ is probably an intermediate which reacts with another molecule of RCOCl.

OS **III**, 28, 422, 488; **IV**, 285; **50**, 1; **51**, 48.

0-30 Acylation of Acids with Acids

$$2RCOOH \xrightleftharpoons{P_2O_5} (RCO)_2O + H_2O$$

Anhydrides can be formed from two molecules of an ordinary acid only if a dehydrating agent is present so that the equilibrium can be driven to the right. Common dehydrating agents are acetic anhydride, trifluoroacetic anhydride, dicyclohexylcarbodiimide,[503] methoxyacetylene,[504] and P_2O_5. The method is very poor for the formation of mixed anhydrides, which in any case generally undergo disproportionation to the two simple anhydrides when they are heated. However, simple heating of dicarboxylic acids does give cyclic anhydrides, provided that the ring formed contains five, six, or seven members. Malonic acid and its derivatives, which would give four-membered cyclic anhydrides, do not give this reaction when heated but instead undergo decarboxylation (reaction **2-39**).

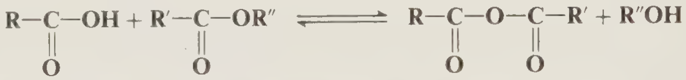
[501] Smalley and Suschitzky, *J. Chem. Soc.* 755 (1964).

[502] Svetlakov, Stepanova, and Shafigullin, *J. Org. Chem. USSR* **5**, 2183 (1969).

[503] For example, see Schüssler and Zahn, *Chem. Ber.* **95**, 1076 (1962); Rammler and Khorana, *J. Am. Chem. Soc.* **85**, 1997 (1963). See also Hata, Tajima, and Mukaiyama, *Bull. Chem. Soc. Jpn.* **41**, 2746 (1968).

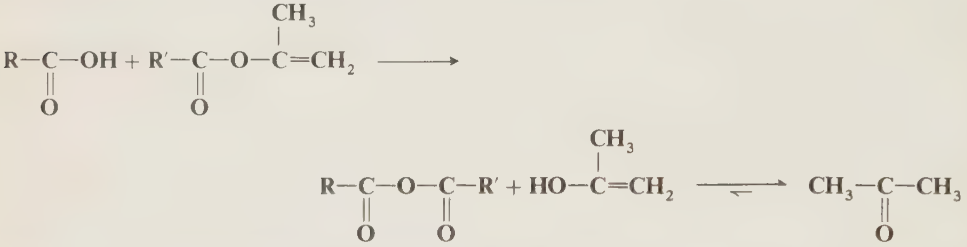
[504] See for example, Eglinton, Jones, Shaw, and Whiting, *J. Chem. Soc.* 1860 (1954); Arens and Doornbos, *Recl. Trav. Chim. Pays-Bas* **74**, 79 (1955).

Carboxylic acids exchange with amides and esters, and these methods are sometimes used to prepare anhydrides if the equilibrium can be shifted; e.g.,



$$\mathrm{R-\underset{\overset{\|}{O}}{C}-OH + R'-\underset{\overset{\|}{O}}{C}-OR'' \rightleftharpoons R-\underset{\overset{\|}{O}}{C}-O-\underset{\overset{\|}{O}}{C}-R' + R''OH}$$

Enolic esters are especially good for this purpose, since the equilibrium is shifted by formation of the ketone.



$$\mathrm{R-\underset{\overset{\|}{O}}{C}-OH + R'-\underset{\overset{\|}{O}}{C}-O-\overset{\overset{CH_3}{|}}{C}{=}CH_2 \longrightarrow}$$

$$\mathrm{R-\underset{\overset{\|}{O}}{C}-O-\underset{\overset{\|}{O}}{C}-R' + HO-\overset{\overset{CH_3}{|}}{C}{=}CH_2 \rightleftharpoons CH_3-\underset{\overset{\|}{O}}{C}-CH_3}$$

Acids also exchange with anhydrides; indeed, this is how acetic anhydride acts as a dehydrating agent in this reaction.

Anhydrides can be formed by treatment of the triethylammonium *salt* of a carboxylic acid with phosgene:[505]

$$\mathrm{2RCOO^{\ominus}\ \overset{\oplus}{N}HEt_3 \xrightarrow{COCl_2} RCOOCOR + 2\overset{\oplus}{N}HEt_3\ Cl^- + CO_2}$$

or of thallium(I) carboxylates with thionyl chloride,[457] or of mercury(II) carboxylates with a thioester.[506]

OS **I,** 91, 410; **II,** 194, 368, 560; **III,** 164, 449; **IV,** 242, 630, 790; **V,** 8, 822. Also see OS **54,** 79.

G. Other Oxygen Nucleophiles

0-31 Formation of Oxonium Salts

$$\mathrm{RX + R_2O \xrightarrow{AgBF_4} R_3O^+\ BF_4^- + AgX}$$

$$\mathrm{RX + R'_2CO \xrightarrow{AgBF_4} R'_2C{=}\overset{\oplus}{O}-R\quad BF_4^- + AgX}$$

Alkyl halides can be alkylated by ethers or ketones to give oxonium salts, if a very weak, negatively charged nucleophile is present to serve as a counterion and a Lewis acid is present to combine with X .[507] A typical procedure consists of treating the halide with the ether or the ketone in the presence of $AgBF_4$ or $AgSbF_6$. The Ag^+ serves to remove X^-, and the BF_4^- or SbF_6^- acts as the counterion. Another method involves treatment of the halide with a complex formed between the oxygen compound and a Lewis acid, e.g., $R_2O{-}BF_3 + RF \rightarrow R_3O^+ \; BF_4^-$, though this method is most satisfactory when the oxygen and halogen atoms are in the same molecule so that a cyclic oxonium ion is obtained. Ethers and oxonium ions also undergo exchange reactions:

$$2R_3O^+ \; BF_4^- + 3R'_2O \rightleftharpoons 2R'_3O^+ \; BF_4^- + 3R_2O$$

Other leaving groups have also been used.[508]

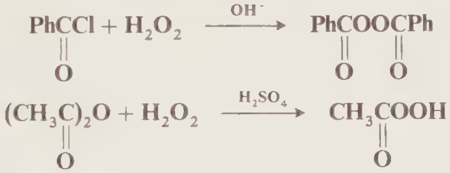
OS V 1080, 1096, 1099; **51**, 142.

0-32 Preparation of Peroxides and Hydroperoxides

$$2RX + O_2^{2-} \longrightarrow ROOR$$
$$RX + OOH^- \longrightarrow ROOH$$

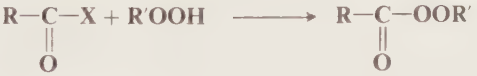
Hydroperoxides can be prepared by treatment of alkyl halides, esters of sulfuric or sulfonic acids, or alcohols with hydrogen peroxide in basic solution, where it is actually HO_2^-.[509] Sodium peroxide is similarly used to prepare dialkyl peroxides. For R = benzyl, the reaction has been shown to proceed by the S_N1cB mechanism with phenylcarbene (PhCH) as an intermediate.[510] Peroxides can also be prepared by treatment of alkyl bromides or tosylates with potassium superoxide KO_2 in the presence of crown ethers.[510a]

Acyl peroxides and hydroperoxides can be similarly prepared[511] from acyl halides or anhydrides,



$$\text{Ph}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{Cl} + \text{H}_2\text{O}_2 \xrightarrow{\text{OH}^-} \text{Ph}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{OO}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{Ph}$$
$$(\text{CH}_3\underset{\underset{\text{O}}{\|}}{\text{C}})_2\text{O} + \text{H}_2\text{O}_2 \xrightarrow{\text{H}_2\text{SO}_4} \text{CH}_3\underset{\underset{\text{O}}{\|}}{\text{C}}\text{OOH}$$

from carboxylic acids,[512] and from amides of the imidazolide type (p. 353).[513] Diacyl peroxides can also be prepared by the treatment of carboxylic acids with hydrogen peroxide in the presence of dicyclohexylcarbodiimide,[514] H_2SO_4, methanesulfonic acid, or some other dehydrating agent. Mixed alkyl-acyl peroxides (peresters) can be made from acyl halides and hydroperoxides.



$$\text{R}{-}\underset{\underset{\text{O}}{\|}}{\text{C}}{-}\text{X} + \text{R}'\text{OOH} \longrightarrow \text{R}{-}\underset{\underset{\text{O}}{\|}}{\text{C}}{-}\text{OOR}'$$

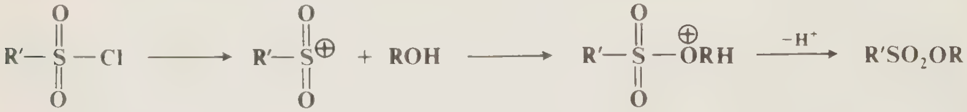
0-33 Preparation of Inorganic Esters

$$\begin{aligned}
&ROH + HONO_2 \xrightarrow{H^+} RONO_2\\
&ROH + HONO \xrightarrow{H^+} RONO\\
&ROH + SOCl_2 \longrightarrow ROSOOR\\
&ROH + POCl_3 \longrightarrow PO(OR)_3\\
&ROH + SO_3 \longrightarrow ROSO_2OH
\end{aligned}$$

The above reactions show a few of the many inorganic esters which can be prepared by attack of an inorganic acid or, better, its acid halide or anhydride, on an alcohol.[515] Although for convenience all these similar reactions are grouped together, the mechanism in many cases is not nucleophilic substitution at the alcoholic carbon. The other possible mechanism is nucleophilic substitution at the inorganic central atom:



$$R'-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-Cl \longrightarrow R'-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}{}^{\oplus} + ROH \longrightarrow R'-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-\overset{\oplus}{O}RH \xrightarrow{-H^+} R'SO_2OR$$

or a corresponding SN2 type (see p. 449). In such cases there is no alkyl-O cleavage. Alkyl and aryl sulfates can be prepared by treatment of the alcohol or phenol with H_2SO_4 in the presence of dicyclohexylcarbodiimide.[516] Mono esters of sulfuric acid (alkylsulfuric acids), which are important industrially because their salts are used as detergents, can be prepared by treating alcohols with SO_3, H_2SO_4, $ClSO_2OH$, or SO_3 complexes.[517]

Alkyl halides are often used as substrates instead of alcohols. In such cases the *salt* of the inorganic acid is usually used, and the mechanism is nucleophilic substitution at the carbon atom. An important example is the treatment of alkyl halides with silver nitrate to form alkyl nitrates. This is often used as a test for alkyl halides. In some cases there is competition from the central atom. Thus nitrite ion is an ambident nucleophile which can give nitrites or nitro compounds (see reaction **0-62**). In some cases ethers may be substrates. Thus dialkyl or aryl alkyl ethers may be cleaved with anhydrous sulfonic acids:[518]

$$ROR' + R''SO_2OH \longrightarrow ROSO_2R'' + R'OH$$

R″ may be alkyl or aryl. For dialkyl ethers, the reaction does not end as indicated above, since R′OH is rapidly converted to R′OR′ by the sulfonic acid (reaction **0-18**), which in turn is further cleaved to $R'OSO_2R''$ so that the product is a mixture of the two sulfonates. For aryl alkyl ethers, cleavage always takes place to give the phenol, which is not converted to the ether under these conditions. Ethers can also be cleaved in a similar manner by mixed anhydrides of sulfonic and carboxylic acids[519] (prepared as in reaction **0-34**).

OS **II,** 106, 108, 109, 112, 204, 412; **III,** 148, 471; **IV,** 955; **V,** 839. Also see OS **II,** 111.

0-34 Preparation of Mixed Organic-Inorganic Anhydrides[520]

$$(RCO)_2O + HONO_2 \longrightarrow RCOONO_2$$

---

[515] For a review, see Ref. 426, pp. 481-497.

[516] Hoiberg and Mumma, *J. Am. Chem. Soc.* **91,** 4273 (1969).

[517] For a review, see Sandler and Karo, Ref. 180, vol. 3, pp. 114-133 (1972).

[518] Klamann and Weyerstahl, *Chem. Ber.* **98,** 2070 (1965).

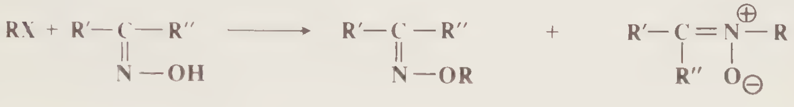
[519] Karger and Mazur, *J. Org. Chem.* **36,** 532, 540 (1971).

[520] For a review, see Satchell, *Q. Rev., Chem. Soc.* **17,** 160-203 (1963), pp. 179-181.

Mixed organic-inorganic anhydrides are seldom isolated, though they are often intermediates when acylation is carried out with acid derivatives catalyzed by inorganic acids. Sulfuric, perchloric, phosphoric, and other acids form similar anhydrides, most of which are unstable or not easily obtained because the equilibrium lies in the wrong direction. These intermediates are formed from amides, acids, and esters, as well as from anhydrides. Organic anhydrides of phosphoric acid are more stable than most others and, for example, $RCOOPO(OH)_2$ can be prepared in the form of its salts.[521] Mixed anhydrides of carboxylic and sulfonic acids ($RCOOSO_2R'$) are obtained in high yields by treatment of sulfonic acids with acyl halides or (less preferred) anhydrides.[522]

OS **I**, 495; **50**, 9.

0-35 Alkylation of Oximes



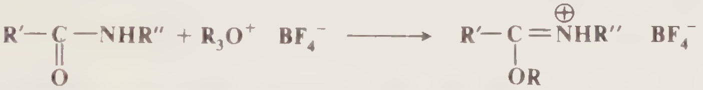
$$RX + R'-\underset{\underset{\displaystyle N-OH}{\|}}{C}-R'' \longrightarrow R'-\underset{\underset{\displaystyle N-OR}{\|}}{C}-R'' + R'-\underset{\underset{\displaystyle R''}{|}}{C}=\overset{\oplus}{\underset{\underset{\displaystyle O^{\ominus}}{|}}{N}}-R$$

A nitrone

Oximes may be alkylated by alkyl halides or sulfates. N-alkylation is a side reaction, yielding a nitrone. The relative yield of oxime ether and nitrone depends on the nature of the reagents, including the configuration of the oxime, and on the reaction conditions. For example, *anti*-benzaldoximes give nitrones, while the syn isomers give oxime ethers.[523]

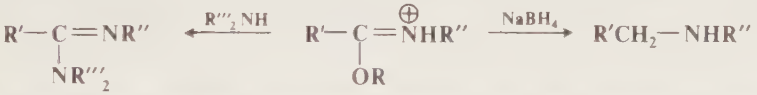
OS **III**, 172; **V**, 1031. Also see OS **V**, 269.

0-36 Alkylation of Amides and Other Carbonyl Compounds[524]



$$R'-\underset{\underset{\displaystyle O}{\|}}{C}-NHR'' + R_3O^+\ BF_4^- \longrightarrow R'-\underset{\underset{\displaystyle OR}{|}}{C}=\overset{\oplus}{N}HR''\ BF_4^-$$

The oxygen atom of amides can be alkylated by oxonium salts to give salts of N-alkylimino esters. These ions can then be treated with a variety of nucleophiles. For example, they can be reduced to amines with $NaBH_4$ or converted to amidines with secondary amines.[525] The reaction



$$R'-\underset{\underset{\displaystyle NR'''_2}{|}}{C}=NR'' \xleftarrow{R'''_2NH} R'-\underset{\underset{\displaystyle OR}{|}}{C}=\overset{\oplus}{N}HR'' \xrightarrow{NaBH_4} R'CH_2-NHR''$$

is also good for lactams, lactones, and esters of carbonic acid but is generally unsuccessful for aldehydes, ketones, and open-chain carboxylic esters.

0-37 Acylation at the Oxygen of Aldehydes (see reaction **6-58**)

Sulfur Nucleophiles

Sulfur compounds are better nucleophiles than their oxygen analogs (p. 322), so that in most cases these reactions take place faster and more smoothly than the corresponding reactions with oxygen nucleophiles.

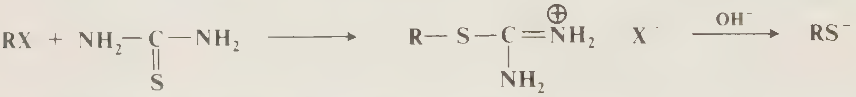
0-38 Attack by SH at an Alkyl Carbon. Formation of Mercaptans[525a]

$$RX + H_2S \longrightarrow RSH_2^+ \longrightarrow RSH + H^+$$

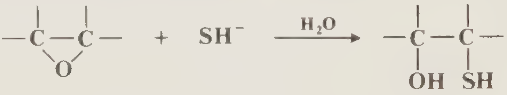
$$RX + HS^- \longrightarrow RSH$$

Sodium sulfhydride (NaSH) is a much better reagent for the formation of mercaptans from alkyl halides than H_2S and is much more often used.[526] It is easily prepared by bubbling H_2S into an alkaline solution. The reaction is most useful for primary halides. Secondary substrates give much lower yields, and the reaction fails completely for tertiary halides because elimination predominates. Sulfuric and sulfonic esters can be used instead of halides. Sulfides (RSR) are often side products. An indirect method for the conversion of an alkyl halide to a mercaptan consists of treatment with thiourea to give an isothiuronium salt, which with alkali or a high-molecular-weight amine is cleaved to the mercaptan:



$$RX + NH_2-\underset{\underset{S}{\|}}{C}-NH_2 \longrightarrow R-S-\underset{\underset{NH_2}{|}}{C}=\overset{\oplus}{N}H_2 \quad X^- \xrightarrow{OH^-} RS^-$$

Another indirect method is hydrolysis of Bunte salts (see reaction **0-42**). When epoxides are substrates, the products are β-hydroxy mercaptans:[526a]



OS **III,** 363, 440; **IV,** 401, 491; **V,** 1046. Also see OS **II,** 345, 411, 573; **IV,** 232; **V,** 223.

0-39 Attack by SR at an Alkyl Carbon. Formation of Sulfides

$$RX + R'S^- \longrightarrow RSR'$$

Sulfides may be prepared by treatment of alkyl halides with salts of mercaptans.[527] R′ may be alkyl or aryl. As in reaction **0-38,** RX cannot be a tertiary halide, and sulfuric and sulfonic esters can be used instead of halides. As in the Williamson reaction (**0-14**) yields are improved by phase-transfer catalysis.[527a] R may be tertiary if an alcohol is the substrate, e.g.,[528]

$$R_3COH + R'_3CSH \xrightarrow{H_2SO_4} R_3CSCR'_3$$

This reaction is analogous to reaction **0-18.** Compounds with other leaving groups have also been used, e.g., $ROPOX_2$ (X = R or OR)[529] and ROC(NHR′)=NR′ (R′ = cyclohexyl).[530]

Mercaptide ions are also useful for the demethylation of certain ethers, esters, and quaternary ammonium salts. Aryl methyl ethers can be cleaved by heating with EtS^- in the dipolar aprotic solvent dimethylformamide: $ROAr + EtS^- \rightarrow ArO^- + EtSR$.[531] Similarly, *n*-PrSLi in HMPT can be used to cleave methyl esters of sterically hindered acids, e.g., methyl mesitoate.[532] A good method for the demethylation of quaternary ammonium salts consists of refluxing them with PhS^- in butanone:[533]

[525a] For a review, see Wardell, in Patai, "The Chemistry of the Thiol Group," pt. 1, pp. 179–211, John Wiley & Sons, New York, 1974.

[526] For a review, see Reid, "Organic Chemistry of Bivalent Sulfur," vol. 1, pp. 21–29, 32–35, vol. 5, pp. 27–34, Chemical Publishing Company, New York, 1958, 1963.

[526a] For a review, see Ref. 525a, pp. 246–251.

[527] For reviews, see Ref. 526, vol. 2, pp. 16–21, 24–29, vol. 3, pp. 11–14 (1960); Peach, in Patai, Ref. 525a, pt. 2, pp. 721–735.

[527a] Herriott and Picker, *Synthesis* 447 (1975), *J. Am. Chem. Soc.* **97,** 2345 (1975).

[528] Fehnel and Carmack, *J. Am. Chem. Soc.* **71,** 84 (1949); Cain, Evans, and Lee, *J. Chem. Soc.* 1694 (1962).

[529] Savignac and Coutrot, *Synthesis* 818 (1974).

[531] Feutrill and Mirrington, *Tetrahedron Lett.* 1327 (1970); *Aust. J. Chem.* **25,** 1719, 1731 (1972).

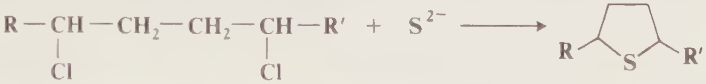
$$R_3\overset{\oplus}{N}Me + PhS^- \xrightarrow{MeCOEt} R_3N + PhSMe$$

A methyl group is cleaved more readily than other simple alkyl groups (such as ethyl), though loss of these groups competes, but benzyl and allyl groups cleave even more easily, and this is a useful procedure for the cleavage of benzyl and allyl groups from quaternary ammonium salts even if methyl groups are also present.[534]

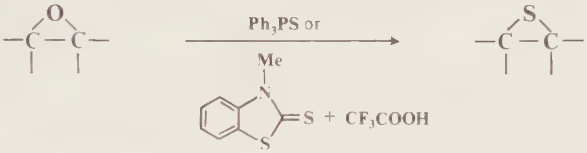
Symmetrical sulfides may also be prepared by treatment of an alkyl halide with sodium sulfide.

$$2RX + Na_2S \longrightarrow RSR$$

This reaction may be carried out internally, by addition of sulfide ions to 1,4- or 1,5-dihalides, to prepare five- and six-membered sulfur-containing heterocyclic rings.



Selenides and tellurides may be prepared similarly.[535] When epoxides are substrates, β-hydroxy sulfides are obtained in a manner analogous to that mentioned in reaction **0-38.** Epoxides can also be directly converted to episulfides,[535a] by treatment with a phosphine sulfide such as Ph_3PS[536] or with 3-methylbenzothiazole-2-thione and trifluoroacetic acid.[536a]

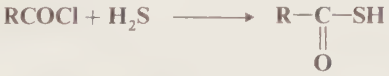


Alkyl halides, treated with sulfides, give sulfonium salts.[537]

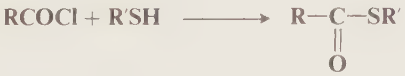
$$RCl + R'_2S \longrightarrow R'_2SR^+ \quad Cl^-$$

OS **II,** 31, 345, 547, 576; **III,** 332, 751, 763; **IV,** 396, 667, 892, 967; **V,** 562, 780, 1046; **50,** 31, 33, 72; **51,** 70; **53,** 1, 90; **54,** 19, 27. See also OS **55,** 127.

0-40 Attack by SH or SR at an Acyl Carbon[538]



$$RCOCl + H_2S \longrightarrow R-\underset{\displaystyle O}{\underset{\|}{C}}-SH$$



$$RCOCl + R'SH \longrightarrow R-\underset{\displaystyle O}{\underset{\|}{C}}-SR'$$

[538] For a review, see Ref. 520, pp. 182–184.

Thiol acids and thiol esters may be prepared in this manner, which is analogous to reactions **0-9** and **0-25.**[539] Anhydrides and aryl esters (RCOOAr)[540] are also used as substrates, but the reagents in these cases are usually SH^- and SR^-. Thiol esters may also be prepared by treatment of carboxylic acids with trisalkylthioboranes $B(SR)_3$,[541] or with a mercaptan and diethyl phosphorocyanidate $NCPO(OEt)_2$ or diphenyl phosphorazidate $N_3PO(OPh)_2$ in dimethylformamide in the presence of Et_3N.[542] Esters RCOOR′ can be converted to thiol esters RCOSR″ by treatment with trimethylsilyl sulfides Me_3SiSR'' and $AlCl_3$.[543]

OS **III,** 116, 599; **IV,** 924, 928.

0-41 Formation of Disulfides

$$2RX + S_2{}^{2-} \longrightarrow RSSR + 2X^-$$

Disulfides[544] can be prepared by treatment of alkyl halides with disulfide ions and also indirectly by the reaction of Bunte salts (see reaction **0-42**) with acid solutions of iodide, thiocyanate ion, or thiourea,[545] or by pyrolysis, or by treatment with hydrogen peroxide.

There are no OS references, but a similar preparation of a polysulfide may be found in OS **IV,** 295.

0-42 Formation of Bunte Salts

$$RX + S_2O_3{}^{2-} \longrightarrow R{-}S{-}SO_3{}^- + X^-$$

Primary and secondary, but not tertiary, alkyl halides are easily converted to Bunte salts ($RSSO_3{}^-$) by treatment with thiosulfate ion.[546] Bunte salts may be hydrolyzed with acids to give the corresponding mercaptans,[547] or converted to disulfides, tetrasulfides, or pentasulfides.[548]

0-43 Alkylation of Sulfinic Acid Salts

$$RX + R'SO_2{}^- \longrightarrow R{-}SO_2{-}R' + X^-$$

Alkyl halides or alkyl sulfates, treated with the salts of sulfinic acids, give sulfones. Alkyl sulfinates R′SO—OR may be side products.[549]

OS **IV,** 674. See also OS **54,** 33.

0-44 Attack by Sulfite Ion

$$RX + SO_3{}^{2-} \longrightarrow R{-}SO_2O^- + X^-$$

Salts of sulfonic acids may be prepared by treatment of primary or secondary alkyl halides with sulfite ion.[550] Even tertiary halides have been used, though the yields are low. Epoxides treated with bisulfite give β-hydroxy sulfonic acids:[551]

0-45 Formation of Alkyl Thiocyanates

$$RX + SCN^- \longrightarrow RSCN + X^-$$

Alkyl halides or sulfuric or sulfonic esters can be heated with sodium or potassium thiocyanate to give alkyl thiocyanates,[552] though the attack by the analogous cyanate ion (reaction **0-64**) gives exclusive N-alkylation.

OS **II**, 366.

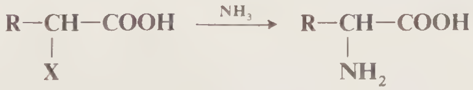
\end{array}$$

The reaction between alkyl halides and ammonia or primary amines is not usually a feasible method for the preparation of primary or secondary amines, since they are stronger bases than ammonia and preferentially attack the substrate. However, the reaction is very useful for the preparation of tertiary amines[553] and quaternary ammonium salts. If ammonia is the nucleophile, the three or four alkyl groups on the nitrogen of the product must be identical. If a primary, secondary, or tertiary amine is used, then different alkyl groups may be placed on the same nitrogen atom. The conversion of tertiary amines to quaternary salts is called the *Menschutkin reaction.*[554] It is sometimes possible to use this method for the preparation of a primary amine by the use of a large excess of ammonia, or a secondary amine by the use of a large excess of primary amine. However, the limitations of this approach can be seen in the reaction of a saturated solution of ammonia in 90% ethanol with ethyl bromide in a 16:1 molar ratio, under which conditions the yield of primary amine was 34.2% (at a 1:1 ratio the yield was 11.3%).[555] In some cases, where field or other effects cause the primary amine to be a weaker base than ammonia, it can easily be prepared in good yield. An important example is the conversion of α-halo acids to α-amino acids:



$$\underset{\displaystyle X}{\text{R—CH—COOH}} \xrightarrow{NH_3} \underset{\displaystyle NH_2}{\text{R—CH—COOH}}$$

---

[552] For discussions, see Bacon, in Kharasch, "Organic Sulfur Compounds," pp. 306–309, Pergamon Press, New York, 1961; Ref. 526, vol. 6, pp. 34–37 (1965); Ref. 525a, pp. 230–231.

[553] For reviews of this reaction, see Gibson, in Patai, Ref. 298, pp. 45–55; Spialter and Pappalardo, "The Acyclic Aliphatic Tertiary Amines," pp. 14–29, The Macmillan Company, New York, 1965.

[554] For a review of stereoselectivity in this reaction, especially where the tertiary nitrogen is included in a ring, see Bottini, *Sel. Org. Transform.* **1**, 89–142 (1970).

[555] Werner, *J. Chem. Soc.* **113**, 899 (1918).

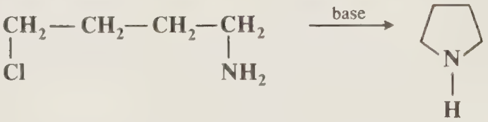
Primary amines can be prepared from alkyl halides by method **0-47** or, more commonly, by the Gabriel synthesis (**0-60**).

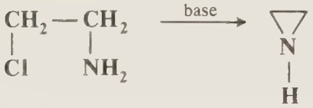
The immediate product in any particular step is the protonated amine, which, however, rapidly loses a proton to another molecule of ammonia or amine in an equilibrium process, e.g.,

$$\mathrm{RX} + \mathrm{R_2NH} \longrightarrow \mathrm{R_3\overset{\oplus}{N}H} + \mathrm{R_2NH} \rightleftharpoons \mathrm{R_3N} + \mathrm{R_2\overset{\oplus}{N}H_2}$$

When it is desired to convert a primary or secondary amine directly to the quaternary salt (*exhaustive alkylation*), then the rate can be increased by the addition of a nonnucleophilic strong base which serves to remove the proton from $RR'NH_2^+$ or $RR'R''NH^+$ and thus liberates the amine to attack another molecule of RX.[556]

The conjugate bases of ammonia and of primary and secondary amines (NH_2^-, RNH^-, R_2N^-) are sometimes used as nucleophiles. However, in most cases they offer no advantages over ammonia or the amines themselves, since the latter are basic enough. This is in contrast to the analogous methods **0-1, 0-14, 0-38,** and **0-39.** Primary arylamines are easily alkylated, but diaryl- and triarylamines are very poor nucleophiles. However, the reaction has been carried out with diarylamines.[557] Sulfates or sulfonates may be used instead of halides. The reaction may be carried out intramolecularly to give cyclic amines, with three-, five-, and six-membered (but not four-membered) rings being easily prepared. Thus, 4-chloro-1-aminobutane treated with base gives pyrrolidine, and 2-chloroethylamine gives aziridine[558] (analogous to reaction **0-15**):





As usual, tertiary substrates do not give the reaction at all but undergo preferential elimination. However, tertiary (but not primary or secondary) halides R_3CCl can be converted to primary amines R_3CNH_2 by treatment with NCl_3 and $AlCl_3$[559] in a reaction related to reaction **0-52.**

Phosphines behave similarly, and compounds of the type R_3P and $R_4P^+\ X^-$ can be so prepared.

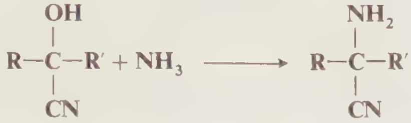
tion, is most successful for active halides such as allylic and benzylic halides and α-halo ketones, and for primary iodides.

OS V, 121.

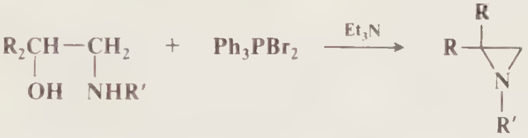
0-48 Replacement of a Hydroxy by an Amino Group



$$R{-}\underset{CN}{\overset{OH}{C}}{-}R' + NH_3 \longrightarrow R{-}\underset{CN}{\overset{NH_2}{C}}{-}R'$$

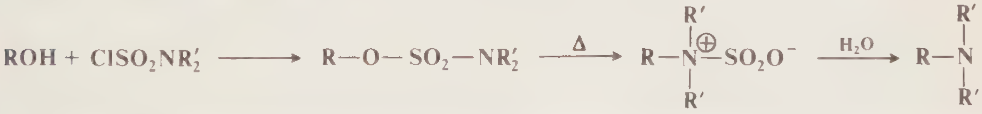
Cyanohydrins can be converted to amines by treatment with ammonia. The use of primary or secondary amines instead of ammonia leads to secondary and tertiary cyanoamines, respectively. It is more common to perform the conversion of an aldehyde or ketone directly to the cyanoamine without isolation of the cyanohydrin (see reaction **6-51**). α-Hydroxy ketones (acyloins and benzoins) behave similarly.[560] Allylic alcohols $RCH{=}CHCH_2OH$ (and their ethers and esters) can be converted to tertiary amines $RCH{=}CHCH_2NR'_2$ by treatment with a secondary amine in the presence of a palladium-triphenylphosphine complex catalyst.[561]

β-Amino alcohols give aziridines when treated with triphenylphosphine dibromide in the presence of triethylamine.[562]



The fact that inversion takes place at the OH carbon indicates that an S_N2 mechanism is involved, with $OPPh_3$ as the leaving group.

Alcohols can be converted to amines in an indirect manner.[563] The salt of the alcohol is treated with a sulfamoyl chloride to give a sulfonamate ester, which on heating rearranges to a zwitterion. Hydrolysis of this gives the amine:



$$ROH + ClSO_2NR'_2 \longrightarrow R{-}O{-}SO_2{-}NR'_2 \xrightarrow{\Delta} R{-}\underset{R'}{\overset{R'}{\overset{\oplus}{N}}}{-}SO_2O^- \xrightarrow{H_2O} R{-}\underset{R'}{\overset{R'}{N}}$$

The reaction has been carried out with R′ = methyl to give tertiary amines. The rearrangement step is an S_Ni process, as shown by retention of configuration at R. The success of the method increases with the stability of R^+ as a carbonium ion (compatible with the ion-pair nature of the S_Ni reaction, see p. 302). Therefore it is a particularly useful method for the preparation of tertiary alkylamines, which are difficult to prepare in other ways. On the other hand, primary (but not secondary or tertiary) alcohols can be converted to carbamates which can be hydrolyzed to amines by heating sodium or trialkylammonium salts of their N-carbalkoxy sulfamates, e.g.,[564]

$$R{-}O{-}SO_2{-}\overset{\ominus}{\bar{N}}{-}COOMe \quad \overset{\oplus}{N}HEt_3 \xrightarrow{95\,^\circ C} R{-}NHCOOMe \xrightarrow{\text{hydrol.}} RNH_2$$

---

[560] For example, see Klemmensen, Schroll, and Lawesson, *Ark. Kemi* **28,** 405 (1968).

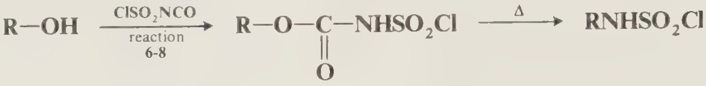
[561] Atkins, Walker, and Manyik, *Tetrahedron Lett.* 3821 (1970). For a similar reaction involving allylic or benzylic alcohols, see Murahashi, Shimamura, and Moritani, *J. Chem. Soc., Chem. Commun.* 931 (1975).

[562] Okada, Ichimura, and Sudo, *Bull. Chem. Soc. Jpn.* **43,** 1185 (1970).

[563] White and Ellinger, *J. Am. Chem. Soc.* **87,** 5261 (1965).

[564] Burgess, Penton, and Taylor, *J. Am. Chem. Soc.* **92,** 5224 (1970).

When the reaction is applied to the corresponding salts of secondary or tertiary alcohols, elimination is observed instead (p. 927). A similar method involves conversion of the alcohol to the N-chlorosulfonyl carbamate and heating of this compound:[565]



$$\text{R—OH} \xrightarrow[\substack{\text{reaction}\\ \textbf{6-8}}]{\text{ClSO}_2\text{NCO}} \text{R—O—}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{—NHSO}_2\text{Cl} \xrightarrow{\Delta} \text{RNHSO}_2\text{Cl}$$

However, this method is satisfactory only for tertiary R and others which give moderately stable carbonium ions. In another indirect method, primary alcohols are converted to alkyloxyphosphonium perchlorates which in dimethylformamide successfully *monoalkylate* not only secondary but also primary amines.[566]

$$\text{ROH} \xrightarrow[\text{2. NH}_4\text{ClO}_4]{\text{1. CCl}_4\text{-P(NMe}_2)_3} \text{RO}\overset{\oplus}{\text{P}}(\text{NMe}_2)_3 \quad \text{ClO}_4^- \xrightarrow[\text{R}'\text{R}''\text{NH}]{\text{DMF}} \text{RR}'\text{R}''\text{N} + \text{OP(NMe}_2)_3$$

Thus by this means secondary as well as tertiary amines can be prepared in good yields.

OS **II,** 29, 231; **IV,** 91, 283. Also see OS **I,** 473; **III,** 272, 471.

0-49 Transamination

$$\text{RNH}_2 + \text{R}'\text{NH}^- \longrightarrow \text{RR}'\text{NH} + \text{NH}_2^-$$

Where the nucleophile is the conjugate base of a primary amine, NH_2 can be a leaving group. The method has been used to prepare secondary amines.[567] Similar exchange, but with the attack by the amine itself, is observed with ethanolamine, where the substrate is a quaternary salt.[568]

$$\text{R}_4\text{N}^+ + \text{NH}_2\text{CH}_2\text{CH}_2\text{OH} \longrightarrow \text{R}_3\text{N} + \text{R}\overset{\oplus}{\text{N}}\text{H}_2\text{CH}_2\text{CH}_2\text{OH}$$

In this reaction, methyl groups are cleaved in preference to other saturated alkyl groups. A similar reaction takes place between a Mannich base (see reaction **6-17**) and a secondary amine, where the mechanism is elimination-addition[569] (see p. 315).

OS **V,** 1018.

0-50 Alkylation of Amines with Diazo Compounds

$$\text{CR}_2\text{N}_2 + \text{R}'_2\text{NH} \xrightarrow{\text{BF}_3} \text{CHR}_2\text{NR}'_2$$

The reaction of diazo compounds with amines is similar to reaction **0-17.**[570] The acidity of amines is not great enough for the reaction to proceed without a catalyst, but BF_3, which converts the amine to the $F_3B\text{-}NHR'_2$ complex, enables the reaction to take place. Cuprous cyanide can also be used as a catalyst.[571] The most common substrate is diazomethane, in which case this is a method for the methylation of amines. Ammonia has been used as the amine but, as in the case of reaction **0-46,** mixtures of primary, secondary, and tertiary amines are obtained. Primary aliphatic amines give mixtures of secondary and tertiary amines. Secondary amines give successful alkylation. Primary aromatic amines also give the reaction, but diaryl or arylalkylamines react very poorly.

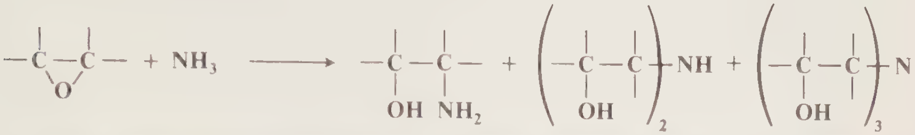
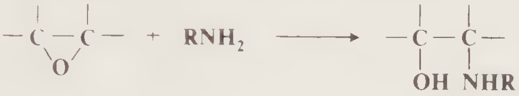
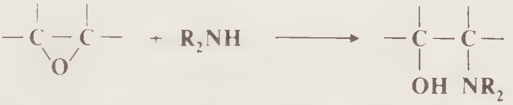
0-51 Amination of Epoxides



The reaction between epoxides and ammonia is a general and useful method for the preparation of β-hydroxyamines.[572] Ammonia gives largely the primary amine, but also some secondary and tertiary amines. The useful solvents, the ethanolamines, are prepared by this reaction. Primary and secondary amines give, respectively, secondary and tertiary amines:





Episulfides, which can be generated in situ in various ways, react similarly to give β-amino mercaptans,[573] and aziridines give 1,2-diamines.[574]

Triphenylphosphine similarly reacts with epoxides to give an intermediate which then undergoes elimination to give olefins (see the Wittig reaction, **6-47**).

0-52 Amination of Alkanes

$$R_3CH + NCl_3 \xrightarrow[0\text{–}10\,C]{AlCl_3} R_3CNH_2$$

Alkanes, arylalkanes, and cycloalkanes can be aminated, at tertiary positions only, by treatment with trichloroamine and aluminum chloride at 0 to 10 C.[575] For example, *p*-cymene (*p*-$MeC_6H_4CHMe_2$) gives *p*-$MeC_6H_4CMe_2NH_2$, methylcyclopentane gives 1-amino-1-methylcyclopentane, and adamantane gives 1-aminoadamantane, all in good yields. This is a useful reaction, since there are not many other methods for the preparation of *t*-alkylamines. The mechanism has been rationalized as an SN1 process with H^- as the leaving group:[575]

$$NCl_3 + AlCl_3 \longrightarrow (Cl_2N{-}AlCl_3)^- Cl^+$$

$$R_3CH \xrightarrow{Cl^+} R_3C^+ \xrightarrow{NCl_2^-} R_3CNCl_2 \xrightarrow[2H^+]{-2Cl^+} R_3CNH_2$$

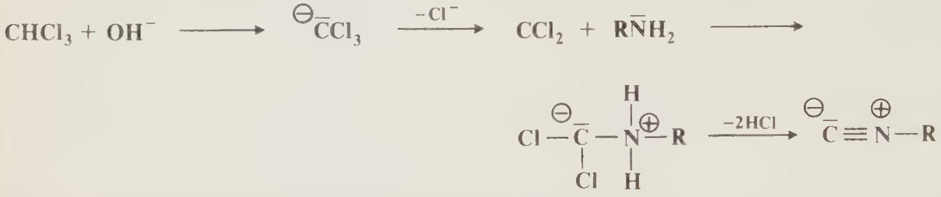
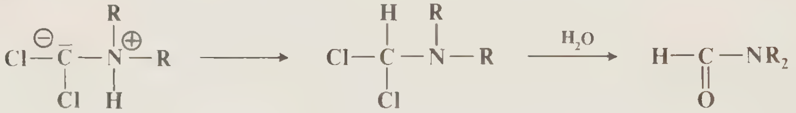
0-53 Formation of Isonitriles

$$\mathrm{CHCl_3 + RNH_2 \xrightarrow{OH^-} R-\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}}}$$

Reaction with chloroform under basic conditions is a common test for primary amines, both aliphatic and aromatic, since isonitriles have bad odors which are very strong. The reaction probably proceeds by an SN1cB mechanism with dichlorocarbene as an intermediate:



The reaction can also be used synthetically for the preparation of isonitriles, though yields are generally not high. An improved procedure has been reported.[576] When secondary amines are involved, the adduct cannot lose two moles of HCl. Instead it is hydrolyzed to an N,N-disubstituted formamide:[577]



OS **55**, 96.

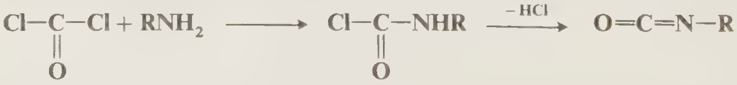
B. Attack by NH_2, NHR, or NR_2 at an Acyl Carbon[578]

0-54 Acylation of Amines by Acyl Halides

$$\mathrm{RCOX + NH_3 \longrightarrow RCONH_2 + HX}$$

The treatment of acyl halides with ammonia or amines is a very general reaction for the preparation of amides.[579] The reaction is highly exothermic and must be carefully controlled, usually by cooling or dilution. Ammonia gives unsubstituted amides, primary amines give N-substituted amides, and secondary amines give N,N-disubstituted amides. Arylamines may be similarly acylated. In some cases aqueous alkali is added to combine with the liberated HCl. This is called the *Schotten-Baumann procedure* as it was in reaction **0-22.**

Hydrazine and hydroxylamine also react with acyl halides to give, respectively, hydrazides $RCONHNH_2$[580] and hydroxamic acids RCONHOH, and these compounds are often made in this way. When phosgene is the acyl halide, both aliphatic and aromatic primary amines give chloroformamides ClCONHR which lose HCl to give isocyanates RNCO. This is one of the most



$$\mathrm{Cl-\underset{\underset{O}{\|}}{C}-Cl + RNH_2 \longrightarrow Cl-\underset{\underset{O}{\|}}{C}-NHR \xrightarrow{-HCl} O{=}C{=}N-R}$$

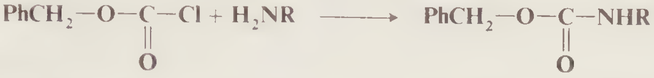
[579] For reviews, see Beckwith, in Zabicky, Ref. 407, pp. 73–185; Sonntag, *Chem. Rev.* **52,** 237–416 (1953), pp. 258–294.

[580] For a review of hydrazides, see Paulsen and Stoye, in Zabicky, Ref. 407, pp. 515–600.

common methods for the preparation of isocyanates.[581] Thiophosgene, similarly treated, gives isothiocyanates. When chloroformates ROCOCl are treated with primary amines, carbamates ROCONHR′ are obtained. An example of this reaction is the use of carbobenzoxy chloride to protect the amino group of amino acids and peptides:



$$PhCH_2-O-\underset{\underset{O}{\|}}{C}-Cl + H_2NR \longrightarrow PhCH_2-O-\underset{\underset{O}{\|}}{C}-NHR$$

Amino groups in general are often protected by conversion to amides. The treatment of acyl halides with lithium nitride gives N,N-diacyl amides (triacylamines):[582]

$$3RCOCl + Li_3N \longrightarrow (RCO)_3N$$

The nitrogen of dimethylformamide may also attack acyl halides in what amounts to an exchange reaction:[583]

$$ROCl + HCONMe_2 \longrightarrow RCONMe_2 + [HCOCl] \longrightarrow HCl + CO$$

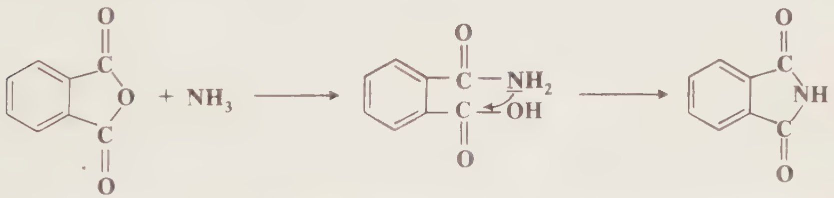
The reactions proceed by the tetrahedral mechanism.[584]

OS **I**, 99, 165; **II**, 76, 208, 278, 328, 453; **III**, 167, 375, 415, 488, 490, 613; **IV**, 339, 411, 521, 620, 780; **V**, 201, 336; **54**, 88.

0-55 Acylation of Amines by Anhydrides

$$R-\underset{\underset{O}{\|}}{C}-O-\underset{\underset{O}{\|}}{C}-R' + NH_3 \longrightarrow R-\underset{\underset{O}{\|}}{C}-NH_2 + R'COOH$$

This reaction, similar in scope and mechanism to reaction **0-54**, can be carried out with ammonia or primary or secondary amines.[585] However, ammonia and primary amines may also give imides, in which two acyl groups are attached to the nitrogen. This is especially easy with cyclic anhydrides which produce cyclic imides.[586]



The second step in this case, which is much slower than the first, is the attack of the amide nitrogen on the carboxylic acid.

Even though formic anhydride is not a stable compound (see p. 493), amines can be formylated with the mixed anhydride of acetic and formic acids HCOOCOMe or with a mixture of formic acid and acetic anhydride. Acetamides are not formed with these reagents. When α-amino acids are treated with trifluoroacetic anhydride, the initial amide rapidly cyclizes and hydrolysis of the product gives an α-keto acid. This is a method of converting α-amino acids to α-keto acids.[587]

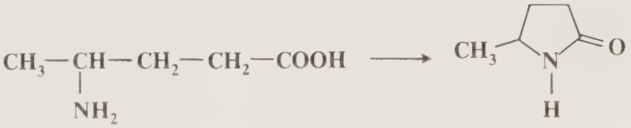
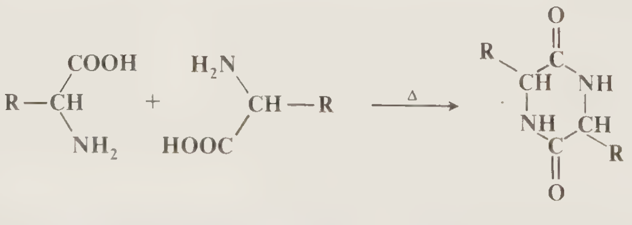
0-56 Acylation of Amines by Acids

$$\mathrm{RCOOH} + \mathrm{NH_3} \longrightarrow \mathrm{RCOO^- \ NH_4^+} \xrightarrow{\text{pyrolysis}} \mathrm{RCONH_2}$$

When carboxylic acids are treated with ammonia or amines, salts are obtained. The salts of ammonia or primary or secondary amines may be pyrolyzed to give amides,[588] but the method is less convenient than reactions **0-54**, **0-55**, and **0-57**[589] and is seldom of preparative value. Lactams are produced fairly easily from γ- or δ-amino acids, for example,



On heating, α-amino acids give diketopiperazines, an example of double amide formation:



Although treatment of acids with amines does not directly give amides, the reaction can be made to proceed in good yield at room temperature or slightly above by the use of coupling agents,[590] the most important of which is dicyclohexylcarbodiimide. This is very convenient and is used a great deal in peptide synthesis.[591] The mechanism is probably the same as in reaction

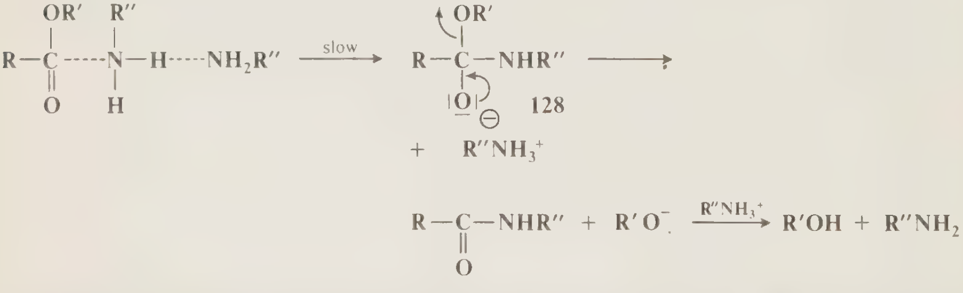
0-57 Acylation of Amines by Esters

$$\mathrm{RCOOR' + NH_3 \longrightarrow RCONH_2 + R'OH}$$

The conversion of esters to amides is a useful reaction, and unsubstituted, N-substituted, and N,N-disubstituted amides can be prepared in this way from the appropriate amine.[602] Both R and R′ may be alkyl or aryl. An especially good leaving group is *p*-nitrophenyl. The reaction is particularly useful because many esters are readily available or easy to prepare even in cases where the corresponding acyl halide or anhydride is not. As in reaction **0-54** hydrazides and hydroxamic acids can be prepared from esters, with hydrazine and hydroxylamine, respectively. Both hydrazine and hydroxylamine react more rapidly than ammonia or primary amines (the alpha effect, p. 325). Phenylhydrazides, prepared with phenylhydrazine, are often used as derivatives for esters, and the formation of hydroxamic acids, which form colored complexes in the presence of ferric ions, is often used as a test for esters. Imidates $\mathrm{RC({=}NH)OR'}$ give amidines $\mathrm{RC({=}NH)NH_2}$[603] (see reaction **0-36**). Lactones, when treated with ammonia or primary amines, give lactams. Lactams are also produced from γ- and δ-amino esters in an internal example of this reaction. The basicity of some amines (for example, arylamines) is so low that the reaction goes with difficulty. However, when arylamines are converted to their conjugate bases $\mathrm{ArNH^-}$ by a strong base such as ethoxide ion, the reaction proceeds at a convenient rate.[604] Isopropenyl formate is a useful compound for the formylation of primary and secondary amines.[605]

$$\mathrm{R_2NH + HCOOCMe{=}CH_2 \longrightarrow R_2NCHO + CH_2{=}CMeOH \rightleftharpoons MeCOMe}$$

Although more studies have been devoted to the mechanism of this reaction than to acylation of amines by other reagents, the mechanistic details are not yet entirely clear.[606] In its broad outlines, the mechanism appears to be essentially BAC2.[607] Under the normal basic conditions the reaction is general base-catalyzed,[608] indicating that a proton is being transferred in the rate-determining step and that two molecules of amine are involved.[609]



Alternatively, another base, such as H_2O or OH^-, can substitute for the second molecule of amine. With some substrates and under some conditions, especially at low pH, the breakdown of

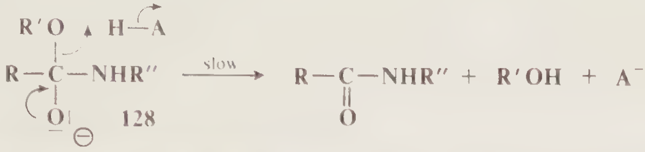
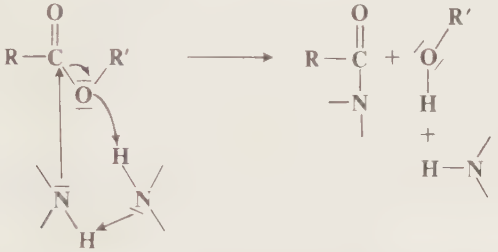
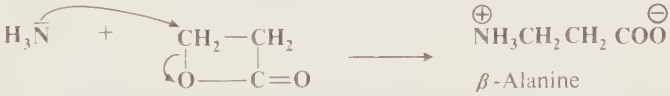
128 may become rate-determining.[610] The reaction also takes place under acidic conditions, and here the reaction is general acid-catalyzed, so that breakdown of **128** is rate-determining and proceeds as follows:[611]



HA may be $R''NH_3^+$ or another acid. **128** may or may not be further protonated on the nitrogen. Even under basic conditions, a proton donor may be necessary to assist leaving-group removal. Evidence for this is that the rate is lower with NR_2^- in liquid ammonia than with NHR_2 in water, apparently owing to the lack of acids to protonate the leaving oxygen.[612] It has been suggested[613] that under some conditions, particularly in aprotic solvents, all the steps can occur simultaneously,[614] with a second molecule of ammonia or amine both pulling a proton from the first molecule and supplying a proton to the leaving group:



In this mechanism, the ammonia or amine acts as an acid and a basic catalyst at the same time. In the special case of β-lactones, where small-angle strain is an important factor, alkyl-oxygen cleavage is observed (BAL2 mechanism, as in the similar case of hydrolysis of β-lactones, reaction **0-11**), and the product is not an amide but a β-amino acid:



A similar result has been found for certain sterically hindered esters.[615] This reaction is similar to reaction **0-46**, with OCOR as the leaving group.

0-58 Acylation of Amines by Amides

$$\mathrm{RCONH_2} + \mathrm{R'}\overset{\oplus}{\mathrm{N}}\mathrm{H_3} \longrightarrow \mathrm{RCONHR'} + \mathrm{NH_4^+}$$

This is an exchange reaction and is usually carried out with the salt of the amine. The leaving group is usually NH_2 rather than NHR or NR_2, and primary amines (in the form of their salts) are the most common reagents. BF_3 can be added to complex with the leaving ammonia. The reaction is often used to convert urea to substituted ureas: $NH_2CONH_2 + RNH_3^+ \rightarrow NH_2CONHR + NH_4^+$. Dimethylformamide can be converted to other formamides by prolonged heating with a primary or secondary amine.[616]

OS **I,** 302 (but see **V,** 589), 450, 453; **II,** 461; **III,** 151, 404; **IV,** 52, 361.

0-59 Acylation of Amines by Other Acid Derivatives

Acid derivatives which can be converted to amides include thiol acids RCOSH, thiol esters RCOSR, silicic esters $(RCOO)_4Si$, 1,1,1-trihalo ketones $RCOCX_3$, α-keto nitriles, acyl azides, and non-enolizable ketones (see the Haller-Bauer reaction **2-32**).

OS **III,** 394; **IV,** 6, 569; **V,** 160, 166.

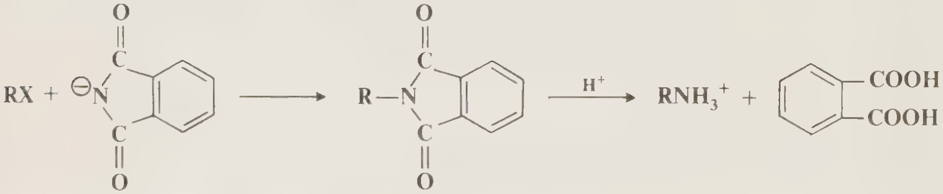
C. Attack by NHCOR

0-60 N-Alkylation of Amides and Imides

$$\mathrm{RX} + {}^{\ominus}\mathrm{NHCOR'} \longrightarrow \mathrm{RNHCOR'}$$

Amides are very weak bases, far too weak to attack alkyl halides, so that they must first be converted to their salts. By this method, unsubstituted amides can be converted to N-substituted, or N-substituted to N,N-disubstituted, amides. Esters of sulfuric or sulfonic acids can also be substrates. Tertiary substrates give elimination. O-alkylation is at times a side reaction.[617]

The *Gabriel synthesis*,[618] for converting halides to primary amines, is based on this reaction. The halide is treated with potassium phthalimide and the product hydrolyzed (reaction **0-12**):



It is obvious that the primary amines formed in this reaction will be uncontaminated by secondary or tertiary amines (unlike reaction **0-46**). The reaction is usually rather slow but can be conveniently speeded by the use of a dipolar aprotic solvent such as dimethylformamide.[619] Hydrolysis of the phthalimide, whether acid- or base-catalyzed (acid catalysis is used far more frequently), is also usually very slow, and a better way is to heat the phthalimide with hydrazine in an exchange reaction (the *Ing-Manske procedure*).[620] The Ing-Manske procedure has largely, though not entirely, superseded hydrolytic methods.

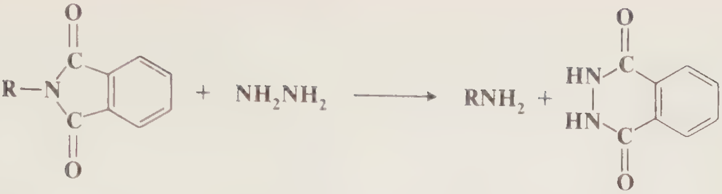
[620] Ing and Manske, *J. Chem. Soc.* 2348 (1926).

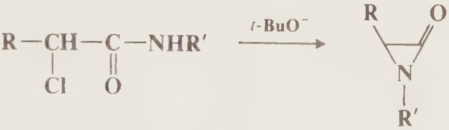


Vinyl bromides react with potassium phthalimide at 165 C in N,N-dimethylacetamide in the presence of CuI.[621] N-Alkylphthalimides can also be prepared starting from alcohols by treatment of the latter with equimolar amounts of phthalimide, triphenylphosphine, and diethyl azodicarboxylate (EtOOCN=NCOOEt) at room temperature.[622]

An alternative to the Gabriel synthesis, in which alkyl halides can be converted to primary amines in good yields, involves treatment of the halide with the strong base guanidine followed by alkaline hydrolysis.[623] In another alternative, alkyl bromides or tosylates are treated with $(PhS)_2NLi$ to give bisbenzenesulfenimides $(PhS)_2NR$ which can be hydrolyzed to RNH_2 by 3 *N* HCl or thiophenol.[624]

Amides can also be alkylated with diazo compounds, as in reaction **0-50**. Salts of sulfonamides ($ArSO_2NH^-$) may be used to attack alkyl halides to prepare N-alkyl sulfonamides ($ArSO_2NHR$) which may be further alkylated to $ArSO_2NRR'$. Hydrolysis of the latter is a good method for the preparation of secondary amines.

Internal N-alkylation has been used to prepare the highly strained compounds α-lactams.[625]



OS **I,** 119, 203, 271; **II,** 25, 83, 208; **III,** 151; **IV,** 810; **V,** 1064.

0-61 N-Acylation of Amides and Imides

$$\mathbf{RCOCl + H_2NCOR' \longrightarrow RCONHCOR'}$$

Imides may be prepared by the attack of amides or their salts on acyl halides, anhydrides, esters, or acids.[626] The best synthetic method for the preparation of acyclic imides is the reaction between an amide and an anhydride at 100 C, catalyzed by H_2SO_4.[627] When acyl chlorides are treated with amides in a 2:1 molar ratio at low temperatures in the presence of pyridine, the products are N,N-diacylamides $(RCO)_3N$.[628]

D. Other Nitrogen Nucleophiles

0-62 Formation of Nitro Compounds[631]

$$RX + NO_2^- \longrightarrow RNO_2$$

Sodium nitrite can be used to form nitro compounds with primary or secondary alkyl bromides or iodides. Silver nitrite gives nitro compounds only when RX is a primary bromide or iodide. Nitrite esters are an important side product in all these cases (reaction **0-33**) and become the major product (by an SN1 mechanism) when secondary or tertiary halides are treated with silver nitrite.

gem-Dinitro compounds can be prepared, in a way which is not a nucleophilic substitution, from silver nitrite and salts of nitro compounds:[632]

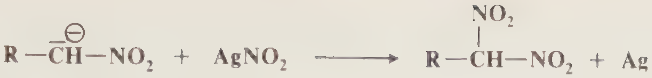
[632] Kaplan and Shechter, *J. Am. Chem. Soc.* **83,** 3535 (1961).



$$R-\overset{\ominus}{C}H-NO_2 + AgNO_2 \longrightarrow R-\overset{NO_2}{C}H-NO_2 + Ag$$

This is an oxidation-reduction reaction.

OS **I,** 410; **IV,** 368, 454, 724.

0-63 Formation of Azides

$$RX + N_3^- \longrightarrow RN_3$$

$$RCOX + N_3^- \longrightarrow RCON_3$$

Alkyl azides can be prepared by treatment of the appropriate halide with azide ion,[633] often in the form of sodium azide, though tetramethylguanidinium azide gives good yields.[634] Other leaving groups have also been used, for example, ONO_2.[635] Tertiary alkyl azides can be prepared by stirring tertiary alkyl chlorides with NaN_3 and $ZnCl_2$ in CS_2 for a period of 10 to 100 hr.[635a] Acyl azides, which can be used in the Curtius reaction (**8-18**), can be similarly prepared from acyl halides or anhydrides.[636]

OS **III,** 846; **IV,** 715; **V,** 273, 586; **50,** 9; **51,** 48; **55,** 32.

0-64 Formation of Isocyanates and Isothiocyanates

$$RX + NCO^- \longrightarrow RNCO$$

$$RX + NCS^- \longrightarrow RNCS$$

When the reagent is the thiocyanate ion, S-alkylation is an important side reaction (**0-45**), but the cyanate ion practically always gives exclusive N-alkylation.[331] When alkyl halides are treated with NCO^- in the presence of ethanol, carbamates can be prepared directly (see reaction **6-8**).[636a] Acyl halides give the corresponding acyl isocyanates and isothiocyanates.[637] For the formation of isocyanides, see reaction **0-103.**

OS **III,** 735.

Halogen Nucleophiles

A. Attack at an Alkyl Carbon

0-65 Halide Exchange. The Finkelstein Reaction

$$RX + X'^- \rightleftharpoons RX' + X^-$$

Halide exchange, sometimes called the *Finkelstein reaction*, is an equilibrium process, but it is often possible to shift the equilibrium. The reaction is most often applied to the preparation of iodides and fluorides. Iodides can be prepared from chlorides or bromides by taking advantage of the fact that sodium iodide, but not the bromide or chloride, is soluble in acetone. When an alkyl chloride or bromide is treated with a solution of sodium iodide in acetone, the equilibrium is shifted by the precipitation of sodium chloride or bromide. This is thus a method for the preparation of alkyl iodides. Since the mechanism is SN2, the reaction is much more successful for primary halides than for secondary or tertiary halides, and sodium iodide in acetone is often used as a test for primary bromides or chlorides. Tertiary chlorides can be converted to iodides by treatment with excess NaI in a nonpolar solvent containing a trace of $FeCl_3$.[638] This procedure is also successful for benzylic chlorides, but not for primary or secondary chlorides. Fluorides are prepared by treatment of other alkyl halides with any of a number of fluorinating agents, among them anhydrous HF (which is useful only for reactive substrates such as benzylic or allylic), AgF, HgF_2, and, for polyhalo compounds (such as chloroform), HF plus SbF_3.[639] A particularly effective reagent is KF in a polar aprotic solvent such as N-methylpyrrolidone or tetramethylene sulfone, or in acetonitrile or benzene in the presence of a crown ether.[640] The equilibria in these cases are shifted because the alkyl fluoride once formed has little tendency to react, owing to the extremely poor leaving-group ability of fluorine.

Alkyl bromides can be converted to chlorides with silver difluorochloroacetate ($ClF_2CCOOAg$).[641] Alkyl chlorides or bromides may be prepared from iodides by treatment with HCl or HBr in the presence of HNO_3, making use of the fact that the leaving I^- is oxidized to I_2 by the HNO_3.[642]

Not only can one halogen be substituted for another, but the halogen exchange reaction can also be carried out with, say, radioactive chloride replacing chloride, for studying mechanisms (see p. 269). Alkyl halides also exchange with *halogens* (X_2 rather than X^-). This is a free-radical reaction.[643]

OS **II,** 476; **IV,** 84, 525.

0-66 Formation of Alkyl Halides from Esters of Sulfuric and Sulfonic Acids

$$\mathbf{ROSO_2R' + X^- \longrightarrow RX}$$

Alkyl sulfates, tosylates, and other esters of sulfuric and sulfonic acids can be converted to alkyl halides with any of the four halide ions. Neopentyl tosylate reacts with Cl^-, Br^-, or I^- without rearrangement in HMPT.[644] Similarly, allylic tosylates can be converted to chlorides without allylic rearrangement by reaction with LiCl in the same solvent.[645] Inorganic esters are intermediates in the conversion of alcohols to alkyl halides with $SOCl_2$, PCl_5, PCl_3, etc. (reaction **0-67**), but are seldom isolated.

OS **I,** 25; **II,** 111, 404; **IV,** 597, 753; **V,** 545.

0-67 Formation of Alkyl Halides from Alcohols

[645] Stork, Grieco, and Gregson, *Tetrahedron Lett.* 1393 (1969).

Alcohols can be converted to alkyl halides with several reagents, the most common of which are halogen acids HX and inorganic acid halides such as $SOCl_2$, PCl_5, PCl_3, $POCl_3$, etc.[646] HBr is usually used for alkyl bromides and HI for alkyl iodides. These reagents are often generated in situ from the halide ion and an acid such as phosphoric or sulfuric. The use of HI sometimes results in reduction of the alkyl iodide to the alkane (reaction **0-77**) and, if the substrate is unsaturated, can also reduce the double bond.[647] The reaction can be used to prepare primary, secondary, or tertiary halides, but alcohols of the isobutyl or neopentyl type often give large amounts of rearrangement products. Tertiary chlorides are easily made with concentrated HCl, but primary and secondary alcohols react with HCl so slowly that a catalyst, usually zinc chloride, is required.[648] This behavior is the basis of the *Lucas test* for distinguishing among primary, secondary, and tertiary alcohols. The test consists of shaking the alcohol with a mixture of concentrated HCl and zinc chloride at room temperature. Tertiary alcohols react at once, secondary alcohols within 5 min, and primary alcohols do not react within this time. Primary alcohols give good yields of chlorides upon treatment with HCl in HMPT.[648a] The inorganic acid chlorides $SOCl_2$, PCl_3, etc., give primary, secondary, or tertiary alkyl chlorides with much less rearrangement than is observed with HCl, and these reagents are often preferred for the preparation of chlorides. Analogous bromides and iodides, especially PBr_3, have also been used, but they are more expensive and less often used than HBr or HI, though some of them, too, may be generated in situ (e.g., PBr_3 from red phosphorus and bromine). Secondary alcohols always give *some* rearranged bromides if another secondary position is available, even with PBr_3, PBr_5, or $SOBr_2$; thus 3-pentanol gives both 2- and 3-bromopentane. Such rearrangement can be avoided by converting the alcohol to a sulfonate and then using reaction **0-66**.[649] HF does not generally convert alcohols to alkyl fluorides.[650] Such conversions can be carried out with SF_4,[651] SeF_4,[652] with α-fluoroamines of the type $R'CF_2NR''_2$,[653] or, indirectly, by conversion to a sulfate or tosylate, etc. (reaction **0-66**). Dialkylaminosulfur trifluorides R_2NSF_3 and bis(dialkylamino)sulfur trifluorides $(R_2N)_2SF_2$ are reagents which convert alcohols to fluorides under mild conditions.[654] Primary fluorides can be made by heating 2-alkyl pseudouronium fluorides $[Ph_2C(OR)NH_2^+ \quad F^-]$ prepared from the alcohol and Ph_2NCN.[655] Secondary and tertiary alcohols can be converted to fluorides with an HF-pyridine mixture.[656] Primary, secondary, and tertiary alcohols can be converted to any of the four halides by treatment with the appropriate NaX, KX, or NH_4X in polyhydrogen fluoride–pyridine solution.[657] This method is even successful for neopentyl halides.

Other reagents have also been used, for example, $(RO)_3PRX$[658] and R_3PX_2[659] (made from R_3P and X_2), which give good yields of primary (including neopentyl), secondary, and tertiary halides without rearrangements, $Cl_2C{=}CClNEt_2$,[660] cyanuric chloride,[661] Me_2SBr_2[662] (prepared from Me_2S and Br_2), and a mixture of PPh_3 and CCl_4:[663]

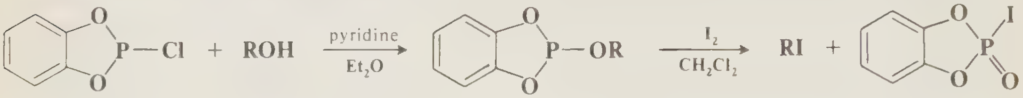
$$\mathbf{ROH + Ph_3P + CCl_4 \longrightarrow RCl + Ph_3PO + HCCl_3}$$

The latter method converts allylic alcohols to the corresponding halides without allylic rearrangements.[664] Another method which yields this result involves treatment of the allylic alcohol with a mixture of CH_3SO_2Cl, LiCl, and *s*-collidine (2,4,6-trimethylpyridine) in dimethylformamide at 0°C.[665] A simple indirect method for the conversion of alcohols to alkyl iodides consists of treating the alcohol with *o*-phenylene phosphorochlorodite (**129**, easily prepared from catechol and PCl_3), and then reaction of the resulting ester with I_2.[666] A simple method which is specific for benzylic and allylic alcohols (and does not give allylic rearrangement) involves reaction with N-chloro- or N-bromosuccinimide and methyl sulfide.[667] The specificity of this method is illustrated by the conversion, in 87% yield, of (*Z*)-$HOCH_2CH_2CMe{=}CHCH_2OH$ to (*Z*)-$HOCH_2CH_2CMe{=}CHCH_2Cl$. Only the allylic OH group was affected.



129

When the reagent is HX, the mechanism is SN1cA or SN2cA; that is, the leaving group is not OH^-, but OH_2 (p. 325). The leaving group is not OH^- with the other reagents either, since in these cases the alcohol is first converted to an inorganic ester, for example, ROSOCl with $SOCl_2$ (reaction **0-33**). The leaving group is therefore $OSOCl^-$ or a similar group (reaction **0-66**). These may react by the SN1 or SN2 mechanism and, in the case of ROSOCl, by the SNi mechanism (p. 302).

0-68 Cleavage of Ethers

$$\mathbf{ROR' + HI \longrightarrow RI + R'OH}$$

Ethers can be cleaved by heating with concentrated HI or HBr.[668] HCl is seldom successful. HBr reacts more slowly than HI, but it is often a superior reagent, since it causes fewer side reactions. Dialkyl ethers and alkyl aryl ethers can be cleaved. In the latter case the alkyl-oxygen bond is the one broken. As in reaction **0-67** the actual leaving group is not OR'^-, but OHR'.

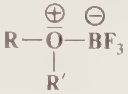
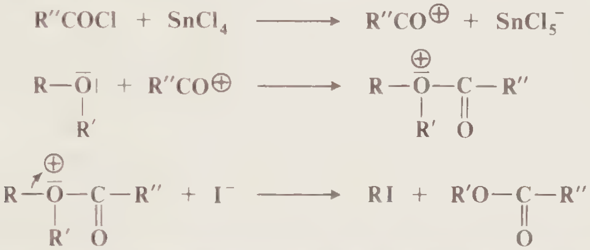
[668] For a review of this reaction, see Burwell, *Chem. Rev.* **54,** 615–685 (1954). For a review of ether cleavage in general, see Ref. 281.

The *Zeisel method* for determination of methoxy groups consists of running this reaction with HI and measuring the amount of methyl iodide formed. Although alkyl aryl ethers always cleave so as to give an alkyl halide and a phenol, there is no general rule for dialkyl ethers. Often cleavage occurs from both sides, and a mixture of two alcohols and two alkyl halides is obtained. However, methyl ethers are usually cleaved so that methyl iodide or bromide is a product. An excess of HI or HBr converts the alcohol product into alkyl halide, so that dialkyl ethers (but not alkyl aryl ethers) are converted to 2 moles of alkyl halide. This procedure is often carried out so that a mixture of only two products is obtained instead of four. Cyclic ethers (usually tetrahydrofuran derivatives) can be similarly cleaved (see reaction **0-69** for epoxides). Ethers have also been cleaved with Lewis acids such as BF_3, BCl_3, BBr_3,[669] or $AlCl_3$.[670] In such cases, the departure of the OR is assisted by complex formation with the Lewis acid:



$$\mathrm{R{-}\overset{\oplus}{\underset{|\atop R'}{\bar{O}}}{-}\overset{\ominus}{B}F_3}$$

Lewis acids are also used in conjunction with acyl halides. In such cases it is the acyl cation which assists in removal of the leaving group:



$$\mathrm{R''COCl + SnCl_4 \longrightarrow R''CO^{\oplus} + SnCl_5^-}$$

$$\mathrm{R{-}\underset{\displaystyle R'}{\bar{O}|} + R''CO^{\oplus} \longrightarrow R{-}\overset{\oplus}{\underset{\displaystyle R'}{\bar{O}}}{-}\underset{\displaystyle O}{\overset{}{C}}{-}R''}$$

$$\mathrm{R{-}\overset{\oplus}{\underset{\displaystyle R'}{\bar{O}}}{-}\underset{\displaystyle O}{C}{-}R'' + I^- \longrightarrow RI + R'O{-}\underset{\displaystyle O}{C}{-}R''}$$

Alkyl aryl ethers can also be cleaved with LiI to give alkyl iodides and salts of phenols[671] in a reaction similar to **0-70**. Triphenyldibromophosphorane (Ph_3PBr_2) cleaves dialkyl ethers to give 2 moles of alkyl bromide.[672]

A closely related reaction is cleavage of oxonium salts:

$$\mathrm{R_3O^+ \;\; X^- \longrightarrow RX + R_2O}$$

For these substrates, HX is not required, and X may be any of the four halide ions.

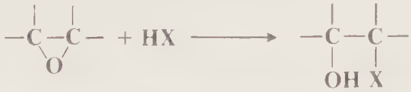
0-69 Formation of Halohydrins from Epoxides



This is a special case of reaction **0-68** and is frequently used for the preparation of halohydrins. In contrast to the situation with open-chain ethers and with larger rings, many epoxides react with all four hydrohalic acids, though with HF[673] the reaction is unsuccessful with simple aliphatic and cycloalkyl epoxides.[674] HF does react with more rigid epoxides, such as those in steroid systems. Epoxides can be converted directly to 1,2-dichloro compounds by treatment with $SOCl_2$ and pyridine[675] or with Ph_3P and CCl_4.[676] These are two-step reactions in which a halohydrin is formed first and then converted by the reagents to the dihalide (reaction **0-67**). As expected, inversion is found at both carbons. HI reduces α-keto epoxides to olefins.

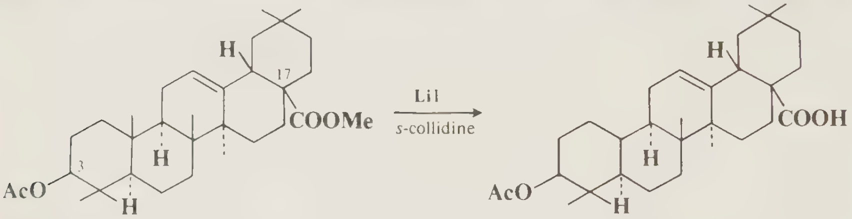
0-70 Cleavage of Esters with Lithium Iodide

$$\mathrm{R'COOR + LiI \xrightarrow[\Delta]{\text{pyridine}} RI + R'COOLi}$$

Carboxylic esters where R is methyl or ethyl can be cleaved by heating with lithium iodide in refluxing pyridine or a higher-boiling amine.[677] The reaction is useful where a molecule is sensitive to acid and base (so that **0-11** cannot be used), or where it is desired to cleave selectively only one ester group in a molecule containing two or more. For example, refluxing O-acetyloleanolic acid methyl ester with LiI in *s*-collidine cleaved only the 17-carbomethoxy group and not



the 3-acetyl group.[678] The reaction is an equilibrium, and the heat of reaction is such that relatively high temperatures are required to drive it to completion. However, the reaction temperature can be lowered if another nucleophile, e.g., OAc^- or CN^-, is added to react with the RI, thus preventing the reverse reaction from taking place.[679] Esters of salicylic acid (o-HOC_6H_4-COOR) are converted to alkyl chlorides RCl on treatment with PCl_5.[680]

0-71 Conversion of Diazo Ketones to α-Halo Ketones

$$\mathrm{RCOCHN_2 + HBr \longrightarrow RCOCH_2Br}$$

When diazo ketones are treated with HBr or HCl, they give the respective α-halo ketones. HI does not give the reaction, since it reduces the product to a methyl ketone (reaction **0-82**). α-Fluoro ketones can be prepared by addition of the diazo ketone to a 70% polyhydrogen fluoride–pyridine solution at 0°C.[681] This method is also successful for diazoalkanes. When a halide ion (Cl^-, Br^-, or I^-) or an N-halosuccinimide is added to this mixture, a mixed *gem*-dihalide is obtained, e.g.,

Diazotization of α-amino acids in the above solvent at room temperature gives α-fluoro acids.[682]

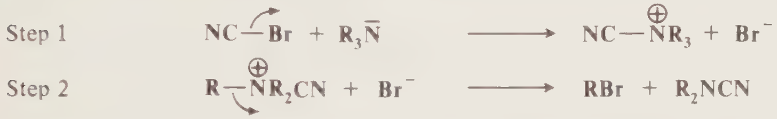
OS III, 119.

0-72 Conversion of Tertiary Amines to Cyanamides. The von Braun Reaction

$$R_3N + BrCN \longrightarrow R_2NCN + RBr$$

The *von Braun reaction*, which involves the cleavage of tertiary amines by cyanogen bromide to give an alkyl bromide and a disubstituted cyanamide, has been applied to many tertiary amines.[683] Usually, the R group which cleaves is the one which gives the most reactive halide (for example, benzyl or allyl). For simple alkyl groups, the smallest are the most readily cleaved. One or two of the groups on the amine may be aryl, but they do not cleave. Cyclic amines have been frequently cleaved by this reaction. Secondary amines also give the reaction, but the results are usually poor.[684]

The mechanism consists of two successive nucleophilic substitutions, with the tertiary amine as the first nucleophile and the liberated bromide ion as the second:



Step 1 $$NC{-}Br + R_3\bar{N} \longrightarrow NC{-}\overset{\oplus}{N}R_3 + Br^-$$

Step 2 $$R{-}\overset{\oplus}{N}R_2CN + Br^- \longrightarrow RBr + R_2NCN$$

The intermediate N-cyanoammonium bromide has been trapped, and its structure confirmed by chemical, analytical, and spectral data.[685]

OS III, 608.

0-73 Conversion of Amines to Halides

$$ArNR_2 + HBr \longrightarrow RBr + ArNHR$$
$$ArNHR + HBr \longrightarrow RBr + ArNH_2$$

Alkyl groups can be cleaved from secondary and tertiary aromatic amines by concentrated HBr in a reaction which is similar to reaction **0-68**.[686] Tertiary aliphatic amines are also cleaved by HI, but useful products are seldom obtained. Tertiary amines can be cleaved by reaction with phenyl chloroformate:[687] $R_3N + ClCOOPh \rightarrow RCl + R_2NCOOPh$. Primary aliphatic amines can be converted to alkyl halides indirectly by first sulfonating them with 2 moles of sulfonyl halide and then treating with I^- or Br^- in dimethylformamide,[292] e.g.,

$$RNH_2 + ArSO_2Cl \longrightarrow RNHSO_2Ar \xrightarrow[2.\ ArSO_2Cl]{1.\ NaH\ in\ DMF} RN(SO_2Ar)_2 \xrightarrow[DMF]{I^-} RI$$

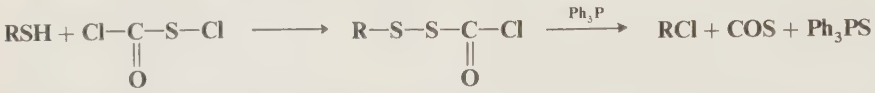
Alkyl halides may be formed when quaternary ammonium salts are heated: $\mathbf{R_4N^+ \quad X \rightarrow R_3N + RX}$.[688]

There are no OS references, but see OS **I,** 428, for a related reaction.

0-74 Replacement of Sulfur by Halogen

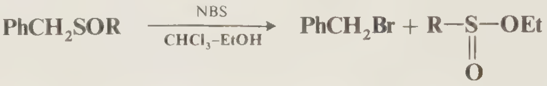
$$\mathrm{RSO_2X + Et_4N^+\,Br^- \xrightarrow{CH_2Cl_2} RBr + SO_2 + Et_4N^+\,X^-}$$

Phenylmethanesulfonyl bromide and chloride ($R = PhCH_2$), as well as methanesulfonyl bromide, can be cleaved by treatment at room temperature with tetraethylammonium bromide in CH_2Cl_2 or acetonitrile.[689] Mercaptans can be converted to chlorides by sequential treatment with chlorocarbonylsulfenyl chloride and Ph_3P.[690]



$$\mathrm{RSH + Cl{-}\underset{\underset{O}{\|}}{C}{-}S{-}Cl \longrightarrow R{-}S{-}S{-}\underset{\underset{O}{\|}}{C}{-}Cl \xrightarrow{Ph_3P} RCl + COS + Ph_3PS}$$

Benzyl and *t*-butyl alkyl or aryl sulfoxides react with N-chloro- or N-bromosuccinimide in $CHCl_3$–EtOH to give benzyl or *t*-butyl halides and sulfinic acid esters, e.g.,[691]



$$\mathrm{PhCH_2SOR \xrightarrow[CHCl_3\text{–}EtOH]{NBS} PhCH_2Br + R{-}\underset{\underset{O}{\|}}{S}{-}OEt}$$

Sulfides are in general resistant to cleavage by concentrated HI or HBr (which would be analogous to reaction **0-68**), but *β*-keto sulfides can be cleaved in this manner.[692]

B. Attack at an Acyl Carbon

0-75 Formation of Acyl Halides from Acids

$$\mathrm{RCOOH + SOCl_2 \longrightarrow RCOCl}$$

The same inorganic acid halides which convert alcohols to alkyl halides (reaction **0-67**) also convert acids to acyl halides.[693] The reaction is the best and the most common method for the preparation of acyl chlorides. Bromides and iodides are also made in this manner, but much less often. Thionyl chloride is the best reagent, since the by-products are gases and the acyl halide is thus easily isolated, but PX_3 and PX_5 ($X = Cl$ or Br) are also commonly used. However, hydrogen halides do not give the reaction. A particularly mild procedure, similar to one mentioned in reaction **0-67,** involves reaction of the acid with Ph_3P in CCl_4, whereupon acyl chlorides are produced without the obtention of any acidic compound as a by-product.[694] Acyl fluorides can be prepared by treatment of carboxylic acids with cyanuric fluoride.[695]

The reaction of acids with inorganic acid halides is unsuccessful for α-keto acids, since under the reaction conditions these compounds give decarbonylation, but if the keto group is protected by conversion to its enol ester, the reaction can be successfully carried out. Acid salts are also sometimes used as substrates. Acyl halides are also used as reagents in an exchange reaction:

---

[688] For examples, see Leffek and Tsao, *Can. J. Chem.* **46,** 1215 (1968); Ko and Leffek, *Can. J. Chem.* **48,** 1865 (1970); 49, 129 (1971).

[691] Jung and Durst, *J. Chem. Soc., Chem. Commun.* 4 (1973).

[692] For example, see Rappe and Gustafsson, *Acta Chem. Scand.* **22,** 2915 (1968).

[693] For a review, see Ansell, in Patai, Ref. 379, pp. 35–68.

[694] Lee, *J. Am. Chem. Soc.* **88,** 3440 (1966).

[695] Olah, Nojima, and Kerekes, *Synthesis* 487 (1973).

$$\mathrm{RCOOH + R'COCl \rightleftharpoons RCOCl + R'COOH}$$

which probably involves an anhydride intermediate. This is an equilibrium reaction which must be driven to the desired side. Oxalyl chloride and bromide are frequently used as the acyl halide reagent, since oxalic acid decomposes to CO and CO_2, and the equilibrium is thus driven to the side of the other acyl halide.

OS **I,** 12, 147, 394; **II,** 74, 156, 169, 569; **III,** 169, 490, 547, 555, 613, 623, 712, 714; **IV,** 34, 88, 154, 263, 339, 348, 554, 608, 616, 620, 715, 739, 900; **V,** 171, 258, 887; **52,** 36; **55,** 27.

0-76 Formation of Acyl Halides from Acid Derivatives

$$\mathrm{(RCO)_2O + HF \longrightarrow RCOF}$$

$$\mathrm{RCOCl + HF \longrightarrow RCOF}$$

These reactions are most important for the preparation of acyl fluorides. Anhydrides can be converted to acyl fluorides by treatment with liquid HF at −10°C.[696] Formyl fluoride, which is a stable compound, can be prepared in this manner from the mixed anhydride of formic and acetic acids.[697] Acyl fluorides can also be obtained by reaction of acyl chlorides with anhydrous HF[696] or with KF. Esters and anhydrides can be converted to acyl halides other than fluorides by the inorganic acid halides mentioned in **0-75,** as well as with Ph_3PX_2 ($X = Cl$ or Br),[698] but this is not often done. Halide exchange can be carried out in a similar manner. When halide exchange is done, it is always acyl bromides and iodides that are made from chlorides, since chlorides are by far the most readily available. As with reaction **0-75,** acyl halides are sometimes used as reagents in an exchange reaction. Acyl hydrazides $RCONHNH_2$ can be treated with chlorine and HCl to give acyl chlorides. This method is apparently unsuccessful for bromides and iodides.[699]

OS **II,** 528; **III,** 422; **V,** 66, 1103. See also OS **IV,** 307.

Hydrogen as Nucleophile

The reactions in this section (**0-77** to **0-85**) are reductions and could have been considered in Chapter 19. They are treated here because they involve replacement of a leaving group by hydrogen, which frequently attacks as the nucleophile hydride ion. However, not all the reactions in this section are true nucleophilic substitutions, and for some of them, more than one kind of mechanism may be involved, depending on the reagents and on the conditions. When cleavage of a carbon-hetero atom bond is accomplished by catalytic hydrogenation, the reaction is called *hydrogenolysis.*

A. Attack at an Alkyl Carbon

0-77 Reduction of Alkyl Halides

$$\mathrm{RX + LiAlH_4 \longrightarrow RH}$$

This type of reduction can be accomplished with many reducing agents, the most common being lithium aluminum hydride.[700] This reagent reduces almost all types of alkyl halide, including vinyl, bridgehead, and cyclopropyl halides.[701] Reduction with lithium aluminum deuteride serves to introduce deuterium into organic compounds. An even more powerful reducing agent, indeed reportedly the strongest SN2 nucleophile known, is lithium triethylborohydride $LiEt_3BH$. This reagent rapidly reduces primary, secondary, allylic, benzylic, and neopentyl halides, but not tertiary (these give elimination) or aryl halides.[702] Another powerful reagent, which reduces primary, secondary, tertiary, allylic, vinylic, aryl, and neopentyl halides, is a complex formed from lithium trimethoxyaluminum hydride $LiAlH(OMe)_3$ and CuI.[703] A milder reducing agent is $NaBH_4$ in a dipolar aprotic solvent such as dimethyl sulfoxide, dimethylformamide, or sulfolane,[704] which at room temperature or above reduces primary, secondary, and some tertiary[705] halides in good yield without affecting other functional groups which would be reduced by $LiAlH_4$, e.g., COOH, COOR, CN. Other reducing agents are HI, alkali metals in liquid ammonia, zinc (with acid or base), $SnCl_2$, and chromium(II) ion,[706] either in the form of simple chromous salts (for active substrates or *gem*-dihalides[707]) or complexed with ethylenediamine or ethanolamine (for ordinary alkyl halides[708]). Sodium arsenite and base, Et_3SiH in the presence of benzoyl peroxide,[709] phosphorus tris(dimethyl)amide $(Me_2N)_3P$,[710] or organotin hydrides R_nSnH_{4-n}[711] (chiefly Bu_3SnH)[712] can be used to reduce just one halogen of a *gem*-dihalide or a 1,1,1-trihalide. Reduction can also be effected by catalytic hydrogenation. A good reducing agent for the removal of all halogen atoms in a polyhalo compound (including vinyl, allylic, geminal, and even bridgehead halogens) is lithium[713] or sodium[714] and *t*-BuOH in tetrahydrofuran. Propargylic halides can often be reduced with allylic rearrangement to give allenes:[715]

[716] Nelson, Detre, and Tanabe, *Tetrahedron Lett.* 447 (1973).

Each reducing agent reduces certain groups and not others. For example, the use of $LiI-BF_3$,[717] CH_3SNa,[718] or aqueous $TiCl_3$[719] provides a means of reducing only the halogen of α-halo ketones, leaving the carbonyl group intact. Another highly selective reagent, for primary and secondary iodo and bromo groups, is sodium cyanoborohydride $NaBH_3CN$ in HMPT.[720] Still more selective is tetrabutylammonium cyanoborohydride, which is fairly specific for primary iodides.[721] Most of the reducing agents mentioned reduce chlorides, bromides, and iodides, but organotin hydrides also reduce fluorides. See page 1116 for a discussion of selectivity in reduction reactions.

With lithium aluminum hydride and most other metallic hydrides, the mechanism usually consists of simple nucleophilic substitution with attack by hydride ion which may or may not be completely free. The mechanism is SN2 rather than SN1, since primary halides react better than secondary or tertiary (tertiary generally give alkenes or do not react at all), and since Walden inversion has been demonstrated. However, rearrangements found in the reduction of bicyclic tosylates with $LiAlH_4$ indicate that the SN1 mechanism can take place.[722] The SN1 mechanism has also been shown for reduction by alkanes (such as isopentane) and aluminum chloride.[723] The aluminum chloride ionizes the substrate, and the resulting carbonium ion abstracts a hydride ion from the alkane:

$$RX + AlCl_3 \longrightarrow AlCl_3X^- + R^+ \xrightarrow{R'H} RH + R'^+$$

Reduction of halides by $NaBH_4$ in 80% aqueous diglyme[724] and by BH_3 in nitromethane[725] also takes place by an SN1 mechanism. $NaBH_4$ in sulfolane reduces tertiary halides possessing a β-hydrogen by an elimination-addition mechanism.[726]

With other reducing agents the mechanism is not always nucleophilic substitution. For example, reductions with organo tin halides generally[727] take place by free-radical mechanisms,[728] as do those with $Fe(CO)_5$[716] and Et_3SiH.[709] Alkyl halides, including fluorides and polyhalides, can be reduced with magnesium and a secondary or tertiary alcohol (most often isopropyl alcohol).[729] This is actually an example of the occurrence in one step of the sequence:

$$RX \longrightarrow RMgX \xrightarrow{H^+} RH$$

More often the process is carried out in two separate steps (reaction **2-37** and reaction **2-21**).

OS **I,** 357, 358, 548; **II,** 320, 393; **V,** 424; **51,** 60; **53,** 107; **54,** 11.

0-78 Reduction of Tosylates and Similar Compounds

$$RCH_2OTs + LiAlH_4 \longrightarrow RCH_3$$

Tosylates and other sulfonates can be reduced with $LiAlH_4$[730] or with $NaBH_4$ in a dipolar aprotic solvent.[731] The scope of the reaction seems to be similar to that of reaction **0-77.**

OS **52,** 109; **53,** 107.

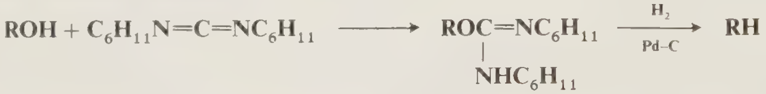
0-79 Hydrogenolysis of Alcohols

$$\mathrm{ROH + H_2 \xrightarrow{catalyst} RH}$$

The hydroxyl groups of most alcohols can seldom be cleaved by catalytic hydrogenation, and alcohols are often used as solvents for hydrogenation of other compounds. However, benzyl-type alcohols undergo the reaction readily, and these have often been reduced.[732] The most common catalysts are copper chromite and palladium-on-charcoal. Diaryl and triarylcarbonols are similarly easy to reduce, and this has been accomplished with $LiAlH_4$–$AlCl_3$,[733] with alcohols and sulfuric or formic acid,[734] and with iodine, water, and red phosphorus (OS **I**, 224). Other reagents have been used, among them tin and hydrochloric acid. 1,3-Glycols are especially susceptible to hydrogenolysis. Tertiary alcohols can be reduced by catalytic hydrogenolysis when the catalyst is platinum bis(triphenylphosphine) dichloride.[734a]

Alcohols can also be reduced indirectly by conversion to a sulfonate and reduction of that compound (reaction **0-78**). The two reactions can be carried out without isolation of the sulfonate if the alcohol is treated with pyridine-SO_3 in tetrahydrofuran, and $LiAlH_4$ then added.[735] Another indirect method involves catalytic reduction of the O-alkyl isourea formed by treating the alcohol with dicyclohexylcarbodiimide.[736]

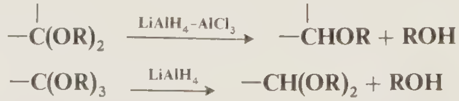


$$\mathrm{ROH + C_6H_{11}N{=}C{=}NC_6H_{11} \longrightarrow \underset{\displaystyle NHC_6H_{11}}{\underset{|}{ROC}}{=}NC_6H_{11} \xrightarrow[Pd\text{–}C]{H_2} RH}$$

Though the mechanisms of most alcohol reductions are obscure,[737] in at least some cases nucleophilic substitution has been demonstrated.[734] Hydrogenolysis of benzyl alcohols can give inversion or retention of configuration, depending on the catalyst.[738]

OS **I**, 224; **IV**, 25, 218, 482; **V**, 339.

0-80 Replacement of Alkoxyl by Hydrogen



$$\mathrm{-\overset{|}{C}(OR)_2 \xrightarrow{LiAlH_4\text{–}AlCl_3} -\overset{|}{C}HOR + ROH}$$

$$\mathrm{-C(OR)_3 \xrightarrow{LiAlH_4} -CH(OR)_2 + ROH}$$

Simple ethers are not normally cleaved by reducing agents, although such cleavage has sometimes been reported (for example, tetrahydrofuran treated with $LiAlH_4$–$AlCl_3$[739] or with a mixture of $LiAlH(O\text{-}t\text{-}Bu)_3$ and Et_3B[740] gave 1-butanol). Certain types of ethers can be cleaved quite well by reducing agents. Among these are allyl aryl,[741] vinyl aryl,[742] and benzyl ethers[732] (for epoxides, see reaction **0-81**). Acetals and ketals are resistant to $LiAlH_4$ and similar hydrides, and carbonyl groups are often converted to acetals or ketals for protection. However, a combination of $LiAlH_4$

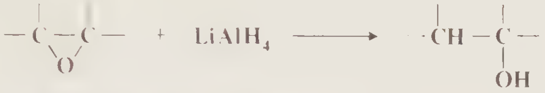
and $AlCl_3$[743] does reduce acetals and ketals, removing one group, as shown above.[744] The actual reducing agents in this case are primarily chloroaluminum hydride AlH_2Cl and dichloroaluminum hydride Al_2HCl, which are formed from the reagents.[745] Ortho esters are easily reduced to acetals by $LiAlH_4$ alone,[746] offering a route to aldehydes, since these are easily prepared by hydrolysis of the acetals (reaction **0-7**). Acetals can also be reduced to ethers by treatment with BH_3 in tetrahydrofuran[747] or with trichlorosilane $SiHCl_3$ under γ irradiation.[748]

OS **III**, 693; **IV**, 798; **V**, 303. Also see OS **III**, 742.

0-81 Reduction of Epoxides



Reduction of epoxides is a special case of reaction **0-80** and is easily carried out. The most common reagent is $LiAlH_4$, which reacts by the S_N2 mechanism, giving inversion of configuration. An epoxide on a substituted cyclohexane ring cleaves in such a direction as to give an axial alcohol. As expected for an S_N2 mechanism, cleavage usually occurs so that a tertiary alcohol is formed if possible. If not, a secondary alcohol is preferred. However, for certain substrates, the epoxide ring can be opened the other way by reduction with BH_3 in tetrahydrofuran[749] in the presence of BF_3 (for aryl-substituted epoxides) or of BH_4^- (for trisubstituted epoxides).[750] The reaction has also been carried out with other reagents, for example, sodium amalgam in EtOH, and Li in ethylenediamine,[751] and by catalytic hydrogenation.[752] Highly hindered epoxides can be conveniently reduced, without rearrangement, with lithium triethylborohydride.[753] See reaction **9-48** for another type of epoxide reduction.

α,β-Unsaturated epoxides can be reduced with concomitant allylic rearrangement, the stereochemistry of the reaction depending on the reagent.[754] Thus, 2-methyl-1,2-oxido-3-butene (**130**)

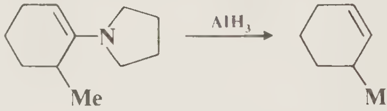
gives 95% (*Z*)-2-methyl-2-buten-1-ol (**131**) when treated with (iso-Bu)$_2$AlH at 68°C in hexane, but 92% of the *E* isomer with calcium in liquid NH_3 at −33 C. Reduction of **130** with $LiAlH_4$ gives the normal nonrearranged product **132.**

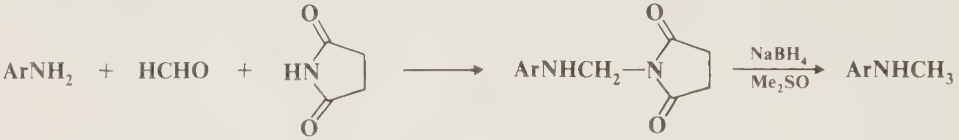
0-82 Reduction of the C—N Bond

$$3RNH_2 + HNF_2 \longrightarrow RH + 2RNH_3^+ \quad F^- + N_2$$

Primary amines have been reduced to alkanes with HNF_2. It is postulated that R—N=N—H is an intermediate,[755] so that the reaction proceeds through the carbonium ion. An indirect means of achieving the same result is conversion of the primary amine to the sulfonamide $RNHSO_2R'$ (reaction **0-120**) and treatment of this with hydroxylamine-O-sulfonic acid $(H_3\overset{\oplus}{N}OSO_3^{\ominus})$.[756] The same intermediate is postulated in this case. Another indirect method involves conversion to N,N-disulfonimides $RN(SO_2R')_2$ and reduction of these with $NaBH_4$ in HMPT.[756a] Allylic and benzylic amines[732] can be reduced by catalytic hydrogenation. Enamines are cleaved to olefins with alane AlH_3,[757] e.g.,



Since enamines can be prepared from ketones (**6-15**), this is a way of converting ketones to alkenes. A method for the monomethylation of arylamines consists of refluxing them with aqueous HCHO and succinimide to form arylaminomethylsuccinimides (a Mannich reaction, **6-17**), which are easily reduced with $NaBH_4$ in dimethyl sulfoxide.[758] Diazo ketones are reduced to methyl ketones by HI: $RCOCHN_2 + HI \rightarrow RCOCH_3$.[759]



Quaternary ammonium salts can be cleaved with $LiAlH_4$[760]

$$R_4N^+ + LiAlH_4 \longrightarrow R_3N + RH$$

as can quaternary phosphonium salts R_4P^+. Other reducing agents have also been used, for example, lithium triethylborohydride (which preferentially cleaves methyl groups)[761] and sodium in liquid ammonia. When quaternary salts are reduced with sodium amalgam in water, the reaction is known as the *Emde reduction*. However, this reagent is not applicable to the cleavage of ammonium salts with four *saturated* alkyl groups. Some tertiary amines have been cleaved with $LiAlH_4$.[762] Of course, aziridines[752] can be reduced in the same way as epoxides (reaction **0-81**).

OS **III,** 148; **IV,** 508.

For reduction of the C—S bond, see reaction **4-37.**

B. Attack at an Acyl Carbon

0-83 Reduction of Acyl Halides

$$\mathrm{RCOCl} \xrightarrow[-78^\circ\mathrm{C}]{\mathrm{LiAlH(O\text{-}\mathit{t}\text{-}Bu)_3}} \mathrm{RCHO}$$

Acyl halides are conveniently reduced to aldehydes[763] by treatment with lithium tri-*t*-butoxyaluminum hydride in diglyme at −78°C.[764] R may be alkyl or aryl and may contain many types of substituents, including NO_2, CN, and EtOOC groups. The reaction stops at the aldehyde stage because steric hindrance prevents further reduction under these conditions. Acyl halides can also be reduced to aldehydes by hydrogenation with palladium-on-barium sulfate as catalyst. This is called the *Rosenmund reduction.*[765] It is sometimes necessary to "poison" the catalyst to prevent further reduction, although many successful reactions have been run without poisons. The most commonly used poison is "quinoline-sulfur," prepared by heating sulfur in refluxing quinoline. A more convenient hydrogenation procedure involves palladium-on-charcoal as the catalyst, with ethyldiisopropylamine as acceptor of the liberated HCl and acetone as the solvent.[766] The reduction of acyl halides to aldehydes has also been carried out with Bu_3SnH,[767] with Et_3SiH catalyzed by Pd/C,[768] with disodium tetracarbonyl ferrate $Na_2Fe(CO)_4$,[769] electrochemically,[770] and by irradiation in the presence of a hydrogen donor.[771] In some of these cases, the mechanisms are free-radical. There are several indirect methods for the conversion of acyl halides to aldehydes, most of them involving prior conversion of the halides to certain types of amides (see reaction **0-85**).[772] There is also a method in which the COOH group is replaced by a completely different CHO group (**0-113**). Also see reaction **9-47.**

OS **III,** 551, 627; **51,** 8; **53,** 52. Also see OS **III,** 818; **51,** 11.

0-84 Reduction of Carboxylic Acids, Esters, and Anhydrides to Aldehydes

$$\mathrm{RCOOH} \xrightarrow[\mathrm{MeNH_2}]{\mathrm{Li}} \mathrm{RCH{=}N{-}Me} \xrightarrow{\mathrm{H_2O}} \mathrm{RCHO}$$

With most reducing agents, reduction of carboxylic acids generally gives the primary alcohol (reaction **9-40**), and the isolation of aldehydes is not feasible. However, simple straight-chain carboxylic acids have been reduced to aldehydes by treatment with Li in $MeNH_2$ or NH_3 followed by hydrolysis of the resulting imine,[773] and by treatment with diaminoaluminum hydrides.[773a] Some aldehydes have also been prepared by heating carboxylic acids with formic acid and thorium oxide (this is actually an example of reaction **0-117**). Caproic and isovaleric acids have been reduced to aldehydes, in 50% yields or better, with $(\text{iso-Bu})_2AlH$ at −75 to −70°C.[774]

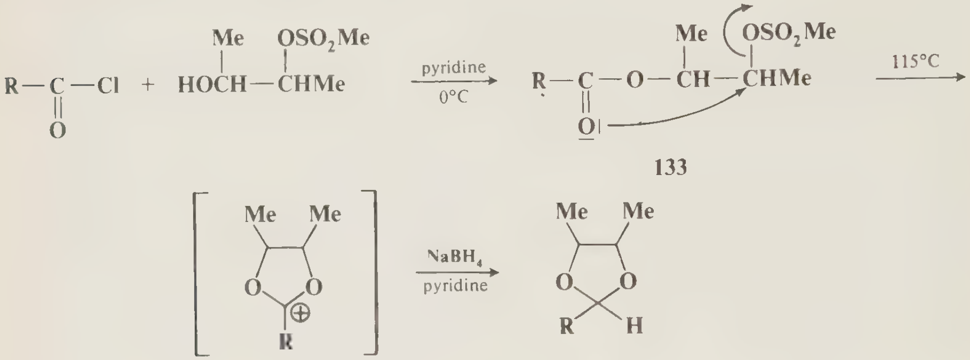
Esters have been reduced to aldehydes with (iso-Bu)$_2$AlH at −70°C, with diaminoaluminum hydrides,[773a] and with NaAlH$_4$ at −65 to −45°C, and (for phenolic esters) with LiAlH(O-*t*-Bu)$_3$ at 0°C.[775] An unusual way of converting acyl halides to aldehydes through an ester is treatment of a 2,3-butanediol monomesylate ester (**133**) with NaBH$_4$ in pyridine at 115°C.[776] Hydrolysis of the acetal (**134**) gives the aldehyde RCHO.



133

134

Anhydrides, both aliphatic and aromatic, as well as mixed anhydrides of carboxylic and carbonic acids, have been reduced to aldehydes in moderate yields with disodium tetracarbonylferrate Na$_2$Fe(CO)$_4$.[777]

OS **51,** 11.

0-85 Reduction of Amides to Aldehydes

$$\mathbf{RCONR'_2 + LiAlH_4 \longrightarrow RCHO + NHR'_2}$$

N,N-Disubstituted amides can be reduced to amines with LiAlH$_4$ (see reaction **9-41**), but also to aldehydes.[778] Keeping the amide in excess gives the aldehyde rather than the amine. Sometimes it is not possible to prevent further reduction, and primary alcohols are obtained instead. Other reagents which give good yields of aldehydes are (iso-Bu)$_2$AlH,[779] LiAlH(O-*t*-Bu)$_3$, LiAlH$_4$-EtOH,[780] NaAlH$_4$,[781] and diaminoaluminum hydrides.[781a]

Aldehydes have been prepared from acids or acyl halides by first converting them to certain types of amides which are easily reducible. The following are some examples:

1. *Reissert compounds*[782] (**135**) are prepared from the acyl halide by treatment with quinoline and cyanide ion. Treatment of **135** with sulfuric acid gives the corresponding aldehyde.

2. Acyl sulfonylhydrazides (**136**) are cleaved with base to give aldehydes. This is known as the *McFadyen-Stevens reduction*[782] and is applicable only to aromatic aldehydes or to aliphatic aldehydes with no α-hydrogen.[783] RCON=NH (see reaction **0-82**) has been proposed as an intermediate in this reaction.[784]

3. Imidazoles (**137**)[406] and N-acylaziridines (**138**)[785] can be reduced to aldehydes with $LiAlH_4$.

4. See also the Sonn-Müller method (reaction **6-30**).

See OS **IV**, 641, for the preparation of a Reissert compound.

Carbon Nucleophiles

In any ionic reaction in which a new carbon-carbon bond is formed, one carbon atom attacks as a nucleophile and the other as an electrophile. Whether to classify a given reaction as nucleophilic or electrophilic is a matter of convention and is usually based on analogy. Although not discussed in this chapter, reactions **1-13** to **1-31** and **2-15** to **2-18** are actually nucleophilic substitutions with respect to one reactant though, following convention, we classify them with respect to the other. Similarly, all the reactions in this section (**0-86** to **0-117**) would be called electrophilic substitutions (aromatic or aliphatic) if we were to consider the reagent as the substrate.

A. Attack at an Alkyl Carbon. In reactions **0-86** to **0-93** the nucleophile is a "carbanion" part of an organometallic compound, often a Grignard reagent. There is much that is still not known about the mechanisms of these reactions, and many of them are not nucleophilic substitutions at all. In those reactions which are nucleophilic substitutions, the attacking carbon brings a pair of electrons with it to the new C—C bond, whether or not free carbanions are actually involved. The connection of two alkyl or aryl groups is called *coupling*. Reactions **0-86** to **0-93** and **0-95** include both symmetrical and unsymmetrical coupling reactions. The latter are also called *cross-coupling reactions*. Other coupling reactions are considered in later chapters.

0-86 Coupling of Alkyl Halides. The Wurtz Reaction

$$2RX + Na \longrightarrow RR$$

The coupling of alkyl halides by treatment with sodium to give a symmetrical product is called the *Wurtz reaction*. Side reactions (elimination and rearrangement) are so common that the reaction is seldom used. Mixed Wurtz reactions of two alkyl halides are even less feasible, because of the number of products obtained. A somewhat more useful reaction (though still not very good) takes place when a mixture of an alkyl and an aryl halide is treated with sodium to give an alkylated aromatic compound (the *Wurtz-Fittig reaction*).[786] However, the coupling of two aryl halides with sodium is impractical (see, however, reaction **3-16**). Other metals have also been used to effect Wurtz reactions, notably silver, zinc,[787] iron,[788] and pyrophoric lead.[789] With the latter reagent, a COOH group may be present in the molecule without being affected; e.g., succinic acid was produced from chloroacetic acid. The complex $VCl_2(py)_4$ dimerizes benzyl halides to give $ArCH_2CH_2Ar$.[790] Benzal bromides ($ArCHBr_2$) can be coupled with CuCl in dimethyl sulfoxide (to give ArCHBrCHBrAr).[791] A zinc-copper couple in dimethylformamide has been used to couple α,α′-dibromo ketones, with concomitant reduction of the other bromines, e.g.,[792]

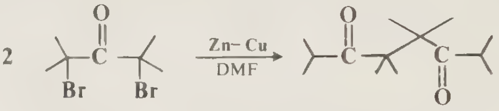
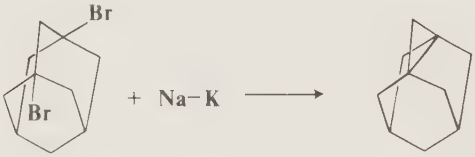
[785] Brown and Tsukamoto, *J. Am. Chem. Soc.* **83**, 4549 (1961).

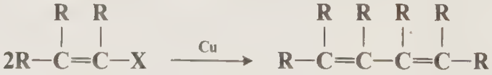


One type of Wurtz reaction which is quite useful is the closing of small rings, especially three-membered rings. For example, 1,3-dibromopropane can be converted to cyclopropane by Zn and NaI. Two highly strained molecules which have been prepared in this way are bicyclobutane[793] and tetracyclo[$3.3.1.1^{3,7}.0^{1,3}$]decane.[794] Three- and four-membered rings can also be closed in



this manner with certain other reagents,[795] including benzoyl peroxide,[796] ethylenediamine-chromium(II) reagent,[795] and lithium amalgam,[797] as well as electrochemically.[798]

Vinyl halides can be coupled to give 1,3-butadienes by treatment with activated copper powder in a reaction analogous to the Ullmann reaction (**3-16**).[799] This reaction is stereospecific,



$$2R-\overset{R}{\underset{|}{C}}=\overset{R}{\underset{|}{C}}-X \xrightarrow{\text{Cu}} R-\overset{R}{C}=\overset{R}{C}-\overset{R}{C}=\overset{R}{C}-R$$

with retention of configuration at both carbons. Vinyl halides can also be coupled with bis(1,5-

cyclooctadiene)nickel,[800] with CuCl,[801] and with Et_4NSnCl_3, $PtCl_2$, and CsF in dimethylformamide containing 2% H_2O.[802] Halides containing aryl groups (e.g., benzyl chloride) can be coupled with Grignard reagents if a small amount of a catalyst such as $CoCl_2$ or $FeCl_3$ is present.[803] The Grignard reagent is not found in the product. For example, benzyl chloride gives bibenzyl regardless of which Grignard reagent is used.

It seems likely that the mechanism of the Wurtz reaction consists of two basic steps. The first is halogen-metal exchange to give an organometallic compound ($RX + M \rightarrow RM$), which in many cases can be isolated (reaction **2-37**). Following this, the organometallic compound reacts with a second molecule of alkyl halide ($RX + RM \rightarrow RR$). This reaction and its mechanism are considered in the next section (**0-87**).

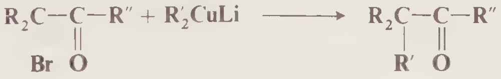
0-87 The Reaction of Alkyl Halides with Organometallic Reagents

$$\mathbf{RX + R'_2CuLi \longrightarrow R{-}R'}$$

The reagents lithium dialkylcopper (which possibly have the structure $Li^+ \; R'_2Cu^-$) react with alkyl bromides, chlorides, and iodides in ether or tetrahydrofuran to give good yields of the cross-coupling products.[804] The reaction is of wide scope.[805] R may be primary (in some cases also secondary) alkyl, allylic, benzylic, aryl, vinyl, or allenic,[806] and may contain keto, COOH, COOR, or $CONR_2$ groups. The reaction at a vinyl substrate occurs stereospecifically, with retention of configuration.[807] Many *gem*-dihalides do not react, but when the two halogens are on a carbon α to an aromatic ring[808] or on a cyclopropane ring,[804] both halogens can be replaced by R; e.g., $PhCHCl_2 \rightarrow PhCHMe_2$. However, 1,2-dibromides give exclusive elimination[809] (reaction **7-27**). R′ in R'_2CuLi may be primary alkyl, vinyl, allyl, or aryl. However, secondary and tertiary alkyl coupling can be achieved (on primary RX) by the use of $R'_2CuLi \cdot PBu_3$[810] (though this procedure introduces problems in the workup) or by the use of PhS(R′)CuLi,[811] which selectively couples a secondary or tertiary R′ with a primary iodide RI to give RR′.[812] The fact that R'_2CuLi do not react with ketones provides a method for the alkylation of ketones[813] (see also



$$\mathbf{R_2C(Br){-}C({=}O){-}R'' + R'_2CuLi \longrightarrow R_2C(R'){-}C({=}O){-}R''}$$

reactions **0-97**, **0-101**), though halogen-metal exchange (**2-38**) is a side reaction and can become the main reaction.[814]

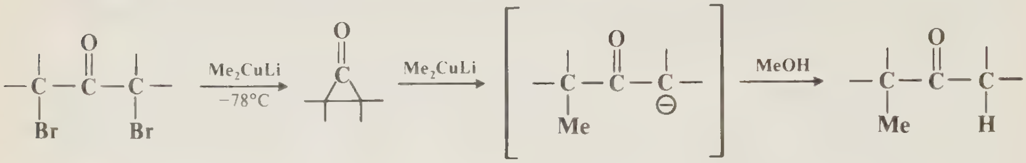
When α,α′-dibromo ketones are treated with Me_2CuLi in ether at −78°C and the mixture quenched with methanol, *mono*methylation takes place[815] (no dimethylation is observed). It has been suggested that the reaction involves initial cyclization (reaction **0-86**) to a cyclopropanone,



139 **140**

followed by nucleophilic attack to give the enolate ion **140** which is protonated by the methanol. If methyl iodide is added instead of methanol, an α,α′-dimethyl ketone is obtained, presumably from SN2 attack by **140** on methyl iodide (reaction **0-97**). Only halides which are highly reactive to SN2 attack (e.g., methyl and benzyl halides) react successfully with **140.** Primary, secondary, *and tertiary* monoalkylation of **139** can be achieved if **139** is treated with a lithium *t*-butoxy(alkyl)copper reagent[816] instead of Me_2CuLi. For example, 2,6-dibromocyclohexanone, treated with lithium *t*-butoxy(*t*-butyl)copper, gave 66% 2-*t*-butylcyclohexanone. This is one of the few methods for introducing a tertiary alkyl group α to a carbonyl group. With an unsymmetrical α,α′-dibromo ketone, monomethylation takes place predominantly on the less substituted side when the incoming group is large, but this predominance decreases with decreasing size until, with methyl, an approximately 1 : 1 mixture of both products is obtained.

R'_2CuLi reagents can be prepared by mixing 2 mol of RLi with 1 mol of cuprous halide in ether solution at low temperatures[816a] (reaction **2-34**), or by dissolving an alkylcopper compound in an alkyllithium solution. The analogous R_3MnLi and R_3FeLi also give coupling reactions but are less effective.[817]

A much older reaction is the coupling of alkyl halides with Grignard reagents.[818] Grignard reagents have the advantage that they are usually simpler to prepare than the corresponding R'_2CuLi, but the reaction is much narrower in scope. Grignard reagents couple only with active halides: allylic (though allylic rearrangements are common) and benzylic. They also couple with tertiary alkyl halides, but in low yields (30 to 50%). Aryl Grignard reagents usually give better yields in these reactions than alkyl Grignard reagents. Furthermore, because Grignard reagents react with the C=O group (reactions **6-31, 6-34**), they cannot be used to couple with halides containing ketone, COOH, or amide functions. Though the coupling of Grignard reagents with ordinary alkyl halides is usually not useful for synthetic purposes, small amounts of symmetrical coupling product are commonly formed while Grignard reagents are being prepared. The usual method for the preparation of Grignard reagents consists of the addition of the halide to magnesium in ether. The coupling products arise from reaction of some of the RMgX which is initially formed with fresh RX which is being added to the solution. Grignard reagents can be made to couple with alkyl halides in good yields by the use of certain catalysts. Among these are Cu(I) salts, which permit the coupling of Grignard reagents with primary alkyl halides in good yield[819]

(organocopper salts are probably intermediates here), and iron(III) complexes, which allow the coupling of Grignard reagents and vinyl halides.[820] Grignard reagents couple with only one halogen of a dihalide, provided the second halogen is at least two carbons away, if the reaction is carried out in tetrahydrofuran in the presence of lithium tetrachlorocuprate.[821] Grignard reagents

$$\mathrm{RMgX + Br(CH_2)_nBr} \xrightarrow[\text{THF}]{\mathrm{Li_2CuCl_4}} \mathrm{R(CH_2)_nBr} \qquad n = 3 \text{ or more}$$

prepared from primary alkyl or aryl halides can be coupled with vinyl or aryl halides in high yields in the presence of a nickel(II) catalyst.[822] Among the catalysts used have been dichloro 1,2-bis(diphenylphosphine)ethane nickel(II) and nickel(II) acetonylacetonate. Grignard reagents prepared from secondary halides also give this reaction, but isomerization to a primary group competes.[823] When a chiral nickel(II) catalyst is used, optically active hydrocarbons can be prepared from achiral reagents.[824]

Other organometallic compounds have also been used to couple with alkyl halides. Organosodium and organopotassium compounds are more reactive than Grignard reagents and couple even with less reactive halides. The difficulty is in preparing and keeping them long enough for the alkyl halide to be added. With particularly stable organosodium or organopotassium reagents, such as triphenylmethylsodium, coupling can be accomplished even with primary and secondary halides. Alkenes can be prepared by the coupling of vinyllithium compounds with primary halides.[825] Organoaluminum compounds couple very well with tertiary (to give products containing a quaternary carbon) and benzylic halides at −78°C.[826] This reaction can also be applied to allylic, secondary, and some primary halides, but here several days standing at room temperature is required (see also reaction **0-90**). Vinylaluminum compounds couple with allylic halides to give 1,4-dienes.[827] Arylpalladium salts "ArPdX" prepared from arylmercury compounds and lithium palladium chloride couple with allylic chlorides in moderate yields, though allylic rearrangements can occur.[828] The advantage of this procedure is that the aryl group may contain nitro, ester, or aldehyde groups, etc., which cannot be present in a Grignard reagent.

Much study has been devoted to the mechanisms of these reactions, but firm conclusions are still lacking, in part because the mechanisms vary depending on the metal, the R group, the catalyst, if any, and the reaction conditions. Two basic pathways can be envisioned: a nucleophilic substitution process (which might be S_N1 or S_N2) and a free-radical mechanism:

$$\mathrm{RX + R'M} \longrightarrow \underset{\text{Solvent cage}}{\left|\begin{array}{c}\mathrm{R\cdot + R'\cdot} \\ \mathrm{+\ MX}\end{array}\right|} \longrightarrow \mathrm{RR'}$$

It is necessary to postulate the solvent cage because, if the radicals were completely free, the products would be about 50% RR′, 25% RR, and 25% R′R′, and this is generally not the case; in most of these reactions RR′ is the predominant or exclusive product.[829] An example where an Sn2 mechanism has been demonstrated (by the finding of inversion of configuration at R) is the reaction between allylic or benzylic lithium reagents with secondary halides.[830] Similarly, inversion has been shown in the reaction of 2-bromobutane with Ph_2CuLi.[810] The fact that in some of these cases the reaction may be successfully applied to aryl and vinyl substrates indicates that a simple Sn process cannot be the only mechanism. One possibility is that the reagents first undergo an exchange reaction: $ArX + RM \rightarrow RX + ArM$; and then a nucleophilic substitution takes place. On the other hand, there is much evidence that many coupling reactions involving organometallic reagents with simple alkyl groups occur by free-radical mechanisms. Among the evidence is the observation of CIDNP in reactions of alkyl halides with simple organolithium reagents[831] (see p. 171), the detection of free radicals by esr spectroscopy[832] (p. 170), and the formation of 2,3-dimethyl-2,3-diphenylbutane when the reaction was carried out in the presence of cumene[833] (this product is formed when a free-radical abstracts a hydrogen from cumene to give $Ph\dot{C}Me_2$, which dimerizes). Evidence for free-radical mechanisms has also been found for the coupling of alkyl halides with simple organosodium compounds (Wurtz),[834] and with Grignard reagents.[835] Free radicals have also been implicated in the metal-ion-catalyzed coupling of alkyl and aryl halides with Grignard reagents.[836]

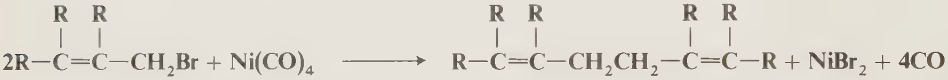
0-88 Allylic and Propargylic Coupling with a Halide Substrate



$$2R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2Br + Ni(CO)_4 \longrightarrow R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2CH_2-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-R + NiBr_2 + 4CO$$

Because of the presence of the 1,5-diene moiety in many naturally occurring compounds, a great deal of effort has been expended in searching for methods to couple allylic groups.[837] In one of these methods, allylic halides, tosylates, and acetates can be symmetrically coupled by treatment with nickel carbonyl at room temperature in a solvent such as tetrahydrofuran or dimethylformamide to give 1,5-dienes.[838] The order of halide reactivity is $I > Br > Cl$. With unsymmetrical allylic substrates, coupling nearly always takes place at the less substituted end. The reaction can be performed intramolecularly: large (11- to 20-membered) rings can be made in good yields (60 to 80%) by the use of high dilution. An example[839] is:

---

[829] When a symmetrical distribution of products *is* found, this is evidence for a free-radical mechanism: the solvent cage is not efficient and breaks down.

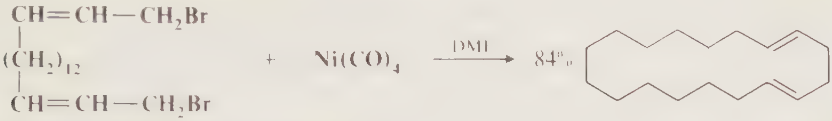
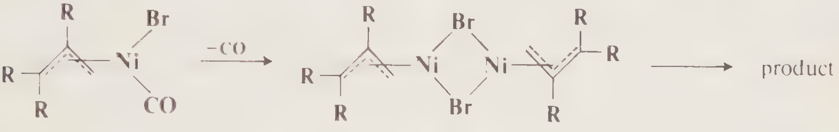
[837] In this section are discussed methods in which one molecule is a halide. For other allylic coupling reactions, see **0-87**, **0-90**, **0-91**, and **4-32**.

[838] For reviews, see Semmelhack, *Org. React.* **19,** 115–198 (1972), pp. 162–170; Baker, *Chem. Rev.* **73,** 487–530 (1973), pp. 512–517; Heimbach, Jolly, and Wilke, *Adv. Organomet. Chem.* **8,** 29–86 (1970), pp. 30–39.



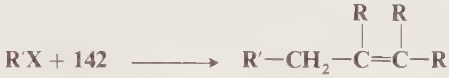
The mechanism is not completely understood, but it is likely that the allylic compound reacts with $Ni(CO)_4$ to give one or more π complexes, of which one may be **141**, which can then lose



141 **142**

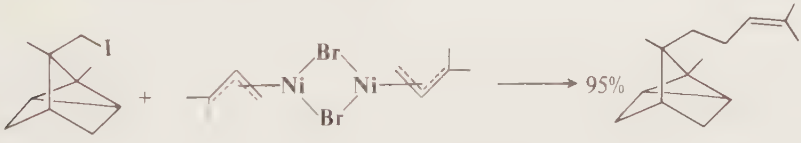
CO to give a π-allylnickel bromide (**142**) which then reacts further, perhaps with CO, to give the product. The complexes **142** can be isolated from the solution and crystallized as stable solids.

Unsymmetrical coupling can be achieved by treating an alkyl halide directly with **142**[840] in a



$$R'X + \mathbf{142} \longrightarrow R'{-}CH_2{-}\overset{\overset{\displaystyle R}{|}}{C}{=}\overset{\overset{\displaystyle R}{|}}{C}{-}R$$

polar aprotic solvent[841] (**142** do not react with alkyl halides in hydrocarbon or ether-type solvents). An example is the synthesis of α-santalene (**143**).[841]



143

Once again, as shown in the example, unsymmetrical allylic groups couple at the less substituted end. In this case too the mechanism is not completely known, but it cannot be simple nucleophilic substitution, since aryl and vinyl halides undergo the reaction as well as or better than simple primary bromides. The order of halide reactivity is I > Br > Cl and, for example, in a molecule containing both I and Cl it is possible for the I to react while the Cl is unaffected. Hydroxy or carbonyl groups in the alkyl halide do not interfere. When **142** reacts with an allylic halide, a mixture of three products is obtained, because of halogen-metal interchange. For example, allyl bromide treated with **142** prepared from methallyl bromide gave an approximately statistical mixture of 1,5-hexadiene, 2-methyl-1,5-hexadiene, and 2,5-dimethyl-1,5-hexadiene.[842]

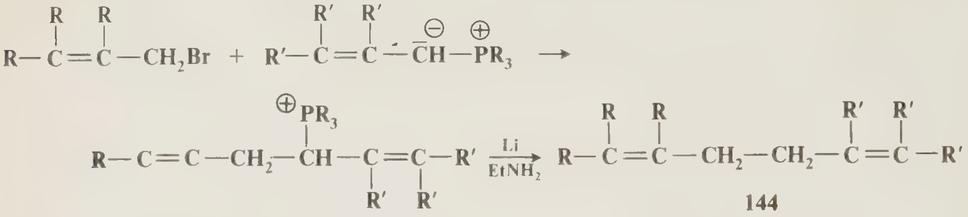
Symmetrical coupling of allylic halides can also be accomplished by heating with magnesium in ether,[843] with a cuprous iodide–dialkylamide complex,[843a] or with iron powder in dimethylformamide.[844] The coupling of two different allyl groups has been achieved by treatment of an allylic bromide with an allyllithium (generated in situ from an allylic mesitoate) at 0°C in tetrahydrofuran,[845] or with an allylic Grignard reagent in tetrahydrofuran containing HMPT.[846]

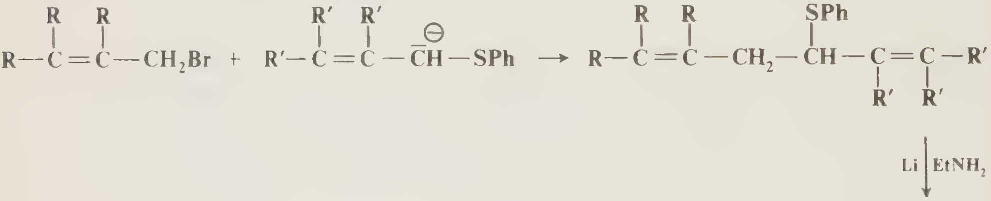
In another method for the coupling of two different allylic groups, a phosphorus ylide (p. 40) derived from one allylic halide combines with another allylic halide.[847] The product is a phosphonium salt which must be reduced (with lithium in ethylamine), but this method has the advantage that, unlike most of the methods previously discussed, the coupling preserves the original positions and configurations of the two double bonds: no allylic rearrangements take place. A similar method involves coupling of an allylic halide with a carbanion derived from a β,γ-unsaturated thioether.[848] In this case too the original positions and configurations of the double bonds are preserved, and a group (here the SPh group) must be removed to give the 1,5-diene.



$$R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2Br + R'-\overset{R'}{\overset{|}{C}}=\overset{R'}{\overset{|}{C}}-\overset{\ominus}{C}H-\overset{\oplus}{P}R_3 \longrightarrow$$

$$R-C=C-CH_2-\overset{\oplus PR_3}{\overset{|}{C}H}-\underset{R'}{\underset{|}{C}}=\underset{R'}{\underset{|}{C}}-R' \xrightarrow[EtNH_2]{Li} R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2-CH_2-\overset{R'}{\overset{|}{C}}=\overset{R'}{\overset{|}{C}}-R'$$

144



$$R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2Br + R'-\overset{R'}{\overset{|}{C}}=\overset{R'}{\overset{|}{C}}-\overset{\ominus}{C}H-SPh \longrightarrow R-\overset{R}{\overset{|}{C}}=\overset{R}{\overset{|}{C}}-CH_2-\overset{SPh}{\overset{|}{C}H}-\underset{R'}{\underset{|}{C}}=\underset{R'}{\underset{|}{C}}-R' \xrightarrow[EtNH_2]{Li}$$

144

In a method for propargylating an alkyl halide without allylic rearrangement, the halide is treated with lithio-1-trimethylsilylpropane (**145**) which is a lithium compound protected by an $SiMe_3$ group.[849] Attack by the ambident nucleophile at its 1 position, which gives an allene, takes place only to a small extent, because of steric blockage by the large $SiMe_3$ group. The $SiMe_3$ group is easily removed by treatment with Ag^+ followed by CN^-. **145** is prepared by treating propynyllithium with Me_3SiCl to give $MeC{\equiv}CSiMe_3$ from which a proton is removed with BuLi.

$$RX + Li\overset{3}{C}H_2-C{\equiv}\overset{1}{C}-SiMe_3 \longrightarrow RCH_2-C{\equiv}C-SiMe_3 \xrightarrow[2.\ CN^-]{1.\ Ag^+} R-CH_2-C{\equiv}CH$$

0-89 Coupling of Organometallic Reagents with Esters of Sulfuric and Sulfonic Acids

$$\mathbf{ROSO_2OR' + R''_2CuLi \longrightarrow RR''}$$

Lithium dialkylcopper reagents couple with alkyl tosylates.[851] High yields are obtained with primary tosylates; secondary tosylates give lower yields. Aryl tosylates do not react. Tosylates and other sulfonates and sulfates also couple with Grignard reagents,[852] most often those prepared from aryl or benzylic halides. Alkyl sulfates and sulfonates generally make better substrates in the reaction with Grignard reagents than the corresponding alkyl halides (reaction **0-87**). The method is useful for primary and secondary R. Allylic tosylates can be symmetrically coupled with $Ni(CO)_4$ (see reaction **0-88**).

OS **I,** 471; **II,** 47, 360.

0-90 Coupling Involving Alcohols

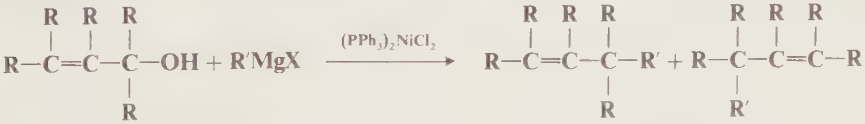
$$\mathbf{2ROH \xrightarrow[-78\text{ C}]{\text{MeLi–TiCl}_3} RR}$$

Allylic or benzylic alcohols can be symmetrically coupled by treatment with methyllithium and titanium trichloride at −78 C,[853] or by refluxing with $TiCl_3$ and $LiAlH_4$.[853a] When the substrate is an allylic alcohol, the reaction is not regiospecific, but a mixture of normal coupling and allylically rearranged products is found. Applying the reaction to a mixture of two different alcohols gives an approximately statistical mixture of RR, R′R, and R′R′, but better yields of RR′ can be obtained by the use of an excess of one alcohol. A free-radical mechanism is involved.[854]

Tertiary alcohols react with trimethylaluminum at 80 to 200 C to give methylation.[855] The

$$\mathbf{R_3COH + Me_3Al \xrightarrow{80\ 200\text{ C}} R_3CMe}$$

presence of side products from elimination and rearrangement, as well as the lack of stereospecificity,[856] indicate an S_N1 mechanism. The reaction can also be applied to primary and secondary alcohols if these contain an aryl group in the α-position. Higher trialkylaluminums are far less suitable, because reduction competes with alkylation (see also reactions of Me_3Al with ketones, **6-31,** and with carboxylic acids, **6-34**). Allylic alcohols couple with Grignard reagents in the presence of dichlorobis(triphenylphosphine)nickel.[857] Both normal products and products of allylic



$$\mathrm{R{-}\overset{R}{\overset{|}{C}}{=}\overset{R}{\overset{|}{C}}{-}\underset{\underset{R}{|}}{\overset{R}{\overset{|}{C}}}{-}OH + R'MgX \xrightarrow{(PPh_3)_2NiCl_2} R{-}\overset{R}{\overset{|}{C}}{=}\overset{R}{\overset{|}{C}}{-}\underset{\underset{R}{|}}{\overset{R}{\overset{|}{C}}}{-}R' + R{-}\underset{\underset{R'}{|}}{\overset{R}{\overset{|}{C}}}{-}\overset{R}{\overset{|}{C}}{=}\overset{R}{\overset{|}{C}}{-}R}$$

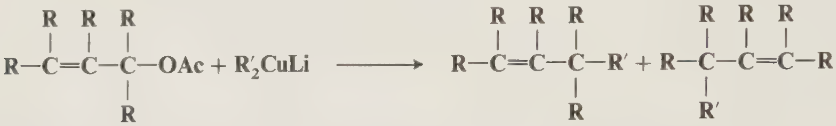
rearrangement are produced. R′ may be alkyl or aryl, but must lack a β-hydrogen (e.g., Me, $PhCH_2$ give the reaction, but not Et), since otherwise the allylic alcohol is simply reduced to an alkene. A π complex between the nickel and the allylic compound is an intermediate.

0-91 Coupling of Organometallic Reagents with Carboxylic Esters



$$\mathrm{R{-}\overset{R}{C}{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{-}OAc + R'_2CuLi \longrightarrow R{-}\overset{R}{C}{=}\overset{R}{C}{-}\underset{R}{\overset{R}{C}}{-}R' + R{-}\underset{R'}{\overset{R}{C}}{-}\overset{R}{C}{=}\overset{R}{C}{-}R}$$

Lithium dialkylcopper reagents couple with allylic acetates to give normal coupling products, or those resulting from allylic rearrangement, depending on the substrate.[858] With propargyl substrates, the products are allenes.[859] Allenes are also obtained when propargyl acetates are treated

$$\mathrm{RC{\equiv}C{-}CR_2{-}OAc + R'_2CuLi \longrightarrow RR'C{=}C{=}CR_2}$$

with methylmagnesium iodide.[860] Lithium dialkylcopper reagents also give normal coupling products with enol acetates of β-dicarbonyl compounds.[861] Allylic acetates can be symmetrically coupled by treatment with $Ni(CO)_4$ (reaction **0-88**).

0-92 Coupling of Grignard Reagents with Compounds Containing the Ether Linkage[861a]

$$\mathrm{R_2C(OR')_2 + R''MgX \longrightarrow R_2CR''(OR') + R'OMgX}$$

$$\mathrm{RC(OR')_3 + R''MgX \longrightarrow RCR''(OR')_2 + R'OMgX}$$

Acetals, ketals, and ortho esters[862] react with Grignard reagents to give, respectively, ethers and acetals (or ketals). The latter can be hydrolyzed to aldehydes or ketones (reaction **0-7**). This procedure is a way of converting a halide R″X (which may be alkyl, aryl, vinyl, or alkynyl) to an aldehyde R″CHO, increasing the length of the carbon chain by one carbon. The ketone synthesis generally gives lower yields. Tertiary amines can be prepared by the reaction of amino ethers with Grignard reagents:[863]

$$\mathrm{R_2N{-}CH_2{-}OR' + R''MgX \longrightarrow R_2N{-}CH_2{-}R''}$$

Amino thioethers R_2NCH_2SAr behave similarly.[864] Alkynyl ethers can be alkylated with primary, secondary, or tertiary alkyl- or aryllithium reagents: $R'C{\equiv}COR'' + RLi \rightarrow R'C{\equiv}CR$.[865] An addition-elimination mechanism has been suggested for this reaction.

Ordinary ethers are not cleaved by Grignard reagents (in fact, diethyl ether and tetrahydrofuran are the most common solvents for Grignard reagents), though more active organometallic compounds often do cleave them.[866] Phenolic ethers have been cleaved by heating to a high temperature with Grignard reagents.

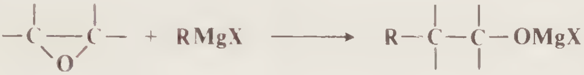
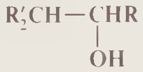
0-93 The Reaction of Organometallic Reagents with Epoxides



The reaction between Grignard reagents and epoxides is very valuable and is often used to increase the length of a carbon chain by two carbons.[867] The Grignard reagent may be aromatic or aliphatic, though tertiary Grignard reagents give low yields. As expected for an SN2 process, attack is at the less substituted carbon. Lithium dialkylcopper reagents also give the reaction, often producing higher yields, and have the additional advantage that they do not react with ester or ketone groups so that the epoxide ring of epoxy esters and ketones may be selectively attacked.[868]

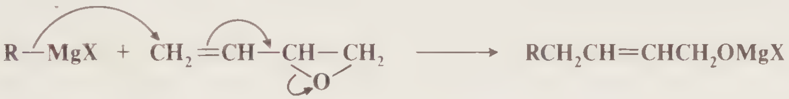
146



147

When *gem*-disubstituted epoxides (**146**) are treated with Grignard reagents (and sometimes other epoxides), the product may be **147;** that is, the new alkyl group may appear on the same carbon as the OH. In such cases, the epoxide is isomerized to an aldehyde or a ketone before reacting with the Grignard reagent. Halohydrins are often side products.

When the substrate is a vinyl epoxide, Grignard reagents generally give a mixture of the normal product and the product of allylic rearrangement:[869]



The latter often predominates. In the case of R_2CuLi, allylic rearrangement takes place almost exclusively.[869]

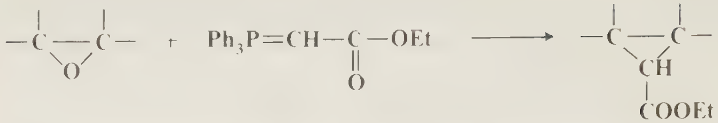
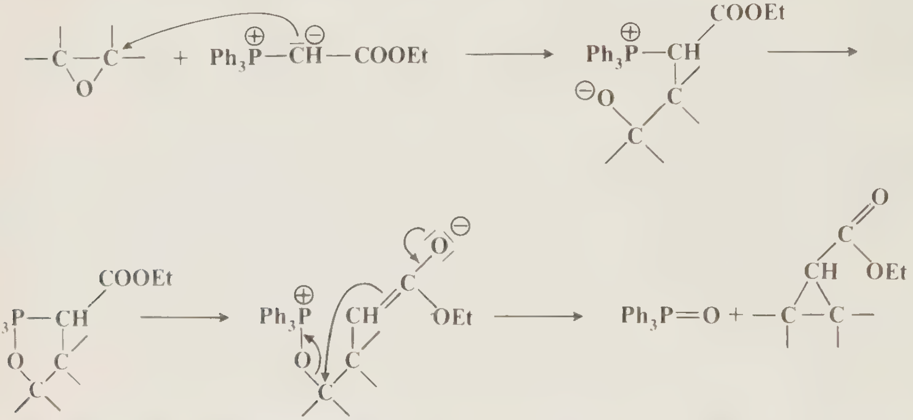
0-94 The Conversion of Epoxides to Cyclopropanes

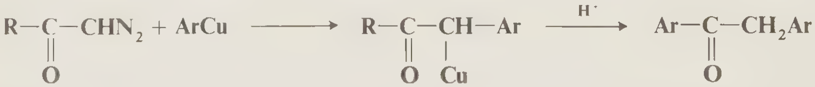


The treatment of epoxides with certain phosphorus ylides gives substituted cyclopropanes[870] in a reaction which is mechanistically related to reaction **0-93.** In this reaction the initial attack on the epoxide is similar to that of the Grignard reagent:



The final step is also a nucleophilic substitution, with $OPPh_3$ as the leaving group. The use of $Bu_3P{=}CHCOOEt$ instead of $Ph_3P{=}CHCOOEt$ led to the predominant formation of unsaturated esters instead of ester-substituted cyclopropanes.[871] Nucleophilic attack by phosphorus ylides is also found in reaction **0-114** and in the Wittig reaction **(6-47)**.

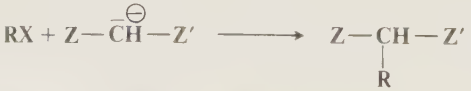
0-95 Arylation of Diazo Ketones and Diazo Esters



$$R-\underset{\underset{O}{\|}}{C}-CHN_2 + ArCu \longrightarrow R-\underset{\underset{O}{\|}}{C}-\underset{\underset{Cu}{|}}{CH}-Ar \xrightarrow{H^+} Ar-\underset{\underset{O}{\|}}{C}-CH_2Ar$$

Diazo ketones and diazo esters can be arylated by treatment with an arylcopper compound (prepared from ArLi or ArMgX and CuBr) followed by hydrolysis.[872] The reaction has also been performed on diazoalkanes.

0-96 Alkylation at a Carbon Bearing an Active Hydrogen



$$RX + Z-\overset{\ominus}{\underline{C}}H-Z' \longrightarrow Z-\underset{\underset{R}{|}}{CH}-Z'$$

Compounds which contain two (or three, but this is rare) strong electron-withdrawing groups on a carbon atom are more acidic than compounds without such groups (p. 240) and are easily converted to their corresponding enolate ions (p. 73). These enolate ions can attack alkyl halides, resulting in their alkylation.[873] Z and Z′ may be COOR′, CHO, COR′, $CONR'_2$, COO^-, CN,[874] NO_2, SOR′, SO_2R', SO_2OR', $SO_2NR'_2$, or similar groups. A carbon atom with any two of these, the same or different, will give up a proton (if it has one) to a suitable base. In the case where $Z = NO_2$, a second Z group is not required, since NO_2 is so powerful an electron-withdrawing group. Some commonly used bases are sodium ethoxide and potassium *t*-butoxide, each in its respective alcohol as solvent. With particularly acidic compounds (e.g., β-diketones Z, Z′ = COR′), sodium hydroxide in water or aqueous alcohol or acetone, or even sodium carbonate, is a strong enough base for the reaction. If at least one Z group is COOR′, saponification is a possible side reaction. In addition to the groups listed above, Z may also be phenyl, but if two phenyl groups are on the same carbon, the acidity is less than in the other cases and a stronger base must be used. However, the reaction can be successfully carried out with diphenylmethane, with $NaNH_2$ as the base.[875] The solvent used in the reaction must not be acidic enough to protonate either the enolate ion or the base, which in most cases rules out water. The use of polar aprotic solvents, e.g., dimethylformamide or dimethyl sulfoxide, markedly increases the rate of alkylation[876] but also increases the extent of alkylation at the oxygen rather than the carbon (p. 339).

---

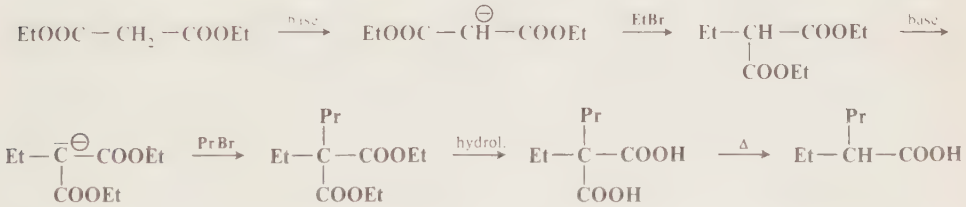
[870] Denney, Vill, and Boskin, *J. Am. Chem. Soc.* **84,** 3944 (1962). For reviews, see Johnson, "Ylid Chemistry," pp. 111–113, Academic Press, Inc., New York, 1966; Trippett, *Q. Rev., Chem. Soc.* **17,** 406–440 (1964), pp. 426–428.

[871] Gerkin and Rickborn, *J. Am. Chem. Soc.* **89,** 5850 (1967).

[872] Cairncross and Sheppard, *J. Am. Chem. Soc.* **90,** 2186 (1968); Sato and Watanabe, *Chem. Commun.* 515 (1969).

Usually the reaction is carried out on a CH_2 group connected to two Z groups. In such cases it is possible to alkylate twice, first removing the proton with a base, then alkylating with RX, then removing the proton from ZCHRZ′, and finally alkylating the resulting enolate ion with the same or a different RX. The reaction is successful for primary and secondary alkyl, allylic (with allylic rearrangement possible), and benzylic RX, but fails for tertiary halides, since these undergo elimination under the reaction conditions (see, however, p. 421). Various functional groups may be present in RX as long as they are not sensitive to base. Side reactions which may cause problems are the above-mentioned competing O-alkylation, elimination (if the enolate ion is a strong enough base), and dialkylation.

An important example of this reaction is the *malonic ester synthesis*, in which both Z groups are COOEt. The product can be hydrolyzed and decarboxylated (reaction **2-39**) to give a carboxylic acid. An illustration is the preparation of 2-ethylpentanoic acid from malonic ester:



$$EtOOC{-}CH_2{-}COOEt \xrightarrow{\text{base}} EtOOC{-}\overset{\ominus}{C}H{-}COOEt \xrightarrow{EtBr} Et{-}\underset{COOEt}{CH}{-}COOEt \xrightarrow{\text{base}}$$

$$Et{-}\underset{COOEt}{\overset{\ominus}{C}}{-}COOEt \xrightarrow{PrBr} Et{-}\underset{COOEt}{\overset{Pr}{C}}{-}COOEt \xrightarrow{\text{hydrol.}} Et{-}\underset{COOH}{\overset{Pr}{C}}{-}COOH \xrightarrow{\Delta} Et{-}\overset{Pr}{CH}{-}COOH$$

It is obvious that many carboxylic acids of the formulas RCH_2COOH and RR′CHCOOH can be synthesized by this method (for some other ways of preparing such acids, see reactions **0-98**, **0-100**, and **0-101**). Another important example is the *acetoacetic ester synthesis*, in which Z is COOEt and Z′ is $COCH_3$. In this case the product can be decarboxylated with acid or dilute base (reaction **2-39**) to give a ketone, or cleaved with concentrated base (reaction **2-42**) to give an ester and a salt of acetic acid:

---

[873] For discussions of reactions **0-96** and **0-97**, see House, "Modern Synthetic Reactions," 2d ed., pp. 492–570, 586–595, W. A. Benjamin, Inc., Menlo Park, Calif., 1972; Carruthers, "Some Modern Methods of Organic Synthesis," pp. 1–29, Cambridge University Press, London, 1971.

[874] For a review of the reactions of malononitrile $CH_2(CN)_2$, see Freeman, *Chem. Rev.* **69**, 591–624 (1969).

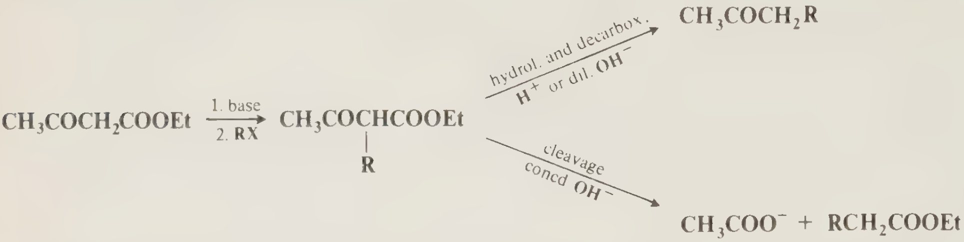
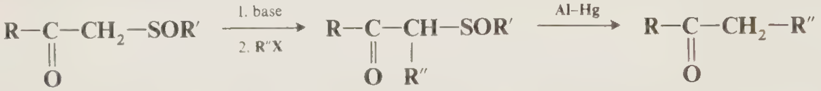
[876] Zaugg, Horrom, and Borgwardt, Ref. 264; Zaugg, Ref. 264; Zaugg, Dunnigan, Michaels, Swett, Wang, Sommers, and DeNet, *J. Org. Chem.* **26**, 644 (1961).



$$CH_3COCH_2COOEt \xrightarrow[2.\ RX]{1.\ \text{base}} \underset{\underset{R}{|}}{CH_3COCHCOOEt} \begin{cases} \xrightarrow[H^+ \text{ or dil. } OH^-]{\text{hydrol. and decarbox.}} CH_3COCH_2R \\ \xrightarrow[\text{concd } OH^-]{\text{cleavage}} CH_3COO^- + RCH_2COOEt \end{cases}$$

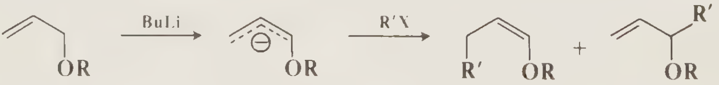
Another way of preparing ketones involves alkylation with primary halides of β-keto sulfoxides[877] or sulfones,[878] e.g.,



$$R-\underset{\underset{O}{\|}}{C}-CH_2-SOR' \xrightarrow[2.\ R''X]{1.\ \text{base}} R-\underset{\underset{O}{\|}}{C}-\underset{\underset{R''}{|}}{CH}-SOR' \xrightarrow{\text{Al-Hg}} R-\underset{\underset{O}{\|}}{C}-CH_2-R''$$

since the product in this case is easily reduced to a ketone in high yields with aluminum amalgam or by electrolysis.[879] The β-keto sulfoxides or sulfones are easily prepared (reaction **0-112**). Other examples of the reaction are the *cyanoacetic ester synthesis*, in which Z is COOEt and Z′ is CN (as in the malonic ester synthesis, the product here can be hydrolyzed and decarboxylated), and the *Sorensen* method of amino acid synthesis, in which the reaction is applied to N-acetylaminomalonic ester $(EtOOC)_2CHNHCOCH_3$. Hydrolysis and decarboxylation of the product in this case gives an α-amino acid. The amino group is also frequently protected by conversion to a phthalimido group.

The reaction is not limited to $Z-CH_2-Z'$ compounds. Other acidic C—H hydrogens, which include, for example, the methyl hydrogens of α-aminopyridines, the methyl hydrogens of ynamines of the form $CH_3C{\equiv}CNR_2$[880] (the product in this case can be hydrolyzed to an amide $RCH_2CH_2CONR_2$), the CH_2 hydrogens of cyclopentadiene and its derivatives (p. 46), hydrogens connected to a triple-bond carbon (reaction **0-102**), and the hydrogen of HCN (reaction **0-103**), can also be removed with a base and the resulting ion alkylated (see also reactions **0-97** to **0-100**). A proton can be removed from an allylic ether by treatment with an alkyllithium at about -70 C (at higher temperatures the Wittig rearrangement—**8-26**—takes place) to give the ion **148** which reacts with alkyl halides to give the products **149** and/or **150**.[881]



148 **149** **150**

Alkylation always takes place at the most acidic position of a reagent molecule; for example, acetoacetic ester (CH_3COCH_2COOEt) is alkylated at the methylene and not at the methyl group, because the former is more acidic than the latter and hence gives up its proton to the base.

---

[877] Gassman and Richmond, *J. Org. Chem.* **31**, 2355 (1966). Such sulfoxides can be alkylated on the other side of the C=O group by the use of two moles of base (p. 337): Kuwajima and Iwasawa, *Tetrahedron Lett.* 107 (1974).

[878] House and Larson, *J. Org. Chem.* **33**, 61 (1968).

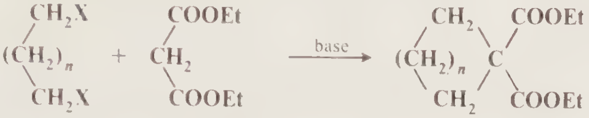
[879] Lamm and Samuelsson, *Acta Chem. Scand.* **23**, 691 (1969).

[880] Corey and Cane, *J. Org. Chem.* **35**, 3405 (1970).

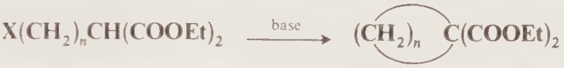
[881] Evans, Andrews, and Buckwalter, *J. Am. Chem. Soc.* **96**, 5560 (1974); Still and Macdonald, *J. Am. Chem. Soc.* **96**, 5561 (1974).

However, if 2 moles of base are used, then not only is the most acidic proton removed but also the second most acidic. Alkylation of this doubly charged anion then takes place at the less acidic position (see p. 337). This technique has been used to alkylate many compounds in the second most acidic position.[333]

When ω,ω′-dihalides are used, ring closures may be effected:



The method has been used to close rings of from three ($n = 0$) to seven members, although five-membered-ring closures proceed in highest yields. Another ring-closing method involves internal alkylation.[882]

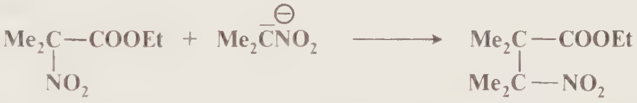


The mechanism of these reactions is usually S_N2, with inversion taking place at a chiral RX, though in certain instances there is evidence that a radical-anion mechanism is involved.[883] Tertiary alkyl groups can be introduced by an S_N1 mechanism if the ZCH_2Z' compound (not the enolate ion) is treated with a tertiary carbonium ion generated in situ from an alcohol or alkyl halide and BF_3 or $AlCl_3$,[884] or with a tertiary alkyl perchlorate.[885]

Other leaving groups are sometimes used. Sulfates, sulfonates, and epoxides give the expected products. Acetals can behave as substrates, one OR group being replaced by ZCHZ′ in a reaction similar to **0-92.**[886] Ortho esters behave similarly, but the product loses R′OH to give an enol ether.[887] The NR_2 group from Mannich bases such as $RCOCH_2CH_2NR_2$ can also act as a

$$ZCH_2Z' + RC(OR')_3 \xrightarrow{Ac_2O} ZZ'C{=}CROR'$$

leaving group in this reaction[888] (elimination-addition mechanism, p. 315). A nitro group can be displaced from α-nitro esters, ketones, nitriles, and α,α-dinitro compounds by salts of nitro paraffins, e.g.,[889]



$$\underset{\displaystyle NO_2}{Me_2C}{-}COOEt + Me_2\overset{\ominus}{C}NO_2 \longrightarrow \begin{array}{l}Me_2C{-}COOEt\\ \quad|\\ Me_2C{-}NO_2\end{array}$$

but this is probably not nucleophilic substitution. A radical-ion mechanism has been suggested.[890] However, with α-nitro sulfones it is the sulfone group which is displaced, rather than the nitro group.[891] Palladium can be the leaving atom if the substrate is a π-allylpalladium complex. The ion of malonic ester reacts with such complexes in the presence of triphenylphosphine,[892] e.g.,

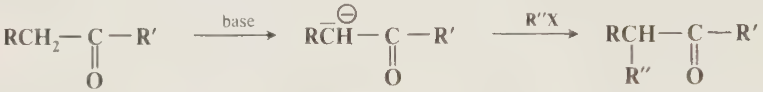
0-97 Alkylation of Ketones, Nitriles, and Esters



$$RCH_2-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{\text{base}} R\overset{\ominus}{\underline{C}}H-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{R''X} R\underset{\underset{R''}{|}}{C}H-\underset{\underset{O}{\|}}{C}-R'$$

Ketones, nitriles, and esters can be alkylated[893] in the α-position in a reaction similar to **0-96,**[873] but a stronger base must be employed, since only one activating group is present. Some typical bases are *t*-BuOK, sodium *t*-pentoxide, $NaNH_2$, Et_2NLi, $(iso\text{-}Pr)_2NLi$, and Ph_3CNa. The base lithium N-isopropyl-N-cyclohexylamide is particularly successful for esters[894] and for nitriles.[895] Some of these bases are strong enough to convert the ketone, nitrile, or ester completely to its conjugate base; others (especially *t*-BuOK) convert a significant fraction of the molecules. In the latter case, aldol condensation (**6-40**) or Claisen condensation (**0-111**) may be a side reaction, since both the free molecule and its conjugate base are present at the same time. In general, it is better to use a base strong enough to convert the starting compound completely. Protic solvents are generally not suitable because they protonate the base (though of course this is not a problem with a conjugate pair, such as *t*-BuOK in *t*-BuOH). Some common solvents are 1,2-dimethoxyethane, dimethylformamide, tetrahydrofuran, and liquid ammonia. Good results can be obtained by the use of butylmagnesium bromide as the base in the solvent HMPT.[896]

As in reaction **0-96,** the alkyl halide may be primary or secondary. Tertiary halides give elimination. Even primary and secondary halides give predominant elimination if the enolate ion is a strong enough base (e.g., the enolate ion from Me_3CCOMe).[897] Also as in **0-96,** this reaction can be used to close rings.[898]

The reaction can be applied to aldehydes, indirectly, by alkylating an imine derivative of the aldehyde.[899] The derivative is easily prepared (**6-15**), and the product easily hydrolyzed to the aldehyde (**6-2**). Either or both R groups may be hydrogen, so that mono-, di-, and trisubstituted

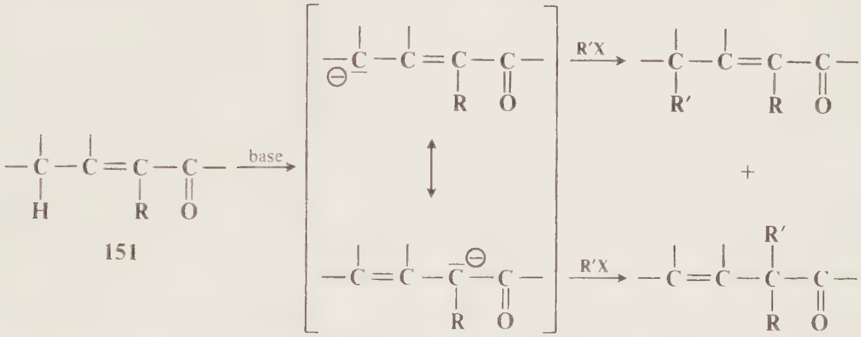
acetaldehydes can be prepared by this method. R' may be primary alkyl, allylic, or benzylic. Direct alkylation of aldehydes is not generally possible because base treatment of aldehydes normally gives rapid aldol condensation (**6-40**), though aldehydes bearing only one α-hydrogen have been alkylated in moderate yield by the use of a phase-transfer catalyst[900] (p. 358).

A convenient method for the alkylation of acetonitrile[901] or ethyl acetate[902] involves treatment of an allylic halide with cyanomethylcopper $CuCH_2CN$ prepared by treating MeCN with *n*-BuLi (to give $LiCH_2CN$) followed by CuI, or ethoxymethylcarbonylcopper $CuCH_2COOEt$ prepared from ethyl acetate in a similar manner. This procedure permits preparation of γ,δ-unsaturated nitriles and esters in good yield. These organocopper reagents do not react with ordinary alkyl halides or even with benzyl halides but react smoothly with allylic halides.

In α,β-unsaturated ketones, nitriles, and esters (e.g., **151**), the γ-hydrogen assumes the acidity normally held by the position α to the carbonyl group, especially when R is not hydrogen and



151

so cannot compete. This principle, called *vinylology*, operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the α-position (with allylic rearrangement) competes with alkylation at the γ-position and often predominates.[903]

α-Hydroxynitriles (cyanohydrins), protected by conversion to acetals with ethyl vinyl ether (reaction **5-5**), can be easily alkylated with primary or secondary alkyl, or allylic, halides.[904]

[903] A method for ensuring alkylation at the γ position, but with rather special R'X, is described by Melvin and Trost, *J. Am. Chem. Soc.* **94,** 1790 (1972); Trost and Melvin, *J. Am. Chem. Soc.* **98,** 1204 (1976).

[904] Stork and Maldonado, *J. Am. Chem. Soc.* **93,** 5286 (1971); Stork, Depezay, and d'Angelo, *Tetrahedron Lett.* 389 (1975). See also Deuchert, Hertenstein, and Hünig, *Synthesis* 777 (1973); Hünig and Wehner, *Synthesis* 180 (1975).

Since the cyanohydrins are easily formed from aldehydes (reaction **6-50**) and the product is easily hydrolyzed to a ketone, this is a method for converting an aldehyde RCHO to a ketone RCOR′ (for other methods, see reactions **0-99, 8-10**). R may be aryl or saturated or unsaturated alkyl.

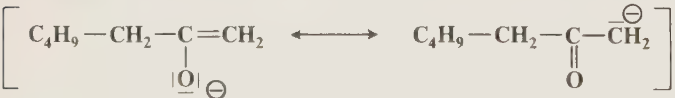
When the compound to be alkylated is a nonsymmetrical ketone, the question arises as to which side will be alkylated. If an α-phenyl or α-vinyl group is present on one side, alkylation goes predominantly on that side. When only alkyl groups are present, the reaction is generally not regiospecific; mixtures are obtained in which sometimes the more alkylated and sometimes the less alkylated side is predominantly alkylated. Which product is found in higher yield depends on the nature of the substrate, the cation, and the solvent. In any case, di- and trisubstitution are frequent, and it is often difficult to stop with the introduction of just one alkyl group. One method for achieving high yields of monoalkylated products is to convert an initial Li or K enolate to an Al enolate by adding Et_3Al to the mixture before adding the alkyl halide.[905] In this case, however, HMPT must be added to the mixture for alkylation to occur in a reasonable amount of time.

Several methods have been developed for ensuring that alkylation takes place regiospecifically on the *desired* side of a ketone.[906] Among these are:

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the *other* side; the blocking group is then removed.[907] A common reaction for this purpose is formylation with ethyl formate (reaction **0-112**); this generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (reaction **2-42**).

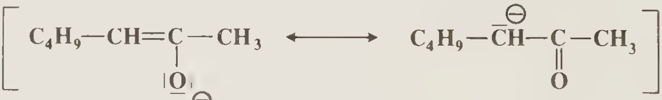
2. Introduce an activating group on one side; alkylation then takes place on *that* side (reaction **0-96**); the activating group is then removed.[907]

3. Prepare the desired one of the two possible enolate ions. The two ions, e.g. **152** and **153** for 2-heptanone, interconvert rapidly only in the presence of the parent ketone or of any stronger acid.[908] In the absence of such acids, it is possible to prepare either **152** or **153** and thus achieve selective alkylation on either the more or less highly alkylated side of the ketone.[909] The desired enolate ion can be obtained by treatment of the corresponding enol acetate with two equivalents of methyllithium in 1,2-dimethoxyethane. Each enol acetate gives the corresponding enolate, e.g.,



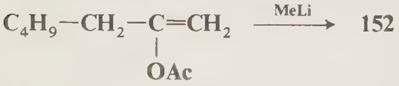
$$\left[C_4H_9-CH_2-\underset{|\underline{O}|^{\ominus}}{\underset{|}{C}}=CH_2 \longleftrightarrow C_4H_9-CH_2-\underset{O}{\underset{\|}{C}}-\overset{\ominus}{C}H_2 \right]$$

152

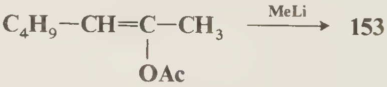


$$\left[C_4H_9-CH=\underset{|\underline{O}|^{\ominus}}{\underset{|}{C}}-CH_3 \longleftrightarrow C_4H_9-\overset{\ominus}{C}H-\underset{O}{\underset{\|}{C}}-CH_3 \right]$$

153



$$C_4H_9-CH_2-\underset{OAc}{\underset{|}{C}}=CH_2 \xrightarrow{MeLi} \mathbf{152}$$



$$C_4H_9-CH=\underset{OAc}{\underset{|}{C}}-CH_3 \xrightarrow{MeLi} \mathbf{153}$$

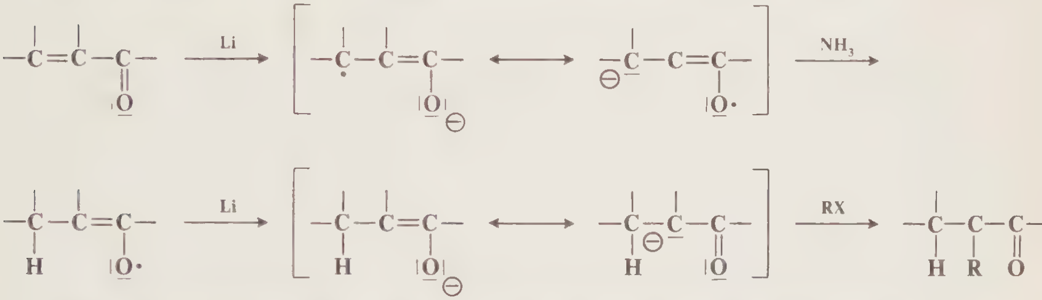
[907] For examples, see House, Ref. 873, pp. 561–563; Carruthers, Ref. 873, pp. 22–23.

[908] House and Trost, *J. Org. Chem.* **30**, 1341 (1965).

[909] House and Trost, *J. Org. Chem.* **30**, 2502 (1965); Whitlock and Overman, *J. Org. Chem.* **34**, 1962 (1969); House, Gall and Olmstead, *J. Org. Chem.* **36**, 2361 (1971). See also Kuwajima and Nakamura, *J. Am. Chem. Soc.* **97**, 3257 (1975).

The enol acetates, in turn, can be prepared by treatment of the parent ketone with an appropriate reagent.[909] Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable.[909] An alternate procedure involves conversion of a trialkylsilyl enol ether[910] or a dialkylboron enol ether[911] (an enol borinate, see p. 434) to the corresponding enolate ion.

4. Begin not with the ketone itself, but with an α,β-unsaturated ketone in which the double bond is present on the side where alkylation is desired. Upon treatment with lithium in liquid NH_3, such a ketone is reduced to an enolate ion. When the alkyl halide is added, it must react with the enolate ion on the side where the double bond was.[912] Of course, this method is not actually an alkylation of the ketone, but of the α,β-unsaturated ketone, though the product is the same as if the saturated ketone had been alkylated on the desired side.



Among other methods for the preparation of alkylated ketones are: (1) the Stork enamine reaction (**2-17**), (2) the acetoacetic ester synthesis (**0-96**), (3) alkylation of β-keto sulfones or sulfoxides (**0-96**), (4) acylation of $CH_3SOCH_2^-$ followed by reductive cleavage (**0-112**), (5) treatment of α-halo ketones with lithium dialkylcopper reagents (**0-87**), and (6) treatment of α-halo ketones with trialkylboranes (**0-101**).

Sulfones and sulfonic esters can also be alkylated in the α-position if strong enough bases are used.[913] The alkylation of allylic sulfoxy compounds followed by a [2,3] sigmatropic rearrangement (reaction **8-40**) is a means for the preparation of allylic alcohols:[914]

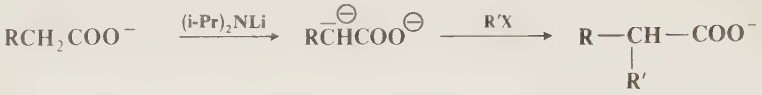
In most cases the alkylation takes place regiospecifically at the α-position, with little or no γ alkylation (see vinylology, p. 423) taking place. The reaction has been applied to primary and allylic R^5X.

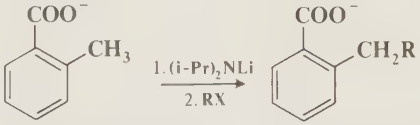
OS **III,** 44, 219, 221, 223, 397; **IV,** 278, 597, 641, 962; **V,** 187, 514, 559, 848; **52,** 33, 39; **54,** 93, 97; **55,** 91.

0-98 Alkylation of Carboxylic Acid Salts



$$RCH_2COO^- \xrightarrow{(i\text{-}Pr)_2NLi} R\overset{\ominus}{C}HCOO^{\ominus} \xrightarrow{R'X} R{-}\underset{R'}{CH}{-}COO^-$$

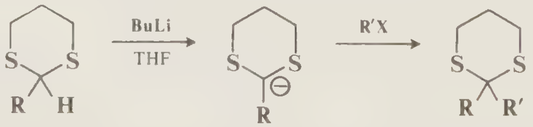
Carboxylic acids can be alkylated in the α-position by conversion of their salts to dianions by treatment with a strong base such as lithium diisopropylamide.[915] The use of Li^+ as the counter-ion is important, because it increases the solubility of the dianionic salt. The reaction has been applied to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form RCH_2COOH and RR″CHCOOH. This method, which is an example of the alkylation of a dianion at its more nucleophilic position (see pp. 337, 421), is an alternative to the malonic ester synthesis (**0-96**) as a means of preparing carboxylic acids and has the advantage that acids of the form RR′R″CCOOH can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure.[916] Ortho methyl groups react best



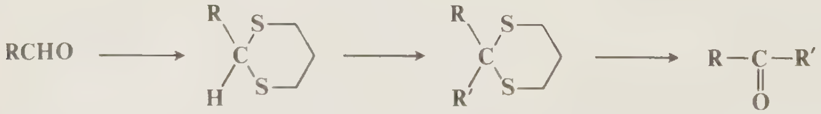
and meta groups most poorly, so it is possible to alkylate just one methyl group when two are present.

OS **V,** 526; **50,** 58.

0-99 Alkylation at a Position α to a Hetero Atom. Alkylation of 1,3-Dithianes



1,3-Dithianes can be alkylated if a proton is first removed by treatment with butyllithium in tetrahydrofuran.[917] Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS **50,** 72) with 1,3-propanedithiol (reaction **6-12**) and can be hydrolyzed (reaction **0-7**), this is a method for the conversion of an aldehyde to a ketone (see also reactions **0-97, 8-10**):

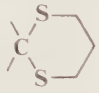


[915] Cregar, *J. Am. Chem. Soc.* **89,** 2500 (1967), **92,** 1397 (1970); Pfeffer and Silbert, *J. Org. Chem.* **35,** 262 (1970); Pfeffer, Silbert, and Chirinko, *J. Org. Chem.* **37,** 451 (1972).

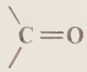
[916] Cregar, *J. Am. Chem. Soc.* **92,** 1396 (1970).

[917] Corey and Seebach, *Angew. Chem. Int. Ed., Engl.* **4,** 1075, 1077 (1965) [*Angew. Chem.* **77,** 1134, 1135]; Seebach, Corey, and Beck, *Chem. Ber.* **107,** 367 (1974); Seebach and Corey, *J. Org. Chem.* **40,** 231 (1975). For reviews, see Seebach, *Synthesis* 17–36 (1969), especially pp. 24–27; Olsen and Currie, in Patai, Ref. 525a, pt. 2, pp. 536–547.

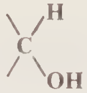
Note that the normal mode of reaction of a carbonyl carbon is reversed. The carbon atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the dithiane, this carbon atom has been induced to perform as a nucleophile[918] (see also the similar reaction of cyanohydrin acetals, p. 423). The reaction can be applied to the unsubstituted dithiane (R = H), and one or two alkyl groups can be introduced, so that a wide variety of aldehydes and ketones can be made starting with formaldehyde.[919] R′ may be primary or secondary alkyl or benzylic. Iodides give the best results. The reaction has been used to close rings.[920] A similar synthesis of aldehydes can be performed starting with ethyl ethylthiomethyl sulfoxide $EtSOCH_2SEt$.[921]



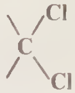
A



B



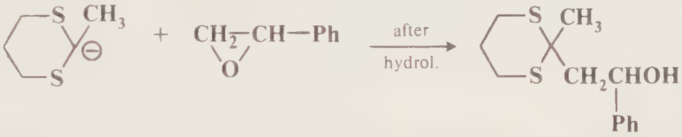
C



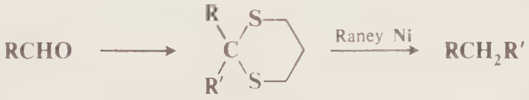
D

The group **A** may be regarded as a structural equivalent for the carbonyl group **B**, since introduction of **A** into a molecule is actually an indirect means of introducing **B**. It is convenient to have a word for units within molecules; such a word is *synthon*, introduced by Corey,[922] which is defined as a structural unit within a molecule which can be formed and/or assembled by known or conceivable synthetic operations. There are many other synthons equivalent to **A** and **B**, for example, **C** (by reactions **6-27** and **9-4**) and **D** (by reactions **0-2** and **6-26**).

Carbanions generated from 1,3-dithianes also react with epoxides[923] to give 1,3-dithiane derivatives of β-hydroxy aldehydes or ketones, e.g.,



Another useful application of this reaction stems from the fact that dithianes can be desulfurated with Raney nickel (reaction **4-37**). Aldehydes can therefore be converted to chain-extended hydrocarbons:[924]



Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.[925]

---

[918] For reviews of such reversals of carbonyl group reactivity, see Seebach and Kolb, *Chem. Ind.* (*London*) 687-692 (1974); Seebach, *Angew. Chem. Int. Ed. Engl.* **8,** 639-649 (1969) [*Angew. Chem.* **81,** 690-700].

[919] For a direct conversion of RX to RCHO, see reaction **0-104.**

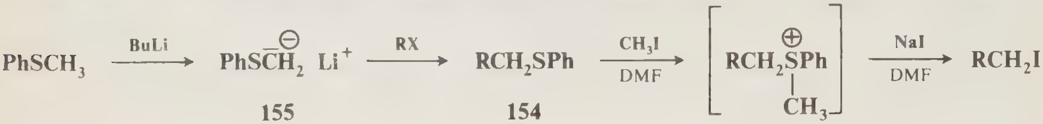
[923] For example, see Corey and Seebach, Ref. 917; Jones and Grayshan, *Chem. Commun.* 141, 741 (1970).

[924] For examples, see Hylton and Boekelheide, Ref. 920; Jones and Grayshan, Ref. 923.

[925] For example, see Seebach, *Angew. Chem. Int. Ed. Engl.* **6,** 442 (1967); [*Angew. Chem.* **79,** 468 (1967)]; Seebach and Steinmüller, *Angew. Chem. Int. Ed. Engl.* **7,** 619 (1968) [*Angew. Chem.* **80,** 617]; Olsson, *Acta Chem. Scand.* **22,** 2390 (1968); Mori, Hashimoto, Takenaka, and Takigawa, *Synthesis* 720 (1975).

The carbanion derived from a 1,3-dithiane is stabilized by two thioether groups. If a strong enough base is used, it is possible to alkylate at a position adjacent to only one such group. For example, benzylic and allylic thioethers ($\mathrm{RSCH_2Ar}$ and $\mathrm{RSCH_2CH{=}CH_2}$) have been successfully alkylated at the carbon adjacent to the sulfur atom.[926] Stabilization by one thioether group has also been used in a method for the homologization of primary halides.[927] Thioanisole is treated

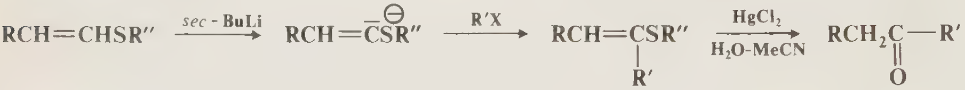


$$\mathrm{PhSCH_3} \xrightarrow{\mathrm{BuLi}} \mathrm{PhS}\overset{\ominus}{\bar{\mathrm{C}}}\mathrm{H_2}\ \mathrm{Li^+} \xrightarrow{\mathrm{RX}} \mathrm{RCH_2SPh} \xrightarrow[\mathrm{DMF}]{\mathrm{CH_3I}} \left[\mathrm{RCH_2}\underset{\mathrm{CH_3}}{\overset{\oplus}{\mathrm{S}}}\mathrm{Ph}\right] \xrightarrow[\mathrm{DMF}]{\mathrm{NaI}} \mathrm{RCH_2I}$$

155 **154**

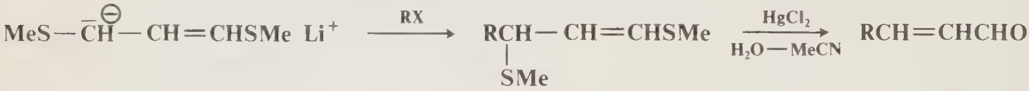
with BuLi to give the corresponding anion[928] which reacts with the halide to give the thioether **154. 154** is then refluxed with a mixture of methyl iodide and sodium iodide in dimethylformamide. By this sequence an alkyl halide RX is converted to its homolog $\mathrm{RCH_2X}$ by a pathway involving only two laboratory steps (the shortest pathway known for this conversion). RX may also be allylic, but here the use of the copper analog of **155** (prepared from **155** and CuI) gives higher yields.[927]

Vinyl sulfides containing an α-hydrogen can also be alkylated[929] by alkyl halides or epoxides. In this case the proton is removed by *sec*-butyllithium. The vinyl sulfide product can be hydrolyzed



$$\mathrm{RCH{=}CHSR''} \xrightarrow{sec\text{-}\mathrm{BuLi}} \mathrm{RCH{=}}\overset{\ominus}{\bar{\mathrm{C}}}\mathrm{SR''} \xrightarrow{\mathrm{R'X}} \mathrm{RCH{=}}\underset{\mathrm{R'}}{\mathrm{C}}\mathrm{SR''} \xrightarrow[\mathrm{H_2O\text{-}MeCN}]{\mathrm{HgCl_2}} \mathrm{RCH_2}\underset{\mathrm{O}}{\overset{}{\mathrm{C}}}\mathrm{{-}R'}$$

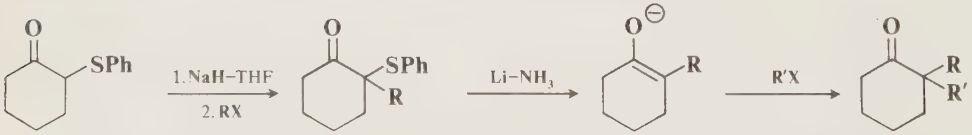
with mercuric chloride in aqueous acetonitrile[930] to give a ketone. In another application, the ion **156**, which can be prepared in three steps from epichlorohydrin, reacts with alkyl halides to



$$\mathrm{MeS{-}}\overset{\ominus}{\bar{\mathrm{C}}}\mathrm{H{-}CH{=}CHSMe\ Li^+} \xrightarrow{\mathrm{RX}} \mathrm{R}\underset{\mathrm{SMe}}{\mathrm{C}}\mathrm{H{-}CH{=}CHSMe} \xrightarrow[\mathrm{H_2O{-}MeCN}]{\mathrm{HgCl_2}} \mathrm{RCH{=}CHCHO}$$

156 **157** **158**

give the bis(methylthio) compound **157**[931] which is easily hydrolyzed. This is a method for converting an alkyl halide RX to an α,β-unsaturated aldehyde **158**, using **156**, which is the synthetic equivalent of the unknown $\overset{\ominus}{\mathrm{H}\bar{\mathrm{C}}}\mathrm{{=}CH{-}CHO}$ ion. α-Phenyl thioaldehydes and thioketones can be *gem*-dialkylated by the following procedure (shown for cyclohexanone):[932]



Alkylation can also be carried out, in certain compounds, at positions α to other hetero atoms. In one application of this, a secondary amine can be alkylated at an α-position if it is first converted to its N-nitroso derivative (reaction **2-50**).[933] The N-nitroso product is easily hydrolyzed

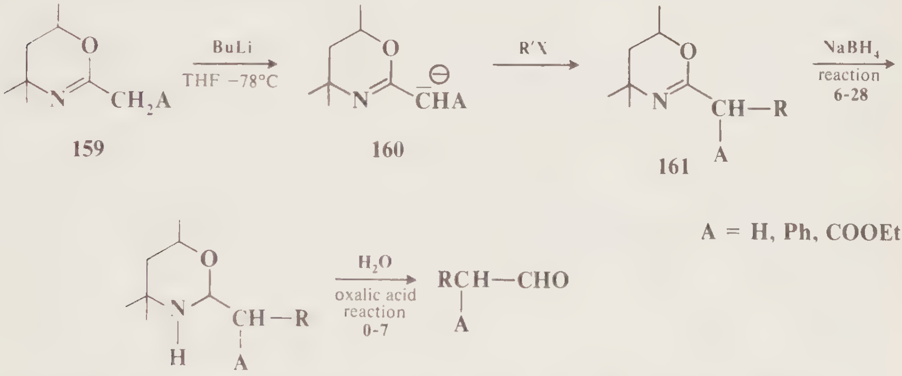
0-100 Alkylation of Dihydro-1,3-Oxazine The Meyers Synthesis of Aldehydes, Ketones, and Carboxylic Acids



159 **160** **161**

A = H, Ph, COOEt

A synthesis of aldehydes developed by Meyers[937] begins with the commercially available (or synthesized from 2-methyl-2,4-pentanediol and a nitrile ACH_2CN) dihydro-1,3-oxazine derivatives **159** (A = H, Ph, or COOEt).[938] Though the ions (**160**) prepared from **159** are ambident, they are regiospecifically alkylated at carbon by a wide variety of alkyl bromides and iodides. R may be primary or secondary alkyl, allylic, or benzylic and may carry another halogen or a CN group.[939]

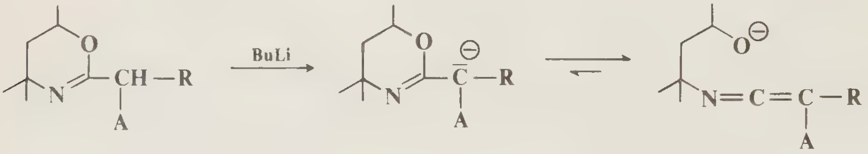
[937] Meyers, Nabeya, Adickes, Politzer, Malone, Kovelesky, Nolen, and Portnoy, *J. Org. Chem.* **38,** 36 (1973).

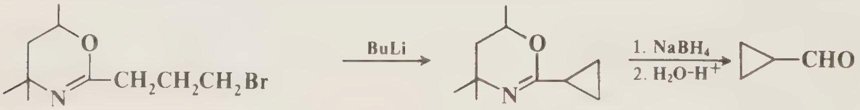
[938] For reviews of the preparation and reactions of **159,** see Schmidt, *Synthesis* 333–350 (1972); Collington, *Chem. Ind. (London)* 987–991 (1973).

[939] Meyers, Malone, and Adickes, *Tetrahedron Lett.* 3715 (1970).

The alkylated oxazine **161** is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements reaction **0-99** which converts RX to an aldehyde containing one more carbon. Since A may be H, mono- or disubstituted acetaldehydes can be produced by this method. Reduction with $NaBD_4$ leads to C-1-deuterated aldehydes. If desired, **161** can be alkylated again (provided A is Ph), with the same or a different alkyl halide, to give a trisubstituted aldehyde after reduction and hydrolysis. If A is H, however, **161** cannot be alkylated again, because the ion formed by BuLi treatment of **161** (which is **160** with an R group replacing the hydrogen) tautomerizes[940] to the ketenimine **162**.[941] An exception is found when a halogen is contained in R. In this case, cyclization can be accomplished to close three, four, and five-membered rings, e.g.,[942]



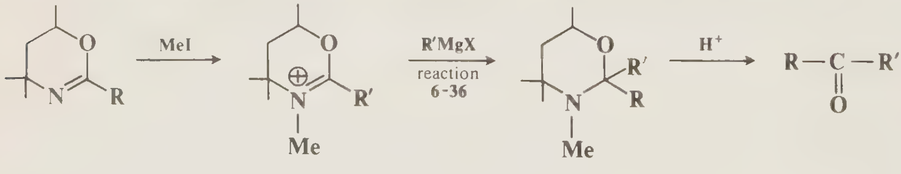
161 **162**



In an alternate procedure, **161** can be hydrolyzed instead of reduced (see reaction **6-2**), producing a carboxylic acid RCHA—COOH.[943]

The ion **160** also reacts with epoxides, to form γ-hydroxy aldehydes after reduction and hydrolysis,[944] and with aldehydes and ketones (reaction **6-42**). Similar aldehyde synthesis has also been carried out with thiazoles[945] and thiazolines[946] (five-membered rings containing N and S in the 1 and 3 positions).

The reaction has been extended to the preparation of ketones:[947] treatment of a dihydro-1,3-oxazine (**163**) with methyl iodide forms the iminium salt **164** (reaction **0-46**) which, when treated



163 **164** **165**

with a Grignard reagent or organolithium compound (reaction **6-36**) produces **165** which can be hydrolyzed to a ketone (for a similar preparation of aldehydes, see reaction **6-36**). R may be alkyl, cycloalkyl, aryl, benzylic, etc., and R′ may be alkyl, aryl, benzylic, or allylic. **159, 161,** and **163** themselves do not react with Grignard reagents.

---

[940] Meyers and Smith, *Tetrahedron Lett.* 4355 (1970).

[941] However, this ketinimine can be alkylated, not with RX, but with RM (reaction **2-17**).

[942] Meyers, Adickes, Politzer, and Beverung, *J. Am. Chem. Soc.* **91,** 765 (1969).

[943] Meyers, Politzer, Bandlish, and Malone, *J. Am. Chem. Soc.* **91,** 5886 (1969).

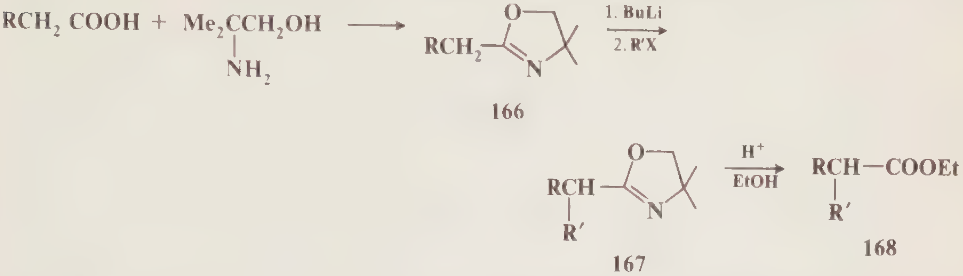
[944] Adickes, Politzer, and Meyers, *J. Am. Chem. Soc.* **91,** 2155 (1969).

[945] Altman and Richheimer, *Tetrahedron Lett.* 4709 (1971).

[946] Meyers and Durandetta, *J. Org. Chem.* **40,** 2021 (1975).

[947] Meyers and Smith, *J. Am. Chem. Soc.* **92,** 1084 (1970); *J. Org. Chem.* **37,** 4289 (1972).

The fact that dihydro-1,3-oxazines do not react with Grignard reagents gives rise to a useful method for the protection of carboxylic acids.[948] These could be converted to dihydro-1,3-oxazines, but in this case it is more convenient to use 2-oxazolines[948a] (**166**) which are readily formed by treatment of the acid with 2-amino-2-methyl-1-propanol [the simplest **166** (R = H) is commercially available].[949] Conversion of a carboxylic acid to a 2-oxazoline permits reaction of a functional group which may be present in R with a Grignard reagent[950] or with $LiAlH_4$[949] without disturbing the oxazoline ring. In a further application, **166** may be alkylated to give **167**[951] which are easily converted directly to the esters **168** by heating in 5 to 7% ethanolic sulfuric acid. **166** and **167** are thus synthons for carboxylic acids, and this is another indirect method for the α alkylation of a carboxylic acid,[952] representing an alternative to the malonic ester synthesis (**0-96**) and to reactions **0-98** and **0-101.** Note that, unlike **159, 166** can be alkylated even if R is alkyl. However, the C=N bond of **166** and **167** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.[953]

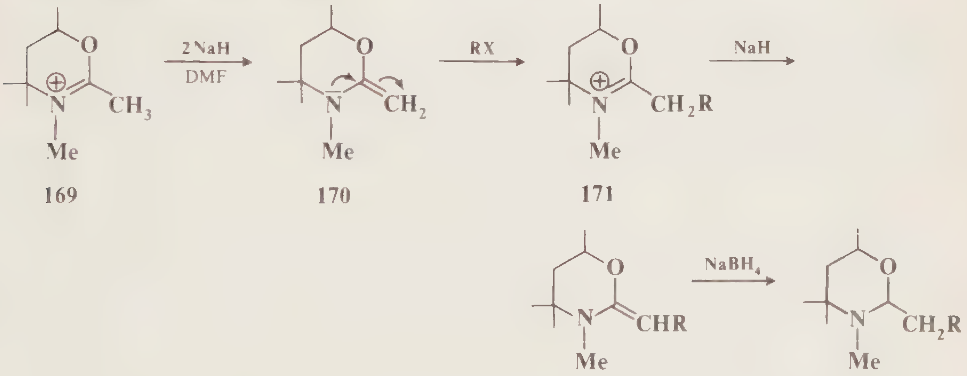


166

167

168

An alternate procedure[954] for aldehyde synthesis begins with **169** which is treated with 2 moles of NaH, the first of which removes a proton to give **170.** An alkyl halide is then added to give **171**



169 **170** **171**

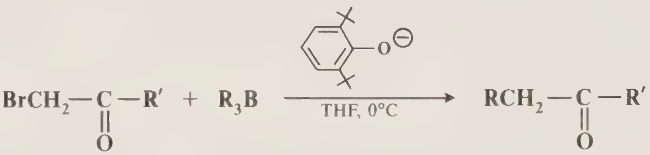
which is immediately converted to **172** by the second mole of NaH. **172** is reduced to **173** by $NaBH_4$, and hydrolysis of **173** produces the aldehyde. This method is easier to carry out and requires a shorter reaction time than the original procedure.

OS **51,** 24.

0-101 Alkylation with Trialkylboranes



$$BrCH_2-\underset{\underset{O}{\|}}{C}-R' + R_3B \xrightarrow[\text{THF, 0°C}]{} RCH_2-\underset{\underset{O}{\|}}{C}-R'$$

Trialkylboranes react rapidly and in high yields with α-halo ketones,[955] α-halo esters,[956] α-halo nitriles,[957] and α-halo sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)[958] in the presence of a base to give, respectively, alkylated ketones, esters, nitriles, and sulfonyl derivatives.[959] Potassium *t*-butoxide is often a suitable base, but potassium 2,6-di-*t*-butylphenoxide at 0°C in tetrahydrofuran gives better results in most cases, possibly because the large bulk of the two *t*-butyl groups prevents the base from coordinating with the R_3B.[960] The trialkylboranes are prepared by treatment of 3 mol of an alkene with 1 mol of BH_3 (reaction **5-15**). However, the use of R_3B prepared in this way has two disadvantages. With α-halo ketones, boranes containing branched R (e.g., isobutyl, *sec*-butyl) do not react; and with any substrate, 2 moles of R are lost. Both of these disadvantages are overcome by the use of a 9-alkyl-9-borabicyclo[3.3.1]nonane (B-R-9-BBN) in place of an ordinary R_3B.[961] These reagents, which can be prepared by addition of 9-borabicyclo[3.3.1]nonane (9-BBN) to an alkene (see p. 719) or by reaction of 9-BBN with an alkyl- or aryllithium followed by treatment with methanesulfonic acid,[962] react nicely with α-halo esters, α-halo ketones, and α-halo nitriles. When R_3B or B-R-9-BBN prepared from an alkene is used, the R must be an alkyl group containing at least two carbons, but the use of B-R-9-BBN prepared the other way allows R to be methyl or aryl. When the R of B-R-9-BBN contains a γ-halogen, treatment with a base gives a cyclopropane,[963] e.g.,

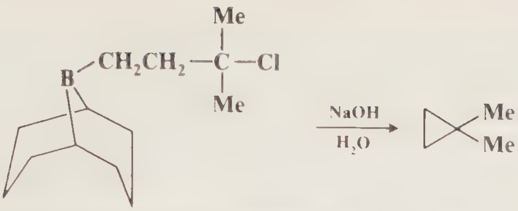
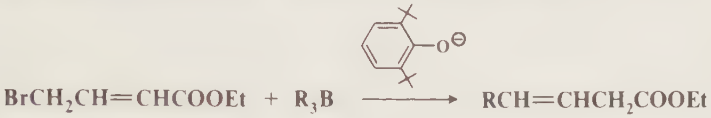
[961] Brown and Rogić, *J. Am. Chem. Soc.* **91,** 2146 (1969); Brown, Rogić, Nambu, and Rathke, *J. Am. Chem. Soc.* **91,** 2147 (1969).

[962] Brown and Rogić, *J. Am. Chem. Soc.* **91,** 4304 (1969).

[963] Brown and Rhodes, *J. Am. Chem. Soc.* **91,** 2149, 4306 (1969). For a review of this type of reaction, see Brown, Ref. 959, pp. 336–340.



The reaction (with R_3B or B-R-9-BBN) can be extended to α,α-dihalo esters[964] and α,α-dihalo nitriles.[965] It is possible to replace just one halogen or both. In the latter case the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R. Another extension is the reaction of boranes with γ-halo-α,β-unsaturated esters.[966] Alkylation takes place in the γ-position, but the double bond migrates, e.g.,

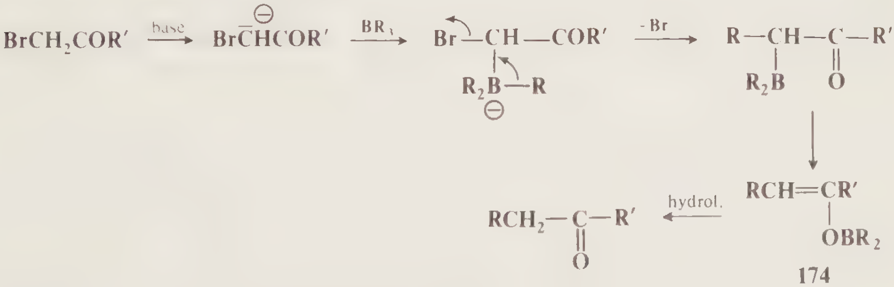


$$BrCH_2CH{=}CHCOOEt + R_3B \longrightarrow RCH{=}CHCH_2COOEt$$

In this case, however, double-bond migration is an advantage, because nonconjugated β,γ-unsaturated esters are usually much more difficult to prepare than their α,β-unsaturated isomers.

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H. C. Brown[967] (see also reactions **5-15**, **5-21**, **8-27** to **8-31**, etc.). These compounds are extremely versatile and can be used for the preparation of many types of compounds. In this reaction, for example, an alkene (through the BR_3 or B-R-9-BBN prepared from it) can be coupled to a ketone, a nitrile, an ester, or a sulfonyl derivative. Note that this is still another indirect way to alkylate a ketone (see **0-97**) or a carboxylic acid (see **0-98**), and provides an additional alternative to the malonic ester and acetoacetic ester syntheses (**0-96**). In yet another alternative to these reactions, ethyl bromocyanoacetate EtOOCCHBrCN and bromomalononitrile $CHBr(CN)_2$ can be alkylated directly with trialkylboranes.[968]

Although superficially this reaction resembles reaction **0-87**, it is likely that the mechanism is quite different, involving migration of an R group from boron to carbon (see also reactions **8-27** to **8-31**). The mechanism is not known with certainty,[968a] but it may be tentatively shown as (illustrated for an α-halo ketone):



174

---

[964] Brown, Rogić, Rathke, and Kabalka, *J. Am. Chem. Soc.* **90**, 1911 (1968).

[965] Nambu and Brown, *J. Am. Chem. Soc.* **92**, 5790 (1970).

[966] Brown and Nambu, *J. Am. Chem. Soc.* **92**, 1761 (1970).

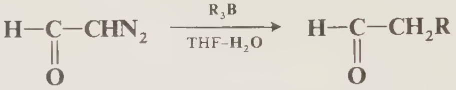
[967] Brown, "Organic Syntheses via Boranes," John Wiley & Sons, New York, 1975, "Hydroboration," W. A. Benjamin, Inc., New York, 1962, "Boranes in Organic Chemistry," Ref. 81.

[968] Nambu and Brown, *Organomet. Chem. Synth.* **1**, 95 (1970).

[968a] See Prager and Reece, *Aust. J. Chem.* **28**, 1775 (1975).

The first step is removal of the acidic proton by the base to give an enolate ion which combines with the borane (Lewis acid–base reaction). An R group then migrates, displacing the halogen leaving group. Another migration then follows, this time of BR_2 from carbon to oxygen to give the enol borinate **174**[969] which is hydrolyzed. Configuration at R is retained.[970]

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes[971] react with trialkylboranes in a similar manner, e.g.,



$$\underset{\displaystyle \overset{\|}{O}}{H-C}-CHN_2 \xrightarrow[THF-H_2O]{R_3B} \underset{\displaystyle \overset{\|}{O}}{H-C}-CH_2R$$

The mechanism is probably also similar. In this case a base is not needed, since the carbon already has an available pair of electrons. The reaction with diazo aldehydes[972] is especially notable, since successful reactions cannot be obtained with α-halo aldehydes. However, the reaction with diazo compounds suffers from the earlier noted disadvantage that two R groups are wasted. An attempt to use B-R-9-BBN here was not successful.[973] However, the use of alkyldichloroboranes $RBCl_2$ (prepared as on p. 720) overcomes this problem and also accommodates bulky groups which react slowly when R_3B is used.[974] Boranes have also been shown to react with

$$R_3B + \overset{\ominus}{\bar{C}}H_2-\overset{\oplus}{S}OMe_2 \longrightarrow RCH_2OH$$

Sulfur ylide

sulfur ylides[975] and with carbanions of the form $Ph\overset{\ominus}{\bar{C}}HSAr$.[976] The latter react with R_3B (R = primary) to give alkylbenzenes $PhCH_2R$.

OS **53,** 77.

0-102 Alkylation at an Alkynyl Carbon

$$RX + R'C{\equiv}C^- \longrightarrow RC{\equiv}CR'$$

The reaction between alkyl halides and acetylide ions is quite useful but is of limited scope.[977] Only primary halides unbranched in the β-position give good yields, though allylic halides can be used if CuI is present.[978] If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides[979] are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base such as $NaNH_2$. Magnesium acetylides (ethynyl Grignard reagents; prepared as in reaction **2-19**) are also frequently used. Another convenient method for preparation of the acetylide ion is the addition of the alkyne to a solution of $CH_3SOCH_2^-$ in dimethyl sulfoxide.[980] This solution can be prepared by the addition of sodium hydride to dimethyl sulfoxide. Alternatively, the alkyl halide can be treated with a lithium acetylide ethylenediamine complex.[981] Tertiary alkyl halides can be coupled by treatment with an organoalkynylalane $(RC{\equiv}C)_3Al$.[981a]

0-103 Preparation of Nitriles

$$\mathbf{RX + CN^- \longrightarrow RCN}$$

The reaction between cyanide ion (isoelectronic with $HC{\equiv}C^-$ and of similar geometry) and alkyl halides is a convenient method for the preparation of nitriles.[982] Primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. Though a number of solvents have been used, the high yields and short reaction times observed with dimethyl sulfoxide make it a very good solvent for this reaction.[983] Another way to obtain high yields under mild conditions is to use a crown ether (p. 324).[984] This is an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (reaction **6-5**). The cyanide ion is an ambident nucleophile, and isonitriles may be side products. If the preparation of isonitriles is desired, they can be made the main products by the use of silver or copper(I) cyanide[985] (p. 338). Vinyl bromides can be converted to vinyl cyanides with CuCN,[986] or with the mixed cyanide "$NaCu(CN)_2$" prepared from NaCN and CuCN,[987] or with $K_4Ni_2(CN)_6$.[988]

The cyanide nucleophile also reacts with compounds containing other leaving groups. Esters of sulfuric and sulfonic acids behave like halides. Epoxides give β-hydroxy nitriles. Ortho esters give α-cyano acetals:

$$\mathbf{RC(OR')_3 + HCN \xrightarrow{ZnCl_2} NC{-}CR(OR')_2}$$

Primary and secondary alcohols are converted to nitriles on refluxing with Ph_3P, CCl_4, and NaCN in dimethyl sulfoxide.[989] NaCN in HMPT selectively cleaves methyl esters in the presence of ethyl esters: $RCOOMe + CN^- \rightarrow MeCN + RCOO^-$.[990] Lactones can be opened up with potassium cyanide:

0-104 Direct Conversion of Alkyl Halides to Aldehydes and Ketones

$$RX + Na_2Fe(CO)_4 \xrightarrow{Ph_3P} \underset{\mathbf{175}}{RCOFe(CO)_3PPh_3^-} \xrightarrow{HOAc} RCHO$$

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished[991] by treatment with sodium tetracarbonylferrate(–II)[991a] in the presence of triphenylphosphine, and subsequent quenching of **175** with acetic acid. The reagent $Na_2Fe(CO)_4$ can be prepared by treatment of iron pentacarbonyl $Fe(CO)_5$ with sodium amalgam in tetrahydrofuran. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is not satisfactory for benzylic bromides. The initial species produced from RX and $Na_2Fe(CO)_4$ is the ion $RFe(CO)_4^-$ (**176**) (which can be isolated[992]); it then reacts with Ph_3P to give **175**.

The synthesis can be extended to the preparation of ketones in five distinct ways.[993]

1. Instead of quenching **175** with acetic acid, the addition of a second alkyl halide at this point gives a ketone: **175** + R′X → RCOR′.

2. Treatment of $Na_2Fe(CO)_4$ with an alkyl halide in the absence of Ph_3P gives rise to a solution of **176**. Addition of a second alkyl halide produces a ketone: **176** + R′X → RCOR′.

3. Treatment of $Na_2Fe(CO)_4$ with an alkyl halide in the presence of CO results in an acylated iron complex (**177**) which can be isolated.[992] Treatment of this with a second alkyl halide

$$RX + Na_2Fe(CO)_4 \xrightarrow{CO} \underset{\mathbf{177}}{RCOFe(CO)_4^-} \xrightarrow{R'X} RCOR'$$

gives a ketone.[994] R′X may also be a perfluorophenyl halide.

4. Treatment of $Na_2Fe(CO)_4$ with an acyl halide produces **177** which, when treated with an alkyl halide, gives a ketone.

5. Alkyl halides and tosylates react with $Na_2Fe(CO)_4$ in the presence of ethylene to give alkyl ethyl ketones.[994a] The reaction was not successful for higher alkenes.

In the first stage of methods 1, 2, and 3 primary bromides, iodides, and tosylates and secondary tosylates may be used. The second stage of the first four methods requires more active substrates, such as primary iodides or tosylates, or benzylic halides. Method 5 has been applied to primary and secondary substrates.

The conversion of alkyl halides to aldehydes can also be accomplished indirectly (reaction **0-99**). See also reaction **2-31.**

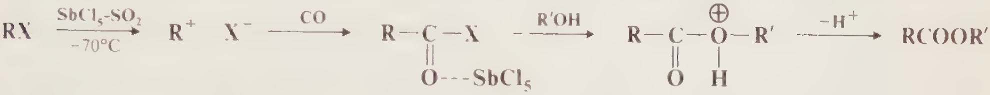
0-105 Conversion of Alkyl Halides, Alcohols, or Alkanes to Carboxylic Acids and Their Derivatives

$$\mathrm{RX + CO + R'OH \xrightarrow[-70\ ^\circ C]{SbCl_5,\ SO_2} RCOOR'}$$

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain extended by one carbon. When an alkyl halide is treated with $SbCl_5$-SO_2 at $-70^\circ C$, it dissociates into the corresponding carbonium ion (p. 152). If carbon monoxide and an alcohol are present, then a carboxylic ester is formed by the following route:[995]



$$\mathrm{RX \xrightarrow[-70^\circ C]{SbCl_5\text{-}SO_2} R^+ \quad X^- \xrightarrow{CO} \underset{\underset{O\text{---}SbCl_5}{\|}}{R{-}C{-}X} \xrightarrow{R'OH} R{-}\underset{\underset{O}{\|}}{C}{-}\overset{\oplus}{\underset{\underset{H}{|}}{O}}{-}R' \xrightarrow{-H^+} RCOOR'}$$

Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen, e.g.,[996]

$$\mathrm{EtCHMe_2 \xrightarrow[2.\ H_2O]{1.\ HF\text{-}SbF_5\text{-}CO} 75\%\ EtCMe_2COOH}$$

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Similarly, alcohols react with H_2SO_4 and CO (which is often generated from HCOOH and the H_2SO_4 in the solution) to give trisubstituted acetic acids in a process called the *Koch-Haaf reaction* (see also reaction **5-25**).[997] If a primary or secondary alcohol is the substrate, the carbonium ion initially formed rearranges to a tertiary ion before reacting with the CO.

Another method[998] for the conversion of alkyl halides to esters is treatment with CO and an alcohol in the presence of cobalt carbonyl anion $Co(CO)_4^-$.[999] The reaction has been applied to

$$\mathrm{RX + CO \xrightarrow[R'OH]{Co(CO)_4^-} RCOOR' + HCo(CO)_4}$$

primary and secondary alkyl halides, sulfates, and sulfonates. Yields in general are low to moderate, though higher yields (80 to 82%) have been achieved in some cases. The reaction also takes place with epoxides,[1000] which give β-hydroxy esters. Treatment of a halide with nickel carbonyl $Ni(CO)_4$ (CO is not needed in this case) in the presence of an alcohol and its conjugate base also gives an ester.[1001] When R′ is primary, then RX may only be a vinyl or an aryl halide; retention of

$$\mathrm{RX + Ni(CO)_4 \xrightarrow[R'OH]{R'O^-} RCOOR'}$$

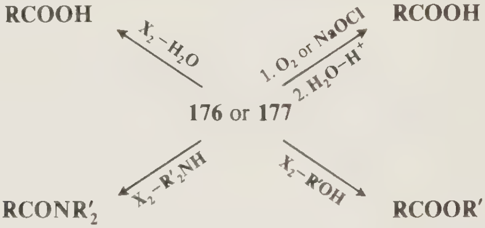
[1000] Heck, *J. Am. Chem. Soc.* **85,** 1460 (1963).

[1001] Corey and Hegedus, *J. Am. Chem. Soc.* **91,** 1233 (1969). See also Crandall and Michaely, *J. Organomet. Chem.* **51,** 375 (1973).

configuration is observed at a vinyl R. Consequently, a carbonium-ion intermediate is not involved here. When R′ is tertiary, then R may be primary alkyl as well as vinyl or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

Still another method for the conversion of halides to acid derivatives makes use of $Na_2Fe(CO)_4$. As described in reaction **0-104**, primary and secondary alkyl halides and tosylates react with this reagent to give the ion $RFe(CO)_4^-$ (**176**) or, if CO is present, the ion $RCOFe(CO)_4^-$ (**177**). Treatment of **176** or **177** with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.[1002] Alternatively, **176** or **177** react with a halogen (for example, I_2) in the presence of an alcohol to give an ester,[1003] or in the presence of a secondary amine or of water to give, respectively, the corresponding amide or free acid. **176** and **177** prepared from primary R give high yields. With secondary R, the best results are obtained in the solvent tetrahydrofuran by the use of **177** prepared from secondary tosylates. Ester and keto groups may be present in R without being affected. A similar reaction has been carried out with epoxides.[1004]



A final method involves treatment of an allylic chloride with CO under pressure in the presence of a π-allylic palladium complex or of $PdCl_2$; the product is a β,γ-unsaturated acyl chloride in high yield.[1005] Palladium metal, and Pt and Rh complexes, have also been found effective. The reaction probably proceeds through an allylic-Pd complex **180**, since both **178** and **179** give the same product. Saturated, vinyl, and benzylic halides fail to react, though benzylic and aryl halides can be converted to esters by treatment with CO, dichlorobis(triphenylphosphine)palladium(II), an alcohol, and NaOAc in an autoclave.[1006]

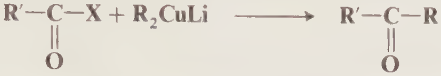
B. Attack at an Acyl Carbon[1007]

0-106 The Conversion of Acyl Halides to Ketones with Organometallic Compounds[1008]



$$R'-\underset{\underset{O}{\|}}{C}-X + R_2CuLi \longrightarrow R'-\underset{\underset{O}{\|}}{C}-R$$

Acyl halides react cleanly and under mild conditions with lithium dialkylcopper reagents[805] (see reaction **0-87**) to give high yields of ketones.[1009] R′ may be primary, secondary, or tertiary alkyl or aryl and may contain iodo, keto, ester, nitro, or cyano groups. R groups which have been used successfully are methyl, primary alkyl, and vinylic. Secondary and tertiary alkyl groups can be introduced by the use of PhS(R)CuLi (p. 409) instead of R_2CuLi.[812] R may be alkynyl if a cuprous acetylide $R''C{\equiv}CCu$ is the reagent.[1010]

Another type of organometallic reagent which gives good yields of ketones when treated with acyl halides are organocadmiums R_2Cd (prepared from Grignard reagents, reaction **2-19**). In this case R may be aryl or primary alkyl. In general, secondary and tertiary alkylcadmium reagents are not stable enough to be useful in this reaction.[1011] An ester group may be present in either R′COX or R_2Cd. Organozinc compounds behave similarly, but are less often used. Organomercury compounds also give the reaction if an $AlBr_3$ catalyst is present.[1012] Still other reagents are lithium aryltrialkylborates[1013] $ArBR_3^-$ Li^+ (which transfer an aryl group) and the alkylrhodium(I) complexes bis(triphenylphosphine)carbonylalkylrhodium(I) $Rh^IR(CO)(Ph_3P)_2$. The latter, generated in situ from $Rh^ICl(CO)(Ph_3P)_2$ (**181**) and a Grignard reagent or organolithium compound, react with acyl halides in tetrahydrofuran at −78°C to give good yields of ketones.[1014] R may be primary alkyl or aryl. An advantage of the rhodium reagents is that they do not react with aldehydes, esters, or nitriles, so that these groups may be present in R′. Another advantage is that the complex **181** is regenerated in reusable form at the end of the reaction.

When the organometallic compound is a Grignard reagent,[1015] ketones are generally not obtained because the initially formed ketone reacts with a second molecule of RMgX to give the salt of a tertiary alcohol (reaction **6-34**). Ketones *have* been prepared in this manner by the use of low temperatures, inverse addition (i.e., addition of the acyl halide to the Grignard reagent, rather than the other way around), excess acyl halide, etc., but the yields are usually low. Some ketones are unreactive toward Grignard reagents for steric or other reasons, and these may be prepared in this way. Also, certain metallic halides, notably ferric and cuprous halides, are catalysts which improve the yields of ketone at the expense of tertiary alcohol.[1016] For these catalysts, both free-radical and ionic mechanisms have been proposed.[1017] The reactions with R_2CuLi, R_2Cd, and the rhodium complexes are successful because these compounds do not generally react with ketones.

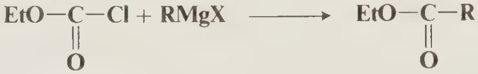
Grignard reagents react with ethyl chloroformate to give esters.

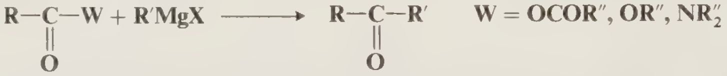


$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}Cl + RMgX \longrightarrow EtO{-}\underset{\underset{O}{\|}}{C}{-}R}$$

Acyl halides can also be converted to ketones by treatment with $Na_2Fe(CO)_4$ followed by R′X (reaction **0-104**, method 4).

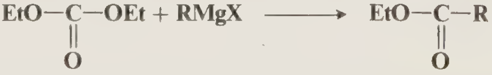
OS **II,** 198; **III,** 601; **IV,** 708; **54,** 97; **55,** 122.

0-107 The Conversion of Anhydrides, Esters, or Amides to Ketones with Organometallic Compounds[1018]



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}W + R'MgX \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}R'} \qquad \mathrm{W = OCOR'', OR'', NR''_2}$$

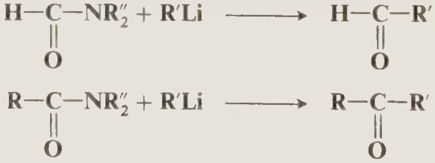
As is the case with acyl halides (reaction **0-106**), anhydrides and esters also give tertiary alcohols (reaction **6-34**) when treated with Grignard reagents. Low temperatures[1019] and inverse addition have been used to increase the yields of ketone. Amides give better yields of ketone at room temperature, but still only about 10 to 50%. 2-Pyridinethiol esters (p. 363) are one type of ester which gives high yields of ketones when added to Grignard reagents.[1020] Thioesters RCOSR′ give good yields of ketones when treated with lithium dialkylcopper reagents R″CuLi (R″ = primary or secondary alkyl or aryl).[1021] Organocadmium reagents are less successful with these substrates than with acyl halides (reaction **0-106**). Esters of formic acid, and dialkylformamides, give good yields of aldehydes, when treated with Grignard reagents. Ethyl carbonate has been used to prepare esters



$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}OEt + RMgX \longrightarrow EtO{-}\underset{\underset{O}{\|}}{C}{-}R}$$

but more often the reaction goes further to give the ketone or the tertiary alcohol.

Alkyllithium compounds have been used to give good yields of ketones from esters. The reaction must be carried out in a high-boiling solvent such as toluene, since reaction at lower temperatures gives tertiary alcohols.[1022] Alkyllithiums also give good yields of carbonyl compounds with N,N-disubstituted amides.[1023] Dialkylformamides give aldehydes, and other disubstituted amides give ketones.



$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}NR''_2 + R'Li \longrightarrow H{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}NR''_2 + R'Li \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}R'}$$

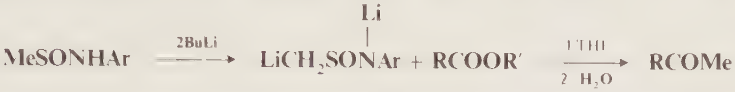
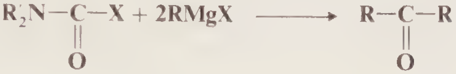
Esters can be converted to methyl ketones by treatment with the dilithio salt of N-methanesulfinyl-*p*-toluidine in tetrahydrofuran followed by addition of water.[1024] N,N-Disubstituted car-



$$\mathrm{MeSONHAr} \xrightarrow{\mathrm{2BuLi}} \mathrm{LiCH_2SO\overset{Li}{\overset{|}{N}}Ar} + \mathrm{RCOOR'} \xrightarrow[\text{2 } H_2O]{\text{1 THF}} \mathrm{RCOMe}$$

bamates (X = OR″) and carbamoyl chlorides (X = Cl) react with 2 moles of an alkyl- or aryllithium or Grignard reagent to give symmetrical ketones, in which both R groups are derived from the organometallic compound.[1025]



$$\mathrm{R'_2N{-}\underset{\underset{O}{\|}}{C}{-}X} + \mathrm{2RMgX} \longrightarrow \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}R}$$

Ketones can also be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent (reaction **6-33**).

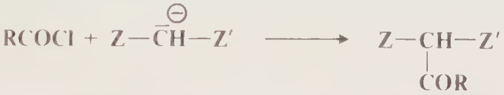
OS **II**, 282; **III**, 353; **IV**, 285; **52**, 75.

0-108 The Coupling of Acyl Halides

$$\mathrm{2RCOCl} \xrightarrow{\text{pyrophoric Pb}} \mathrm{RCOCOR}$$

Acyl halides can be coupled with pyrophoric lead to give symmetrical α-diketones in a Wurtz-type reaction.[1026] The reaction has been performed with R = Me and Ph.

0-109 Acylation by Acyl Halides or Anhydrides at a Carbon Bearing an Active Hydrogen



$$\mathrm{RCOCl} + \mathrm{Z{-}\overset{\ominus}{C}H{-}Z'} \longrightarrow \mathrm{Z{-}\underset{\underset{COR}{|}}{C}H{-}Z'}$$

This reaction is similar to reaction **0-96**, though many fewer examples have been reported. Z and Z′ may be any of the groups listed in **0-96**. Anhydrides react similarly but are less often used. The product contains three Z groups, since RCO is a Z group. One or two of these can then be cleaved (reactions **2-39**, **2-42**). In this way a compound ZCH_2Z' can be converted to ZCH_2Z'', or an acyl halide RCOCl to a methyl ketone $RCOCH_3$. O-Acylation is sometimes a side reaction. When thallium(I) salts of ZCH_2Z' are used, it is possible to achieve regiospecific acylation at either the C or the O position. For example, treatment of the thallium(I) salt of $MeCOCH_2COMe$ with acetyl chloride at −78°C gave >90% O-acylation, while acetyl fluoride at room temperature gave >95% C-acylation.[1027]

The application of this reaction to simple ketones (in parallel with reaction **0-97**) requires a strong base, such as $NaNH_2$, NaH, or Ph_3CNa, and is often complicated by O-acylation, which in many cases becomes the principal pathway because acylation at the oxygen is usually much faster. It is possible to increase the proportion of C-acylated product by employing an excess (2 to 3 equiv) of enolate ion (and adding the substrate to this, rather than vice versa), by the use of a relatively nonpolar solvent and a metal ion (such as Mg^{2+}) which is tightly associated with the enolate oxygen atom, and by the use of an acyl halide rather than an anhydride.[1028] In cases where the use of an excess of enolate ion results in C-acylation, it is because O-acylation takes place first, and the O-acylated product (an enol ester) is then C-acylated. (Note that C-acylation of ketones can be accomplished with BF_3; reaction **0-110.**) Simple esters RCH_2COOEt can be acylated at the α-carbon (at −78 C) if the strong base lithium N-isopropylcyclohexylamide is used to remove the proton.[1029]

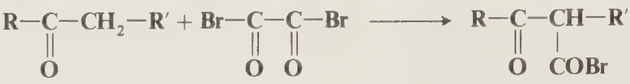
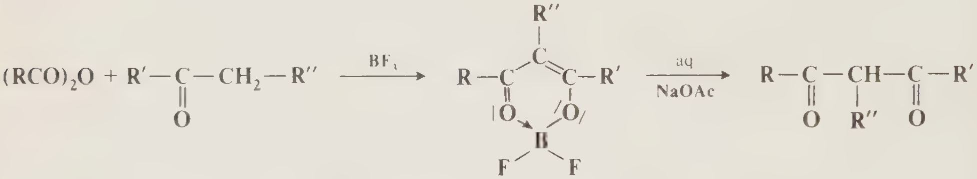
Ketones have been acylated by oxalyl bromide, with CO being lost in the process:[1030]



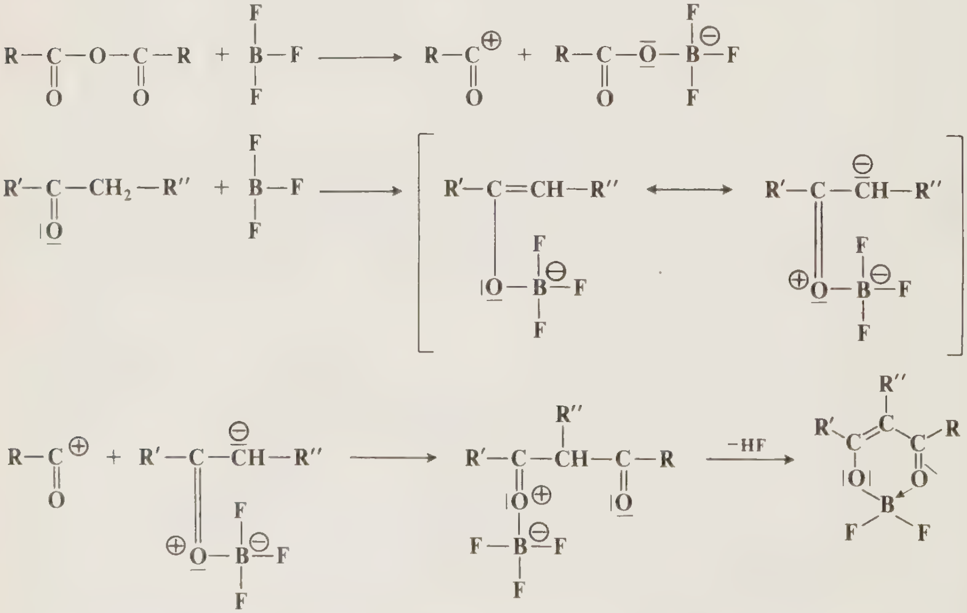
$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}CH_2{-}R' + Br{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{O}{\|}}{C}{-}Br \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{COBr}{|}}{CH}{-}R'}$$

OS **II,** 266, 268, 594, 596; **III,** 390, 637; **IV,** 285, 415, 708; **V,** 384, 937.

0-110 Acylation of Ketones by Anhydrides



Ketones can by acylated by anhydrides, with BF_3 as catalyst,[1031] to give β-diketones. With unsymmetrical ketones, acylation occurs chiefly on the more highly substituted side. The actual product is a complex containing BF_2, which can be decomposed by aqueous sodium acetate to give the acylated ketone. Therefore 1 mole of boron trifluoride is required for each mole of ketone. The boron trifluoride plays a double role in the mechanism. It assists in ionization of the anhydride (an SN1 type of process) and converts the ketone into a boron derivative of the enolate:



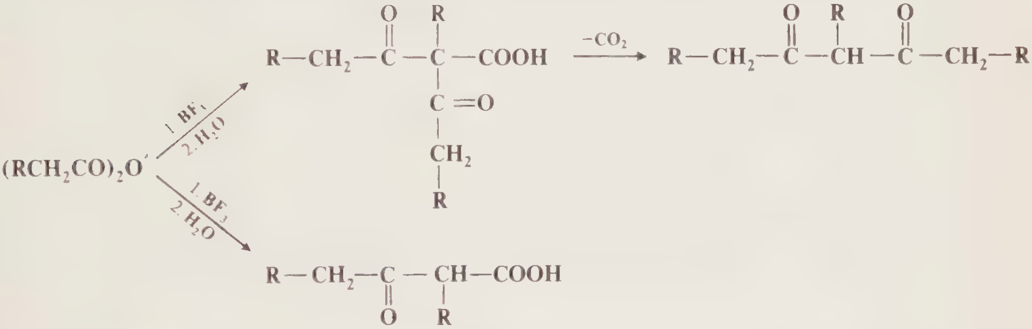
[1029] For example, see Rathke and Deitch, *Tetrahedron Lett.* 2953 (1971). See also Logue, *J. Org. Chem.* **39,** 3455 (1974).

[1030] Treibs, Riemer, and Orttmann, *Chem. Ber.* **93,** 551 (1960).

[1031] For a review, see Hauser, Swamer, and Adams, *Org. React.* **8,** 59–196 (1954), pp. 98–106.

With respect to the ketone, this is an electrophilic substitution with a mechanism similar to that of the bromination of ketones (reaction **2-4**). There is evidence that at least in some cases the enol is first O-acylated, and then the resulting enol ester is attacked by another acyl cation to give the β-diketone.[1032] Indeed, enol esters obtained in other ways can be converted to β-diketones in a similar manner.

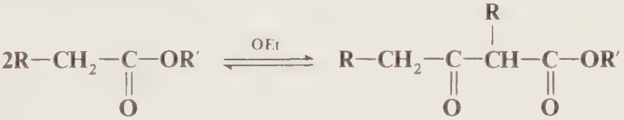
A side reaction is self-condensation of the anhydride, providing it has an α-hydrogen, to give either a β-diketone or a β-keto acid. In the former case, decarboxylation takes place (see reaction **2-39**). Of course, the β-keto acid can also be decarboxylated. These reactions are examples of acylation of anhydrides by anhydrides and are sometimes used as preparative methods. In the latter process, an anhydride is converted to a symmetrical ketone (after decarboxylation of the β-keto acid):[1033]



Another means of accomplishing essentially the same result is discussed in reaction **0-117.** Mixed carboxylic-carbonic anhydrides can react with magnesium enolates to give β-keto esters.[1034]

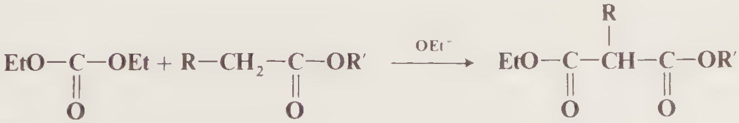
OS **III,** 16; **51,** 90.

0-111 Acylation of Esters by Esters. The Claisen and Dieckmann Condensations



$$2\mathrm{R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}OR'} \xrightleftharpoons{\mathrm{OEt}} \mathrm{R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

When esters containing an α-hydrogen are treated with a strong base such as sodium ethoxide, a condensation occurs to give a β-keto ester. This reaction is called the *Claisen condensation.*[1035] When the condensation is carried out with a mixture of two different esters, each of which possesses an α-hydrogen, a mixture of all four products is generally obtained and the reaction is seldom useful synthetically. However, if only one of the esters has an α-hydrogen, then the mixed reaction is frequently satisfactory. Among esters lacking α-hydrogens (hence acting as the substrate ester) which are commonly used in this way are esters of benzoic and other aromatic acids, and ethyl carbonate and ethyl oxalate. Ethyl carbonate gives malonic esters,



$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}OEt} + \mathrm{R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}OR'} \xrightarrow{\mathrm{OEt^-}} \mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}OR'}$$

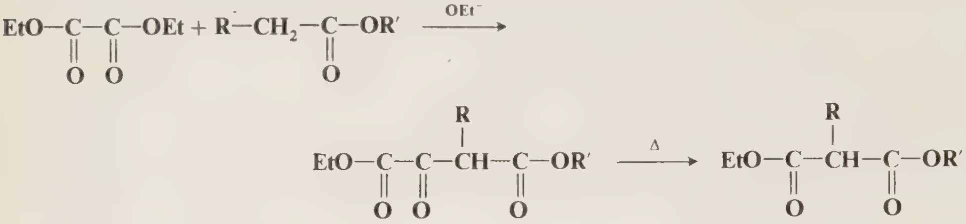
[1032] Mao, Frostick, Man, Manyik, Wells, and Hauser, *J. Org. Chem.* **34,** 1425 (1969).

[1033] See Musso and Figge, *Justus Liebigs Ann. Chem.* **668,** 1, 15 (1963).

[1034] Bram and Vilkas, *Bull. Soc. Chim. Fr.* 945 (1964).

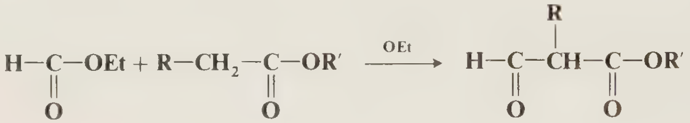
[1035] For a review, see Hauser and Hudson, *Org. React.* **1,** 266–302 (1942).

while ethyl oxalate gives α-keto esters, which may then be decarbonylated (reaction **0-13**) to the same malonic esters.



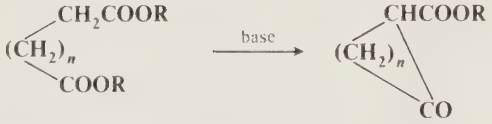
$$\text{EtO}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OEt}+\text{R}-\text{CH}_2-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}'\xrightarrow{\text{OEt}^-}\text{EtO}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\overset{\overset{\text{R}}{|}}{\text{C}}\text{H}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}'\xrightarrow{\Delta}\text{EtO}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\overset{\overset{\text{R}}{|}}{\text{C}}\text{H}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}'$$

Ethyl formate serves to introduce the formyl group:



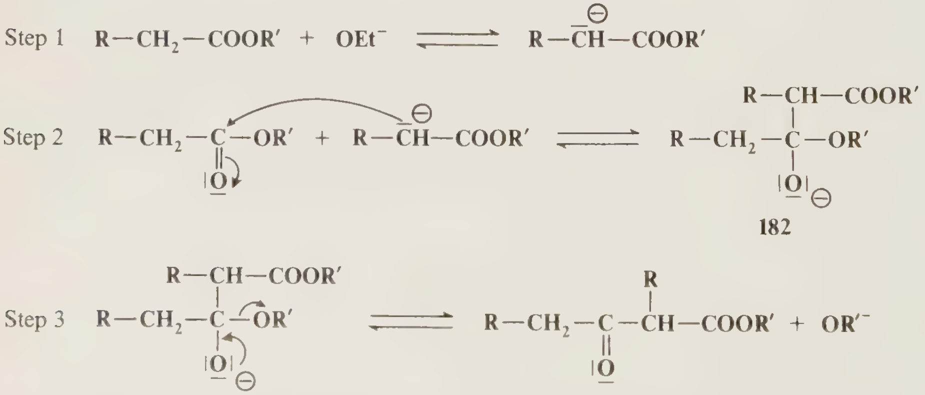
$$\text{H}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OEt}+\text{R}-\text{CH}_2-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}'\xrightarrow{\text{OEt}}\text{H}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\overset{\overset{\text{R}}{|}}{\text{C}}\text{H}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}'$$

When the two ester groups involved in the condensation are in the same molecule, the product is a cyclic β-keto ester and the reaction is called the *Dieckmann condensation.*[1036]



The Dieckmann condensation is most successful for the formation of five-, six-, and seven-membered rings. Yields for rings of nine to twelve members are very low or nonexistent; larger rings can be closed with high-dilution techniques. Reactions in which large rings are to be closed are generally assisted by high dilution, since one end of the molecule has a better chance of finding the other end than of finding another molecule.

The mechanism of the Claisen and the Dieckmann reactions is the ordinary tetrahedral mechanism, with one molecule of ester being converted to a nucleophile by the base and the other serving as the substrate.



Step 1 $\text{R}-\text{CH}_2-\text{COOR}' + \text{OEt}^- \rightleftharpoons \text{R}-\overset{\ominus}{\underline{\text{C}}}\text{H}-\text{COOR}'$

Step 2 $\text{R}-\text{CH}_2-\underset{\underset{|\underline{\text{O}}}{\|}}{\text{C}}-\text{OR}' + \text{R}-\overset{\ominus}{\underline{\text{C}}}\text{H}-\text{COOR}' \rightleftharpoons \text{R}-\text{CH}_2-\overset{\overset{\text{R}-\text{CH}-\text{COOR}'}{|}}{\underset{\underset{|\underline{\text{O}}|^{\ominus}}{|}}{\text{C}}}-\text{OR}'$

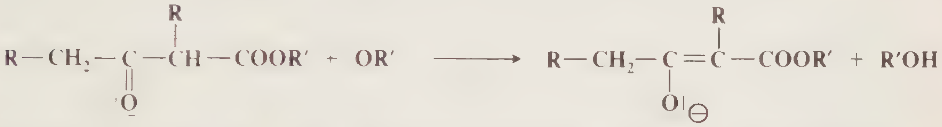
182

Step 3 $\text{R}-\text{CH}_2-\overset{\overset{\text{R}-\text{CH}-\text{COOR}'}{|}}{\underset{\underset{|\underline{\text{O}}|^{\ominus}}{|}}{\text{C}}}-\text{OR}' \rightleftharpoons \text{R}-\text{CH}_2-\underset{\underset{|\underline{\text{O}}}{\|}}{\text{C}}-\overset{\overset{\text{R}}{|}}{\text{C}}\text{H}-\text{COOR}' + \text{OR}'^-$

[1036] For a review, see Schaefer and Bloomfield, *Org. React.* **15**, 1–203 (1967).

This reaction illustrates the striking difference in behavior between esters on the one hand and aldehydes and ketones on the other. When a carbanion such as an enolate ion is added to the carbonyl group of an aldehyde or ketone (reaction **6-42**), the H or R is not lost, since these groups are much poorer leaving groups than OR. Instead the intermediate similar to **182** adds a proton at the oxygen to give a hydroxy compound.

In contrast to reaction **0-96** ordinary esters react quite well; that is, two Z groups are not needed. A lower degree of acidity is satisfactory because it is not necessary to convert the attacking ester entirely to its ion. Step 1, conversion of the ester to its ion, is an equilibrium reaction, and the equilibrium lies well over to the left. Nevertheless, the small amount of enolate ion formed is sufficient to attack the readily approachable ester substrate. All the steps in the reaction are equilibria. The reaction proceeds because the product is converted to its conjugate base by the base present (that is, a β-keto ester is a stronger acid than an alcohol):

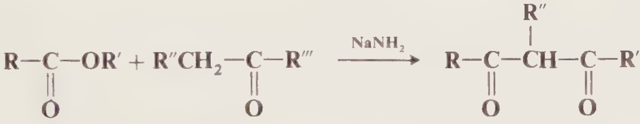


$$\mathrm{R{-}CH_2{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R}{|}}{C}H{-}COOR' + OR'} \longrightarrow \mathrm{R{-}CH_2{-}\underset{\underset{O|^{\ominus}}{|}}{C}{=}\overset{\overset{R}{|}}{C}{-}COOR' + R'OH}$$

The use of a stronger base, such as sodium amide, sodium hydride, or potassium hydride,[1036a] often increases the yield. For some esters stronger bases *must* be used, since sodium ethoxide is ineffective. Among these are esters of the type $R_2CHCOOEt$, the products of which ($R_2CHCOCR_2$-COOEt) lack an acidic hydrogen, so that they cannot be converted to enolate ions by sodium ethoxide.

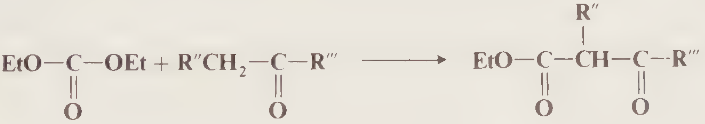
OS **I**, 235; **II**, 116, 194, 272, 288; **III**, 231, 300, 379, 510; **IV**, 141; **V**, 288, 687, 989.

0-112 Acylation of Ketones and Nitriles by Esters



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OR' + R''CH_2{-}\underset{\underset{O}{\|}}{C}{-}R'''} \xrightarrow{\mathrm{NaNH_2}} \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R''}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}R'''}$$

Esters can be treated with ketones to give β-diketones in a reaction which is essentially the same as reaction **0-111**.[1035] The reaction is so similar that it is sometimes also called the Claisen condensation, though this usage is unfortunate. A fairly strong base, such as sodium amide or sodium hydride, is required. Esters of formic acid R = H give β-keto aldehydes. Ethyl carbonate gives β-keto esters.



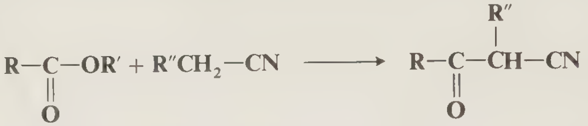
$$\mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}OEt + R''CH_2{-}\underset{\underset{O}{\|}}{C}{-}R'''} \longrightarrow \mathrm{EtO{-}\underset{\underset{O}{\|}}{C}{-}\overset{\overset{R''}{|}}{C}H{-}\underset{\underset{O}{\|}}{C}{-}R'''}$$

In the case of unsymmetrical ketones, the attack usually comes from the less highly substituted side, so that CH_3 is more reactive than RCH_2, and the R_2CH group rarely attacks. This is in sharp contrast to reaction **0-110**, and the two reactions are thus complementary. As in the case of reaction **0-111**, this reaction has been used to effect cyclization, especially to prepare five-

---

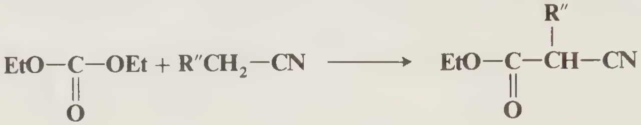
[1036a] Brown, *Synthesis* 326 (1975).

and six-membered rings. Nitriles are frequently used instead of ketones, the products being β-keto nitriles.



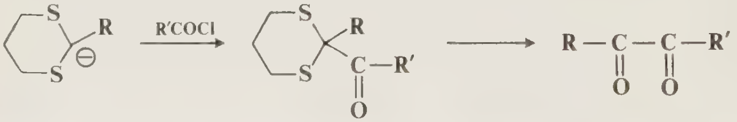
$$\mathrm{R{-}\underset{\underset{\textstyle O}{\|}}{C}{-}OR' + R''CH_2{-}CN \longrightarrow R{-}\underset{\underset{\textstyle O}{\|}}{C}{-}\overset{\overset{\textstyle R''}{|}}{C}H{-}CN}$$

Similarly, α-cyano esters can be obtained on treatment of ethyl carbonate with nitriles.

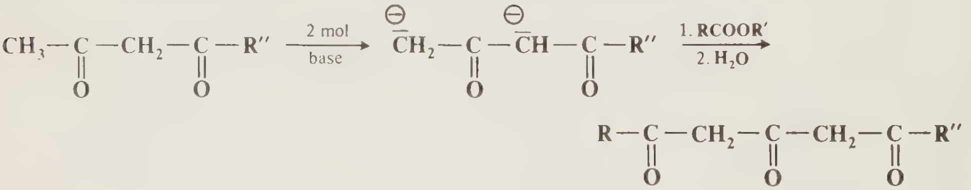


$$\mathrm{EtO{-}\underset{\underset{\textstyle O}{\|}}{C}{-}OEt + R''CH_2{-}CN \longrightarrow EtO{-}\underset{\underset{\textstyle O}{\|}}{C}{-}\overset{\overset{\textstyle R''}{|}}{C}H{-}CN}$$

Other carbanionic groups, such as acetylide ions, and ions derived from α-methylpyridines have also been used as nucleophiles. A particularly useful nucleophile is the methylsulfinyl carbanion $CH_3SOCH_2^-$,[1037] the conjugate base of dimethyl sulfoxide, since the β-keto sulfoxide produced can easily be reduced to a methyl ketone (p. 420). The methylsulfonyl carbanion $CH_3SO_2CH_2^-$, the conjugate base of dimethyl sulfone, behaves similarly,[1038] and the product can be similarly reduced. Certain esters, acyl halides, and dimethylformamide acylate 1,3-dithianes[1039] (see reaction **0-99**) to give, after oxidative hydrolysis with N-bromo- or N-chlorosuccinimide, α-keto aldehydes or α-diketones,[1040] e.g.,



As in reaction **0-96**, a ketone attacks with its second most acidic position if 2 moles of base are used. Thus, β-diketones have been converted to 1,3,5-triketones.[1041]



$$\mathrm{CH_3{-}\underset{\underset{\textstyle O}{\|}}{C}{-}CH_2{-}\underset{\underset{\textstyle O}{\|}}{C}{-}R'' \xrightarrow[\text{base}]{\text{2 mol}} \overset{\ominus}{\bar{C}}H_2{-}\underset{\underset{\textstyle O}{\|}}{C}{-}\overset{\ominus}{\bar{C}}H{-}\underset{\underset{\textstyle O}{\|}}{C}{-}R'' \xrightarrow[\text{2. }H_2O]{\text{1. RCOOR}'} R{-}\underset{\underset{\textstyle O}{\|}}{C}{-}CH_2{-}\underset{\underset{\textstyle O}{\|}}{C}{-}CH_2{-}\underset{\underset{\textstyle O}{\|}}{C}{-}R''}$$

Side reactions are condensation of the ketone with itself (reaction **6-40**), of the ester with itself (reaction **0-111**), and of the ketone with the ester but with the ester supplying the α-position (reaction **6-41**). The mechanism is the same as in reaction **0-111**.[1042]

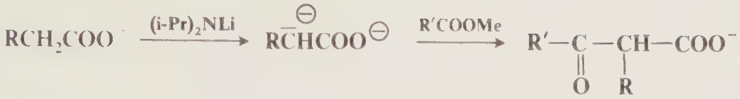
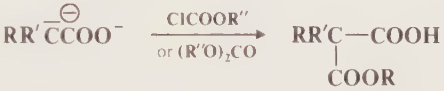
0-113 Acylation of Carboxylic Acid Salts



$$RCH_2COO^- \xrightarrow{(i\text{-}Pr)_2NLi} R\overset{\ominus}{C}HCOO^{\ominus} \xrightarrow{R'COOMe} R'-\underset{\substack{\| \\ O}}{C}-\underset{\substack{| \\ R}}{CH}-COO^-$$

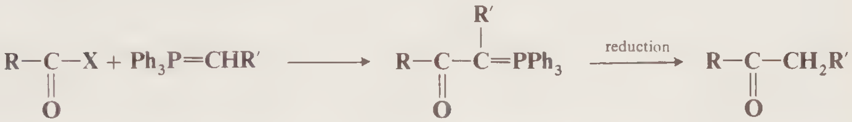
We have previously seen (reaction **0-98**) that dianions of carboxylic acids can be alkylated in the α-position. These ions can also be acylated on treatment with an ester[1043] to give salts of β-keto acids, which are isolated by conversion to trimethylsilyl esters which in turn are hydrolyzed to the free β-keto acids. As in reaction **0-98**, the carboxylic acid may be of the form RCH_2COOH or $RR''CHCOOH$. Since β-keto acids are so easily converted to ketones (reaction **2-39**), this is also a method for the preparation of ketones $R'COCH_2R$ and $R'COCHRR''$, where R′ can be primary, secondary, or tertiary alkyl, or aryl. If the ester is ethyl formate, an α-aldehydo carboxylate salt ($R' = H$) is formed, which on acidification spontaneously decarboxylates into an aldehyde.[1044] This is a method, therefore, for achieving the conversion $RCH_2COOH \rightarrow RCH_2CHO$, and as such is an alternative to the reduction methods discussed in reaction **0-83**.

When the substrate is an alkyl chloroformate or a dialkyl carbonate, mono esters of malonic acids are obtained.[1045]



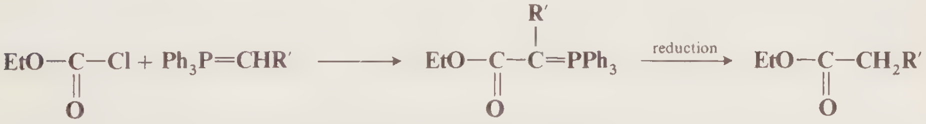
$$RR'\overset{\ominus}{C}COO^- \xrightarrow[\text{or }(R'O)_2CO]{ClCOOR''} RR'\underset{\substack{| \\ COOR}}{C}-COOH$$

0-114 Acylation of Phosphoranes



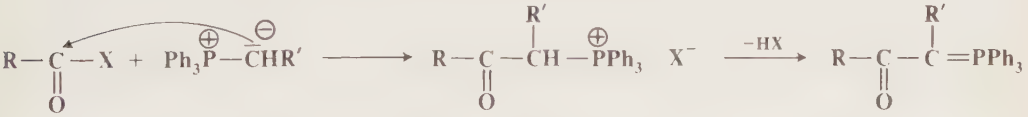
$$R-\underset{\substack{\| \\ O}}{C}-X + Ph_3P{=}CHR' \longrightarrow R-\underset{\substack{\| \\ O}}{C}-\overset{\substack{R' \\ |}}{C}{=}PPh_3 \xrightarrow{\text{reduction}} R-\underset{\substack{\| \\ O}}{C}-CH_2R'$$

Acyl halides, esters, and certain other acid derivatives react with phosphorus ylides (phosphoranes) containing an α-hydrogen to give stable β-keto alkylidene phosphoranes which can then be reduced to ketones.[1046] Ethyl chloroformate similarly gives esters:



$$EtO-\underset{\substack{\| \\ O}}{C}-Cl + Ph_3P{=}CHR' \longrightarrow EtO-\underset{\substack{\| \\ O}}{C}-\overset{\substack{R' \\ |}}{C}{=}PPh_3 \xrightarrow{\text{reduction}} EtO-\underset{\substack{\| \\ O}}{C}-CH_2R'$$

The initial reaction product is a phosphonium salt which loses HX:



$$R-\underset{\substack{\| \\ O}}{C}-X + Ph_3\overset{\oplus}{P}-\overset{\ominus}{C}HR' \longrightarrow R-\underset{\substack{\| \\ O}}{C}-\overset{\substack{R' \\ |}}{C}H-\overset{\oplus}{P}Ph_3 \quad X^- \xrightarrow{-HX} R-\underset{\substack{\| \\ O}}{C}-\overset{\substack{R' \\ |}}{C}{=}PPh_3$$

When acyl halides are substrates, certain phosphoranes in which R′ = COR give O-acylated rather than C-acylated products.[1047]

0-115 Preparation of Acyl Cyanides

$$\mathrm{RCOX + CuCN \longrightarrow RCOCN}$$

Acyl cyanides can be prepared by treatment of acyl halides with copper cyanide.[1048] The mechanism is not known and might be free-radical or nucleophilic substitution. Sodium cyanide can also be employed if phase-transfer catalysts (p. 358) are used.[1049]

OS **III,** 119.

0-116 Preparation of Diazo Ketones

$$\mathrm{RCOX + CH_2N_2 \longrightarrow RCOCHN_2}$$

The reaction between acyl halides and diazomethane is of wide scope and is the best way to prepare diazo ketones.[1050] Diazomethane must be present in excess, or the HX produced will react with the diazo ketone (reaction **0-71**). This reaction is the first step of the Arndt-Eistert synthesis (reaction **8-9**). Diazo ketones can also be prepared directly from a carboxylic acid and diazomethane or diazoethane in the presence of dicyclohexylcarbodiimide.[1051]

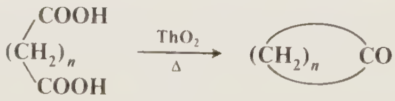
OS **III,** 119; **50,** 77; **53,** 35.

0-117 Ketonic Decarboxylation[1052]

$$\mathrm{2RCOOH \xrightarrow[ThO_2]{400\text{-}500^\circ C} RCOR + CO_2}$$

Carboxylic acids can be converted to symmetrical ketones by pyrolysis in the presence of thorium oxide. An alternative method involves heating of the ferrous salt of the acid.[1053] Although many books assert that ketones are prepared by heating calcium or barium salts of acids, in reality this reaction gives very low yields.[1054] However, methyl ketones have been prepared by heating barium acetate with barium salts of other acids in an example of a mixed process. In another mixed reaction, formic acid and another acid heated over thorium oxide give aldehydes. Mixed alkyl aryl ketones have been prepared by heating mixtures of ferrous salts.[1055] When the R group is large, the methyl ester rather than the acid can be decarbmethoxylated over thorium oxide to give the symmetrical ketone.

The reaction has been performed on dicarboxylic acids, whereupon cyclic ketones are obtained:



This process, called the *Ruzicka cyclization*, is good for the preparation of rings of six and seven members and, with lower yields, of eight members. In contrast to the lack of success with monocarboxylic acids, calcium and barium salts of dicarboxylic acids can be heated to give cyclic ketones of large rings (C_9 to C_{19}) as well as of five-, six-, and seven-membered rings. Cyclization can also be achieved by heating the dicarboxylic acid with $CdCO_3$.[1056]

Not much work has been done on the mechanism of this reaction. However, a free-radical mechanism has been suggested on the basis of a thorough study (by means of a combined chromatograph mass spectrometer computer system) of all the side products.[1057]

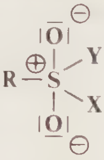
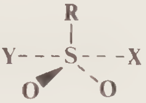
Nucleophilic Substitution at a Sulfonyl Sulfur Atom[1058]

Nucleophilic substitution at RSO_2X is similar to attack at RCOX. Many of the reactions are essentially the same, though sulfonyl halides are not as active as halides of carboxylic acids. Less work has been done on these reactions than on those at an acyl carbon. The actual mechanisms are not identical, because a "tetrahedral" intermediate in this case (**183**) would have five groups on the central atom.[1059] Though this is possible, since sulfur can accommodate up to 12 electrons in its valence shell, it seems more likely that these mechanisms more closely resemble the SN2 mechanism, with a trigonal pyramidal transition state (**184**). There are two major experimental results leading to this conclusion.



183



184

1. The stereospecificity of this reaction is more difficult to determine than that of nucleophilic substitution at a saturated carbon, where chiral compounds are relatively easy to prepare, but it may be recalled (p. 89) that optical activity is possible in a compound of the form RSO_2X if one oxygen is ^{16}O and the other ^{18}O. When a sulfonate ester possessing this type of chirality was converted to a sulfone with a Grignard reagent (reaction **0-123**), inversion of configuration was found.[1060] This is not incompatible with an intermediate such as **183,** but it is also in good accord with an SN2-like mechanism with backside attack.

2. More direct evidence against **183** (though still not conclusive) was found in an experiment involving acid and basic hydrolysis of aryl arenesulfonates, where it has been shown by the use of ^{18}O that an intermediate like **183** is not reversibly formed, since ester recovered when the reaction was stopped before completion contained no ^{18}O when the hydrolysis was carried out in the presence of labeled water.[1061]

Other evidence favoring the SN2-like mechanism comes from kinetics and substituent effects.[1062] However, evidence for the mechanism involving **183** is that the rates did not change much with changes in the leaving group[1063] and that ρ values were large, indicating that a negative charge builds up in the transition state.[1064]

[1062] See for example, Robertson and Rossall, *Can. J. Chem.* **49,** 1441 (1971); Rogne, *J. Chem. Soc. B* 1855 (1971), *J. Chem. Soc., Perkin Trans. 2* 489 (1972).

[1063] Ciuffarin, Senatore, and Isola, *J. Chem. Soc., Perkin Trans. 2* 468 (1972).

[1064] Ciuffarin and Senatore, *Tetrahedron Lett.* 1635 (1974).

In certain cases in which the substrate carries an α-hydrogen, there is strong evidence[1065] that at least some of the reaction takes place by an elimination-addition mechanism (similar to the one shown on p. 352), going through a *sulfene* intermediate, e.g., the reaction between methanesulfonyl chloride and aniline.

$$CH_3{-}SO_2Cl \xrightarrow{\text{base}} \underset{\text{A sulfene}}{CH_2{=}SO_2} \xrightarrow{PhNH_2} CH_3{-}SO_2{-}NHPh$$

In the special case of nucleophilic substitution at a sulfonic ester, RSO_2OR', where R′ is alkyl, R′—O cleavage is much more likely than S—O cleavage, because the OSO_2R group is such a good leaving group (p. 326). Many of these reactions have been considered previously (e.g., reactions **0-4**, **0-16**, etc.), because they are nucleophilic substitutions at an alkyl carbon atom and not at a sulfur atom. However, when R′ is aryl, then the S—O bond is much more likely to cleave because of the very low tendency aryl substrates have for nucleophilic substitution.[1066]

The order of nucleophilicity toward a sulfonyl sulfur has been reported as $OH^- > RNH_2 > N_3^- > F^- > AcO^- > Cl^- > H_2O > I^-$.[1067] This order is similar to that at a carbonyl carbon (p. 324). Both these substrates can be regarded as relatively hard acids, in comparison with a saturated carbon which is considerably softer and which has a different order of nucleophilicity (p. 324).

0-118 Attack by OH. Hydrolysis of Sulfonic Acid Derivatives

$$RSO_2Cl \xrightarrow{H_2O} RSO_2OH$$

$$RSO_2OR' \xrightarrow[H^+]{H_2O} RSO_2OH$$

$$RSO_2NR'_2 \xrightarrow[H^+]{H_2O} RSO_2OH$$

Sulfonyl chlorides, and esters and amides of sulfonic acids, can be hydrolyzed to the corresponding acids. Sulfonyl chlorides can be hydrolyzed with water or with an alcohol in the absence of acid or base. Basic catalysis is also used, though the salt of course is the product obtained. Esters are readily hydrolyzed, many with water or dilute alkali. This is actually the same reaction as **0-4**, and usually involves R′—O cleavage, except when R′ is aryl. However, in some cases retention of configuration has been shown at alkyl R′, indicating S—O cleavage in these cases.[1068] Sulfonamides are generally not hydrolyzed by alkaline treatment, not even with hot concentrated alkali,[1069] but acids hydrolyze them, though less readily than they do sulfonyl halides or sulfonic esters. Of course, ammonia or the amine appears as the salt. However, sulfonamides can be hydrolyzed with base if the solvent is HMPT.[1070] Sulfonamides of the form RSO_2NH_2 can also be hydrolyzed with HNO_2 in a reaction similar to **0-5**. Primary and secondary amines can be obtained from N-substituted and N,N-disubstituted sulfonamides, respectively,[1071] and alcohols from sulfonic esters,[1072] by treatment with sodium naphthalene radical ion in 1,2-dimethoxyethane or tetrahydrofuran.

0-119 Attack by OR. Formation of Sulfonic Esters

$$\mathbf{RSO_2Cl + R'OH \xrightarrow{\text{base}} RSO_2OR'}$$

$$\mathbf{RSO_2NR''_2 + R'OH \xrightarrow{\text{base}} RSO_2OR' + NHR''_2}$$

Sulfonic esters are most frequently prepared by treatment of the corresponding halides with alcohols in the presence of a base. The method is much used for the conversion of alcohols to tosylates,[1073] brosylates, and similar sulfonic esters (p. 326). Both R and R′ may be alkyl or aryl. The base is often pyridine, which functions as a nucleophilic catalyst,[1074] as in the similar alcoholysis of carboxylic acyl halides (**0-22**). Primary alcohols react the most rapidly, and it is often possible to sulfonate selectively a primary OH group in a molecule which also contains secondary or tertiary OH groups. The reaction with sulfonamides has been much less often used and is limited to N,N-disubstituted sulfonamides; that is, R″ may not be hydrogen. However, within these limits it is a useful reaction.[1069] The nucleophile in this case is actually $R'O^-$. However, R″ may be hydrogen (as well as alkyl) if the nucleophile is a phenol, so that the product is RSO_2OAr. Acidic catalysts are used in this case.[1075]

0-120 Attack by Nitrogen. Formation of Sulfonamides

$$\mathbf{RSO_2Cl + NH_3 \longrightarrow RSO_2NH_2}$$

The treatment of sulfonyl chlorides with ammonia or amines is the usual way of preparing sulfonamides. Primary amines give N-alkyl sulfonamides, and secondary amines give N,N-dialkyl sulfonamides. The reaction is the basis of the *Hinsberg test* for distinguishing between primary, secondary, and tertiary amines. N-Alkyl sulfonamides, having an acidic hydrogen, are soluble in alkali, while N,N-dialkyl sulfonamides are not. Since tertiary amines are usually recovered unchanged, primary, secondary, and tertiary amines can be told apart. However, the test is limited for at least two reasons.[1076] (1) Many N-alkyl sulfonamides in which the alkyl group has six or more carbons are insoluble in alkali, despite their acidic hydrogen,[1077] so that a primary amine may appear to be a secondary amine. (2) If the reaction conditions are not carefully controlled, tertiary amines may not be recovered unchanged.[1076] In fact, the reason the test often does succeed with aliphatic tertiary amines is not that they do not react with RSO_2Cl, but that (when the reagents are mixed in a 1 : 1 ratio) the reaction gives quaternary sulfonamide salts $RSO_2NR_3^+\ \ X^-$ which are hydrolyzed to RSO_2O^- under the usual aqueous basic conditions. When other proportions are used, or when aryl tertiary amines ($ArNR_2$) are involved, other reactions may take place and, if so, the test is negated.

A primary or a secondary amine can be protected by reaction with phenacylsulfonyl chloride ($PhCOCH_2SO_2Cl$) to give a sulfonamide $RNHSO_2CH_2COPh$ or $R_2NSO_2CH_2COPh$.[1078] The protecting group can be removed when desired with zinc and acetic acid. Sulfonamides can also be prepared from other sulfonamides in a transamination reaction.[1069] Sulfonyl chlorides react with azide ion to give sulfonyl azides RSO_2N_3.[1079]

0-121 Attack by Halogen. Formation of Sulfonyl Halides

$$\mathbf{RSO_2OH + PCl_5 \longrightarrow RSO_2Cl}$$

This reaction, parallel with reaction **0-75,** is the standard method for the preparation of sulfonyl halides. Also used are PCl_3 and $SOCl_2$, and sulfonic acid salts can also serve as substrates. Sulfonyl bromides and iodides have been prepared from sulfonyl hydrazides ($ArSO_2NHNH_2$, themselves prepared by reaction **0-120**) by treatment with bromine or iodine.[1080]

OS **I,** 84; **IV,** 571, 693, 846, 937; **V,** 196.

0-122 Attack by Hydrogen. Reduction of Sulfonyl Chlorides

$$\mathbf{2RSO_2Cl + Zn \longrightarrow (RSO_2)_2Zn \xrightarrow{H^+} 2RSO_2H}$$

Sulfinic acids can be prepared by reduction of sulfonyl chlorides.[1081] Though mostly done on aromatic sulfonyl chlorides, the reaction has also been applied to alkyl compounds. Besides zinc, sodium sulfite, hydrazine, sodium sulfide, and other reducing agents have been used. For reduction of sulfonyl chlorides to mercaptans, see reaction **9-55.**

OS **I,** 7, 492; **IV,** 674.

0-123 Attack by Carbon. Preparation of Sulfones

$$\mathbf{ArSO_2Cl + Ar'MgX \longrightarrow ArSO_2Ar'}$$

Grignard reagents convert aromatic sulfonyl chlorides to sulfones. Esters of aromatic sulfonic acids can also serve as substrates.

Eleven

Aromatic Electrophilic Substitution

Most substitutions at an aliphatic carbon are nucleophilic. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring attracts positive species and not negative ones. In electrophilic substitutions the attacking species is a positive ion or the positive end of a dipole or induced dipole. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitutions, the chief leaving groups are those best able to carry the unshared pair: Br^-, H_2O, OTs^-, etc., that is, the weakest bases. In electrophilic substitutions, the most important leaving groups are those which can best exist without the pair of electrons necessary to fill the outer shell, that is, the weakest Lewis acids. The most common leaving group in electrophilic aromatic substitutions is the proton.

MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceed by just one mechanism with respect to the substrate.[1] In this mechanism, which we call the *arenium-ion mechanism*, the electrophilic attacks in the first step, giving rise to a positively charged intermediate (the arenium ion), and the leaving group departs in the second step, so that there is a resemblance to the tetrahedral mechanism of Chapter 10, but with the charges reversed. Another mechanism, much less common, consists of the opposite behavior: the leaving group departs *before* the electrophile arrives. This mechanism, the SE1 mechanism, corresponds to the SN1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to SN2) are not found at all. An addition-elimination mechanism has been postulated in one case (see reaction **1-6**).

The Arenium-ion Mechanism[2]

In the arenium-ion mechanism, the attacking species may be produced in various ways, often in several different ways even for the same reaction, and the same reaction may have different attacking species under different conditions, but what happens to the aromatic ring is basically the same in all cases. For this reason most attention in the study of this mechanism centers around the identity of the attacking entity and how it is produced.[3]

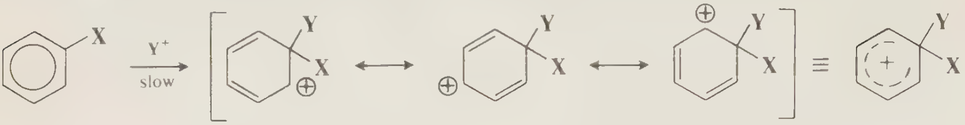
---

[1] For monographs, see Norman and Taylor, "Electrophilic Substitution in Benzenoid Compounds," American Elsevier Publishing Company, New York, 1965; de la Mare and Ridd, "Aromatic Substitution—Nitration and Halogenation," Academic Press, Inc., New York, 1959; for a review, see Taylor, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 13, pp. 1-406, American Elsevier Publishing Company, New York, 1972.

[2] This mechanism is sometimes called the SE2 mechanism, because it is bimolecular, but in this book we reserve that name for aliphatic substrates (see Chapter 12).

[3] For a review of the mechanism of the substitution process itself, see Berliner, *Prog. Phys. Org. Chem.* **2**, 253-321 (1964).

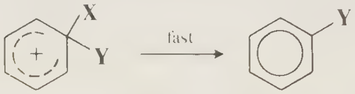
The electrophile may be a positive ion or a dipole. If it is a positive ion, it attacks the ring, removing a pair of electrons from the sextet, to give a carbonium ion:



1 2

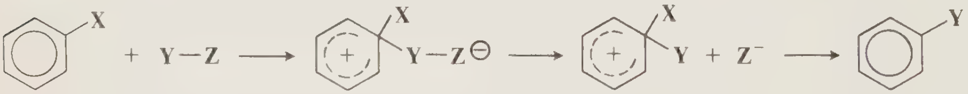
which is a resonance hybrid, as shown in **1**, and is frequently represented as in **2**. Ions of this type are called[4] *Wheland intermediates*, *σ complexes*, or *arenium ions*.[5] In the case of benzenoid systems they are cyclohexadienyl cations. It may easily be seen that the great stability associated with an aromatic sextet is no longer present in **1**, although the ion is stabilized by resonance of its own. The arenium ion is generally a highly reactive intermediate and must stabilize itself by a further reaction, though it has been isolated (see p. 456).

Carbonium ions may stabilize themselves in various ways (see p. 159), but for an ion of this type the most likely way[6] is by loss of either X^+ or Y^+, since the aromatic sextet will then be restored, and in fact this is the second step of the mechanism:



The second step is nearly always faster than the first, so that the first is rate-determining and the reaction is second order (unless the *formation* of the attacking species is slower still, in which case the aromatic compound does not take part in the rate expression at all). If Y^+ is lost, then there is no net reaction, but if X^+ is lost, an aromatic substitution has taken place. If X^+ is a proton, then a base is necessary to help remove it.

If the attacking species is not an ion but a dipole, then the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, e.g.,



The questions as to what the attacking entity is in each case, and how it is formed, are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium-ion mechanism is mainly of two kinds:

1. *Isotope effects.*[7] If the hydrogen ion departed before the arrival of the electrophile (SE1 mechanism) or if the arrival and departure were simultaneous, then there should be a substantial isotope effect (that is, deuterated substrates should undergo substitution more slowly than nondeuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium-ion mechanism, the C—H bond is not broken in the rate-determining step, and so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.[8] This result is incompatible with either the SE1 or the simultaneous mechanism.

---

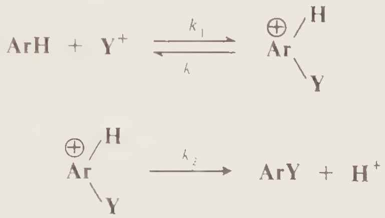
[4] Just what to call these ions has been a matter for debate. The term σ complex is a holdover from the time when much less was known about the structure of carbonium ions and it was thought they might be complexes of the type discussed in Chapter 3. Other names have also been used. Henceforth we will call them arenium ions, following the suggestion of Olah, *J. Am. Chem. Soc.* **94**, 808 (1972).

[5] For reviews of arenium ions formed by addition of a proton to an aromatic ring, see Brouwer, Mackor, and MacLean, in Olah and Schleyer, "Carbonium Ions," vol. 2, pp. 837–897, Interscience Publishers, New York, 1970; Perkampus and Baumgarten, *Angew. Chem. Int. Ed. Engl.* **3**, 776–783 (1964) [*Angew. Chem.* **76**, 965–972]; Perkampus, *Adv. Phys. Org. Chem.* **4**, 195–304 (1966).

[6] For a discussion of cases in which **1** stabilizes itself in other ways, see de la Mare, *Acc. Chem. Res.* **7**, 361–368 (1974).

[7] For reviews of hydrogen isotope effects in aromatic substitutions, see Zollinger, *Adv. Phys. Org. Chem.* **2**, 163–200 (1964); Ref. 3, pp. 281–294.

However, in many instances isotope effects have been found. Since the values are generally much lower than we would expect for either the SE1 or the simultaneous mechanisms (for example, 1 to 3 for k_{H} k_{D} instead of 6 to 7), we must look elsewhere for the explanation. For the case where hydrogen is the leaving group, the arenium-ion mechanism may be summarized:



Step 1 $$\mathrm{ArH} + \mathrm{Y}^+ \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \overset{\oplus}{\mathrm{Ar}}(\mathrm{H})(\mathrm{Y})$$

Step 2 $$\overset{\oplus}{\mathrm{Ar}}(\mathrm{H})(\mathrm{Y}) \xrightarrow{k_2} \mathrm{ArY} + \mathrm{H}^+$$

Isotope effects can arise from this mechanism in at least two ways.[9] If the second step has a rate comparable to or less than the first ($k_2[\mathrm{ArHY}^+] \lesseqgtr k_1[\mathrm{ArH}][\mathrm{Y}^+]$), then there will obviously be an isotope effect. However, it is probable that most isotope effects in aromatic substitutions are not caused by this circumstance and that the first step is generally much slower than the second. It is likely that most isotope effects arise from the reversibility of step 1 by a *partitioning effect*. The rate at which ArHY^+ reverts to ArH should be essentially the same as that at which ArDY^+ (or ArTY^+) reverts to ArD (or ArT), since the Ar—H bond is not cleaving. However, ArHY^+ should go to ArY faster than either ArDY^+ or ArTY^+, since the Ar—H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter: since a large majority of the intermediates go to product, the rate is determined only by the slow step ($k_1[\mathrm{ArH}][\mathrm{Y}^+]$), and no isotope effect is predicted. However, if $k_2 \lesseqgtr k_{-1}$, then reversion to starting materials is important. If k_2 for ArDY^+ (or ArTY^+) is less than k_2 for ArHY^+, but k_{-1} is the same, then a larger proportion of ArDY^+ reverts to starting compounds. That is, k_2 k_{-1} (the *partition factor*) for ArDY^+ is less than that for ArHY^+. Consequently, the reaction is slower for ArD than for ArH, and an isotope effect is observed.

One circumstance which could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of **3** gave no isotope effect, while coupling of **5** gave a $k_{\mathrm{H}}/k_{\mathrm{D}}$ ratio of 6.55.[10] For steric reasons it is much more difficult for **6** to lose a proton (it is harder for a base to approach) than it is for **4**, so k_2 is greater for the latter. Since no base is necessary to remove $\mathrm{ArN_2}^+$, k_{-1} does not depend on steric factors[11] and is about the same for each. Thus the partition factor k_2 k_{-1} is sufficiently different for **4** and **6** that **5** exhibits a large isotope effect and **3** exhibits none.[12] Base

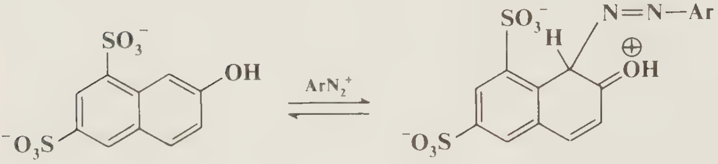
3 4



5 6

catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Small isotope effects can also arise in other ways (for example, in the step $ArXH^+ \rightarrow ArH$ there may be a *secondary* isotope effect), and not all the results are fully understood.

Evidence for the arenium-ion mechanism has also been obtained from another kind of isotope-effect experiment, involving substitutions of the type

$$ArMR_3 + H_3O^+ \longrightarrow ArH + R_3MOH_2^+$$

where M was Si, Ge, Sn, or Pb, and R was methyl or ethyl. In these reactions the proton is the electrophile. If the arenium-ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55 to 3.05 were obtained,[13] in accord with the arenium-ion mechanism.

2. *Isolation of arenium ion intermediates.* Very strong evidence for the arenium-ion mechanism comes from the isolation of arenium ions in a number of instances.[14] For example, **7** was isolated as a solid with melting point −15°C from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at −80 C. When **7** was heated, the normal substitution product **8** was obtained.[15]

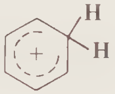
TABLE 1 Relative stabilities of arenium ions and π complexes and relative rates of chlorination and nitration

In each case, p-xylene = 1.00

Substituents	Relative arenium-ion stability[18]	Relative π-complex stability[18]	Rate of chlorination[19]	Rate of nitration[24]
None (benzene)	0.09	0.61	0.0005	0.51
Me	0.63	0.92	0.157	0.85
p-Me$_2$	1.00	1.00	1.00	1.00
o-Me$_2$	1.1	1.13	2.1	0.89
m-Me$_2$	26	1.26	200	0.84
1,2,4-Me$_3$	63	1.36	340	
1,2,3-Me$_3$	69	1.46	400	
1,2,3,4-Me$_4$	400	1.63	2000	
1,2,3,5-Me$_4$	16,000	1.67	240,000	
Me$_5$	29,000		360,000	

Even the simplest such ion, the benzenium ion (**9**) has been prepared in $HF–SbF_5–SO_2ClF–SO_2F_2$ at −134°C, where it could be studied spectrally.[16]



9

In Chapter 3 it was mentioned that positive ions can form addition complexes with π systems. Since the initial step of electrophilic substitution involves attack by a positive ion on an aromatic ring, it has been suggested[17] that such a complex, called a *π complex* (represented as **10**), is formed first and then is converted to the arenium ion **11.** Stable solutions of arenium ions or π complexes (e.g., with Br_2, I_2, picric acid, Ag^+, or HCl) can be formed at will. For example, π complexes are formed when aromatic hydrocarbons are treated with HCl alone, but the use of HCl plus a Lewis acid (e.g., $AlCl_3$) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity (showing positive and negative ions are present), while a π complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a π complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and $AlCl_3$ gives deuterium exchange. The relative stabilities of some methylated arenium ions and π complexes are shown in Table 1.

[17] Dewar, "Electronic Theory of Organic Chemistry," Clarendon Press, Oxford, 1949.

The arenium ion stabilities listed here were determined by the relative basicity of the substrate toward HF.[18] The π-complex stabilities are relative equilibrium constants for the reaction[19] between the aromatic hydrocarbon and HCl. As shown in Table 1, the relative stabilities of the two types of species are very different, the π-complex stability changing very little with methyl substitution, but the arenium-ion stability changing a great deal. There are at least two reasons for this difference. (1) A methyl group stabilizes an adjacent positive charge (p. 153). In an arenium ion a full unit of positive charge is present on the ring, but in a π complex very little charge has been transferred to the ring. (2) In a π complex, the small amount of charge is spread over the entire ring, so that a methyl group can stabilize it more or less equally from any position, but an arenium ion is a hybrid of three canonical forms (**1**), and the charge is localized on three of the six carbons. A methyl group located on one of these three is particularly effective in stabilizing a positive charge.

How can we tell if **10** is present on the reaction path? If it is present, then there are two possibilities: (1) The formation of **10** is rate-determining (the conversion of **10** to **11** is much faster), or (2) the formation of **10** is rapid, and the conversion **10** to **11** is rate-determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 1. If the relative rates resemble the arenium-ion stabilities, then we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the π complexes, then the latter are formed in the slow step.[20] When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium-ion and not to the π-complex stabilities. For example, Table 1 lists chlorination rates.[19] Similar results have been obtained in room-temperature bromination with Br_2 in acetic acid[21] and in acetylation with $CH_3CO^+ \ SbF_6^-$.[22] It is clear that in these cases the π complex either does not form at all, or if it does, its formation is not rate-determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of $NO_2^+ \ BF_4^-$) the relative rates resembled[23] π-complex stabilities much more than they did arenium-ion stabilities (Table 1),[24] and similar results were obtained for bromination with Br_2 and $FeCl_3$ in nitromethane.[25] These results were taken to mean[24,25] that in these cases π-complex formation is rate-determining (which means of course that they must be on the reaction path); and if so, it is likely that π complexes are also on the reaction path even where formation of arenium ions is rate-determining. However, the conclusion that π-complex formation is rate-determining has been challenged[26] on several grounds, especially for the nitration case. The current position seems to be that there is no conclusive evidence that π complexes are involved at all[27] (for further discussion of this question, see p. 472).

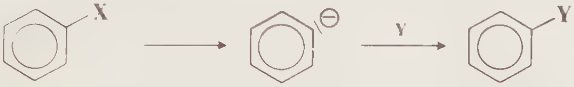
Soc.* **93,** 6964 (1971); Olah and Lin, *J. Am. Chem. Soc.* **96,** 2892 (1974).

The SE1 Mechanism

The SE1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see reactions **1-42, 1-43**), or when a very strong base is present (see reactions **1-1, 1-12, 1-48**).[28] It consists of two steps with an intermediate carbanion.



Reactions **2-40, 2-44,** and **2-45** also take place by this mechanism when applied to aryl substrates.

ORIENTATION AND REACTIVITY

Orientation and Reactivity in Monosubstituted Benzene Rings[29]

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position, and the substitution may be slower or faster than with benzene itself. The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups which increase the reaction rate are called *activating*, and those which slow it, *deactivating*. Some groups are predominantly meta-directing; all of these are deactivating. Others are mostly ortho-para-directing; some of these are deactivating too, but most are activating. Groups direct *predominantly*, but usually not *exclusively*. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the isomer.

The orientation and reactivity effects of each group are explained on the basis of resonance and field effects on the stability of the intermediate arenium ion. In order to understand why we can use this approach, it is necessary to know that in these reactions the product is usually kinetically and not thermodynamically controlled (see p. 194). Some of the reactions are irreversible, and the others are usually stopped well before equilibrium is reached. Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products, but on the activation energy necessary to form each of the three intermediates. It is not easy to predict which of the three activation energies is lowest, but we make the assumption that the free-energy profile resembles either Figure 2 or 3 in Chapter 6 (p. 193). In either case, the transition state is closer in energy to the arenium-ion intermediate than it is to the starting compounds. Invoking the Hammond postulate (p. 194), we can then assume that the geometry of the transition state also resembles that of the intermediate and that anything which will increase the stability of the intermediate will also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, we can use the relative stabilities of the three intermediates as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, we may get product ratios which are quite different. For example, the sulfonation of naphthalene at 80°C, where the reaction does not reach equilibrium, gives mostly α-naphthalenesulfonic acid,[30] while at 160°C, where equilibrium is obtained, the β-isomer predominates[31] (the α-isomer is thermodynamically less stable, because of steric interaction between the SO_3H group and the hydrogen at the 8 position). An example from the benzene series is as follows: when ethylbenzene is ethylated under the usual Friedel-Crafts conditions (reaction **1-13**), the products are chiefly the *o*- and *p*-diethylbenzenes, but treatment of either *o*-, *m*-, or *p*-diethylbenzene with $AlCl_3$ eventually gives an equilibrium mixture which contains 3% *o*-, 69% *m*-, and 28% *p*-diethylbenzenes.[32] This result is in accord with the thermodynamic stabilities of the products.[33]

---

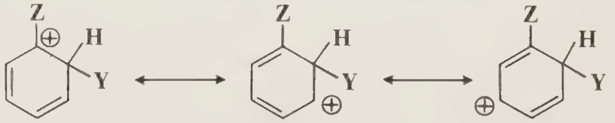
[27] For an excellent discussion of the whole question, see Banthorpe, *Chem. Rev.* **70,** 295–322 (1970), especially sections VI and IX.

[28] It has also been found with a metal ($SnMe_3$) as electrofuge: Eaborn, Hornfeld, and Walton, *J. Chem. Soc. B* 1036 (1967).

[29] For reviews of orientation and reactivity in benzene and other aromatic rings, see Hoggett, Moodie, Penton, and Schofield, "Nitration and Aromatic Reactivity," pp. 122–145, 163–220, Cambridge University Press, London, 1971; Ferguson, *Chem. Rev.* **50,** 47–67 (1952).

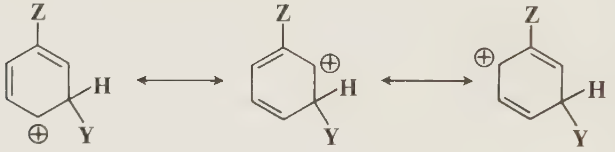
Now that we see why we can use the relative stabilities of the arenium ions to predict orientation effects, let us examine the three possible ions:

Ortho

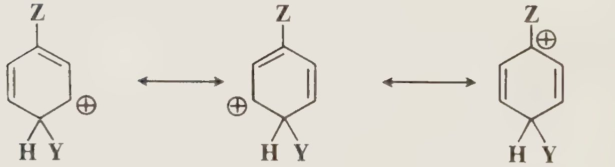


12

Meta



Para



13

For each ion we see that the ring has a positive charge. We can therefore predict that any group Z which has an electron-donating field effect should stabilize all three ions (relative to **1**), but that electron-withdrawing groups, which increase the positive charge on the ring, should destabilize them. But we can make a further prediction concerning field effects. These taper off with distance and are thus strongest at the carbon connected to the group Z. But of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge there, and so the hybrid has none either. Therefore, $+I$ groups should stabilize all three ions but mostly the ortho and para, so they should be not only activating but ortho-para-directing as well. On the other hand, $-I$ groups, by removing electron density, should destabilize all three ions but mostly the ortho and para, and should be not only deactivating but also meta-directing.

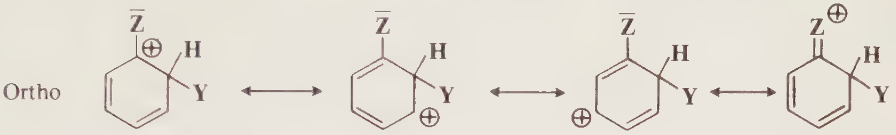
[32] Olah, Meyer, and Overchuk, *J. Org. Chem.* **29**, 2313 (1964).

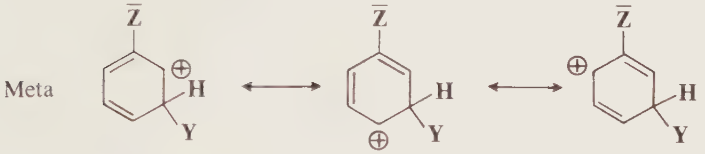
[33] Stull, in Olah, "Friedel-Crafts and Related Reactions," vol. 1, pp. 980–982, Interscience Publishers, New York, 1963. Actually, the values in this reference are for the three xylenes, but the order of stability is undoubtedly the same for the diethylbenzenes.

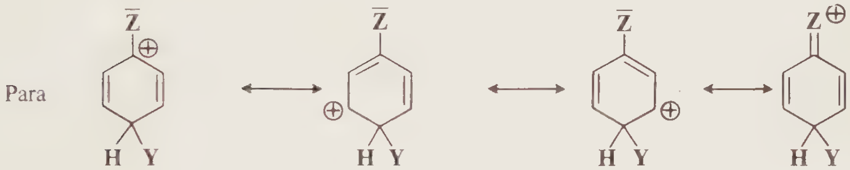
These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases there is *resonance interaction* between Z and the ring, and this also affects the relative stability, in some cases in the same direction as the field effect, but in others differently.

Some Z groups have a pair of electrons (usually unshared) which may be contributed *toward* the ring. The three arenium ions would then look like this:



14





15

For each ion the same three canonical forms may be drawn as before, but now we may draw an extra form for the ortho and the para ions. The stability of these two is increased by the extra form not only because it is another canonical form, but because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except of course hydrogen) in these forms (**14** and **15**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (p. 37), but also because it spreads the positive charge over a larger area—out onto the group Z. Groups with a pair of electrons to contribute would be expected then, in the absence of field effects, not only to direct ortho and para, but also to activate the reaction for these positions.

On the basis of these discussions, we may distinguish three types of groups.

1. Groups which contain an unshared pair of electrons on the atom connected to the ring. In this category are O^-, NR_2, NHR, NH_2,[34] OH, OR, NHCOR, OCOR, SR, and the four halogens.[35] The SH group would probably belong here too, except that in the case of thiophenols electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.[36] The resonance explanation predicts that all these groups should be ortho-para-directing, and they are, though all except O are electron-withdrawing by the field effect (p. 21). Therefore, for these groups, resonance is more important than the field effect. This is especially true for NR_2, NHR, NH_2, and OH, which are *strongly* activating, as is O^-. The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring even though they direct ortho-para, we must assume that the canonical forms **14** and **15** make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta even though the $-I$ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted **1**. For the other groups which contain an unshared pair, the ortho and para ions are more stable than either the meta ion or the unsubstituted ion. For most of the groups in this category, the meta ion is more stable than **1**, so that groups such as NH_2, OH, etc., activate the meta positions too, but not so much as the ortho and para positions (see also the discussion on pp. 468–470).

---

[34] It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta-directing (type 2). Therefore in acid (which is the most common medium for electrophilic substitutions) amino groups may direct meta. However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho-para direction is often found even under acidic conditions.

2. Groups which lack an unshared pair on the atom connected to the ring and which are $-I$. In this category we may list, in approximate order of decreasing deactivating ability, NR_3^+, NO_2, CN, SO_3H, CHO, COR, COOH, COOR, $CONH_2$, CCl_3, and NH_3^+. Also in this category are all other groups with a positive charge on the atom directly connected to the ring[37] (for example, SR_2^+, PR_3^+, etc.), and many groups with positive charges on atoms farther away, since often these are still powerful $-I$ groups. The field-effect explanation predicts that these should all be meta-directing and deactivating, and (except for NH_3^+) this is the case. This is especially true for groups with a positive charge on the atom directly connected to the ring (this includes nitro) since, for these, canonical forms **12** and **13** have two positive charges on adjacent atoms, which destabilize the ortho and para arenium ions even more than otherwise. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.[38] The NH_2Me^+, $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.[39]

3. Groups which lack an unshared pair on the atom connected to the ring and which are ortho-para-directing. In this category are alkyl groups, aryl groups, and the COO^- group,[40] all of which activate the ring. We shall discuss them separately. Since aryl groups are $-I$ groups, they might seem to belong to category 2. They are nevertheless ortho-para-directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so that we have forms like **16**. The effect of

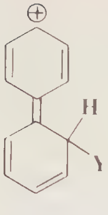
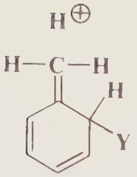
[40] Spryskov and Golubkin, *J. Gen. Chem. USSR* **31,** 833 (1961). Since the COO^- group is present only in alkaline solution, where electrophilic substitution is not often done, it is seldom met with.



16



17

negatively charged groups like COO is easily explained by the field effect (negatively charged groups are of course electron-donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but in addition, we can also draw canonical forms even though there is no unshared pair. These of course are hyperconjugation forms like **17**. This effect, like the field effect, predicts activation and ortho-para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups (which sums up both field and hyperconjugation effects) is that (for $Z = R$) the ortho and para arenium ions are more stable because each contains a form (**12** and **13**) which is a tertiary carbonium ion, while all the canonical forms for the meta ion and for **1** are secondary carbonium ions. In activating ability, alkyl groups usually follow the Baker-Nathan order (p. 70), but not always.[41] The cyclopropyl group is highly activating, since cyclopropylbenzene could be brominated at −75 C and nitrated at −50 C.[42]

The Ortho/Para Ratio[43]

When an ortho-para-directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much the para isomer. Indeed, these proportions may depend greatly on the reaction conditions. For example, chlorination of toluene gives anywhere from 62% *o*-chlorotoluene and 38% of the para isomer to 34% of the ortho and 66% of the para compound.[44] Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the arenium ion **9**, arising from protonation of benzene, has the approximate charge distribution shown.[45] If we accept this as a model for the arenium ion in aromatic substitution, then a para substituent would have a greater stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that more than 33% para and less than 67% ortho substitution would be found. In hydrogen exchange (reaction **1-1**), where other effects are absent, it has been found for a number of substituents that the average ratio of the logarithms of the partial rate factors for these positions (see p. 468 for a definition of partial rate factor) was close to 0.865,[46] which is not far from the value predicted from the ratio of charge densities in **9**, as shown on p. 464. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho para ratios greater than 67 : 33[47] (of course the total amount

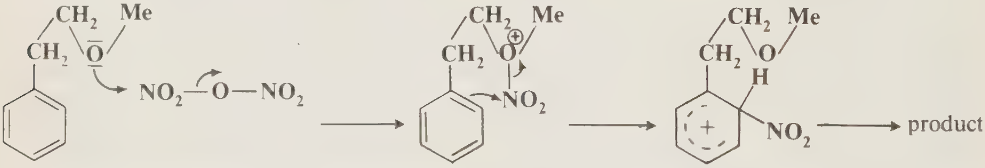
9

of ortho and para substitution with these groups is small, but the *ratios* are generally greater than 67 : 33). Another important factor which affects the ortho/para ratio is the steric effect. If either the group on the ring or the attacking group is large, then steric hindrance inhibits formation of the ortho product and thus increases the amount of the para isomer. An example of this may be seen in the nitration, under the same conditions, of toluene and *t*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *t*-butyl group gave 16% of the ortho product and 73% of the para.[48] A few groups are so large that they direct almost entirely para.

When the ortho-para-directing group is one with an unshared pair (this of course applies to most of them), there is another effect which increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (p. 461) shows that **14** is a canonical form with an ortho-quinonoid structure, while **15** has a para-quinonoid structure. Since we know that *para*-quinones are more stable than the ortho isomers, it seems reasonable to assume that **15** is more stable than **14** and therefore contributes more to the hybrid and increases its stability in comparison with the ortho intermediate.

In some cases a high ortho/para ratio is observed because of interaction between the electrophile and the directing group. For example, methyl phenethyl ether gives a higher ortho/para ratio when nitrated with N_2O_5 than it does with the more usual mixture of nitric and sulfuric acids, where the attacking entity is NO_2^+ (reaction **1-2**). This behavior has been ascribed to the following mechanism:[49]



One further point can be made: with groups where the field effect is important, we should look for a greater effect at the ortho position than at the para, since field effects decrease with distance. Fluorine, which has the strongest $-I$ effect of the four halogens, should therefore have a greater relative deactivating effect at the ortho position compared to the para than chlorine, and the effect of chlorine should be greater than that of bromine, etc. Consequently, in electrophilic substitution on the halobenzenes, iodobenzene should give the largest amount of ortho product and fluorobenzene the smallest. Nitration of the halobenzenes gave ortho products as follows: PhF, 12%; PhCl, 30%; PhBr, 38%; PhI, 41%.[50] Note that this is opposite to what would be predicted on the basis of steric effects alone.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing cyclohexaamylose, a molecule in which the anisole is almost entirely enclosed (similar to the inclusion compounds discussed at p. 83). With a high enough concentration of cyclohexaamylose, it was possible to achieve an ortho para ratio of 21.6[51] (in the absence of cyclohexaamylose the ratio was only 1.48). This behavior is a model for the regiospecificity found in the action of enzymes.

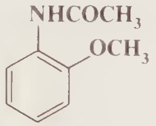
Orientation in Benzene Rings with More than One Substituent[52]

It is often possible in these cases to predict the correct isomer. In many cases the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position, since this is ortho to one group and para to the other, but not at the 5 position, which is meta to both. Likewise the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult. In a case such as **18**, where two groups of about equal directing ability are in competing positions, all four products may be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Results are often hard to explain. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

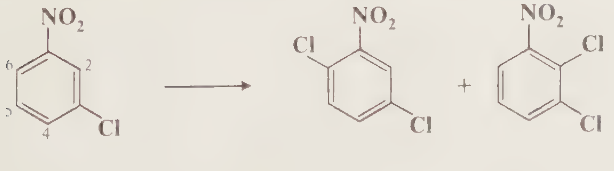


18

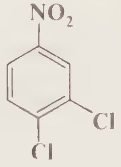
1. If a strongly activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxy* group and not to the methyl. For this purpose we can arrange the groups thusly: NH_2, OH, NR_2, O^- > OR, OCOR, NHCOR > R, Ar > halogen > meta-directing groups.

2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This effect is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.

3. When a meta-directing group is meta to an ortho-para-directing group, the incoming group primarily goes ortho to the meta-directing group, rather than para. For example, chlorination of **19** gives mostly **20**. The importance of this effect is underscored by the fact that **21**, which is in



19 **20** **21**



22

---

[51] Breslow and Campbell, *J. Am. Chem. Soc.* **91**, 3085 (1969).

[52] For a quantitative discussion, see pp. 468–470.

violation of the preceding rule, is formed in smaller amounts, but **22** is not formed at all. This is called the *ortho effect*,[53] and many such examples are known.[54] Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it, rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.

It is interesting that chlorination of **19** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attack is therefore at position 6.

Orientation in Other Ring Systems[55]

In fused ring systems the positions are not equivalent, and there is usually a preferred orientation even in the unsubstituted hydrocarbon. The preferred positions may often be predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when naphthalene is attacked at the α-position than when it is attacked at the β-position, and the α-position is the preferred site of attack,[56] though, as previously mentioned (p. 460), the isomer formed by substitution at the β-position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene, and substitution is faster at both positions. Similarly, anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar. Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.[57] Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine[58] it is not the free base which is attacked, but the conjugate acid, pyridinium ion.[59] The 3 position is most reactive, but the reactivity in this case is much less than that of benzene, being similar to that of nitrobenzene. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine N-oxide.[60]

When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (**23**) is activated by the methyl group; ring B is not (though the presence of a substituent in a fused ring system affects all the rings, the effect is generally greatest on the ring to which it is attached). We therefore expect substitution in ring A. The methyl group activates the positions ortho to itself

---

[53] This is not the same as the ortho effect discussed on p. 258.

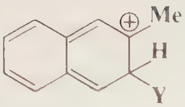
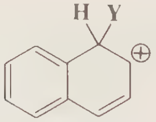
23



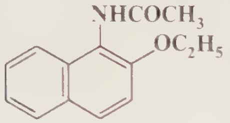
24



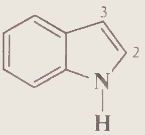
25

(1 and 3) but not position 4, which is meta to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. All we can write are forms like **24**, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **25**) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.[61] However, in some cases predictions are much harder to make. For example, chlorination or nitration of **26** gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.[62]

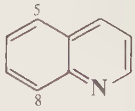
For fused heterocyclic systems too, we can often make predictions based on the above principles, though many exceptions are known. Thus, indole (**27**) is chiefly substituted in the pyrrole ring (at position 3), and reacts faster than benzene, while quinoline (**28**) generally reacts in the benzene ring (not the pyridine ring) at the 5 and 8 positions and slower than benzene, though faster than pyridine.



26

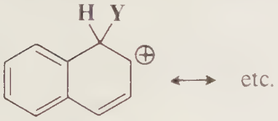


27



28

In alternant hydrocarbons (p. 51) the reactivity at a given position is proportional to its free valence (p. 69), not only for electrophilic substitution, but also for nucleophilic and free-radical substitution, because the same kind of resonance can be shown in all three types of intermediate (compare **25**, **29**, and **30**). Attack at the position which will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Since free valence is a measure of the ability of the system to spread the charge in the intermediate, it is proportional to the reactivity.[63] Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+, NH_2^-, and Ph•, and always more readily than benzene.



25

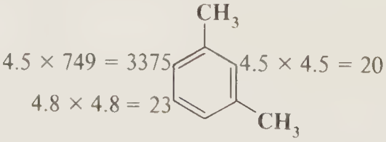
5	0.34	2.5

Quantitative Treatments of Reactivity in the Substrate

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogens which can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates which have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position.* These can be calculated from the overall rates and a careful determination of the proportion of isomers formed. We may thus define the *partial rate factor* for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors are: for the ortho position $o_f^{Me} = 4.5$, for the meta $m_f^{Me} = 4.8$, and for the para $p_f^{Me} = 749$.[64] This means that toluene is acetylated at the ortho position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor greater than 1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once we know the partial rate factors, we can predict the proportions of isomers to be obtained when two or more groups are present on a ring, *if we make the assumption that the effect of substituents is additive.* For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, we can calculate the theoretical partial rate factors at each position by multiplying those from toluene, so that they should be as indicated:



From this it is possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth of the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347,[65] and the calculated and observed isomer distributions are listed in Table 2. In this case, and in many others, agreement is fairly good, but many cases are known where the effects are

not additive.[66] For example, the treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer.[67] The treatment is thrown off by steric effects such as those mentioned earlier (p. 465), and by resonance interaction *between* groups (for example, **31**), which must make the results deviate from simple additivity of the effects of the groups.

---

[66] For some examples where additivity fails, see Fischer, Vaughan and Wright, *J. Chem. Soc. B* 368 (1967); Coombes, Crout, Hoggett, Moodie, and Schofield, *J. Chem. Soc. B* 347 (1970); Richards, Wilkinson, and Wright, *Aust. J. Chem.* **25,** 2369 (1972); Cook, Phillips, and Ridd, *J. Chem. Soc., Perkin Trans. 2* 1166 (1974). For a theoretical treatment of why additivity fails, see Godfrey, *J. Chem. Soc. B* 1545 (1971).

[67] Obviously, the additivity treatment can only be valid if all of the cases being compared are run under exactly the same conditions. The importance of conditions in this example is emphasized by the work of Friedman and Honour, *J. Am. Chem. Soc.* **91,** 6344 (1969), which showed that acylation of 1,2,3-trimethylbenzene can give either the 4 or 5 isomer in more than 95% purity, depending on the reaction conditions.

31

Another approach which avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates which contain only one leaving group. This is most easily accomplished by use of a leaving group other than hydrogen. By this means overall rate ratio can be measured for specific positions. Table 3 contains the results of two such studies.[69a] The results are in good agreement with each other and give a reactivity order quite consistent with that given before for hydrogen as leaving group.

A Quantitative Treatment of Reactivity of the Electrophile. The Selectivity Relationship

Not all electrophiles are equally powerful. The nitronium ion attacks not only benzene, but also aromatic rings which contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the power of the attacking group. The most obvious way to do this is with the Hammett equation (p. 252):

$$\log \frac{k}{k_0} = \rho\sigma$$

For aromatic substitution, k_0 is divided by 6, and for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for say the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those which are electron-donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more satisfactory correlations can be made even for electron-donating groups (see p. 253 for a list of σ^+ values). Groups with a negative value of σ_p^+ or σ_m^+ are activating for that position; groups with a positive value are deactivating. The ρ values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The ρ values vary not only with the electrophile but also with conditions. A large negative value of ρ means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, is called the *selectivity relationship*,[70] and is based on the principle that reactivity of a species varies inversely with selectivity. Table 4 shows how electrophiles can be arranged in order of selectivity as measured by two

---

Nitration	23	2.8	33.9
Mercuration	7.9	9.5	69.5
Isopropylation	1.8	25.9	46.2

indexes: (1) their selectivity in attacking toluene rather than benzene, and (2) their selectivity between the meta and para positions in toluene.[71] As the table shows, an electrophile more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more stable and hence less reactive than others show a higher selectivity, as would be expected. For example, the *t*-butyl cation is more stable than the isopropyl (p. 152) and more selective, and Br_2 is more selective than Br^+. However, deviations from the relationship are known. Selectivity depends not only on the nature of the electrophile, but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene, and he defined the selectivity S_f of a reaction as

$$S_f = \log \frac{p_f^{\text{Me}}}{m_f^{\text{Me}}}$$

That is, the more reactive an attacking species, the less preference it has for the para position as against the meta. If we combine the Hammett-Brown $\sigma^+\rho$ relationship with the linearity between $\log S_f$ and $\log p_f^{\text{Me}}$ and between $\log S_f$ and $\log m_f^{\text{Me}}$, it is possible to derive the following expressions:

$$\log p_f^{\text{Me}} = \frac{\sigma_p^+}{\sigma_p^+ - \sigma_m^+} S_f$$

$$\log m_f^{\text{Me}} = \frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} S_f$$

S_f is related to ρ by:

$$S_f = \rho(\sigma_p^+ - \sigma_m^+)$$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 5.[72] It is obvious that this type of treatment can be extended

---

[72] Stock and Brown, *J. Am. Chem. Soc.* **81**, 3323 (1959). Stock and Brown, Ref. 70, present many tables of these kinds of data.

TABLE 5 Values of m_f^{Me}, p_f^{Me}, S_f, and ρ for three reactions of toluene[72]

Reaction	m_f^{Me}	p_f^{Me}	S_f	ρ
$\mathrm{PhMe + EtBr} \xrightarrow[\text{benzene, 25°C}]{\mathrm{GaBr_3}}$	1.56	6.02	0.587	−2.66
$\mathrm{PhMe + HNO_3} \xrightarrow[\text{45°C}]{\text{90\% HOAc}}$	2.5	58	1.366	−6.04
$\mathrm{PhMe + Br_2} \xrightarrow[\text{25°C}]{\text{85\% HOAc}}$	5.5	2420	2.644	−11.40

to substituents other than methyl and for other aromatic rings. For other substituents, the treatment works well with groups which, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles. Failure in these cases has been attributed[73] to rate-determining formation of a π complex (p. 457), which would mean that the *position* of attack is not determined in the slow step, so that the p/m ratio would not be related to the rate of the reaction, and it is possible to have high positional but low substrate selectivity.[74] However, we have seen (p. 458) that the evidence for rate-determining formation of π complexes is not very strong, and an alternate explanation for the failure of the selectivity relationship with strong electrophiles is that with these powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter between the electrophile and the substrate) that the presence of additional activating groups can no longer increase the rate.[75] This explanation too is compatible with the observed high positional but low substrate selectivity. More complex treatments have been devised.[76]

The Effect of the Leaving Group

In the vast majority of aromatic electrophilic substitutions, the leaving group is $\mathrm{H^+}$ (it is certainly one of the best), and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested:[77] (1) for leaving groups which depart without assistance (SN1 process with respect to the leaving group), $\mathrm{NO_2^+} < \text{iso-Pr}^+ \sim \mathrm{SO_3} < t\text{-Bu}^+ \sim \mathrm{ArN_2^+} < \mathrm{ArCHOH^+} < \mathrm{NO^+} < \mathrm{CO_2}$; (2) for leaving groups which depart with assistance from an outside nucleophile (SN2 process), $\mathrm{Me^+ < Cl^+ < Br^+ < D^+ \sim RCO^+ < H^+ \sim I^+ < Me_3Si^+}$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion **1** once it has been formed, and so obtain an idea of which electrophile substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which the original electrophile attacks directly at that position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called *ipso partial rate factors* ($i_f{}^X$).[78] Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo, *p*-bromo-, and *p*-chloroanisole, respectively.[79] This means, for example, that the electrophile in this case attacks the 4 position (called the *ipso* position) of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than it attacks the 4 position of anisole itself, so that the presence of the iodo group greatly slows the reaction at that position. Thus halogens deactivate the ipso position just as they do the other positions (p. 462).[80]

REACTIONS

The reactions in this chapter are classified according to leaving group, hydrogen replacements being treated first, then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

Hydrogen as the Leaving Group in Simple Substitution Reactions

A. Hydrogen as the Electrophile

1-1 Hydrogen Exchange

$$\mathrm{ArH + D^+ \rightleftharpoons ArD + H^+}$$

Aromatic compounds can exchange hydrogens when treated with acids. The reaction is used chiefly to study mechanistic questions[81] (including substituent effects), but can also be useful to deuterate or tritiate aromatic rings selectively. The usual directive effects apply and, for example, phenol, treated with D_2O, gives slow exchange on heating, with only ortho and para hydrogens being exchanged.[82] Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium-ion mechanism. Among the evidence are the orientation effects noted above, and the finding that the reaction is general-acid-catalyzed, which means that a proton is being transferred in the slow step[83] (p. 236). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.[5] Simple aromatic compounds can be extensively deuterated in a convenient fashion by heating at 200 to 300°C with a dilute solution of HCl in D_2O.[84]

Hydrogen exchange may also be effected with strong bases,[84a] such as $NH_2{}^-$. In these cases the slow step is the proton transfer:

$$\mathrm{ArH + B \longrightarrow Ar^- + BH^+}$$

so that the SE1 mechanism and not the usual arenium-ion mechanism is operating.[85] As would be expected from the SE1 mechanism, only field and not resonance effects of substituents affect the rates, $-I$ groups causing increases, and $+I$ groups causing decreases.[86] The effect is most strongly felt at the ortho position. Aromatic rings can also be deuterated by treatment with D_2O and a platinum catalyst,[87] or with C_6D_6 and an alkylaluminum dichloride catalyst,[88] though rearrangements may take place during the latter procedure. Tritium can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.[88]

B. Nitrogen Electrophiles

1-2 Nitration

$$\mathrm{ArH + HNO_3 \xrightarrow{H_2SO_4} ArNO_2}$$

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.[89] For benzene and the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids, but for active substrates, the reaction can be carried out with nitric acid alone, or in water, acetic acid, or acetic anhydride. In fact, these milder conditions are necessary for active compounds, like amines and phenols, since reaction with mixed nitric and sulfuric acids would be too violent. If anhydrous conditions are required, nitration can be effected with N_2O_5 in CCl_4 in the presence of P_2O_5, which removes the water formed in the reaction. Nitration in alkaline media can be accomplished with esters of nitric acid such as ethyl nitrate ($EtONO_2$). These reagents can also be used with proton or Lewis acid catalysts. Other nitrating agents are mixed anhydrides such as acetyl nitrate CH_3COONO_2 (see reaction **0-34** for their preparation), nitryl halides with a Friedel-Crafts catalyst such as $FeCl_3$,[90] methyl nitrate and BF_3,[91] and nitronium salts[92] such as $NO_2^+\ BF_4^-$, $NO_2^+\ PF_6^-$, and $NO_2^+\ CF_3SO_3^-$. The last-mentioned salt gives a very high yield of products at low temperatures.[93] With active substrates such as amines and phenols, nitration may be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids, so that what actually happens is nitrosation (reaction **1-3**) followed by oxidation:

$$\mathrm{ArH + HONO \longrightarrow ArNO + N_2O_4 \longrightarrow ArNO_2}$$

The N_2O_4 is formed by reaction between HNO_3 and HONO.[94]

When amines are nitrated under strong-acid conditions, meta orientation is generally observed, since the species undergoing nitration is actually the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho-para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also p. 462). Because of these factors, and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (reaction **0-54**) or acetic anhydride (reaction **0-55**). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen which is attacked to give an N-nitro compound Ar—NH—NO_2 which rapidly undergoes rearrangement (see reaction **1-36**) to give the product.[95]

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene itself can be nitrated if vigorous conditions are applied. This has been accomplished with $NO_2^+ \ BF_4^-$ in FSO_3H at 150°C.[96]

With most of the reagents mentioned (except for oxidative nitrosation) the attacking species is the nitronium ion NO_2^+. Among the ways in which this ion is formed are the following:

1. In concentrated sulfuric acid, by an acid-base reaction in which nitric acid is the base:

$$\mathbf{HNO_3 + 2H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2HSO_4^-}$$

This ionization is essentially complete.

2. In concentrated nitric acid alone, by a similar acid-base reaction in which one molecule of nitric acid is the acid and another the base:

$$\mathbf{2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O}$$

This equilibrium lies to the left (about 4% ionization), but enough NO_2^+ is formed for nitration to occur.

3. The equilibrium just mentioned occurs to a small extent even in organic solvents.

4. With N_2O_5 in CCl_4 there is spontaneous dissociation:

$$\mathbf{N_2O_5 \rightleftharpoons NO_2^+ + NO_3^-}$$

but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.

5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters, anhydrides, and acyl halides of nitric acid all ionize to form NO_2^+.

There is a great deal of evidence for the fact that the nitronium ion is present in most nitrations and that it is the attacking entity.[97] Some of this evidence is as follows:

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at 1400 cm^{-1} attributable to NO_2^+ and one at 1050 cm^{-1} due to HSO_4^-.[98]

2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization had taken place.[99] This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.

[99] Gillespie, Graham, Hughes, Ingold, and Peeling, *J. Chem. Soc.* 2504 (1950).

3. The fact that nitronium salts in which nitronium ion is known to be present (by x-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.

4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+ and not to that of other species. When the reagent produces this ion in small amounts, the attack is slow, and only active substrates can be nitrated. In concentrated and aqueous mineral acids the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents like nitromethane, acetic acid, and CCl_4, the kinetics are first order in nitric acid alone, and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

In a few cases (mostly when organic solvents are used) the attacking entity may not be nitronium ion, but a species such as $NO_2\text{–}OH_2^+$ or NO_2OAcH^+. It is obvious that in species like these another molecule (in these cases water and acetic acid, respectively) acts as a "carrier" of nitronium ions. In such cases the mechanism is essentially the same, but the carrier drops off somewhere in the process (p. 454).

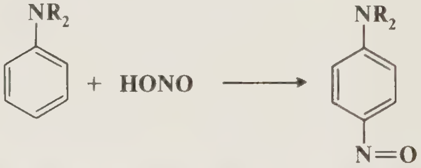
1-3 Nitrosation



Ring nitrosation with nitrous acid is normally carried out only with active substrates such as amines and phenols. However, primary aromatic amines give diazonium ions (reaction **2-48**) when treated with nitrous acid, and secondary amines tend to give N-nitroso rather than C-nitroso compounds (reaction **2-50**); hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless secondary aromatic amines can be C-nitrosated in two ways. The N-nitroso compound first obtained may be isomerized to a C-nitroso compound (the Fischer-Hepp rearrangement, **1-37**), or it may be treated with another mole of nitrous acid to give an N,C-dinitroso compound. Certain primary and secondary aromatic amines not containing electron-withdrawing groups (e.g., *m*-toluidine, α-naphthylamine) can be directly C-nitrosated in the para position by nitrosylsulfuric acid in concentrated H_2SO_4.[100] Nitroso groups can be introduced into less active aromatic rings by increasing the electrofugal ability of the leaving group: substituted trimethylphenylstannanes $ArSnMe_3$ treated with nitrosyl chloride in CH_2Cl_2 at -25 to 0°C give the nitroso compounds ArNO.[101] Ar-containing methyl and methoxy groups, as well as unsubstituted Ar, give good yields, but Ar-containing halogens give low yields (25 to 30%).

Much less work has been done on the mechanism of this reaction than on the preceding one. In some cases the attacking entity is NO^+, but in others it is apparently NOCl, NOBr, N_2O_3, etc., in each of which there is a carrier of NO^+. Evidence is that in many nitrosations NO^+ cannot be detected. NOCl and NOBr are formed during the normal process of making nitrous acid: the treatment of sodium nitrite with HCl or HBr. Nitrosation requires active substrates because NO^+ is much more stable than NO_2^+ and hence much less reactive. Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+.[102] A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (p. 455) and isotope effects are found.[103] Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (p. 38).

1-4 Diazonium Coupling

$$ArH + Ar'N_2^+ \longrightarrow Ar{-}N{=}N{-}Ar'$$

Aromatic diazonium ions normally couple only with active substrates such as amines and phenols.[104] Presumably because of the size of the attacking species, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in strongly alkaline solution, because the diazonium ion is converted to a diazo hydroxide Ar—N=N—OH. Primary and secondary amines face competition from attack at the nitrogen. However, the resulting N-azo compounds (aryl triazenes) may be isomerized to C-azo compounds (reaction **1-38**). Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+. Some coupling reactions which are otherwise very slow (in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed on p. 456. Coupling of an aliphatic diazo compound to an aromatic ring has been reported.[105]

OS **I,** 49, 374; **II,** 35, 39, 145.

1-5 Direct Introduction of the Diazonium Group

$$ArH \xrightarrow[HX]{2HONO} ArN_2^+ \quad X^-$$

Diazonium salts can be prepared directly, by replacement of an aromatic hydrogen, without the necessity of going through the amino group.[106] The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. As in reaction **1-3,** and for the same reason, tertiary amines containing an ortho substituent react extremely slowly.[107] Since the reagents and the substrate are the same as in reaction **1-3**, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.[108]

[107] Patel and Tedder, *J. Chem. Soc.* 4889 (1963).

This reaction can also be performed on inactive substrates, even those containing a meta-directing group, if $HgSO_4$ is introduced as a catalyst, but the yields are lower.[109] The reaction pathway is entirely different in this case. The mercury salt attacks the ring to give $ArHg^+$, so that the NO^+ replaces Hg^{2+} and not H^+.

1-6 Direct Amination[110]

$$\mathrm{ArH + NH_2{-}O{-}SO_2{-}OH \xrightarrow{AlCl_3} ArNH_2}$$

Aromatic compounds can be aminated by hydroxylamine-O-sulfonic acid,[111] but yields are fairly low, and the reaction is not often carried out. The mechanism has not been studied, but our knowledge of aromatic substitutions in general leads us to suspect that the attacking entity is NH_2^+ or a carrier of it. Other reagents which might give rise to this kind of attacking entity have also been tried, e.g., salts of hydroxylamine,[112] but yields are no better. However, hydrazoic acid in the presence of $AlCl_3$ or sulfuric acid gave direct amination in yields of 10 to 65%.[113] N-Substituted hydroxylamine ethers (RNHOMe and R_2NOMe) have been employed with Friedel-Crafts catalysts in attempts to introduce directly the NHR and NR_2 groups.[114] Secondary amines *were* formed in about 25% yield, but the method was not very practical for tertiary amines. However, tertiary amines have been prepared in fairly good yields (about 50 to 90%) by treatment of aromatic hydrocarbons with N-chlorodialkylamines, by heating in 96% sulfuric acid; or with $AlCl_3$ or $FeCl_3$ in nitroalkane solvents; or by irradiation.[115]

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate to high yields by amination with an N-chlorodialkylamine (or an N-chloroalkylamine) and a metallic ion catalyst (e.g., Fe^{2+}, Ti^{3+}, Cu^+, Cr^{2+}) in the presence of sulfuric acid.[116] The attacking species in this case is the radical ion $R_2\overset{+}{N}H\cdot$ formed by

$$\mathrm{R_2\overset{\oplus}{N}HCl + M^+ \longrightarrow R_2\overset{\oplus}{N}H\cdot + M^{2+} + Cl^-}$$

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused ring systems react well.

Unusual orientation has been reported for amination with haloamines and with NCl_3 in the presence of $AlCl_3$. For example, toluene gave predominantly meta amination.[117] It has been suggested that initial attack in this case is by Cl^+ and that a nitrogen nucleophile (whose structure is not known but is represented here as NH_2^- for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon-carbon double bond, and that elimination of HCl follows:[118]

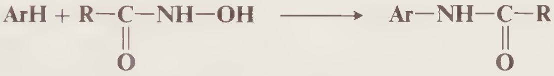
Thus the actual electrophilic attack, according to this suggestion, is at the para position (or the ortho, which leads to the same product), and the meta orientation of the amino group arises indirectly. This mechanism is called the *σ-substitution mechanism.*

Aromatic compounds which do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at −60°C: $ArH + Ar'N_3 \rightarrow ArNHAr'$.[119]

Direct *amidation* can be carried out in moderate yields if an aromatic compound is heated with an excess of a hydroxamic acid in polyphosphoric acid.[120] The mechanism is not known, but it is



$$ArH + R\text{—}\underset{\underset{O}{\|}}{C}\text{—}NH\text{—}OH \longrightarrow Ar\text{—}NH\text{—}\underset{\underset{O}{\|}}{C}\text{—}R$$

possible that an oxime (ArCR=NOH) is first formed, which in polyphosphoric acid rapidly isomerizes to the amide (Beckmann rearrangement, **8-21**).

Also see reactions **3-18** and **3-19.**

C. Sulfur Electrophiles

1-7 Sulfonation

$$ArH + H_2SO_4 \longrightarrow ArSO_2OH$$

The sulfonation reaction is very broad in scope, and many aromatic hydrocarbons (including fused ring systems), aryl halides, ethers, carboxylic acids, acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.[121] Phenols can also be successfully sulfonated, but attack at oxygen may compete. Sulfonation is often accomplished with concentrated sulfuric acid, but it may be done with fuming sulfuric acid, SO_3, $ClSO_2OH$, or other reagents. As with nitration (**1-2**), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this is a reversible reaction (see reaction **1-47**), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow, and the forward reaction is then practically irreversible.[122] SO_3 reacts much more rapidly than sulfuric acid—with benzene it is nearly instantaneous. Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see reaction **1-44**).

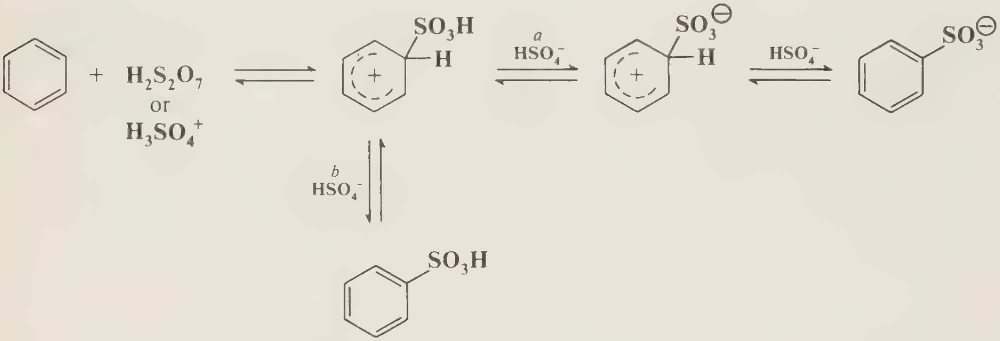
[121] For reviews, see Suter and Weston, *Org. React.* **3,** 141–197 (1946); Nelson, in Olah, Ref. 33, vol. 3, pp. 1355–1392 (1964); Gilbert, "Sulfonation and Related Reactions," pp. 62–83, 87–124, Interscience Publishers, New York, 1965.

Although a great deal of work has been done on the mechanism,[123] the identity of the attacking species has proven difficult to establish with certainty, largely because of the complicated nature of the solutions under study. However, largely from the work of Cerfontain and coworkers, indications are that the electrophile varies with the reagent, though in all cases SO_3 is involved, either free or combined with a carrier. In aqueous H_2SO_4 solutions the electrophile is thought to be $H_3SO_4^+$ (or a combination of H_2SO_4 and H_3O^+) at concentrations below about 80 to 85% H_2SO_4, and $H_2S_2O_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this[124] (the changeover point varies with the substrate[125]). Evidence for a change in electrophile is that in the dilute and in the concentrated solutions the rate of the reaction was proportional to the activity of $H_3SO_4^+$ and $H_2S_2O_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as:[124]



The other product of the first step is HSO_4^- or H_2O, from $H_2S_2O_7$ or $H_3SO_4^+$, respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With $H_3SO_4^+$ the first step is rate-determining under all conditions, but with $H_2S_2O_7$ the first step is the slow step only up to about 96% H_2SO_4, when a subsequent proton transfer becomes partially rate-determining.[126] $H_2S_2O_7$ is more reactive than $H_3SO_4^+$. Values of ρ for $H_2S_2O_7$ and $H_3SO_4^+$ attack were calculated as −6.1 and −9.3, respectively.[124] In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is thought to be $H_3S_2O_7^+$ (protonated $H_2S_2O_7$) up to about 104% H_2SO_4, and $H_2S_4O_{13}$ ($H_2SO_4 + 3SO_3$) beyond this concentration.[127] Again, these conclusions were reached from the fact that the rates of sulfonation were proportional to the

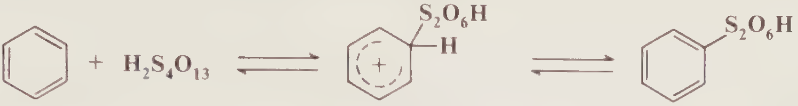
concentrations of these species. For $H_3S_2O_7^+$ the mechanism shown above (with path *b*) seems to hold, while with $H_2S_4O_{13}$ the following mechanism has been proposed:



Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.[128] Free SO_3 is the most reactive of all these species, so that attack here is generally fast, and a subsequent step is usually rate-determining.

1-8 Halosulfonation

$$\mathbf{ArH + ClSO_2OH \longrightarrow ArSO_2Cl}$$

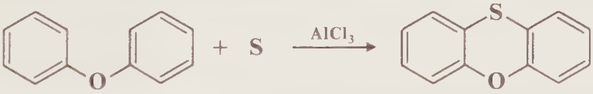
Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.[129] Since sulfonic acids can also be prepared by the same reagent (reaction **1-7**), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid. The reaction has also been effected with bormo- and fluorosulfuric acids.

OS **I,** 8, 85.

1-9 Sulfurization

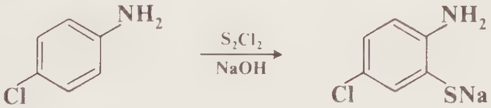
$$\mathbf{ArH + SCl_2 \xrightarrow{AlCl_3} ArSAr}$$

Diaryl sulfides can be prepared by treating aromatic compounds with SCl_2 and a Friedel-Crafts catalyst. Other reagents which can bring about the same result are S_2Cl_2, thionyl chloride, and even sulfur itself. A catalyst is not always necessary. The reaction has been used for ring closure:



When thionyl chloride is used, it is possible to obtain diaryl sulfoxides as the main products.[130] Unsymmetrical diaryl sulfides may be obtained by treatment of an aromatic compound with an aryl sulfenyl chloride (ArSCl) in the presence of a trace amount of iron powder.[131]

With certain substrates (primary amines with a chloro group, or a group not replaceable by chloro, in the para position), treatment with S_2Cl_2 and NaOH gives thiophenolate salts:



This is called the *Herz reaction.*[132]

1-10 Sulfonylation

$$ArH + RSO_2Cl \xrightarrow{AlCl_3} ArSO_2R$$

Aryl sulfones can be formed by treatment of aromatic compounds with sulfonyl halides and a Friedel-Crafts catalyst.[133] R may also be aryl. This reaction is analogous to Friedel-Crafts acylation with carboxylic acid halides (reaction **1-15**). Alternatively, the aromatic compound may be treated with a sulfonic acid with polyphosphoric acid as catalyst.[134]

1-11 Thiocyanation

$$ArH + (SCN)_2 \longrightarrow ArSCN$$

Phenols and aromatic amines can be converted to thiocyanates by treatment with thiocyanogen.[135] Substitution generally takes place in the para position if available, otherwise in the ortho position. Phenolic ethers and acylated aromatic amines do not react with $(SCN)_2$ but can be thiocyanated with thiocyanogen chloride (ClSCN).

D. Halogen Electrophiles

1-12 Halogenation[136]

1. *Chlorine and bromine.*

$$ArH + Br_2 \xrightarrow{Fe} ArBr$$

Aromatic compounds can be brominated or chlorinated by treatment with bromine or chlorine in the presence of a catalyst, most often iron. However, the real catalyst is not the iron itself, but the ferric bromide or ferric chloride formed in small amounts from the reaction between iron and the reagent. Ferric chloride and other Lewis acids are often directly used as catalysts, as is iodine. When thallium(III) acetate is the catalyst, many substrates are brominated with high regiospecificity para to an ortho-para-directing group.[137] For active substrates, including amines, phenols, naphthalene, and polyalkylbenzenes[138] such as mesitylene and isodurene, no catalyst is needed. Indeed, for amines and phenols the reaction is so rapid that it is carried out with a dilute solution of Br_2 or Cl_2 in water at room temperature. Even so, with amines it is not possible to stop the reaction before all the available ortho and para positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX. For this reason, primary amines are often converted to the corresponding anilides if monosubstitution is desired. Another method of obtaining monosubstitution (para) of amines is to use the reagent 2,4,4,6-tetrabromocyclohexa-2,5-dienone in CH_2Cl_2 or $CHCl_3$.[139] With phenols it is possible to stop after one group has entered. The rapid room-temperature reaction with amines and phenols is often used as a test for these compounds. Chlorine is a more active reagent than bromine. Phenols can be brominated exclusively in the ortho position (disubstitution of phenol gives 2,6-dibromophenol) by treatment at about −70°C with Br_2 in the presence of *t*-butylamine or triethylenediamine, which precipitates out the liberated HBr.[140]

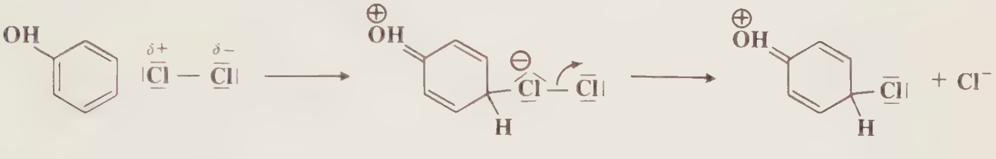
Other reagents have also been used, among them HOCl, HOBr, and N-chloro and N-bromo amides (especially N-bromosuccinimide). In all these cases the reaction is catalyzed by the addition of acids. Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent[141] for substrates with strongly deactivating substituents.[142] A particularly powerful reagent consists of S_2Cl_2 and $AlCl_3$ in sulfuryl chloride (SO_2Cl_2).[143] Halogenation has also been accomplished with benzoyl peroxide and lithium halide.[144] If the substrate contains alkyl groups, then side-chain halogenation (reaction **4-1**) is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible.

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 which has been polarized by the ring:[145]



32 **33**

Although the equation as written shows an intermediate which has two chlorines, the Cl—Cl bond may also be broken in the course of the attack, so that the only intermediate is **33.**

If **32** *is* present (note that the central chlorine has 10 electrons in its outer shell), then its stability may be such that an outside entity, such as the solvent, may be required to remove Cl^-. If this is the rate-determining step in these cases, then the rate should be different in different solvents. This has been shown to be the case.[146] Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, including especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^-, the addition of chloride should decrease the rate and acids should increase it.

When a Lewis acid catalyst is used along with chlorine or bromine, then the attacking entity is probably Cl^+ or Br^+, formed in this manner:

$$AlCl_3 + Br_2 \longrightarrow AlCl_3Br^- + Br^+$$

With other reagents, the attacking entity in brominations may be Br^+, or it may be a species such as H_2OBr^+ (the conjugate acid of HOBr), in which H_2O is a carrier of Br^+.[147] With HOCl in water the electrophile may be Cl_2O, Cl_2, or H_2OCl^+; in acetic acid it is generally AcOCl. All these species are more reactive than HOCl itself. It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl.[148] It has been demonstrated in the reaction between N-methylaniline and calcium hypochlorite that the chlorine attacking entity attacks the *nitrogen* to give N-chloro-N-methylaniline, which rearranges (as in reaction **1-39**) to give a mixture of ring-chlorinated N-methylanilines in which the ortho isomer predominates.[149] Ir spectra of the reaction mixture showed a continuous disappearance of the N—H peak.

[148] Swain and Crist, *J. Am. Chem. Soc.* **94,** 3195 (1972).

$FeCl_3$ itself,[150] and also $CuCl_2$, $SbCl_5$, etc.,[151] can give moderate yields of aryl chlorides.[152] The electrophile here might be a species such as $FeCl_2^+$, but the reactions can also take place by a free-radical mechanism.[153]

When chlorination or bromination is carried out at high temperatures (e.g., 300 to 400°C), ortho-para-directing groups direct meta, and vice versa.[154] A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the SE1 mechanism, e.g., in the *t*-BuOK-catalyzed bromination of 1,3,5-tribromobenzene.[155]

2. *Iodine.* Iodine is the least reactive of the halogens in aromatic substitution. Except for active substrates, an oxidizing agent must normally be present to oxidize I_2 to a better electrophile.[156] Examples of such oxidizing agents are HNO_3, HIO_3, SO_3, and H_2O_2. ICl is a better iodinating agent than iodine itself. Iodination can also be accomplished by treatment of the substrate with I_2 (or virtually any group I–VIII metallic iodide) in the presence of copper salts,[157] or with I_2 and $SbCl_5$.[158]

The actual attacking species is less clear in this case than with bromine or chlorine. Iodine itself is too unreactive, except for active species such as phenols, where there is good evidence that I_2 is the attacking entity.[159] There is evidence that AcOI may be the attacking entity when peroxyacetic acid is the catalyst,[160] and I_3^+ when SO_3 or HIO_3 is the catalyst.[161] Another possibility in some situations is I^+. For an indirect method for accomplishing aromatic iodination, see reaction **2-28.**

3. *Fluorine.* Direct fluorination of aromatic rings with F_2 is not feasible at room temperature, because of the extreme reactivity of F_2. It has been accomplished at low temperatures (e.g., -70 to -20°C, depending on the substrate),[162] but the reaction is not yet of preparative significance.[163] Fluorination has also been reported with XeF_2[164] and with fluoroxytrifluoromethane CF_3OF[165] under various conditions and with various yields, in some cases by electrophilic and in other cases by free-radical mechanisms. However, none of these methods seems likely to displace the Schiemann reaction (**3-25**) as the most common method for introducing fluorine into aromatic rings.

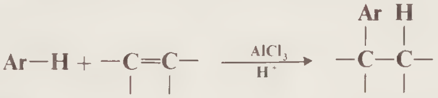
E. Carbon Electrophiles In the reactions in this section, a new carbon-carbon bond is formed. With respect to the aromatic ring they are electrophilic substitutions, since a positive species attacks the ring, and we treat them in this manner because it is customary. However, with respect to the electrophile most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them. Some are not substitutions with respect to the reagent. For example, reaction **1-13,** when performed with an olefin as reagent, is addition to a C=C double bond, and reaction **1-25** is addition to a C=O double bond.

1-13 Friedel-Crafts Alkylation

$$\mathrm{ArH + RCl \xrightarrow{AlCl_3} ArR}$$

The alkylation of aromatic rings, called *Friedel-Crafts alkylation,* is a reaction of very broad scope.[166] The most important reagents are alkyl halides, olefins, and alcohols, but many other types of reagent have also been employed.[166] When alkyl halides are used, the reactivity is in the order F > Cl > Br > I[167] and, for example, $FCH_2CH_2CH_2Cl$ reacts with benzene to give $PhCH_2CH_2CH_2Cl$[168] when the catalyst is BCl_3. By the use of this catalyst it is therefore possible to place a halo alkyl group on a ring (see also reaction **1-27**).[169] Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of aromatic compound, and it is usually not possible to stop the reaction earlier. Thus, benzene with CH_2Cl_2 gives not $PhCH_2Cl$, but Ph_2CH_2; and benzene with $CHCl_3$ gives Ph_3CH. With CCl_4, however, the reaction stops when only three rings have been substituted, and the product is Ph_3CCl.

Olefins are especially good alkylating agents. With respect to them the reaction is addition of ArH to a C=C double bond:



$$\mathrm{Ar{-}H + {-}\underset{|}{C}{=}\underset{|}{C}{-} \xrightarrow[H^+]{AlCl_3} {-}\overset{Ar}{\underset{|}{\overset{|}{C}}}{-}\overset{H}{\underset{|}{\overset{|}{C}}}{-}}$$

Acetylene reacts with 2 moles of aromatic compound to give 1,1-diarylethanes, but other alkynes react poorly if at all. Alcohols are more active than alkyl halides, though if a Lewis acid catalyst is used, more catalyst is required, since the catalyst complexes with the OH group. However, proton acids, especially H_2SO_4, are often used to catalyze alkylation with alcohols. When esters are the reagents, there is competition between alkylation and acylation (reaction **1-15**). Though this competition may often be controlled by choice of catalyst, and alkylation is usually favored, esters are not often employed in Friedel-Crafts reactions. Other alkylating agents are ethers, mercaptans, sulfides, thiocyanates, sulfates, sulfonates, and even alkanes and cycloalkanes, under conditions where these are converted to carbonium ions. Notable here are ethylene oxide, which puts the CH_2CH_2OH group onto the ring, and cyclopropane. For all types of reagent the reactivity order is allyl, benzyl type > tertiary > secondary > primary.

---

Volume 1 covers general aspects, such as catalyst activity, intermediate complexes, etc. Volume 2 covers alkylation and related reactions. In this volume the various reagents are treated by the indicated authors as follows: alkenes and alkanes, Patinkin and Friedman, pp. 1–288; dienes and substituted alkenes, Koncos and Friedman, pp. 289–412; alkynes, Franzen, pp. 413–416; alkyl halides, Drahowzal, pp. 417–475; alcohols and ethers, Schriesheim, pp. 477–595; sulfonates and inorganic esters, Drahowzal, pp. 641–658. For a monograph in which five chapters of the above treatise are reprinted and more recent material added, see Olah, "Friedel-Crafts Chemistry," John Wiley & Sons, Inc., New York, 1973. Review articles are by Price, *Org. React.* **3,** 1–82 (1946); Baddeley, *Q. Rev., Chem. Soc.* **8,** 355–379 (1954); Roberts, *Chem. Eng. News* **43**(4) 96–112 (Jan. 25, 1965); and Norman and Taylor, Ref. 1, pp. 156–173.

[167] For example, see Calloway, *J. Am. Chem. Soc.* **59,** 1474 (1937); Brown and Jungk, *J. Am. Chem. Soc.* **77,** 5584 (1955).

[168] Olah and Kuhn, *J. Org. Chem.* **29,** 2317 (1964).

[169] For a review of selectivity in this reaction, i.e., which group preferentially attacks when the reagent contains two or more, see Olah, in Olah, Ref. 166, vol. 1, pp. 881–905. This review also covers the case of alkylation versus acylation.

Regardless of which reagent is used, a catalyst is always required. Aluminum chloride is the most common, but many other Lewis acids have been used, and also proton acids such as HF and H_2SO_4.[170] For active halides a trace of a less active catalyst, for example, $ZnCl_2$, may be enough. For an unreactive halide, such as methyl chloride, a more powerful catalyst is needed, for example, $AlCl_3$, and in larger amounts. In some cases, especially with olefins, a Lewis acid catalyst causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: $AlBr_3 > AlCl_3 > GaCl_3 > FeCl_3 > SbCl_5 > ZrCl_4$, $SnCl_4 > BCl_3$, BF_3, $SbCl_3$;[171] but the reactivity order in each case depends on the substrate, reagent, and conditions. A survey of the field has shown that "in all probability in Friedel-Crafts type reactions no simple monotonic series of catalytic activity of Lewis acid and related proton acid catalysis is possible."[172] The most common solvent for Friedel-Crafts alkylation is carbon disulfide.

Friedel-Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating, so that di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl, isopropyl) is such that compounds with these groups as substituents are attacked in Friedel-Crafts alkylations only about 1.5 to 3 times as fast as benzene,[173] and so it is often possible to obtain high yields of monoalkyl product. Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.[174] This factor may be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring.

Also unusual is the fact that the OH, OR, NH_2, etc., groups do not facilitate the reaction, since the catalyst coordinates with these basic groups. Although phenols give the usual Friedel-Crafts reactions, orienting ortho and para,[175] the reaction is very poor for amines. However, amines can undergo the reaction if olefins are used as reagents and aluminum anilides as catalysts.[176] In this method the catalyst is prepared by treating the amine to be alkylated with $\frac{1}{3}$ mole of $AlCl_3$. A similar reaction may be performed with phenols, though here the catalyst is $Al(OAr)_3$.[177] Primary aromatic amines (and phenols) can be methylated regiospecifically in the ortho position by an indirect method (see reaction **1-29**).

Naphthalene and other fused ring compounds generally give poor yields in Friedel-Crafts alkylation, because they are so reactive that they react with the catalyst. Heterocyclic rings are usually also poor substrates for the reaction. Furan, thiophene, and pyridine cannot usually be alkylated. Although some furans and thiophenes have been alkylated, a true alkylation of a pyridine or a quinoline has never been described.[178] However, alkylation of pyridine and other nitrogen heterocycles can be accomplished by a free-radical (reaction **4-21**) and by a nucleophilic method (reaction **3-17**).

[178] Drahowzal, in Olah, Ref. 166, vol. 2, p. 433.

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful Friedel-Crafts alkylations when electron-withdrawing groups are present.[179] This is not because the attacking species is not powerful enough; indeed we have seen (p. 471) that alkyl carbonium ions are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, Friedel-Crafts alkylation can be accomplished.[180] Aromatic nitro compounds can be methylated by a nucleophilic mechanism (reaction **3-17**).

An important synthetic limitation of Friedel-Crafts alkylation is that rearrangement frequently takes place in the reagent. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary → secondary → tertiary and occurs mostly by migration of H^-, but also of R^- (see discussion of rearrangement mechanisms in Chapter 18). However, it is sometimes possible to choose conditions which yield unrearranged products. For example, when treated with *n*-propyl chloride at room temperature, benzene gives mostly *n*-propylbenzene; and straight-chain alcohols usually do not rearrange when the catalyst is $AlCl_3$, though they do with BF_3[181] or H_2SO_4.[182] When unrearranged products are obtained, it is frequently the result of thermodynamic rather than kinetic control of the products. The order of thermodynamic stability of alkylbenzenes is primary > secondary > tertiary.[183] For example, the lack of rearrangement in the case of primary alcohols and $AlCl_3$ is only apparent: the products are actually the result of *two* rearrangements.[184] The initially formed product is the secondary alkylbenzene, which then rearranges to the thermodynamically more stable primary product.

Because of the rearrangements which usually accompany alkylation with primary reagents, *n*-alkylbenzenes are often prepared by *acylation* (reaction **1-15**) followed by Clemmensen or Wolff-Kishner reduction (reaction **9-39**). However, rearrangements are not the only reason for using this alternate approach. Alkylation is more active than acylation, and therefore less selective. For example, toluene with ethyl bromide and $GaBr_3$ gave 38.4% *o*-ethyltoluene, 40.6% of the para isomer, and 21.0% of the meta isomer, while acylation gave 97.6% *p*-methylacetophenone.[185] Hence, even in this case, where isomerization is not a factor, it is profitable to acylate and reduce, rather than to separate the mixture of isomers.

An important use of the Friedel-Crafts alkylation reaction is to effect ring closure.[186] The most common method is to heat with aluminum chloride an aromatic compound having a halogen, hydroxy, or olefinic group in the proper position, as, for example, in the preparation of tetralin:

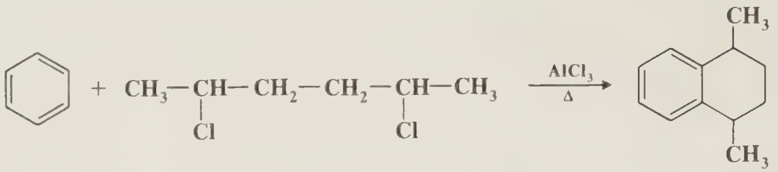
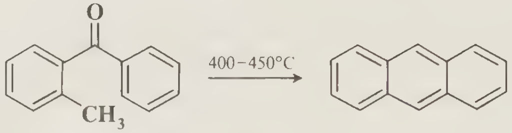
[186] For a review, see Barclay, in Olah, Ref. 166, vol. 2, pp. 785–977.

Another way of effecting ring closure through Friedel-Crafts alkylation is to use a reagent containing two groups, for example:



These reactions are most successful for the preparation of six-membered rings,[187] though five- and seven-membered rings have also been closed in this manner.

A ring-closure reaction which is somewhat similar is called the *Elbs reaction*.[188] Diaryl ketones containing an ortho methyl group can by cyclized by heating, although the yields are usually quite low:



Since water is lost, this is a cyclodehydration. Since the reaction requires no catalyst, it is probably not a true Friedel-Crafts reaction. The value of the reaction is that it can be used to prepare compounds, even in low yields, that are very difficult to prepare any other way.

For other Friedel-Crafts ring-closure reactions see reactions **1-14**, **1-15**, and **1-26**.

From what has been said thus far it is evident that the electrophile in Friedel-Crafts alkylation is a carbonium ion, at least in most cases.[189] This is in accord with the knowledge that carbonium ions rearrange in the direction primary → secondary → tertiary (see Chapter 18). In each case the carbonium ion is formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are:

From alkyl halides: $\mathrm{RCl + AlCl_3 \longrightarrow R^+ + AlCl_4^-}$

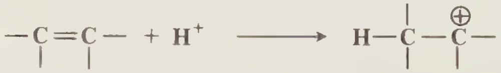
From alcohols and Lewis acids:

$$\mathrm{ROH + AlCl_3 \longrightarrow ROAlCl_2 \longrightarrow R^+ + {}^-OAlCl_2}$$

From alcohols and proton acids:

$$\mathrm{ROH + H^+ \longrightarrow ROH_2^+ \longrightarrow R^+ + H_2O}$$

From olefins (a supply of protons is always required):



$$-\underset{|}{\mathrm{C}}=\underset{|}{\mathrm{C}}- \;+\; \mathrm{H^+} \longrightarrow \mathrm{H}-\underset{|}{\overset{|}{\mathrm{C}}}-\underset{|}{\overset{\oplus}{\mathrm{C}}}-$$

In the case of olefins, Markovnikov's rule (p. 687) is followed. Alkylation has also been effected by carbonium ions generated by the diazotization of primary amines (see p. 328).[190] Carbonium-ion formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride[191] and 1-chloroadamantane[192] alkylate activated aromatic rings (e.g., phenols, amines) with no catalyst or solvent. When the triphenylmethyl cation is generated from triphenylcarbinol and acid, the reaction is called the *Baeyer-Villiger condensation*, not to be confused with the Baeyer-Villiger rearrangement (reaction **8-23**). Ions as stable as this are less reactive than other carbonium ions and often attack only active substrates. The tropylium ion, for example, alkylates anisole but not benzene.[193]

[189] For a discussion of the mechanism, see Taylor, Ref. 1, pp. 139–158.

[190] Pearson, Breder, and Craig, *J. Am. Chem. Soc.* **86,** 5054 (1964); Olah, Overchuk, and Lapierre, *J. Am. Chem. Soc.* **87,** 5785 (1965); Jurewicz, Bayless, and Friedman, *J. Am. Chem. Soc.* **87,** 5788 (1965); Friedman and Jurewicz, *J. Am. Chem. Soc.* **91,** 1808 (1969).

However, there is much evidence that many Friedel-Crafts alkylations, especially with primary reagents, do not go through a completely free carbonium ion. The ion may exist as a tight ion pair, with say $AlCl_4^-$ as the counterion, or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,[194] though if the same species attacked in each case we would expect the same ratios. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.[195] In these instances a mechanism in which the carbonium ion is slowly formed and then rapidly attacks the ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbonium ions, once formed, rapidly attack the ring, there are no free carbonium ions here. Another possibility (with alkyl halides) is that some alkylations take place by an SN2 mechanism (with respect to the halide), in which case no carbonium ions would be involved at all. However, a completely SN2 mechanism requires inversion of configuration, and most investigations of Friedel-Crafts stereochemistry, even where an SN2 mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion. A few exceptions have been found,[196] most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.[197]

Rearrangement is possible even with a non-carbonium-ion mechanism. The rearrangement could occur *before* the attack on the ring takes place at all. It has been shown that treatment of $CH_3{}^{14}CH_2Br$ with $AlBr_3$ *in the absence of any aromatic compound* gave a mixture of the starting material and $^{14}CH_2CH_2Br$.[198] Similar results were obtained with $PhCH_2{}^{14}CH_2Br$, in which case the rearrangement was so fast that the rate could be measured only below −70°C. Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see reaction **1-41**).[199] If there are ion pairs present, rearrangement may take place by hydride-ion shift without disturbing the ion-pair relationship.[200]

See reactions **4-19** and **4-21** for *free-radical* alkylation.

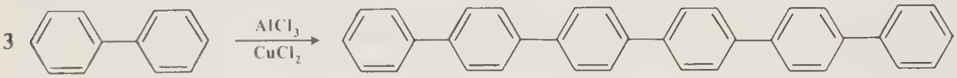
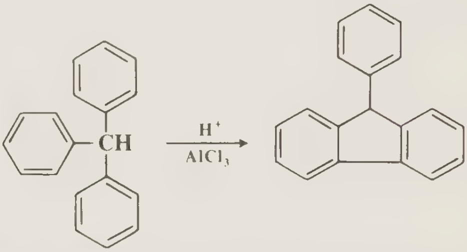
1-14 Friedel-Crafts Arylation. The Scholl Reaction

$$2\text{ArH} \xrightarrow[\text{H}^+]{\text{AlCl}_3} \text{Ar—Ar} + \text{H}_2$$

The coupling of two aromatic molecules by treatment with a Lewis acid and a proton acid is called the *Scholl reaction.*[201] Yields are low, and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates which are destroyed by these conditions. Because the reaction becomes important with large fused ring systems, ordinary Friedel-Crafts reactions (**1-13**) on these systems are rare. For example, naphthalene gives binaphthyl under Friedel-Crafts conditions. Yields may be increased by the addition of a salt such as $CuCl_2$ or $FeCl_3$, which acts as an oxidant.[202] Thus biphenyl gave more than 50% *p*-sexiphenyl on treatment at 80°C with $AlCl_3$ and $CuCl_2$:[203]



Intramolecular Scholl reactions, e.g.,



are much more successful than the intermolecular kind. There are some who apply the term Scholl reaction only to the intramolecular type.

The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of the type **9** (p. 457), which would then be the electrophile which attacks the other ring.[204] Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free-radical arylations, see reactions **4-16** to **4-20.**

OS **IV,** 482. Also see OS **V,** 102, 952.

1-15 Friedel-Crafts Acylation

$$\text{ArH} + \text{RCOCl} \xrightarrow{\text{AlCl}_3} \text{ArCOR}$$

The most important method for the preparation of aryl ketones is known as *Friedel-Crafts acylation.*[205] The reaction is of wide scope. Reagents used are not only acyl halides but also carboxylic acids, anhydrides, and ketenes. Esters usually give predominant alkylation (see reaction **1-13**). R may be aryl as well as alkyl. Rearrangement of R is never found, whether R is straight-chain or branched. Because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides may be used, though chlorides are most commonly employed. The order of activity is usually, but not always, I > Br > Cl > F.[206] Catalysts are Lewis acids, similar to those in reaction **1-13**, but in acylation a little more than 1 mole of catalyst is required per mole of reagent, since the first mole coordinates with the oxygen of the reagent:[207]

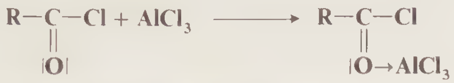
[204] For a discussion, see Clowes, *J. Chem. Soc. C* 2519 (1968).

[205] For reviews of Friedel-Crafts acylation, see Olah, "Friedel-Crafts and Related Reactions," Interscience Publishers, New York, 1963-1964, as follows: vol. 1, Olah, pp. 91–115; vol. 3, Gore, pp. 1–381; Peto, pp. 535–910; Sethna, pp. 911–1002; Jensen and Goldman, pp. 1003–1032. Other reviews are by Baddeley, *Q. Rev., Chem. Soc.* **8,** 355–379 (1954); Gore, *Chem. Rev.* **55,** 229–281 (1955); *Chem. Ind.* (*London*) 727–731 (1974); Norman and Taylor, Ref. 1, pp. 174–182.



$$\underset{\underset{|\mathrm{O}|}{\|}}{\mathrm{R{-}C{-}Cl}} + \mathrm{AlCl_3} \longrightarrow \underset{\underset{|\mathrm{O}\rightarrow \mathrm{AlCl_3}}{\|}}{\mathrm{R{-}C{-}Cl}}$$

Frequently this 1 : 1 complex is separately prepared, and then the aromatic compound added. Proton acids may be used as catalysts when the reagent is a carboxylic acid. The mixed carboxylic sulfonic anhydrides $RCOOSO_2CF_3$ are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.[208] With active substrates (e.g., aryl ethers, fused ring systems, thiophenes) Friedel-Crafts acylation can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all. Ferric chloride, iodine, zinc chloride, and iron are the most common catalysts when the reaction is carried out in this manner.[209]

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in reaction **1-13**. Compounds containing ortho-para-directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from N- or O-acylation; however, O-acylated phenols can be converted to C-acylated phenols by the Fries rearrangement (reaction **1-34**). Friedel-Crafts acylation is usually prevented by meta-directing groups. Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles but not pyridines or quinolines, may be acylated in good yield (however, pyridines and quinolines can be acylated by a free-radical mechanism, reaction **4-21**). Gore, in Ref. 205 (pp. 36–100; with tables, pp. 105–321), presents an exhaustive summary of the substrates to which this reaction has been applied.

When a mixed anhydride RCOOCOR′ is the reagent, it is possible to get two products, ArCOR and ArCOR′. Which product predominates depends on two factors. If R contains electron-withdrawing groups, then ArCOR′ is chiefly formed, but if this factor is approximately constant in R and R′, then the ketone with the larger R group predominantly forms.[210] This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid HCOOCOR.

An important use of the Friedel-Crafts acylation is to effect ring closure.[211] This may be done if an acyl halide, anhydride, or acid group is in the proper position. An example is

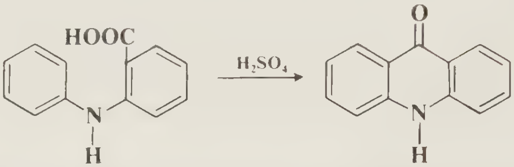
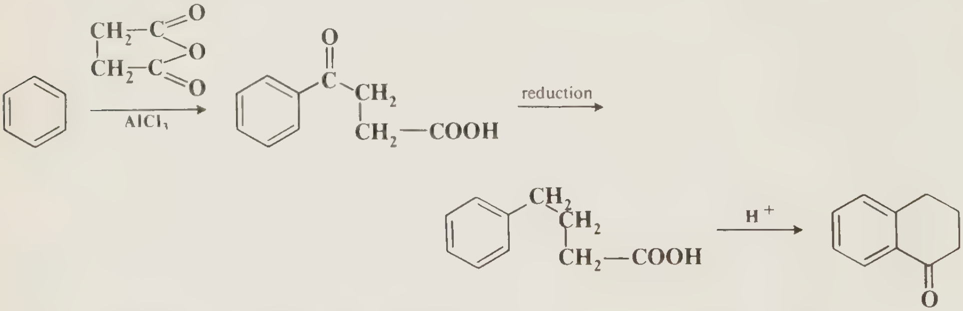
[211] For reviews, see Johnson, *Org. React.* **2,** 114–177 (1944); Sethna, Ref. 205.

The reaction is mostly used to close six-membered rings but has also been done for five- and seven-membered rings, which close less readily. Even larger rings may be closed by high-dilution techniques.[212] Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring, an example being the formation of acridone:



Many fused ring systems are made in this manner. If the bridging group is CO, then the product is a quinone.[213] One of the most common catalysts for intramolecular Friedel-Crafts acylation is polyphosphoric acid[214] (because of its high potency), but $AlCl_3$, H_2SO_4, and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Friedel-Crafts acylation is often carried out with cyclic anhydrides,[215] in which case the product contains a carboxyl group in the side chain. When succinic anhydride is used, the product is $ArCOCH_2CH_2COOH$. This can be reduced (reaction **9-39**) to $ArCH_2CH_2CH_2COOH$, which can then be cyclized by an internal Friedel-Crafts acylation. The total process is called the *Haworth reaction:*



The mechanism of Friedel-Crafts acylation is not completely understood, but at least two mechanisms probably operate, depending on conditions.[216] In most cases the attacking species is the acyl cation, either free or as an ion pair, formed by[217]

$$RCOCl + AlCl_3 \longrightarrow RCO^+ + AlCl_4^-$$

If R is tertiary, then RCO^+ may lose CO to give R^+, so that in such cases the alkylarene ArH is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride Me_3CCOCl gives the normal acyl product with anisole, but the alkyl product Me_3CPh with benzene. In the other mechanism an acyl cation is not involved, but the 1 : 1 complex attacks directly:[218]

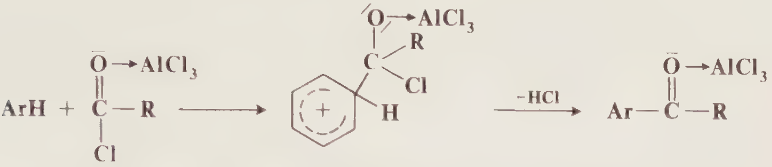
[213] For a discussion, see Thomson, in Patai, "The Chemistry of the Quinonoid Compounds," pt. 1, pp. 136–139, John Wiley & Sons, Inc., New York, 1974.

[214] For reviews of this catalyst, see Uhlig and Snyder, *Adv. Org. Chem.* **1**, 35–81 (1960); Popp and McEwen, *Chem. Rev.* **58**, 321–401 (1958).

[215] For reviews, see Berliner, *Org. React.* **5**, 229–289 (1949); Peto, Ref. 205.

[216] For a review of the mechanism, see Taylor, Ref. 1, pp. 166–185.

[217] After 2 min, exchange between PhCOCl and $Al(^{36}Cl)_3$ is complete: Oulevey and Susz, *Helv. Chim. Acta* **47**, 1828 (1964).

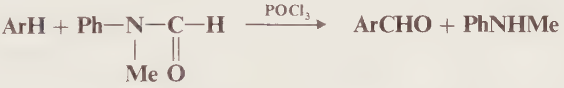


Free-ion attack is more likely for sterically hindered R.[219] The ion CH_3CO^+ has been detected (by ir spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents such as nitrobenzene; but in nonpolar solvents such as chloroform only the complex and not the free ion is present.[220] In any event, 1 mole of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with $RCO^+ \quad SbF_6^-$, no catalyst is required, and the free ion[221] (or ion pair) is undoubtedly the attacking entity.[222]

OS **I**, 109, 353, 476, 517; **II**, 3, 8, 15, 81, 156, 169, 304, 520, 569; **III**, 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; **IV**, 8, 34, 88, 898, 900; **V**, 111; **51**, 100; **53**, 5.

Reactions **1-16** through **1-21** are direct formylations of the ring.[223] Reaction **1-13** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 hr at −60 C[224] but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in impure form, but it slowly decomposes at room temperature.[225] It has not yet been used for aromatic formylations. Mixed anhydrides of formic and other acids are known[226] and can be used to formylate amines (see reaction **0-55**) and alcohols but, when they are applied to aromatic rings, no formylation takes place (p. 491).

1-16 Formylation with Disubstituted Formamides



$$\mathrm{ArH} + \mathrm{Ph{-}\underset{Me}{N}{-}\underset{O}{\overset{}{C}}{-}H} \xrightarrow{\mathrm{POCl_3}} \mathrm{ArCHO} + \mathrm{PhNHMe}$$

The reaction with disubstituted formamides and phosphorus oxychloride, which is called the *Vilsmeier* or the *Vilsmeier-Haack reaction*, is today the most common method for the formylation of aromatic rings.[227] However, it is applicable only to active substrates, such as amines and phenols. Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes, ferrocenes). Though N-phenyl-N-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used. $COCl_2$ has been used in place of $POCl_3$. The reaction has also been carried out with other amides to give ketones (actually an example of reaction **1-15**), but not often. The attacking species is **34**,[228] and the mechanism is probably as follows.

1-17 Formylation with Carbon Monoxide and HCl. The Gatterman-Koch Reaction

$$\mathrm{ArH + CO + HCl \xrightarrow[CuCl]{AlCl_3} ArCHO}$$

Certain aromatic compounds can be formylated with a mixture of CO and HCl in the presence of $AlCl_3$. The method is known as the *Gatterman-Koch reaction*.[230] The mixture of CO and HCl apparently behaves as if it were formyl chloride. The reaction has been largely limited to benzene and alkylbenzenes. It fails for phenols, phenolic ethers, and rings which contain meta-directing substituents. Substitution is largely para. An easy way to prepare the reagent mixture is to drop chlorosulfuric acid HSO_3Cl on formic acid, which generates CO, HCl, and H_2SO_4. Cuprous chloride is necessary if the reaction is to be carried out at atmospheric pressure. Without it, pressures of 100 to 250 atm are required. The mechanism has not been extensively investigated, but it is probable that the attacking species is the ion pair $HCO^+ \ AlCl_4^-$, formed by transfer of a proton from the initially formed $H^+AlCl_4^-$ (itself formed by reaction between HCl and $AlCl_3$) to the carbon monoxide.[223] The function of the cuprous chloride is to coordinate with the CO, providing a higher local concentration of it. At high pressures the concentration is high enough to make the CuCl unnecessary.

OS **II,** 583.

1-18 Formylation with Zinc Cyanide and HCl. The Gatterman Reaction

$$\mathrm{ArH + Zn(CN)_2 \xrightarrow{HCl} ArCH{=}NH_2^+\ \ Cl^- \xrightarrow{H_2O} ArCHO}$$

Formylation with $Zn(CN)_2$ and HCl is called the *Gatterman reaction.*[231] In contrast to reaction **1-17** this method may be successfully applied to phenols and their ethers and to many heterocyclic compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction the substrate was treated with HCN, HCl, and $ZnCl_2$, but the use of $Zn(CN)_2$ and HCl (HCN and $ZnCl_2$ are thus generated in situ) makes the reaction more convenient to carry out and does not reduce yields. The reaction also takes place when an activated substrate is treated with *s*-triazine and HCl.[232] The mechanism of the Gatterman reaction has not been investigated very much, but there is an initial nitrogen-containing product which is normally not isolated but is hydrolyzed to aldehyde. The above structure is presumed for this product. The Gatterman reaction may be regarded as a special case of reaction **1-30.**

OS **III,** 549.

1-19 Formylation with Formyl Fluoride

$$\mathrm{ArH + FCHO \xrightarrow{BF_3} ArCHO}$$

In contrast to formyl chloride, formyl fluoride is stable enough to be used to formylate aromatic rings, with BF_3 as catalyst.[233] The scope of the reaction has not been extensively investigated. It has been successful for benzene, alkylbenzenes, chloro- and fluorobenzene, and naphthalene. The mechanism is presumably the same as that of reaction **1-15.**

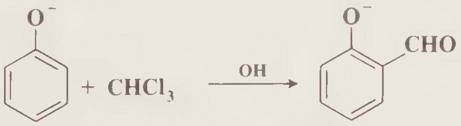
1-20 Formylation with Dichloromethyl Methyl Ether

$$\mathrm{ArH + Cl_2CHOMe \xrightarrow{AlCl_3} ArCHO}$$

Dichloromethyl methyl ether can formylate aromatic rings with Friedel-Crafts catalysts.[234] ArCHClOMe is probably an intermediate. Orthoformates have also been used in a similar reaction.[235] When phenoxymagnesium halides (ArOMgX) are formylated with orthoformates, only ortho products are obtained, in yields of 10 to 50%.[236]

OS **V,** 49.

1-21 Formylation with Chloroform. The Reimer-Tiemann Reaction



In the *Reimer-Tiemann reaction* chloroform and hydroxide ion are used to formylate aromatic rings.[237] The method is useful only for phenols and certain heterocyclic compounds such as pyrroles and indoles. Among the formylation methods (reactions **1-16** to **1-21**) it is the only method conducted in basic solution. Yields are generally low, seldom rising above 50%. The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para. Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, **36** and **38** gave, respectively, **37** and **39** as well as the normal aldehyde products. From the nature of the reagents and from the kind of abnormal products

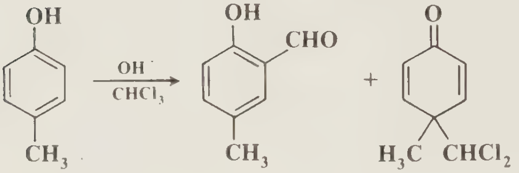
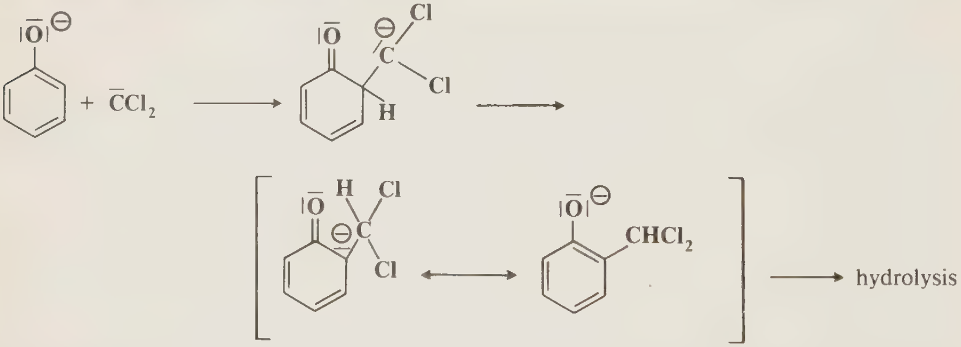
36 **37**



38 **39**

obtained, it is clear that the attacking entity in this reaction is dichlorocarbene CCl_2. This is known to be produced by treatment of chloroform with bases (p. 342); it is an electrophilic reagent, and it is known to give ring expansion of aromatic rings (see reaction **5-53**), accounting for products like **37**. The mechanism of the normal reaction is thus something like this:[238]



The proton transfer shown above probably does not occur by a single 1,2 proton shift, but by two intermolecular proton transfers;[239] that is, first the CCl_2^- group acquires a proton from the solvent, and then the ring proton is lost to the solvent. The formation of **39** in the case of **38** may be explained by attack of some of the CCl_2 para to the OH group. Since this position does not contain a hydrogen, normal proton loss cannot take place, and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the Reimer-Tiemann reaction is the *Duff reaction*, in which hexamethylenetetramine $(CH_2)_6N_4$ is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed, and the yields are low.

[238] Robinson, *J. Chem. Soc.* 1663 (1961); Hine and van der Veen, *J. Am. Chem. Soc.* **81**, 6446 (1959).

[239] Kemp, *J. Org. Chem.* **36**, 202 (1971).

A mechanism[240] has been proposed which involves initial aminoalkylation (reaction **1-28**) to give $ArCH_2NH_2$, followed by dehydrogenation to ArCH=NH and hydrolysis of this to the aldehyde product. When $(CH_2)_6N_4$ is used in conjunction with F_3CCOOH, the reaction can be applied to simple alkylbenzenes; yields are much higher, and a high degree of regiospecifically para substitution is found.[241] In this case too an imine seems to be an intermediate.

OS **III**, 463; **IV**, 866.

Reactions **1-22** and **1-23** are direct carboxylations of aromatic rings.[242]

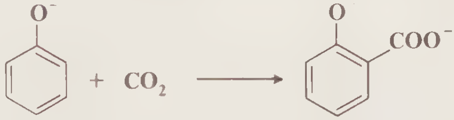
1-22 Carboxylation with Carbonyl Halides

$$\mathrm{ArH + COCl_2 \xrightarrow{AlCl_3} ArCOOH}$$

Phosgene, in the presence of Friedel-Crafts catalysts, can carboxylate the ring. This process is analogous to reaction **1-15**, but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl attacks another ring to give a ketone ArCOAr. A number of other reagents have been used to get around this difficulty, among them oxalyl chloride, urea hydrochloride, alkyl thiolchloroformates RSCOCl,[243] carbamoyl chloride H_2NCOCl, and N,N-diphenylcarbamoyl chloride.[244] With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. With RSCOCl the product is a thiol ester ArCOSR; but of course these compounds can be hydrolyzed to the corresponding carboxylic acids. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.

OS **V**, 706.

1-23 Carboxylation with Carbon Dioxide. The Kolbe-Schmitt Reaction



Sodium phenoxides can be carboxylated, mostly in the ortho position, by carbon dioxide. The process is called the *Kolbe-Schmitt reaction.*[245] The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants[246] making the carbon of the CO_2 more positive and putting it in a good position to attack the ring. Potassium phenoxide,

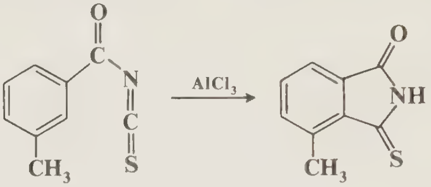
which is less likely to form such a complex,[247] is chiefly attacked in the para position.[248] Carbon tetrachloride may be used instead of CO_2, under Reimer-Tiemann (reaction **1-21**) conditions. Sodium or potassium phenoxide may be carboxylated regiospecifically in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.[249] ^{14}C labeling showed that it is the carbonate carbon which appears in the *p*-hydroxybenzoic acid product.[250] The CO is converted to sodium or potassium formate.

OS **II**, 557.

1-24 Amidation with Isocyanates

$$\mathrm{ArH + RNCO \xrightarrow{AlCl_3} ArCONHR}$$

N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.[251] R may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides. The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.[252] In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; therefore this represents a way of putting a carboxyl group on a ring ortho to one which is already there (**40** is prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $ArCH_2CONCS$, where six-membered rings are formed.

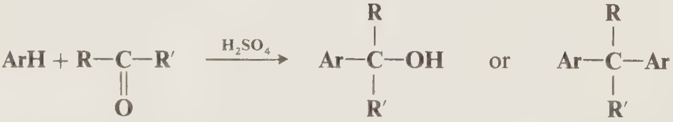


40

OS **V**, 1051; **50**, 52.

Reactions **1-25** to **1-29** involve the introduction of a CH_2Z group, where Z is halogen, hydroxy, amino, or alkylthio. They are all Friedel-Crafts reactions of aldehydes and ketones and, with respect to the carbonyl compound, additions to the C=O double bond. They follow mechanisms discussed in Chapter 16.

1-25 Hydroxyalkylation



$$\mathrm{ArH + R{-}\underset{\underset{O}{\|}}{C}{-}R' \xrightarrow{H_2SO_4} Ar{-}\overset{\overset{R}{|}}{\underset{\underset{R'}{|}}{C}}{-}OH \quad or \quad Ar{-}\overset{\overset{R}{|}}{\underset{\underset{R'}{|}}{C}}{-}Ar}$$

---

[247] There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO_2: Hirao and Kito, *Bull. Chem. Soc. Jpn.* **46,** 3470 (1973).

[248] Actually, the reaction seems to be more complicated than this. At least part of the potassium *p*-hydroxybenzoate which forms comes from a rearrangement of initially formed potassium salicylate. Sodium salicylate does not rearrange. See Shine, "Aromatic Rearrangements," Ref. 289, pp. 344–348. See also Ota, *Bull. Chem. Soc. Jpn.* **47,** 2343 (1974).

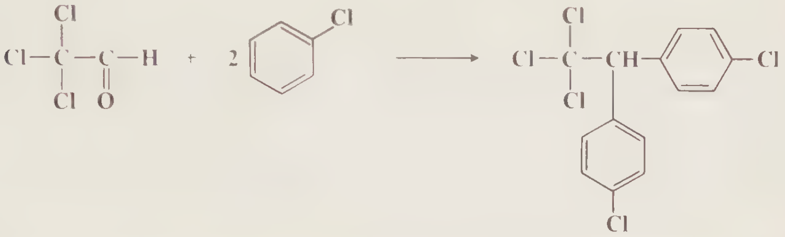
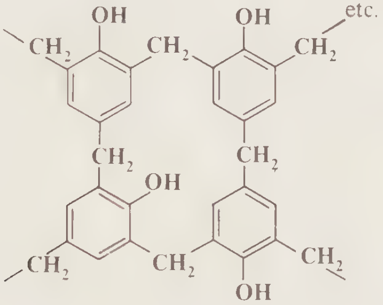
The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.[253] The reaction is not generally useful as a method for the preparation of alcohols, though it has been used for that purpose, largely with ketones as reagents. More often, the alcohol initially produced reacts with another molecule of aromatic compound (reaction **1-13**) to give diarylation. For this the reaction is quite useful, an example being the preparation of DDT:



The diarylation reaction is especially common with phenols (the diaryl product here is called a *bisphenol*). The reaction is normally carried out in alkaline solution, on the phenolate ion.[254] The hydroxymethylation of phenols with formaldehyde is called the *Lederer-Manasse reaction.* This reaction must be carefully controlled, since it is possible for the para and both ortho positions to be substituted and then for each of these to be rearylated, so that a polymeric structure (**41**) is produced.



41

However, such polymers, which are of the Bakelite type (phenol-formaldehyde resins), are of considerable commerical importance.

The attacking species is the carbonium ion,  $\mathrm{R{-}\overset{\oplus}{\underset{OH}{C}}{-}R'}$, formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution. The reaction of benzophenones with phenols to give triarylcarbinols and/or tetraarylmethanebisphenols can also in some cases be performed photochemically.[255]

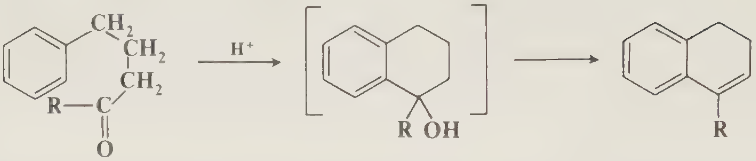
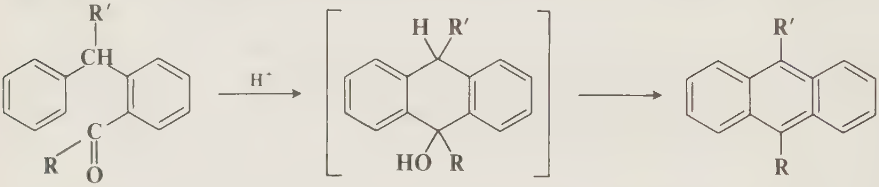
1-26 Cyclodehydration of Aldehydes and Ketones



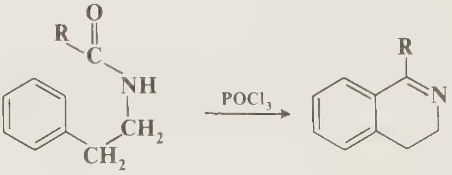
When an aromatic compound contains an aldehyde or ketone function which is in a position suitable for closing a six-membered ring, then treatment with acid results in cyclodehydration. The reaction is a special case of **1-25**, but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring. The method is very general and is widely used to close both carbocyclic and heterocyclic rings. Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,[256] diaryl-



methanes containing a carbonyl group in the ortho position can be cyclized to anthracene derivatives. In this case 1,4-dehydration takes place, at least formally.

Among the applications of cyclodehydration to the formation of heterocyclic systems are the following:

1. *The Bischler-Napieralski reaction.*[257] In this reaction amides of the type **42** are cyclized with phosphorus oxychloride:



42

If the starting compound contains a hydroxyl group in the α-position, then an additional dehydration takes place and the product is an isoquinoline. Higher yields can be obtained if the amide is treated with PCl_5 to give an imidoyl chloride $ArCH_2CH_2N{=}CR{-}Cl$, which is isolated and then cyclized by heating.[258] The nitrilium ion $ArCH_2CH_2\overset{\oplus}{N}{\equiv}CR$ is an intermediate here.

2. *The third step of the Skraup synthesis.*[259] In the Skraup synthesis a primary aromatic amine

---

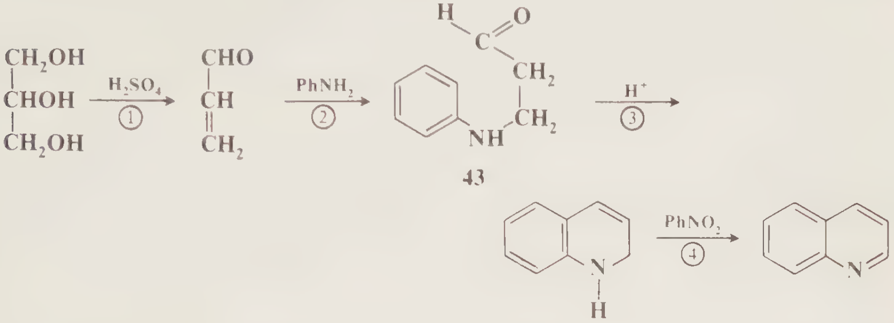
[259] For a review, see Manske and Kulka, *Org. React.* **7**, 59–98 (1953).

is treated with glycerol, sulfuric acid, and an aromatic nitro compound (usually nitrobenzene) to give a quinoline. The reaction has four steps, as shown:



43

The third step is the Friedel-Crafts ring closure. The first step is a dehydration (reaction **7-1**), the second a Michael-type reaction (**5-9**), and the fourth an oxidative aromatization (reaction **9-1**) in which, presumably, nitrobenzene is the oxidizing agent. Other oxidizing agents have also been used. Intermediates of the type **43** have been isolated from the reaction mixture[260] and have been shown to give quinolines under these conditions.[261] It has been shown that the oxidation step can take place before the cyclization step.[262] Since in the first step glycerol is dehydrated to acrolein, it might be expected that other α,β-unsaturated aldehydes and ketones also give the reaction. This is true, the reaction being called the *Doebner-Miller reaction.*

3. *The Pechmann* (*or von Pechmann*) *reaction.*[263] In this reaction phenols are condensed with β-keto esters to give coumarins. The first step is a transesterification (reaction **0-25**), and the second a Friedel-Crafts ring closure:

1-27 Haloalkylation

$$ArH + HCHO + HCl \xrightarrow{ZnCl_2} ArCH_2Cl$$

When certain aromatic compounds are treated with formaldehyde and HCl, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation.* The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.[264] The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reaction.

[263] For a review, see Sethna and Phadke, *Org. React.* **7**, 1–58 (1953).

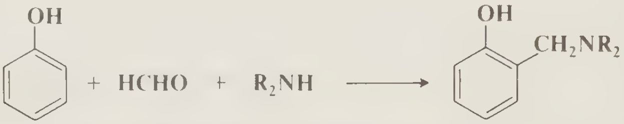
[264] For reviews, see Olah and Tolgyesi, in Olah, Ref. 205, vol. 2, pp. 659–784; and Fuson and McKeever, *Org. React.* **1**, 63–90 (1942).

Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether $ClCH_2OMe$, bis-(chloromethyl) ether $(ClCH_2)_2O$,[265] or 1-chloro-4-(chloromethoxy)butane.[266] Zinc chloride is the most common catalyst, but other Friedel-Crafts catalysts are also employed. As with reaction **1-25**, and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in reaction **1-25**, and then the HCl converts this to the chloroalkyl compound.[267] The acceleration of the reaction by $ZnCl_2$ has been attributed[268] to the raising of the acidity of the medium, causing a consequent increase in the concentration of $HOCH_2^+$ ions.

OS **III**, 195, 197, 468, 557; **IV**, 980.

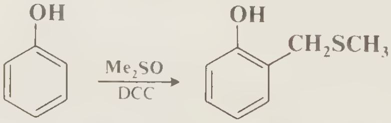
1-28 Aminoalkylation



Phenols, secondary and tertiary aromatic amines,[269] pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminomethylation is a special case of the Mannich reaction (**6-17**).

OS **I**, 381; **IV**, 626; **V**, 434; **51**, 136.

1-29 Thioalkylation



A methylthiomethyl group can be inserted into the ortho position of phenols by heating with dimethyl sulfoxide and dicyclohexylcarbodiimide (DCC).[270] Other reagents can be used instead of DCC, among them pyridine-SO_3[271] and acetic anhydride.[272] Alternatively, the phenol can be treated with dimethyl sulfide and N-chlorosuccinimide, followed by triethylamine.[273] The reaction can be applied to amines (to give *o*-$NH_2C_6H_4CH_2SMe$) by treatment with *t*-BuOCl, Me_2S, and NaOMe in CH_2Cl_2.[274] It is possible to convert the CH_2SMe group to the CHO group,[275] so that this becomes an indirect method for the preparation of ortho-amino and ortho-hydroxy aromatic aldehydes; or to the CH_3 group (with Raney nickel reaction **4-37**), making this an indirect method for the introduction of a CH_3 group ortho to an OH or NH_2 group.[274]

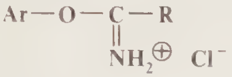
1-30 Acylation with Nitriles. The Hoesch Reaction

$$\mathrm{ArH + RCN \xrightarrow[ZnCl_2]{HCl} ArCOR}$$

Friedel-Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben-Hoesch reaction*.[276] In most cases, a Lewis acid is necessary, zinc chloride being the most common. The reaction is useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds, e.g., pyrrole. Monohydric phenols, however, generally do not give ketones, but are attacked at the oxygen to produce imino esters (**44**). Many nitriles have been used. Even aryl nitriles give good

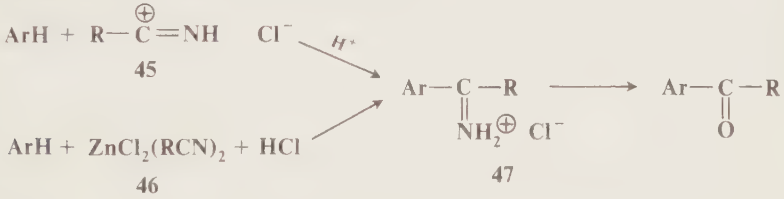


$$\mathrm{Ar{-}O{-}\underset{NH_2^{\oplus}}{\overset{}{C}}{-}R \quad Cl^-}$$

44

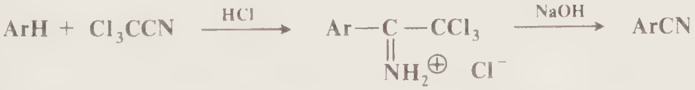
yields if they are first treated with HCl and $ZnCl_2$, and then the substate added at 0 C.[277] In fact, this procedure increases yields with any nitrile. If thiocyanates RSCN are used, thiol esters ArCOSR can be obtained. The Gatterman reaction (**1-18**) is a special case of the Hoesch synthesis.

The reaction mechanism is complex and not completely settled.[278] The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (**47**). Among the possible attacking species are **45** and **46**. In the second stage, the salts are hydrolyzed to the products:



OS **II**, 522.

1-31 Direct Cyanogenation



$$\mathrm{ArH + Cl_3CCN \xrightarrow{HCl} Ar{-}\underset{NH_2^{\oplus}\ Cl^-}{\overset{}{C}}{-}CCl_3 \xrightarrow{NaOH} ArCN}$$

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanogenated with trichloroacetonitrile, BrCN, or mercury fulminate $Hg(ONC)_2$.[279] In the case of Cl_3CCN, the actual attacking entity is probably $Cl_3C{-}\overset{\oplus}{C}{=}NH$, formed by addition of a proton to the cyano nitrogen. The cyano group has also been introduced electrolytically, by applying a potential to a mixture of the aromatic compound, HCN, and NaCN in methanol,[280] as well as photochemically.[280a]

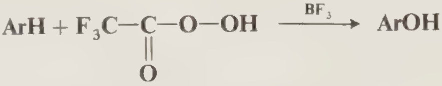
OS **III**, 293.

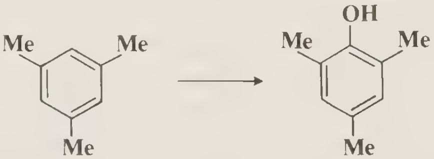
F. Oxygen Electrophiles Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there are two reactions which may be mentioned.

1-32 Direct Hydroxylation



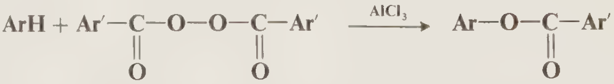
$$\mathrm{ArH} + \mathrm{F_3C{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}OH} \xrightarrow{\mathrm{BF_3}} \mathrm{ArOH}$$

There have been only a few reports of direct hydroxylation by an electrophilic process (see, however, reactions **2-23**, **3-20**, and **4-5**).[281] In general, poor results are obtained, in part because the introduction of an OH group activates the ring to further attack. Quinone formation is common. However, alkyl-substituted benzenes such as mesitylene or durene may be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.[282] In the case of mesitylene, the product is not subject to further attack:



Low to moderate yields of phenols can be obtained by treatment of simple alkylbenzenes with H_2O_2 catalyzed by $AlCl_3$[283] or by liquid HF, in some cases under CO_2 pressure.[284] With the latter procedure even benzene could be converted to phenol in 37% yield (though 37% hydroquinone and 16% catechol were also obtained).

1-33 Direct Introduction of an Acyloxy Group



$$\mathrm{ArH} + \mathrm{Ar'{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}Ar'} \xrightarrow{\mathrm{AlCl_3}} \mathrm{Ar{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}Ar'}$$

An acyloxy group can be introduced into reactive nuclei (e.g., mesitylene, anisole) in low yields by treatment with a diacyl peroxide containing electron-withdrawing groups (e.g., *p,p'*-dinitrobenzoyl peroxide) and $AlCl_3$.[285] It had been reported[286] that benzene underwent this reaction when treated with benzoyl peroxide, but it has been shown[285] that the phenyl benzoate formed in this case does not arise from attack of benzoyl peroxide on benzene, but from a rearrangement

of the peroxide, catalyzed by $AlCl_3$; that is, both phenyl groups in the phenyl benzoate came from the benzoyl peroxide, and neither from the benzene. *p,p'*-Dinitrobenzoyl peroxide is less prone to rearrange than benzoyl peroxide and can thus attack an active substrate.

Aryl sulfonyl peroxides react with aromatic compounds to give sulfonic acids in a manner analogous to *p,p'*-dinitrobenzoyl peroxide.[287] Acyloxylation has also been accomplished by treatment with potassium peroxydisulfate in glacial acetic acid, catalyzed by Pd(II) amine complexes.[288]

$$\mathrm{ArH + Ar'{-}SO_2{-}O{-}O{-}SO_2{-}Ar' \longrightarrow Ar{-}O{-}SO_2{-}Ar'}$$

G. Metal Electrophiles Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (reactions **2-19** and **2-20**).

Hydrogen as the Leaving Group in Rearrangement Reactions

In these reactions a group is first detached from a *side chain* and then attacks the ring, but in other aspects they resemble the reactions already treated in this chapter.[289] Since a group moves from one position to another in a molecule, these are rearrangements. In all these reactions the question arises as to whether the group which cleaves from a given molecule attacks the same molecule or another one, that is, is the reaction intramolecular or intermolecular? For those that are intermolecular the mechanism is the same as ordinary aromatic substitution, but for intramolecular cases the migrating group could never be completely free, or else it would be able to attack another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, intramolecular reactions are more likely to lead to ortho products than are the intermolecular type; and this characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular.

The Claisen (**8-38**) and benzidine (**8-44**) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

A. Groups Cleaving from Oxygen

1-34 The Fries Rearrangement

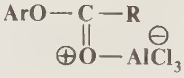
[289] For a monograph, see Shine, "Aromatic Rearrangements," American Elsevier Publishing Company, New York, 1967. For reviews, see Shine, *MTP Int. Rev. Sci.: Org. Chem., Ser. One,* **3,** 66–103 (1973); Williams, in Bamford and Tipper, Ref. 1, pp. 433–486; Dewar, in Mayo, "Molecular Rearrangements," vol. 1, pp. 295–299, 306–323, Interscience Publishers, New York, 1963.

Phenolic esters may be rearranged by heating with Friedel-Crafts catalysts in a synthetically useful reaction known as the *Fries rearrangement*.[290] Both *o*- and *p*-acylphenols may be produced, and it is often possible to select conditions so that either one predominates. The ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Though exceptions are known, low temperatures generally favor the para product, and high temperatures the ortho product. R may be aliphatic or aromatic. Any meta-directing substituent on the ring interferes with the reaction, as might be expected for a Friedel-Crafts process.

The exact mechanism has still not been completely worked out. Opinions have been expressed that it is completely intermolecular,[291] completely intramolecular,[292] and partially inter- and intramolecular.[293] One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, then the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments*) have been carried out; and sometimes crossover products have been found and sometimes not. As in reaction **1-15**, an initial complex (**48**) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1 : 1 is required. There is evidence that both a mono- (**48**) and a di-$AlCl_3$ catalyst can be formed.[294]



$$\mathrm{ArO{-}\underset{\overset{\|}{\oplus O}}{C}{-}R}\quad \mathrm{O{-}\overset{\ominus}{A}lCl_3}$$

48

The Fries rearrangement can also be carried out with uv light, in the absence of a catalyst.[295] This reaction, called the *photo-Fries rearrangement*,[296] is predominantly an intramolecular free-radical process. Both ortho and para migration are observed. Unlike the Lewis-acid-catalyzed Fries rearrangement, the photo-Fries reaction can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following mechanism[297] for the photo-Fries rearrangement[298] (illustrated for para attack):

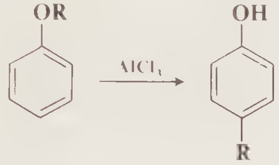
[297] Proposed by Kobsa, Ref. 295.

[298] It has been suggested that a second mechanism, involving a four-center transition state, is also possible: Belluš, Schaffner, and Hoigné, *Helv. Chim. Acta* **51**, 1980 (1968); Sander, Hedaya, and Trecker, *J. Am. Chem. Soc.* **90**, 7249 (1968); Belluš, Ref. 296.

The phenol ArOH is always a side product, resulting from some ArO• which leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogens), phenol was the chief product, and virtually no *o*- or *p*-hydroxyacetophenone was found.[299] Other evidence for the mechanism is that CIDNP (p. 171) has been observed during the course of the reaction,[300] and that the ArO• radical has been detected by flash photolysis.[301]

OS **II,** 543; **III,** 280, 282.

1-35 Rearrangement of Phenolic Ethers



This reaction bears the same relationship to reaction **1-34** that reaction **1-13** bears to **1-15.**[302] However, yields are generally low, and this reaction is much less useful synthetically. Isomerization of the R group is usually found when that is possible. Evidence has been found for both inter- and intramolecular processes. The fact that dialkylphenols can often be isolated shows that at least some intermolecular processes occur. Evidence for intramolecular reaction is that conversion of optically active *p*-tolyl *sec*-butyl ether to 2-*sec*-butyl-4-methylphenol proceeded with some retention of configuration,[303] and that rearrangement of benzyl phenyl ethers (with $AlBr_3$ or $AlCl_3$) takes place with virtually exclusive ortho migration.[304] The mechanism is probably similar to that of reaction **1-13.** The fact that isomerization is generally found in the migrating group and the finding[305] that *sec*-butyl phenyl ether containing deuterium in the 2 position of the *sec*-butyl group gives *sec*-butylphenols in which the deuterium has been scrambled between the 2 and the 3 positions (arising from hydride shifts in the carbonium ion) indicate that carbonium ions are often involved, but the demonstration of partial inversion of configuration in the conversion of optically active *sec*-butyl phenyl ether to *o*- and *p*-*sec*-butylphenols[306] shows that an SN2 mechanism can also operate, probably featuring attack by a complex between the catalyst and one molecule of the ether on the ortho or para position of another molecule of the ether, to give an *o*- or *p*-*sec*-butylphenyl *sec*-butyl ether which is then cleaved. In substantiation of this hypothesis, both *o*- and *p*-*sec*-butylphenyl *sec*-butyl ethers were detected in the reaction mixture.[306] In at least some cases the reaction can proceed without a catalyst. For example, simple heating at 250 C of phenyl benzyl ether gave *o*- and *p*-benzylphenol.[307] The fact that phenol and toluene are also obtained shows that the thermal reaction is intermolecular. It is probably a free-radical reaction. The rearrangement can also be induced photochemically.[308]

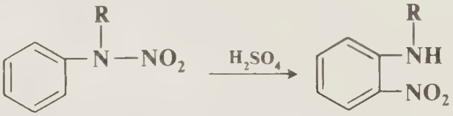
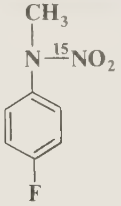
B. Groups Cleaving from Nitrogen[309] It has been shown that $Ph\overset{\oplus}{N}H_2D$ rearranges to *o*- and *p*-deuterioaniline.[310] The migration of OH, formally similar to reactions **1-36** to **1-40**, is a nucleophilic substitution and is treated in Chapter 13 (reaction **3-28**).

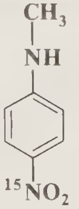
1-36 Migration of the Nitro Group



N-Nitro aromatic amines rearrange on treatment with acids to give *o*- and *p*-nitroamines, with the ortho compounds predominating.[311] Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,[312] though direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring and then attacks another molecule must be ruled out. Further results indicating an intramolecular process are that rearrangement of N-nitroaniline, N-nitro-1-naphthylamine, and N-nitro-N-methyl-1-naphthylamine in the presence of $K^{15}NO_3$ gave products containing no ^{15}N,[313] and that rearrangement of a mixture of $PhNH^{15}NO_2$ and unlabeled *p*-$MeC_6H_4NHNO_2$ gave 2-nitro-4-methylaniline containing no ^{15}N.[314] On the other hand, rearrangement of **49** in the presence of unlabeled $PhNMeNO_2$ gave labeled **50** which did not arise by displacement of F.[315] As indicated by the examples given, R may be hydrogen or alkyl.

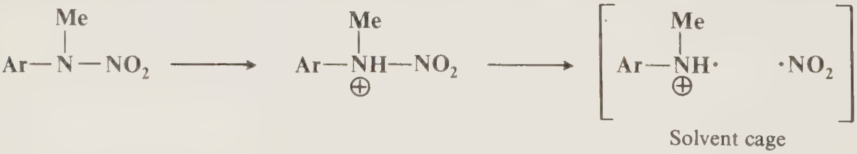


49



50

Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,[316] and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.[317] Among the evidence for the



$$Ar-\overset{Me}{\overset{|}{N}}-NO_2 \longrightarrow Ar-\underset{\oplus}{\overset{Me}{\overset{|}{N}H}}-NO_2 \longrightarrow \left[Ar-\underset{\oplus}{\overset{Me}{\overset{|}{N}H}}\cdot \quad \cdot NO_2\right]$$

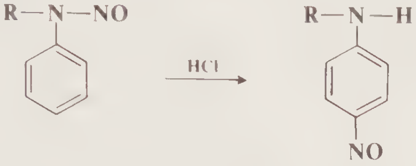
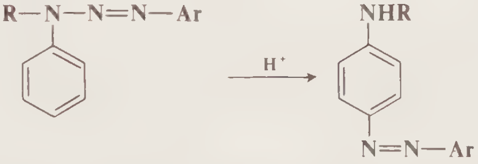
latter view[318] are the effects of substituents on the rate of the reaction,[319] and the fact that both N-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-N-methylaniline.[320] These side products are formed when the radicals escape from the solvent cage.

1-37 Migration of the Nitroso Group. The Fischer-Hepp Rearrangement



The migation of a nitroso group, formally similar to reaction **1-36**, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct C-nitrosation of secondary aromatic amines (see reaction **2-50**). The reaction is known as the *Fischer-Hepp rearrangement*,[321] and is brought about by treatment of N-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems the para product is exclusively formed. The mechanism of the rearrangement is not completely understood. It had been earlier believed that the rearrangement was intermolecular, in part because the amine ArNHR was a side product, but the fact that the reaction takes place in a large excess of urea[322] shows that it is intramolecular[323] since, if NO^+, NOCl, or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement. The ArNHR is formed by an independent process[324] not leading to rearrangement. It is because they promote this side process that acids other than HCl give poor yields of rearrangement product. The exclusive formation of para product is puzzling, since this is not what we would expect from an intramolecular rearrangement.

1-38 Migration of an Arylazo Group



Rearrangement of aryl triazenes is used to prepare azo derivatives of primary and secondary aromatic amines.[325] These are first diazotized at the amino group (see reaction **1-4**) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied. The reaction is intermolecular, the migrating species probably being ArN_2^+.[326]

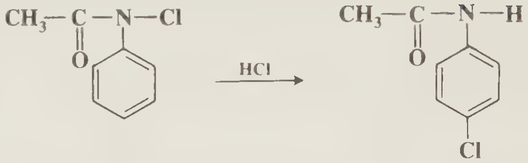
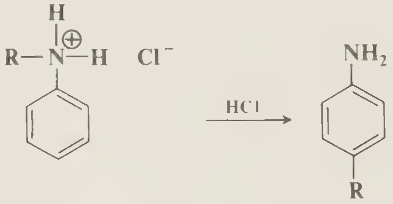
1-39 Migration of Halogen. The Orton Rearrangement



Migration of a halogen from a nitrogen side chain to the ring by treatment with HCl is called the *Orton rearrangement.*[327] The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with N-chloro- and N-bromoamines, and less often with N-iodo compounds. The amine must be acylated, except that $PhNCl_2$ gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is much evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process. First the HCl reacts with the starting material to give $ArNHCOCH_3$ and Cl_2, and then the chlorine halogenates the ring as in reaction **1-12.** Among the evidence for this is that chlorine has been isolated from the reaction mixture. The Orton rearrangement can also be brought about photochemically[328] and by heating in the presence of benzoyl peroxide.[329] These are free-radical processes.

1-40 Migration of an Alkyl Group[330]



When HCl salts of arylalkylamines are heated at about 200 to 300°C, migration occurs. This is called the *Hofmann-Martius reaction.* It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine, but also aniline and di- and trimethylanilines.[331] As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an S_N2 reaction:

$$\overset{\oplus}{RNH_2Ar} + Cl^- \longrightarrow RCl + ArNH_2$$

Evidence for this view is that alkyl halides have been isolated from the reaction mixture, and that Br^-, Cl^-, and I^- gave different ortho/para ratios, indicating that the halogen is involved in the reaction.[331] Further evidence is that the alkyl halides isolated are unrearranged (as would be expected if they are formed by an S_N2 mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal Friedel-Crafts alkylation process (reaction **1-13**), accounting for the rearrangement. When R is secondary or tertiary, carbonium ions may be directly formed so that the reaction does not go through the alkyl halides.[332]

[328] For example, see Hodges, *J. Chem. Soc.* 240 (1933).

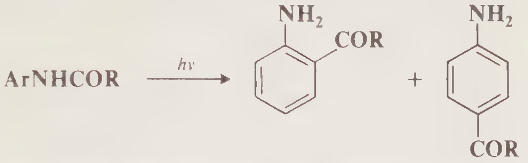
[329] For example, see Ayad, Beard, Garwood, and Hickinbottom, *J. Chem. Soc.* 2981 (1957); Coulson, Williams, and Johnston, *J. Chem. Soc. B* 174 (1967).

[330] For reviews, see Grillot, *Mech. Mol. Migr.* **3**, 237–270 (1971); Shine, "Aromatic Rearrangements," Ref. 289, pp. 249–257.

[331] Ogata, Tabuchi, and Yoshida, *Tetrahedron* **20**, 2717 (1964).

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350°C with a metal halide such as $CoCl_2$, $CdCl_2$, or $ZnCl_2$. When this is done, the reaction is called the *Reilly-Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.[333] The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to olefins under these conditions. The mechanism of the Reilly-Hickinbottom rearrangement is probably similar to that of the Hofman-Martius rearrangement.

When acylated arylamines are photolyzed, migration of an acyl group takes place[334] in a process which resembles the photo-Fries reaction (**1-34**). N,N-disubstituted amides ArNR′COR also give the reaction.



Other Leaving Groups

Three types of reactions are considered in this section.

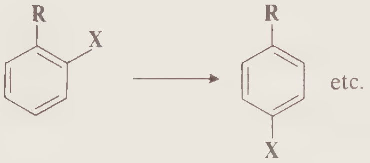
1. Reactions in which hydrogen replaces another leaving group:

$$ArX + H^+ \longrightarrow ArH$$

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

$$ArX + Y^+ \longrightarrow ArY$$

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another:



Such migrations may be either inter- or intramolecular.

The three types are not treated separately, but reactions are classified on the basis of the nature of the leaving group.

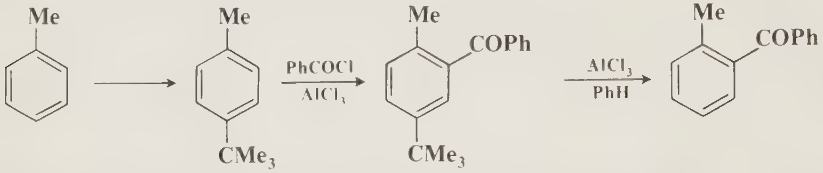
A. Carbon Leaving Groups

1-41 Reversal of Friedel-Crafts Alkylation

$$\text{ArR} + \text{H}^+ \xrightarrow{\text{AlCl}_3} \text{ArH}$$

Alkyl groups may be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *t*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed. For example,[335]



Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using Friedel-Crafts catalysts (Lewis or proton acids) on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an olefin, occurs only at high temperatures: above 400°C.[336] At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another, or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5 product the most favored among the trialkylbenzenes, because these have the highest thermodynamic stabilities (p. 460). Alkyl migrations may be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes[337] (entirely intermolecular); propylbenzene labeled in the β-position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the α position and not at all in the γ-position[338] (both intra- and intermolecular); *o*-xylene treated with HBr and $AlBr_3$ gave a mixture of *o*- and *m*- but no *p-xylene*, while *p*-xylene gave *p*- and *m*- but no *o-xylene*, and no trimethyl compounds could be isolated in these experiments[339] (exclusively intramolecular rearrangement). Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.[340]

The mechanism[341] of intermolecular rearrangement may involve free carbonium ions, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. When rearrangement does occur, it may be of the type that could not arise from a free carbonium ion. For example, *t*-pentylbenzene when heated with $AlCl_3$ gave 65% neopentylbenzene, while the latter was almost unchanged.[342] A free carbonium ion would almost certainly rearrange the other way. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbonium ions which are separated from the ring.[343]

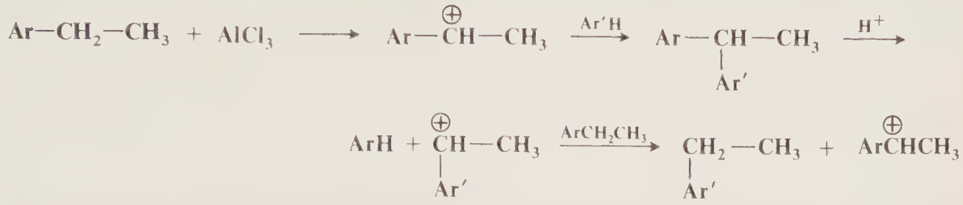
[340] Allen, Alfrey, and Yats, *J. Am. Chem. Soc.* **81**, 42 (1959); Allen, Yats, and Erley, *J. Am. Chem. Soc.* **82**, 4853 (1960); Allen, *J. Am. Chem. Soc.* **82**, 4856 (1960).

[341] For a review of the mechanism of this and closely related reactions, see Shine, "Aromatic Rearrangements," Ref. 289, pp. 1–55.

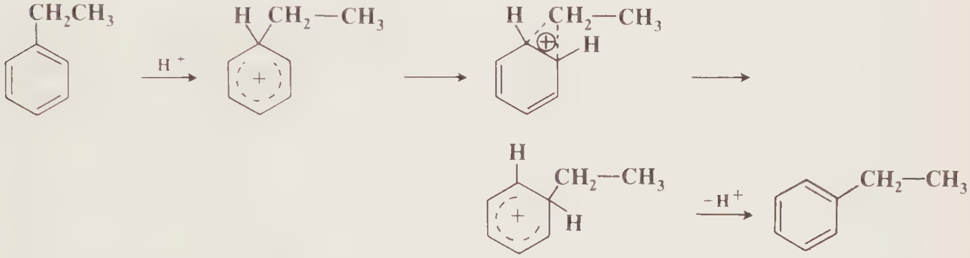
[342] Roberts and Han, *Tetrahedron Lett.* no. 6, 5 (1959).



$$\mathrm{Ar{-}CH_2{-}CH_3 + AlCl_3 \longrightarrow Ar{-}\overset{\oplus}{C}H{-}CH_3 \xrightarrow{Ar'H} Ar{-}\underset{Ar'}{CH}{-}CH_3 \xrightarrow{H^+}}$$

$$\mathrm{ArH + \underset{Ar'}{\overset{\oplus}{C}H}{-}CH_3 \xrightarrow{ArCH_2CH_3} \underset{Ar'}{CH_2}{-}CH_3 + Ar\overset{\oplus}{C}HCH_3}$$

Evidence for this mechanism was that optically active $PhCHDCH_3$ labeled in the ring with ^{14}C and treated with $GaBr_3$ in the presence of benzene gave ethylbenzene containing no deuterium and two deuteriums, and that the rate of loss of radioactivity was about equal to the rate of loss of optical activity.[343] The mechanism of intramolecular rearrangement is not very clear. 1,2 shifts of this kind have been proposed:[344]



There is evidence from ^{14}C labeling that intramolecular migration occurs only though 1,2 shifts.[345] Any 1,3 or 1,4 migration takes place by a series of two or more 1,2 shifts. The mechanism of the conversion of *t*-pentylbenzene to neopentylbenzene, mentioned above, does not involve migration of an alkyl group from one position to another in the same or a different ring, but migration of the benzene ring from one position to another in the alkyl group[346] (reaction **8-1**).

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with $AlCl_3$ H_2O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.[347] Alkyl groups have also been replaced by groups other than hydrogen, for example, nitro groups.[348]

1-42 Decarbonylation of Aromatic Aldehydes

$$\mathrm{ArCHO \xrightarrow{H_2SO_4} ArH + CO}$$

The decarbonylation of aromatic aldehydes with H_2SO_4[349] is the reverse of reaction **1-17.** It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium-ion mechanism: the attacking species is H^+, and the leaving group is HCO^+, which can lose a proton to give CO or combine with OH^- from the water solvent to give formic acid.[350] Aromatic aldehydes have also been decarbonylated over Pd,[351] and with basic catalysts.[352] When basic catalysts are used, the mechanism is probably similar to the SE1 process of reaction **1-43.** See also reaction **4-27.**

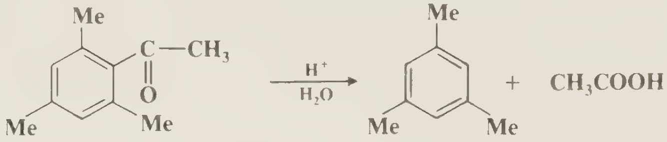
[348] For a review, see Nightingale, *Chem. Rev.* **40,** 117 (1947).

[349] For reviews of the mechanism, see Schubert and Kintner, in Patai, "The Chemistry of the Carbonyl Group," vol. 1, pp. 695 760, Interscience Publishers, New York, 1966; Taylor, Ref. 1, pp. 316-323.

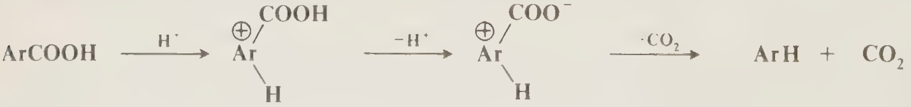
Aromatic ketones can also be cleaved, but only when sterically hindered, e.g.,



1-43 Decarboxylation of Aromatic Acids

$$\mathrm{ArCOOH} \xrightarrow[\text{quinoline}]{\text{Cu}} \mathrm{ArH} + \mathrm{CO_2}$$

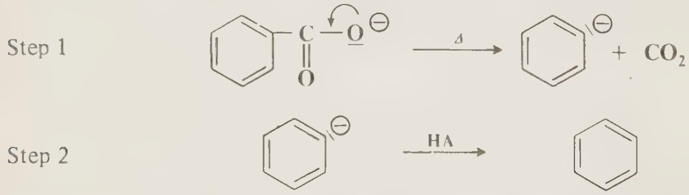
The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method the salt of the acid ($ArCOO^-$) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in the ortho and para positions, and by the steric effect of groups in the ortho positions; in benzene systems it is generally limited to substrates which contain such groups. In this method decarboxylation takes place by the arenium-ion mechanism,[353] with H^+ as the electrophile and CO_2 as the leaving group.[354] Evidently, the order of electrofugal ability is $CO_2 > H^+ > COOH^+$, so



$$\mathrm{ArCOOH} \xrightarrow{H^+} \overset{+}{\mathrm{Ar}}(\mathrm{COOH})(\mathrm{H}) \xrightarrow{-H^+} \overset{+}{\mathrm{Ar}}(\mathrm{COO^-})(\mathrm{H}) \xrightarrow{-CO_2} \mathrm{ArH} + \mathrm{CO_2}$$

that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being essentially of the SE1 type. Evidence for this mechanism is that the reaction is first order, and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.



Despite its synthetic importance, the mechanism of the copper-quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.[355] In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid which actually undergoes the decarboxylation.[355] According to this suggestion the aryl group of ArCOO$^-$ is coordinated with Cu$^+$ which helps to stabilize the negative charge which develops on the ring as the CO_2 cleaves. The resulting Ar$^-$ (coordinated with Cu$^+$) rearranges to give ArCu which then reacts with some molecule in the solution (reaction **1-50**) to give the product. It has been shown that cuprous salts of aromatic acids are easily decarboxylated by heating in quinoline,[356] and that arylcopper compounds are intermediates which can be isolated in some cases.[356]

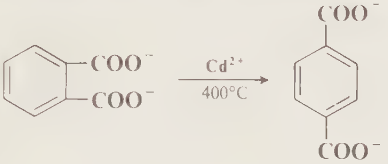
In certain cases the carboxyl group can be replaced by electrophiles other than hydrogen, e.g., NO[357] or Br.[358]

Rearrangements are also known to take place. For example, when the phthalate ion (**51**) is heated with a catalytic amount of cadmium ion, the terphthalate ion (**52**) is produced:[359]



51 **52**

In a similar process, potassium benzoate heated with cadmium salts disproportionates to benzene and **52**. The term *Henkel reaction* is used for these rearrangements. An SE1 mechanism has been suggested.[360] The terphthalate is the main product, because it crystallizes from the reaction mixture, driving the equilibrium in that direction.[361]

For aliphatic decarboxylation, see reaction **2-39.**

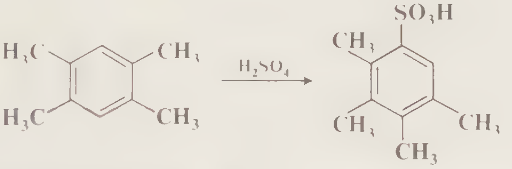
1-44 The Jacobsen Reaction



When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but in addition, rearrangement takes place.[362] The reaction, known as the *Jacobsen reaction*, is limited to benzene rings which have at least four substituents, which may be any combination of alkyl and halogen groups, where the alkyl groups may be ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *t*-butyl groups are on the ring, these groups are cleaved to give olefins. Since a sulfo group can later be removed (reaction **1-46**), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, etc., indicating an intermolecular process, at least partially. Similar rearrangements take place when polyalkylbenzenes are trichloromethylated, with CCl_4 and $AlCl_3$.[363]

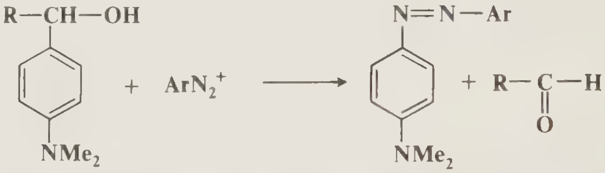
[361] Ratuský, *Chem. Ind.* (*London*) 1093 (1967), *Collect. Czech. Chem. Commun.* **33,** 2346 (1968).

[362] For a review, see Smith, *Org. React.* **1,** 370–384 (1942).

The mechanism of the Jacobsen reaction is not established,[364] but a likely possibility is attack by a sulfonating species (see reaction **1-7**) at a position occupied by an alkyl group, with the alkyl group thus freed migrating inter- or intramolecularly to another position. However, other mechanisms have also been suggested, including one which involves a radical cation intermediate.[365] It has been shown by labeling that ethyl groups migrate without internal rearrangement.[366]

1-45 The Stiles-Sisti Reaction



α-Hydroxyalkyl groups are replaced by azo groups when there is a dialkylamino group in the para position. The reaction is similar to reaction **1-4**, except that the leaving group is not hydrogen. The reaction is used to prepare aldehydes[367] and ketones.[368]

α-Hydroxyalkyl groups have also been replaced by halogen.[369] In this case too, best results are obtained when there is an activating group in the para position.

OS V, 46.

B. Oxygen Leaving Groups

1-46 Reduction of Aromatic Ethers

$$\mathrm{ArOR} \xrightarrow{\text{Raney Ni}} \mathrm{ArH} + \mathrm{RH}$$

Aromatic ethers may be reductively cleaved by heating with Raney nickel.[370] The hydrogen comes from that normally contained in this material, and from the solvent. R may also be aromatic, but if it is, it is usually reduced to a cyclohexane ring, unless degassed Raney nickel is used. The mechanism proposed is that, on the surface of the catalyst,

$$\mathrm{Ar{-}O{-}R} + \mathrm{H^-}\ \text{(from the catalyst)} \longrightarrow \mathrm{Ar^-} + \mathrm{ROH}$$

---

[363] See for example, Hart and Janssen, *J. Org. Chem.* **35**, 3637 (1970).

[364] For discussions, see Suzuki, *Bull. Chem. Soc. Jpn.* **36**, 1642 (1963); Taylor, Ref. 1, pp. 22–32, 48–55; Cerfontain, Ref. 123, pp. 214–226.

[370] Chandler and Sasse, *Aust. J. Chem.* **16**, 20 (1963).

The Ar^- takes a proton from the solvent. The ROH is then reduced as in reaction **0-79.** This mechanism is similar to the carboxylate ion mechanism in reaction **1-43.** With diaryl ethers, cleavage takes place so that the more stable carbanion is formed. See also reaction **3-9.**

C. Sulfur Leaving Groups

1-47 Desulfonation

$$ArSO_3H \xrightarrow[\text{dil. } H_2SO_4]{135\text{–}200^\circ C} ArH + H_2SO_4$$

The cleavage of sulfo groups from aromatic rings is the reverse of reaction **1-7.**[371] By the principle of microsopic reversibility, the mechanism is also the reverse. Dilute H_2SO_4 is generally used, as the reversibility of sulfonation decreases with increasing H_2SO_4 concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta and then to be removed. Migration has also been found, so that *o*-methylbenzenesulfonic acid has been converted to *p*-methylbenzenesulfonic acid.[372] The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.[373] In another catalytic process, aromatic sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with chlorotris(triphenylphosphine)rhodium(I).[374] This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in reaction **4-41.**

$$ArSO_2Br \xrightarrow{RhCl(PPh_3)_3} ArBr$$

OS **I,** 388; **II,** 97; **III,** 262; **IV,** 364. Also see OS **I,** 519; **II,** 128; **V,** 1070.

D. Halogen Leaving Groups

1-48 Dehalogenation

$$ArX \xrightarrow{AlCl_3} ArH$$

Aryl halides can be dehalogenated by Friedel-Crafts catalysts. Iodine is the most easily cleaved. Dechlorination is seldom performed, and defluorination apparently never. The reaction is most successful when a reducing agent, say Br^- or I^-, is present to combine with the I^+ or Br^+ coming off.[375] Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found, both intramolecular and intermolecular.[376] An example of the latter was conversion of *p*-dibromobenzene to a mixture containing 6% *o*-, 59% *m*-, and 35% *p*-dibromobenzene, as well as bromobenzene and some tribromobenzenes, by heating at 200°C with $AlBr_3$.[377] On the other hand, radioactive labeling showed that the $AlCl_3$-catalyzed isomerization of *o*-dichlorobenzene to a mixture consisting mostly of *m*-dichlorobenzene was largely intramolecular.[378] *p*-Bromophenols undergo isomerization and debromination under mild conditions: treatment with HBr at 25°C.[379]

[375] Pettit and Piatak, *J. Org. Chem.* **25,** 721 (1960).

[376] Olah, Tolgyesi, and Dear, *J. Org. Chem.* **27,** 3441, 3449, 3455 (1962); Olah and Meyer, *J. Org. Chem.* **27,** 3464 (1962); de Valois, van Albada, and Veenland, *Tetrahedron* **24,** 1835 (1968).

[377] Kooyman and Louw, *Recl. Trav. Chim. Pays-Bas* **81,** 365 (1962); Augustijn, Kooyman, and Louw, *Recl. Trav. Chim. Pays-Bas* **82,** 965 (1963).

[378] Koptyug, Isaev, Gershtein, and Berezovskii, *J. Gen. Chem. USSR* **34,** 3830 (1964); Erykalov, Becker, and Belokurova, *J. Org. Chem. USSR* **4,** 2054 (1968).

[379] O'Bara, Balsley, and Starer, *J. Org. Chem.* **35,** 16 (1970).

The reaction is useful for preparing polyiodo aromatic compounds. Thus 2,4,5,6-tetraiodo-1,3,-dimethylbenzene was prepared by treatment of 4,6-diiodo-1,3-dimethylbenzene with sulfuric acid.[380] The mechanism is probably the reverse of that of reaction **1-12.**[381] Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases; e.g., 1,2,4-tribromobenzene is converted to 1,3,5-tribromobenzene by treatment with PhNHK.[382] This reaction, which involves aryl carbanion intermediates (S_E1 mechanism) has been called the *halogen dance*.[383]

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Ph_3SnH,[384] HI, Sn and HBr, Ph_3P,[385] Cu and H_2O,[386] hydrazine and Pd–C,[387] catalytic hydrogenation, $LiAlH_4$,[388] $NaAlH_4$,[389] *t*-BuOK in 1 : 1 *t*-BuOH–Me_2SO,[390] $NaBH_4$ in the presence of Pd–C,[391] NaH,[392] and Raney nickel in alkaline solution,[393] the latter method being effective for fluorine as well as for the other halogens. Not all these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free-radical processes. Photochemical reduction is also known.[394] Halogen can also be removed from aromatic rings indirectly, by conversion to Grignard reagents (**2-37**) followed by hydrolysis (**2-21**).

OS **III,** 132, 475, 519; **V,** 149, 346, 998; **52,** 62.

1-49 Formation of Organometallic Compounds

$$\mathrm{ArBr + M \longrightarrow ArM}$$

$$\mathrm{ArBr + RM \longrightarrow ArM + RBr}$$

These reactions are considered along with their aliphatic counterparts (reactions **2-37** and **2-38**).

E. Metal Leaving Groups

1-50 Hydrolysis of Organometallic Compounds

$$\mathrm{ArM + H^+ \longrightarrow ArH + M^+}$$

Organometallic compounds can be hydrolyzed by acid treatment. For active metals such as Mg, Li, etc., water is sufficiently acidic. The most important example of this reaction is hydrolysis of Grignard reagents, but M may be many other metals or metalloids. Examples are SiR_3, HgR,

Na, $B(OH)_2$. Since aryl Grignard and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids, e.g.,

$$\mathrm{PhMgBr} + \mathrm{H{-}C{\equiv}C{-}H} \longrightarrow \mathrm{H{-}C{\equiv}C^-}\quad \mathrm{MgBr^+} + \mathrm{PhH}$$

Where the bond between the metal and the ring is covalent, the usual arenium-ion mechanism operates.[395] Where the bonding is essentially ionic, this is a simple acid-base reaction. Other electrophiles can replace metals. For example, azo compounds can be prepared by attack of diazonium ions on arylzinc or arylmercury compounds[396] or on Grignard reagents,[397] and aryltrimethylsilanes $ArSiMe_3$ react with acyl chlorides in the presence of $AlCl_3$ to give ketones ArCOR.[398] For the aliphatic counterpart of this reaction, see reaction **2-21.**

Other reactions of aryl organometallic compounds are treated with their aliphatic analogs: reactions **2-22** through **2-35.**

Twelve
Aliphatic Electrophilic Substitution

In Chapter 11 it was pointed out that the most important leaving groups in electrophilic substitution are those which can best exist with an outer shell which is deficient in a pair of electrons. For aromatic systems the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions, for example, α to a carbonyl group, or at an alkynyl position ($RC{\equiv}CH$). Since metallic ions are easily able to bear positive charges, we might expect that organometallic compounds would be especially susceptible to electrophilic substitution, and this is indeed the case.[1] Another important type of electrophile substitution, known as *anionic cleavage*, involves the breaking of C—C bonds: in these reactions there are carbon leaving groups (reactions **2-39** to **2-45**). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is what remains when a positive species is removed from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), since the weakest acids are those in which the hydrogen is bound to carbon.

MECHANISMS

The mechanistic picture for aliphatic electrophilic substitution is less clear than it is for aliphatic nucleophilic substitution (Chapter 10) or aromatic electrophilic substitution (Chapter 11). However, we can distinguish at least four possible major mechanisms,[2] which we call SE1, SE2 (front), SE2 (back), and SEi. The SE1 is unimolecular; the other three are bimolecular.

Bimolecular Mechanisms. SE2 and SEi

The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the SN2 mechanism (p. 266) in that the new bond forms as the old one breaks. However, in the SN2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away *its* electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this means also that the incoming group attacks backside, at a position 180° from the leaving group, so that inversion of configuration is found. When the attacking species is an electrophile, which brings to the substrate only a vacant orbital, it is obvious that this consideration does not apply, and we cannot a priori predict from which direction the attack must come. We can therefore imagine two main possibilities: attack from the front, which we call SE2 (front), and attack from the rear, which we call SE2 (back). These possibilities can be pictured thus (charges not shown):

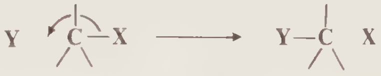
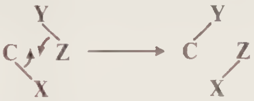
SE2 (front)



SE2 (back)

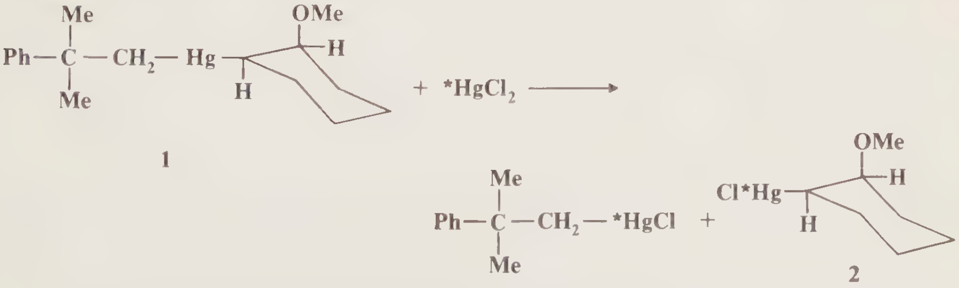
With substrates in which we can distinguish the possibility, the former mechanism should result in retention of configuration and the latter in inversion. When the electrophile attacks from the front, there is a third possibility. A portion of the electrophile may assist in removal of the leaving group, forming a bond with it at the same time that the new C—Y bond is formed:



SEi

This mechanism, which we call the SEi mechanism,[3] also results in retention of configuration. Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

It is evident that these three mechanisms are not easy to distinguish. All three give second-order kinetics, and two result in retention of configuration. In fact, although much work has been done on this question, there are few cases in which we can unequivocally say that one of these three and not another is actually taking place. Clearly, a study of the stereochemistry can distinguish between SE2 (back) on the one hand and SE2 (front) or SEi on the other. Many such investigations have been made, and in the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an SE2 (front) or SEi mechanism. For example, when *cis*-**1** was treated with labeled mercuric

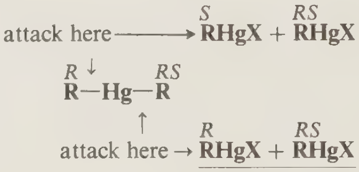


---

[3] The names for these mechanisms vary throughout the literature. For example, the SEi mechanism has also been called the SF2 and the SE2 (cyclic) mechanism. The original designations, SE1, SE2, etc., were devised by the Hughes-Ingold school.

chloride, the **2** produced was 100% cis. The bond between the mercury and the ring must have been broken (as well as the other Hg—C bond), since each of the products contained about half of the labeled mercury.[4] Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (see p. 268).[5] Still another indication is the behavior of neopentyl as a substrate. SN2 reactions at neopentyl are extremely slow (p. 315), because attack from the rear is sterically blocked. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl[6] is further evidence for frontside attack. One final elegant experiment may be noted. The compound di-*sec*-butylmercury was prepared with one *sec*-butyl group optically active and the other racemic.[7] This was accomplished by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 moles of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking:

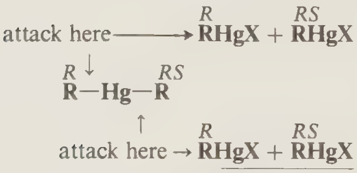
If inversion,



$$\text{attack here} \longrightarrow \overset{S}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$
$$\overset{R\downarrow}{\mathbf{R}}\mathbf{-Hg-}\overset{RS}{\mathbf{R}}$$
$$\uparrow$$
$$\text{attack here} \rightarrow \overset{R}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$

The sum is a
racemic mixture

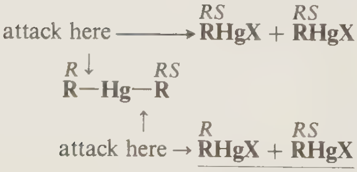
If retention,



$$\text{attack here} \longrightarrow \overset{R}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$
$$\overset{R\downarrow}{\mathbf{R}}\mathbf{-Hg-}\overset{RS}{\mathbf{R}}$$
$$\uparrow$$
$$\text{attack here} \rightarrow \overset{R}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$

The sum has
one-half of the
original activity

If racemization,



$$\text{attack here} \longrightarrow \overset{RS}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$
$$\overset{R\downarrow}{\mathbf{R}}\mathbf{-Hg-}\overset{RS}{\mathbf{R}}$$
$$\uparrow$$
$$\text{attack here} \rightarrow \overset{R}{\mathbf{RHgX}} + \overset{RS}{\mathbf{RHgX}}$$

The sum has
one-quarter of
the original
activity

The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

[6] Hughes and Volger, *J. Chem. Soc.* 2359 (1961).

[7] Jensen, *J. Am. Chem. Soc.* **82,** 2469 (1960); Ingold, Ref. 2.

On the other hand, inversion of configuration has been found in certain cases, demonstrating that the SE2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (reaction **2-28**) gives inverted *sec*-butyl bromide.[8] A number of

$$sec\text{-}\mathbf{BuSnR_3} + \mathbf{Br_2} \longrightarrow sec\text{-}\mathbf{BuBr} \qquad \mathbf{R} = \text{neopentyl}$$

other organometallic compounds have also been shown to give inversion when treated with halogens.[9] It may be that still other examples of backside attack exist[10] but have escaped detection because of the difficulty in preparing compounds which contain a configurationally stable carbon-metal bond. Compounds which are chiral because of an asymmetric carbon at which a carbon-metal bond is located are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,[11] and most stereochemical investigations have therefore been made with these substrates. It is only comparatively recently that an optically active Grignard reagent has been prepared[12] (that is, one in which the only asymmetric center is the carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C—Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl Grignard reagent with $HgBr_2$ (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.[13]

The SE2 (back) mechanism can therefore be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the SE2 (front) and the SEi mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods which lead to unequivocal conclusions. One method which has been used in an attempt to distinguish between the SEi mechanism on the one hand and the SE2 pathways on the other involves the study of salt effects on the rate. It may be recalled (p. 333) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the SEi mechanism would be less influenced by salt effects than would either of the SE2 mechanisms. On this basis Abraham and coworkers[14] concluded that the reactions $R_4Sn + HgX_2 \rightarrow RHgX + R_3SnX$ ($X = Cl$ or I) take place by SE2 and not by SEi mechanisms. Similar investigations involve changes in solvent polarity[15] (see also p. 530). Information from salt-effect studies can be put on a quantitative basis: the extent of charge separation in the transition state (Z) can be calculated from the kinetic values.[16] A high value of Z means an "open" transition state (SE2), while a low value indicates a "closed" transition state (SEi).

[9] For example, see Applequist and Chmurny, *J. Am. Chem. Soc.* **89,** 875 (1967); Glaze, Selman, Ball, and Bray, *J. Org. Chem.* **34,** 641 (1969); Brown and Lane, *Chem. Commun.* 521 (1971); Whitesides and Boschetto, *J. Am. Chem. Soc.* **93,** 1529 (1971); Jensen, Madan, and Buchanan, *J. Am. Chem. Soc.* **93,** 5283 (1971); Casey, Whitesides, and Kurth, *J. Org. Chem.* **38,** 3406 (1973); Espenson and Williams, *J. Am. Chem. Soc.* **96,** 1008 (1974); Bock, Boschetto, Rasmussen, Demers, and Whitesides, *J. Am. Chem. Soc.* **96,** 2814 (1974).

[10] Cases of inversion involving replacement of a metal by a metal have been reported. See Tada and Ogawa, *Tetrahedron Lett.* 2639 (1973); Fritz, Espenson, Williams, and Molander, *J. Am. Chem. Soc.* **96,** 2378 (1974); Gielen and Fosty, *Bull. Soc. Chim. Belg.* **83,** 333 (1974).

[11] Organomercury compounds were first resolved by three groups: Jensen, Whipple, Wedegaertner, and Landgrebe, *J. Am. Chem. Soc.* **81,** 1262 (1959); Charman, Hughes, and Ingold, *J. Chem. Soc.* 2523, 2530 (1959); Reutov and Uglova, *Bull. Acad. Sci. USSR, Div. Chem. Sci.* 735 (1959).

[12] Walborsky and Young, *J. Am. Chem. Soc.* **86,** 3288 (1964).

[13] Jensen and Nakamaye, *J. Am. Chem. Soc.* **88,** 3437 (1966).

[14] Abraham and Spalding, *J. Chem. Soc. A* 784 (1969); Abraham and Johnston, *J. Chem. Soc. A* 188 (1970).

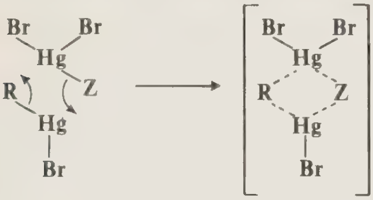
[15] See for example, Abraham and Dorrell, *J. Chem. Soc., Perkin Trans. 2* 444 (1973).

[16] Abraham and Behbahany, *J. Chem. Soc. A* 1469 (1971).

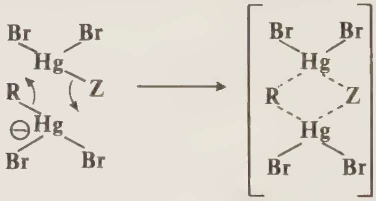
The effect of added salts has also been investigated in a different way. The reaction between *sec*-butylmercuric bromide and labeled mercuric bromide:

$$sec\text{-}\mathbf{Bu{-}HgBr} + {}^{*}\mathbf{HgBr_2} \rightleftharpoons sec\text{-}\mathbf{Bu{-}{}^{*}HgBr} + \mathbf{HgBr_2}$$

is second order and involves retention of configuration (which rules out the backside SE2 mechanism). It is catalyzed by I^-, Br^-, Cl^-, and acetate ion, in that order,[17] but interestingly, there are *two* catalytic processes at work, since the rate rises linearly with the addition of catalyst until a concentration of catalyst is reached which is equal to the concentration of $HgBr_2$, after which it again rises linearly but with a different slope. The catalysis is evidence for the SEi mechanism, since these ions are known to coordinate with mercury, and the strength of the coordination is in the same order. On the other hand, acetic acid and nitrate ion, neither of which coordinate with mercury, do not catalyze the reaction. The catalyst changes the attacking species from $HgBr_2$ to, say, $HgBr_2I^-$. It is hardly likely that such a change would increase the rate of an SE2 mechanism, since $HgBr_2I^-$ is a poorer electrophile than $HgBr_2$, but it would increase the rate of an SEi mechanism because the added nucleophile would assist in the removal of the leaving group. The transition state for the catalysis at the lower concentration of added ions (the one-ion catalysis) may thus be shown as in **A**.[18] The second anion catalyzes the reaction by coordinating with the other mercury atom; the transition state for the two-ion catalysis is shown in **B**.



A

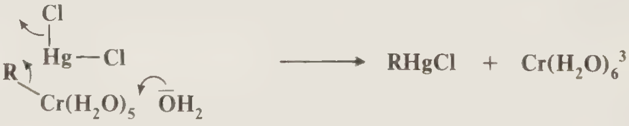


B

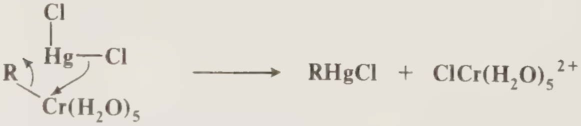
Another method for distinguishing the SE2 from the SEi mechanisms, which can be used in certain cases but unfortunately is not generally applicable, may be illustrated for the reaction of alkylchromium ions with mercuric chloride.[19] In this case we examine the chromium-containing products. If the mechanism is SE2 then the product can be $Cr(H_2O)_6{}^{3+}$ as shown, or $ClCr(H_2O)_5{}^{2+}$

$$\mathbf{RCr(H_2O)_5{}^{2+} + HgCl_2 \xrightarrow{H_2O} RHgCl + Cr(H_2O)_6{}^{3+} + X^-}$$

SE2



SEi



---

[17] Charman, Hughes, Ingold, and Volger, *J. Chem. Soc.* 1142 (1961).

[18] It has been contended that the transition state **A** cannot be accurate, since it apparently violates the law of microscopic reversibility (Jensen and Rickborn, Ref. 2, p. 171; Matteson, Ref. 2, p. 278). However, a careful study has shown that there are several possible pathways available for this reaction which do not violate the law: Abraham, Dodd, Johnson, Lewis, and More O'Ferrall, *J. Chem. Soc. B* 762 (1971).

[19] Coombes and Johnson, *J. Chem. Soc. A* 1805 (1966). See also Coombes, Johnson, and Vamplew, *J. Chem. Soc. A* 2297 (1968).

if Cl^- takes the place of H_2O as shown in the equation, or a mixture of both. On the other hand, an SEi mechanism can give *only* $ClCr(H_2O)_5^{2+}$ (it is important to note that $ClCr(H_2O)_5^{2+}$ and $Cr(H_2O)_6^{3+}$ are not interconvertible under the reaction conditions). The finding that only $Cr(H_2O)_6^{3+}$ was produced thus indicates that one of the SE2 mechanisms operates here.[19] Another method for distinguishing the SE2 (back) mechanism from the others is discussed on p. 530.

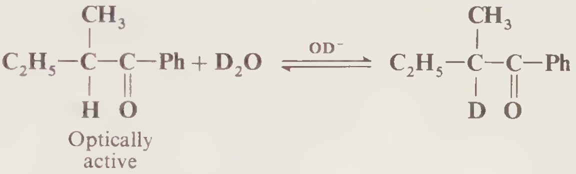
The SE1 Mechanism

The SE1 mechanism is analogous to the SN1 (p. 270). It involves two steps: a slow ionization and a fast combination.

Step 1 $\quad \mathrm{R{-}X} \xrightarrow{\text{slow}} \overline{\mathrm{R}}^- + \mathrm{X}^+$

Step 2 $\quad \overline{\mathrm{R}}^- + \mathrm{Y}^+ \longrightarrow \mathrm{R{-}Y}$

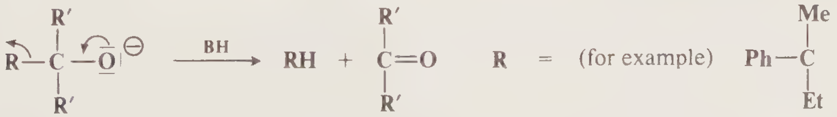
First-order kinetics are predicted, and many such examples have been found. Other evidence for the SE1 mechanism was obtained in a study of base-catalyzed tautomerism. In the reaction



the rate of deuterium exchange was the same as the rate of racemization,[20] and there *was* an isotope effect.[21] SN1 reactions do not proceed at bridgehead carbons in small bicyclic systems (p. 272) because at these carbons planar carbonium ions cannot form. However, carbanions not stabilized by resonance are probably not planar, and SE1 reactions should readily occur with this type of substrate. This is the case.

Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the SE1 reaction. If a carbanion is planar (as are carbonium ions), then racemization should occur. If it is pyramidal and *can hold its structure*, then the result should be retention of configuration. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure, that is, if there is an umbrella effect as with amines (p. 90). Unfortunately, the only carbanions that can be easily studied are those stabilized by resonance, which makes them planar, as expected (p. 165). For simple alkyl carbanions, the main approach to determining structure has been to study the stereochemistry of SE1 reactions, rather than the other way around. What is found is almost always racemization. Whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

However, even planar carbanions need not give racemization. Cram found that retention and even inversion may occur in the alkoxide cleavage reaction (**2-40**):

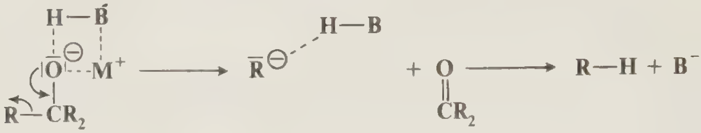


---

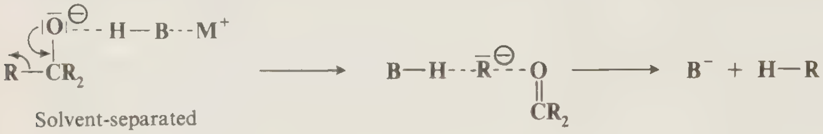
[20] Hsu, Ingold, and Wilson, *J. Chem. Soc.* 78 (1938).

[21] Wilson, *J. Chem. Soc.* 1550 (1936).

which is a first-order, SE1 reaction involving resonance-stabilized planar carbanions (here designated R^-).[22] By changing the solvent Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion which is not completely free but is solvated. In nondissociating, nonpolar solvents, such as benzene or dioxane, the alkoxide ion exists as an ion pair, which is solvated by the solvent BH:

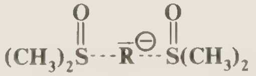


In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. As is easily seen, this solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents, such as diethylene glycol, a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so that the solvent can solvate it only from the opposite side:



Solvent-separated
ion pair

When C—H bond formation occurs, the result is inversion. Racemization results in polar aprotic solvents like dimethyl sulfoxide. In these solvents the carbanions are relatively long-lived (because the solvent has no proton to donate) and symmetrically solvated:

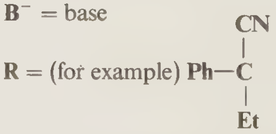


$$(CH_3)_2\overset{\overset{O}{\|}}{S}\cdots\overline{R}^{\ominus}\cdots\overset{\overset{O}{\|}}{S}(CH_3)_2$$

Similar behavior was found for carbanions generated by base-catalyzed hydrogen exchange (reaction **2-1**):[23]

$$R{-}H + B{-}D \xrightleftharpoons{B^-} R{-}D + B{-}H$$

B^- = base



R = (for example) $Ph{-}\overset{\overset{CN}{|}}{\underset{\underset{Et}{|}}{C}}$

In this case information was obtained from measurement of the ratio of k_e (rate constant for isotopic exchange) to k_α (rate constant for racemization). A k_e/k_α ratio substantially greater than 1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A k_e/k_α ratio of about 1 indicates racemization, and a ratio of $\frac{1}{2}$ corresponds to inversion (see p. 269). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_α ratio was found to be *less* than 0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:

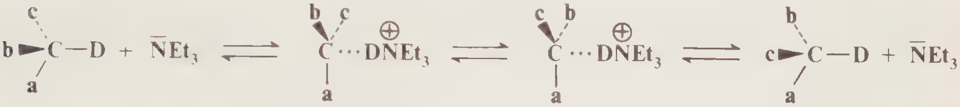
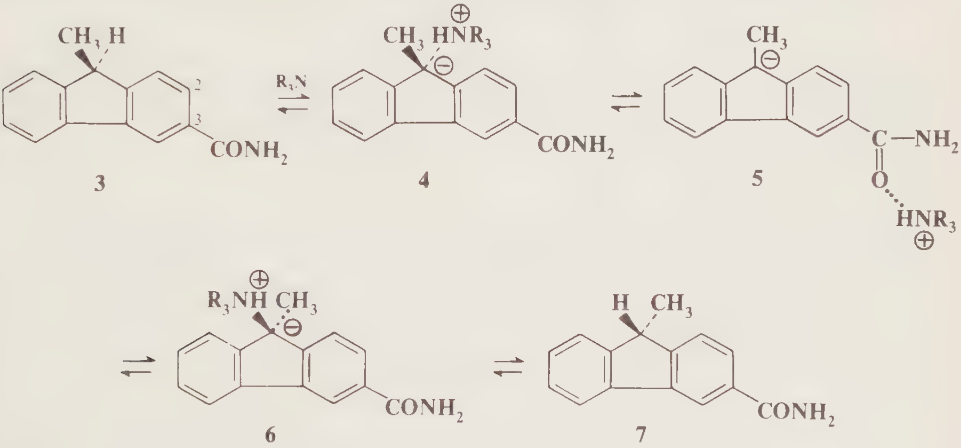
Chem. Soc.* **81,** 5754 (1959); Cram, Mateos, Hauck, Langemann, Kopecky, Nielsen, and Allinger, *J. Am. Chem. Soc.* **81,** 5774 (1959); Hoffman and Cram, *J. Am. Chem. Soc.* **91,** 1009 (1969). For a discussion, see Cram, "Fundamentals of Carbanion Chemistry," pp. 138–158, Academic Press, Inc., New York, 1965.

[23] Cram, Kingsbury, and Rickborn, *J. Am. Chem. Soc.* **83,** 3688 (1961); Cram, Rickborn, Kingsbury, and Haberfield, *J. Am. Chem. Soc.* **83,** 3678 (1961); Cram and Gosser, *J. Am. Chem. Soc.* **85,** 3890 (1963), **86,** 5445, 5457 (1964); Cram and Wingrove, *J. Am. Chem. Soc.* **86,** 5490 (1964); Kollmeyer and Cram, *J. Am. Chem. Soc.* **90,** 1779 (1968); Roitman and Cram, *J. Am. Chem. Soc.* **93,** 2225, 2231 (1971); Cram and Cram, *Intra-Sci. Chem. Rep.* **7**(3), 1–17 (1973). For a discussion, see Cram, Ref. 22, pp. 85–105.



Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion.*

The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (**3**) with Pr_3N in *t*-BuOH, it has been proposed that the amine removes a proton from the 9 position of **3** and conducts the proton out



to the C=O oxygen (**5**), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of **6** gives the inverted product **7**. Of course **5** could also go back to **3**, but a molecule which undergoes the total process **3** → **4** → **5** → **6** → **7** has experienced an inversion without an exchange. Evidence for this pathway, which is called the *conducted tour mechanism*,[24] is that the 2-carboxamido isomer of **3** does not give isoracemization. In this case the negative charge on the oxygen atom in the anion corresponding to **5** is less, because a canonical form in which oxygen acquires a full negative charge (**8**) results in disruption of the aromatic sextet in both benzene rings (compare **9** where one benzene ring is intact). Whether the isoracemization process takes place by

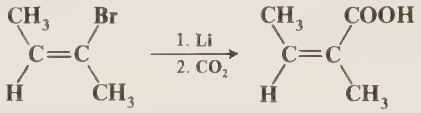
9

the conducted tour mechanism or by a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.[25]

The four types of steric behavior, retention, inversion, racemization, and isoracemization, are not mutually exclusive, and two or more processes often operate simultaneously. The k_e/k_α ratios provide only a qualitative measure of the overall stereochemical course of the reaction. Two other methods have been devised[26] to dissect the overall outcome into its components, one being a purely kinetic method and the other (called the *reresolution method*) based on isotopic analysis.[26]

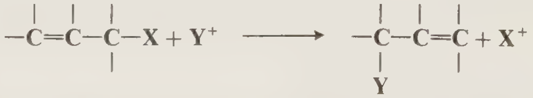
It is known that vinyl carbanions *can* maintain configuration, so that SE1 mechanisms should produce retention there. This has been found to be the case. For example, *trans*-2-bromo-2-butene was converted to 64–74% angelic acid:[27]



Only about 5% of the cis isomer, tiglic acid, was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (p. 166), and SE1 reactions involving them proceed with retention of configuration.

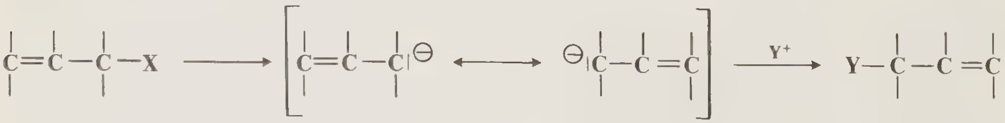
Electrophilic Substitution Accompanied by Double-Bond Shifts

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged:



$$-\overset{|}{C}=\overset{|}{C}-\underset{|}{\overset{|}{C}}-X + Y^+ \longrightarrow -\underset{\underset{Y}{|}}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}} + X^+$$

This type of process is analogous to the nucleophilic allylic shifts discussed in Chapter 10 (p. 303). There are two principal pathways. The first of these is analogous to the SE1 mechanism, in that the leaving group is first removed, giving a resonance-stabilized allyl type of carbanion, and then the electrophile attacks.



$$\underset{|}{\overset{|}{C}}=\overset{|}{C}-\underset{|}{\overset{|}{C}}-X \longrightarrow \left[\underset{|}{\overset{|}{C}}=\overset{|}{C}-\underset{|}{\overset{|}{C}}^{\ominus} \longleftrightarrow {}^{\ominus}\underset{|}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}}\right] \xrightarrow{Y^+} Y-\underset{|}{\overset{|}{C}}-\overset{|}{C}=\underset{|}{\overset{|}{C}}$$

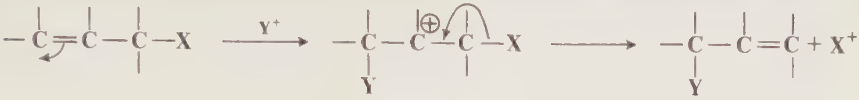
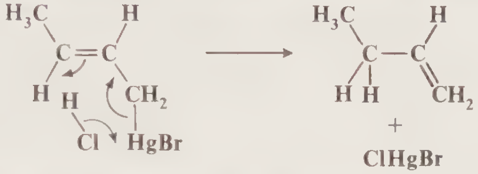
In the other pathway the Y group first attacks, giving a carbonium ion, which then loses X.

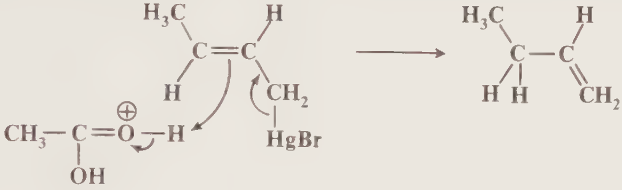


These mechanisms are more fully discussed under reaction **2-2.**

Most electrophilic allylic rearrangements involve hydrogen as the leaving group, but they have also been observed with metallic leaving groups.[28] Sleezer, Winstein, and Young found that crotylmercuric bromide reacted with HCl about 10^7 times faster than *n*-butylmercuric bromide, and the product was more than 99% 1-butene.[29] These facts point to an SEi′ mechanism:



The reaction of the same compound with acetic acid–perchloric acid seems to proceed by an SE2′ mechanism:[29]



Other Mechanisms

Elimination-addition (see reaction **2-1**), addition-elimination (reaction **2-15**), and cyclic mechanisms (reaction **2-39**) are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions, and the exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

REACTIVITY

Only a small amount of work has been done in this area, in comparison to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Only a few conclusions, most of them sketchy or tentative, can be drawn.[30]

[30] For a discussion, see Abraham, Ref. 2, pp. 211–241.

1. *Effect of substrate.* For SE1 reactions electron-donating groups decrease rates and electron-withdrawing groups increase them. This is as would be expected from a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the SE2 (back) mechanism, Jensen and Davis[8] showed that the reactivity of alkyl groups is similar to that for the SN2 mechanism (i.e., Me > Et > Pr > iso-Pr > neopentyl), as would be expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the SE2 (back) mechanism in cases where stereochemical investigation is not feasible, since the other second-order mechanisms do not show this order. It has been proposed that the SE2 (front) mechanism also has a characteristic order: Me > Et > Pr > Bu > iso-Bu > neopentyl > iso-Pr.[31] Other rate orders reported for second-order mechanisms have shown great variability. For example, rate orders of vinyl > phenyl > Et > iso-Pr > Pr > Me,[32] of *t*-Bu > *sec*-Bu > Bu > vinyl > phenyl > Me,[33] and of *t*-Bu > Me > iso-Pr ~ Et > Pr ~ Bu[34] have been reported. Part of this variability may be caused by the presence of varying amounts of SE2 (front) and SEi processes, but it has been suggested that even where reactions are compared all of which have the SEi mechanism, no single reactivity series is possible.[35] Obviously, the SEi mechanism [and perhaps the SE2 (front) mechanism also] seems to be sensitive to relatively small changes in reaction conditions.

2. *Effect of leaving group.* For both SE1 and second-order mechanisms, the more polar the C—X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence greater than 1, the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials RHgW. Because a more electronegative W decreases the polarity of the C—Hg bond and furthermore results in a less stable HgW^+, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, for example, HgR′ (from RHgR′) is a better leaving group than HgCl (from RHgCl). It might be expected that, when metals are the leaving groups, SE1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the results so far reported have been just about the reverse of this. For carbon leaving groups the mechanism is usually SE1, while for metallic leaving groups the mechanism is almost always SE2 or SEi. A number of reports of SE1 reactions with metallic leaving groups have appeared,[36] but the mechanism is not easy to prove, and many of these reports have been challenged.[37] Reutov and coworkers[36] have expressed the view that in such reactions a nucleophile (which may be the solvent) must assist in the removal of the electrofuge and refer to such processes as SE1(*N*) reactions. For second-order mechanisms the leaving group may also help determine whether the SEi or one of the SE2 mechanisms takes place. The SEi mechanism is least likely in cases where the leaving group is unable to coordinate with the incoming group and where the leaving metal is not an exceedingly strong Lewis acid.[38]

3. *Effect of solvent.* In addition to the solvent effects on certain SE1 reactions, mentioned earlier (p. 526), solvents can influence the mechanism which is preferred. As with nucleophilic substitution (p. 331), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case SE1, in comparison with the second-order mechanisms, which do not involve ions. The solvent can also exert an influence as between the SE2 (front or back) and SEi mechanisms in at

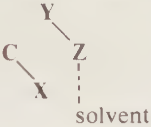
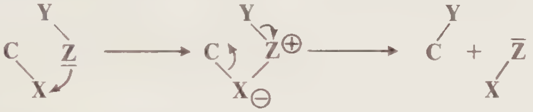
least two ways. (1) As previously mentioned (p. 523), the rates of SE2 mechanisms should be increased by an increase in solvent polarity, while SEi mechanisms are much less affected. (2) We would predict that in polar solvents SE2 mechanisms should be further favored at the expense of SEi, since in these solvents Z would be solvated, leaving it less free to attack X:[39]



Results have been found in accord with this prediction, but since the conclusions are based on reactivity order in second-order reactions, we have seen (p. 530) that they must be taken with great caution. These results are as follows. It has been found that in polar solvents, such as methanol, acetic acid, or dimethylformamide, where SE2 mechanisms would be favored (as against SEi), the second-order rate constants for the reaction $R_4Sn + X_2 \rightarrow R_3SnX + RX$ were in the order Me > Et > Pr > iso-Pr.[40] As we have seen (p. 530), this sequence is compatible with the SE2 (back) mechanism. In less polar solvents, such as chlorobenzene or carbon tetrachloride, the order was Me < Et > Pr < iso-Pr. This order is ascribed to a combination of steric and field effects. Some reactions have been found which do not follow either sequence, but rather a strict polarity sequence: Me < Et, Pr < iso-Pr < *t*-Bu.[41] It has been suggested that in such cases the mechanism involves initial bond formation between the leaving group (before it becomes detached) and the electrophile, and a subsequent bond-breaking step



This process has been called the SEC[41] or SE2 (co-ord)[42] mechanism.

REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last. The following reactions, treated in other chapters, are also electrophilic substitutions with respect to the attacking molecule: **0-86** to **0-117**, **0-123**, **3-11** to **3-16**, **5-17** to **5-21**, and **6-31** to **6-56**.

Hydrogen as Leaving Group

A. Hydrogen as the Electrophile

2-1 Hydrogen Exchange

$$R{-}H + D^+ \rightleftharpoons R{-}D + H^+$$

Hydrogen exchange can be accomplished by treatment with acids or bases. As with reaction **1-1**, the exchange reaction is mostly used to study mechanistic questions such as relative acidities, but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids such as H_2SO_4 are used, only fairly acidic protons exchange, e.g., acetylenic, allylic, etc. However, primary, secondary, and tertiary hydrogens of alkanes can be exchanged by treatment with super-acids (p. 226).[43] The order of hydrogen reactivity is tertiary > secondary > primary. Where C—C bonds are present, these may be cleaved also (reaction **2-46**). The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the

Methanonium ion

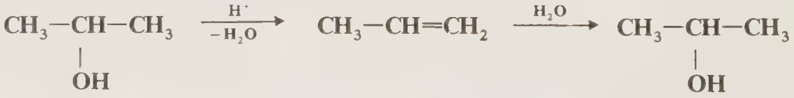
C—H bond to give the pentavalent methanonium ion which loses H_2 to give a carbonium ion. The three-center, two-electron bond is similar to that encountered in the 2-norbornyl cation (p. 297). It is not known whether the methanonium ion $CH_5{}^+$ is a transition state or a true intermediate, but an ion $CH_5{}^+$ has been detected in mass spectra.[44] Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogens, leaving the $CH_3{}^+$ free (the forward reaction), or they can unite the CH_3 with either of the two hydrogens, leaving the other hydrogen as a free H^+ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH_4 by the route shown (leading to H^+ exchange), or it can react with additional CH_4 molecules (reaction **2-16**) to yield, eventually, the *t*-butyl cation, which is stable in these super-acid solutions. Hydride ion can also be removed from alkanes (producing carbonium ions) by treatment with pure SbF_5 in the absence of any source of H^+.[45] It has been proposed[45] that SbF_5 directly abstracts the hydride ion to give $R^+ \quad SbF_5H^-$.

Exchange with bases involves an SE1 mechanism (see p. 526).

Step 1 $\qquad RH + B^- \longrightarrow R^- + BH$

Step 2 $\qquad R^- + BD \longrightarrow RD + B^-$

Of course, such exchange is most successful for relatively acidic protons, such as those α to a carbonyl group,[46] but even weakly acidic protons can exchange with bases if the bases are strong enough (see p. 161). Still another mechanism has been found for the slow acid exchange of hydrogens β to an OH group (such as the methyl protons in 2-propanol). This is an elimination-addition mechanism in which the alcohol is first dehydrated (reaction **7-1**) and then water re-adds (reaction **5-2**).[47]



$$\underset{\displaystyle OH}{CH_3-\underset{|}{CH}-CH_3} \xrightarrow[-H_2O]{H^+} CH_3-CH{=}CH_2 \xrightarrow{H_2O} \underset{\displaystyle OH}{CH_3-\underset{|}{CH}-CH_3}$$

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated by treatment with D_2 gas and a catalyst such as Rh, Pt, or Pd.[48]

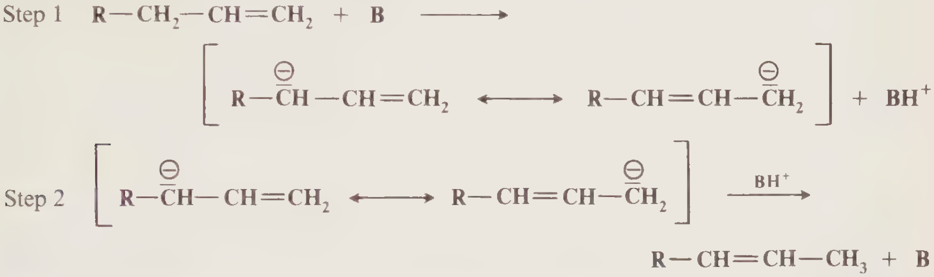
2-2 Migration of Double Bonds

$$C_5H_{11}{-}CH_2{-}CH{=}CH_2 \xrightarrow[Me_2SO]{KNH_2} C_5H_{11}{-}CH{=}CH{-}CH_3$$

The double bonds of many unsaturated compounds are shifted on treatment with strong bases.[49] In many cases equilibrium mixtures are obtained, and the most thermodynamically stable isomer predominates. Thus, if the new double bond can be in conjugation with one already present or with an aromatic ring, it goes that way. If the choice is between an exocyclic and an endocyclic double bond (in a six-membered ring), it chooses the latter. In the absence of considerations like these, Zaitsev's rule (p. 910) applies, and the double bond goes to the carbon with the fewest hydrogens. All these considerations lead us to predict that terminal olefins can be isomerized to internal ones, nonconjugated olefins to conjugated, exo six-membered-ring olefins to endo, etc., and not the other way around. This is indeed usually the case.

This reaction, for which the term *prototropic rearrangement* is often used, is an example of electrophilic substitution with an accompanying allylic rearrangement. The mechanism involves abstraction by the base to give a resonance-stabilized carbanion, which then combines with a proton at the position which will give the more stable olefin:



$$\text{Step 1}\quad R{-}CH_2{-}CH{=}CH_2 + B \longrightarrow \left[R{-}\overset{\ominus}{C}H{-}CH{=}CH_2 \longleftrightarrow R{-}CH{=}CH{-}\overset{\ominus}{C}H_2\right] + BH^+$$

$$\text{Step 2}\quad \left[R{-}\overset{\ominus}{C}H{-}CH{=}CH_2 \longleftrightarrow R{-}CH{=}CH{-}\overset{\ominus}{C}H_2\right] \xrightarrow{BH^+} R{-}CH{=}CH{-}CH_3 + B$$

This mechanism is exactly analogous to the allylic-shift mechanism for nucleophilic substitution, discussed in Chapter 10 (p. 303). Uv spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^- are identical, showing that the same carbanion is present in both cases, as required by this mechanism.[50] It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.[51] The intramolecularity has been ascribed to a conducted tour mechanism (p. 527) in which the base leads the proton from one carbanionic site to the other:[52]

[50] Rabinovich, Astaf'ev, and Shatenshtein, *J. Gen. Chem. USSR* **32,** 746 (1962).

[51] See, for example, Cram and Uyeda, *J. Am. Chem. Soc.* **86,** 5466 (1964); Bank, Rowe, and Schriesheim, *J. Am. Chem. Soc.* **85,** 2115 (1963); Doering and Gaspar, *J. Am. Chem. Soc.* **85,** 3043 (1963); Bergson, *Acta Chem. Scand.* **17,** 2691 (1963); Bergson and Ohlsson, *Acta Chem. Scand.* **21,** 1393 (1967); Ohlsson, Wold, and Bergson, *Ark. Kemi* **29,** 351 (1968).

[52] Almy and Cram, *J. Am. Chem. Soc.* **91,** 4459 (1969).

The complete process shown (**10** → **11** → **12** → **13**) leads to isomerization without the introduction of external hydrogen. However, with certain substrates and under certain conditions, **11** or **12** may exchange BH^+ with a molecule from the environment, in which case the rearrangement is intermolecular. It has been suggested that the more stable the carbanion, the greater the intramolecular character of the reaction.[53]

Triple bonds may also migrate in the presence of bases, but through the allene intermediate:[54]

$$R{-}CH_2{-}C{\equiv}CH \rightleftharpoons R{-}CH{=}C{=}CH_2 \rightleftharpoons R{-}C{\equiv}C{-}CH_3$$

In general, strong bases such as $NaNH_2$ convert internal alkynes to terminal alkynes (a particularly good base for this purpose is potassium 3-aminopropylamide $NH_2CH_2CH_2CH_2NHK$[55]), because the equilibrium is shifted by formation of the acetylide ion; while with weaker bases such as NaOH (which are not strong enough to remove the acetylenic proton), the internal alkynes are favored because of their greater thermodynamic stability. In some cases the reaction can be stopped at the allene stage, and the reaction then becomes a method for the preparation of allenes.[56]

Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained, giving a carbonium ion; and then another is lost:

$$\text{Step 1} \quad CH_3{-}CH_2{-}CH{=}CH_2 + H^+ \longrightarrow CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3$$

$$\text{Step 2} \quad CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3 \longrightarrow CH_3{-}CH{=}CH{-}CH_3 + H^+$$

As in the case of the base-catalyzed reaction, the thermodynamically most stable olefin is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbonium ions give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture which contains not only 1-decene and *cis-* and *trans-*2-decene, but also the cis and trans isomers of 3-, 4-, and 5-decene, as well as branched alkenes resulting from rearrangement of carbonium ions. It is true that the most stable olefins predominate, but many of them have stabilities which are close together. Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., $HF{-}PF_5$) are used.[57] If the mechanism is the same as that for double bonds, then vinyl cations are intermediates.

Double-bond isomerization may also take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (p. 303). Electrocyclic and sigmatropic rearrangements are treated at reactions **8-32** to **8-40.** Isomerization of double bonds with HBr or I_2 and uv light is a free-radical process:[58]

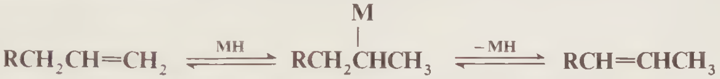
$$HBr \xrightarrow{h\nu} Br\cdot + H\cdot$$

$$CH_3CH_2CH{=}CH_2 + Br\cdot \longrightarrow$$

$$[CH_3{-}\dot{C}H{-}CH{=}CH_2 \longleftrightarrow CH_3{-}CH{=}CH{-}\dot{C}H_2] + HBr$$

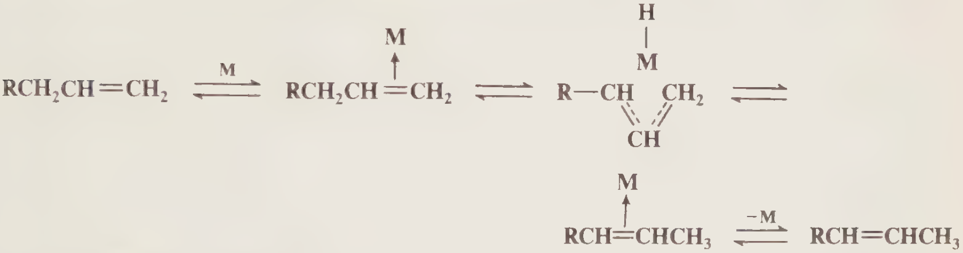
$$CH_3CH{=}CH\dot{C}H_2 + HBr \longrightarrow CH_3CH{=}CHCH_3 + Br\cdot$$

Olefins may also be isomerized on pyrolysis at, say, 400 to 500°C. Carbonium ions are presumably involved. Double-bond migrations have also been accomplished photochemically,[59] and by means of metallic ion or metal carbonyl catalysts.[60] In the latter case there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition-elimination mechanism*:



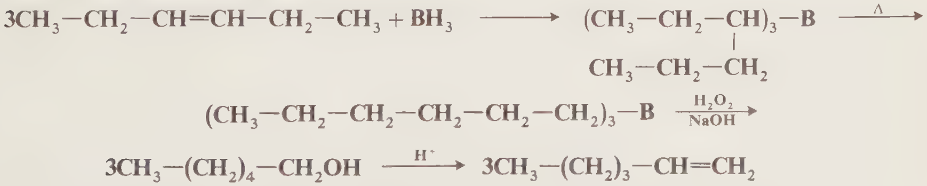
$$RCH_2CH{=}CH_2 \xrightleftharpoons{MH} RCH_2\overset{\displaystyle M}{\overset{|}{C}}HCH_3 \xrightleftharpoons{-MH} RCH{=}CHCH_3$$

The other mechanism, called the *π-allyl complex mechanism*, does not require external hydrogen:



Another difference between the two mechanisms is that the former involves 1,2 and the latter 1,3 shifts. The isomerization of 1-butene by rhodium(I) is an example of a reaction which takes place by the metal hydride mechanism,[61] while an example of the π-allyl complex mechanism is found in the $Fe_3(CO)_{12}$-catalyzed isomerization of 3-ethyl-1-pentene.[62]

No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable olefin is usually formed in the largest amount in most cases, though a few anomalies are known. However, there is another, indirect, method of double-bond isomerization, by means of which migration in the other direction can often be carried out. This involves conversion of the olefin to a borane (reaction **5-15**), rearrangement of the borane (reaction **8-14**), oxidation and hydrolysis of the newly formed borane to the alcohol (reaction **2-26**), and dehydration of the alcohol (reaction **7-1**):



$$3CH_3{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_3 + BH_3 \longrightarrow (CH_3{-}CH_2{-}\underset{\displaystyle CH_3{-}CH_2{-}CH_2}{\underset{|}{C}H})_3{-}B \xrightarrow{\Delta}$$

$$(CH_3{-}CH_2{-}CH_2{-}CH_2{-}CH_2{-}CH_2)_3{-}B \xrightarrow[NaOH]{H_2O_2}$$

$$3CH_3{-}(CH_2)_4{-}CH_2OH \xrightarrow{H^+} 3CH_3{-}(CH_2)_3{-}CH{=}CH_2$$

[62] Casey and Cyr, *J. Am. Chem. Soc.* **95**, 2248 (1973).

Since the migration reaction is always toward the end of a chain, terminal olefins may be produced from internal ones, so that the migration is often opposite to that with the other methods. Alternatively, the rearranged borane may be converted directly to the olefin by heating with an alkene of molecular weight higher than that of the product (reaction **7-15**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.[63]

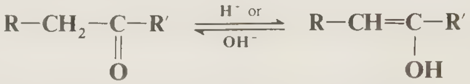
If a hydroxy group is present in the chain, *it* may lose a proton, so that a ketone is the product. For example,[64]

$$R_2C{=}CHCH_2CH_2CHOHCH_3 \xrightarrow[\text{acid}]{\text{polyphosphoric}} R_2CHCH_2CH_2CH_2COCH_3$$

Similarly, α-hydroxy triple-bond compounds have given α,β-unsaturated ketones.

OS **II,** 140; **III,** 207; **IV,** 189, 192, 195, 234, 398, 683; **50,** 97; **51,** 17; **54,** 1; **55,** 12.

2-3 Keto-Enol Tautomerization

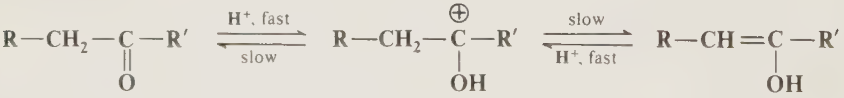


$$R-CH_2-\underset{\underset{O}{\|}}{C}-R' \underset{OH^-}{\overset{H^+\text{ or}}{\rightleftharpoons}} R-CH=\underset{\underset{OH}{|}}{C}-R'$$

The tautomeric equilibrium between enols and ketones or aldehydes is not normally a preparative reaction, though for some ketones both forms can be prepared (see p. 71 for a discussion of this and other aspects of tautomerism). For most ketones and aldehydes, only the keto form is detectable, though the equilibrium must occur, since aldehydes and ketones often react through their enol forms.

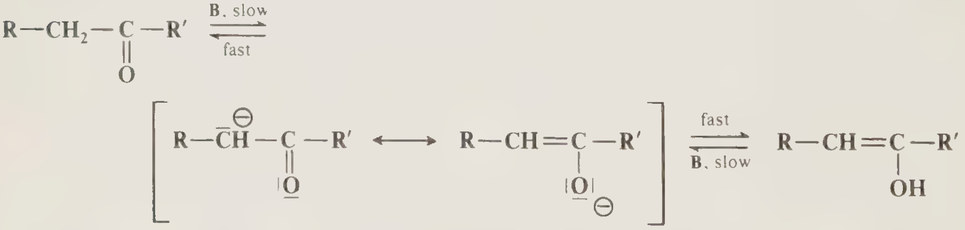
Neither the forward nor the reverse reaction can take place without at least a trace of acid or base, ruling out a direct shift of a hydrogen from carbon to oxygen, or vice versa. The mechanisms are identical to those in reaction **2-2**:[65]

Acid-catalyzed



$$R-CH_2-\underset{\underset{O}{\|}}{C}-R' \underset{\text{slow}}{\overset{H^+\text{, fast}}{\rightleftharpoons}} R-CH_2-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R' \underset{H^+\text{, fast}}{\overset{\text{slow}}{\rightleftharpoons}} R-CH=\underset{\underset{OH}{|}}{C}-R'$$

Base-catalyzed



$$R-CH_2-\underset{\underset{O}{\|}}{C}-R' \underset{\text{fast}}{\overset{B\text{, slow}}{\rightleftharpoons}} \left[R-\overset{\ominus}{\overline{C}H}-\underset{\underset{|\underline{O}}{\|}}{C}-R' \longleftrightarrow R-CH=\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}-R'\right] \underset{B\text{, slow}}{\overset{\text{fast}}{\rightleftharpoons}} R-CH=\underset{\underset{OH}{|}}{C}-R'$$

14

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of microscopic reversibility. As expected from mechanisms in which the C—H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of about 5) in both the basic-[66] and the acid[67]-catalyzed processes.

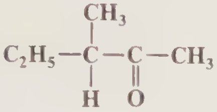
Chem.* **33,** 1671 (1968); Barltrop and Wills, *Tetrahedron Lett.* 4987 (1968); Jorgenson and Gundel, *Tetrahedron Lett.* 4991 (1968); Reardon and Krauss, *J. Am. Chem. Soc.* **93,** 5593 (1971).

[64] Colonge and Brunie, *Bull. Soc. Chim. Fr.* 1799 (1963).

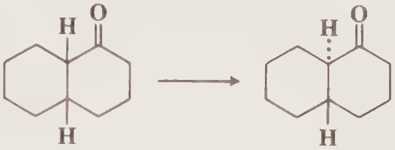
[65] For discussions of the mechanism, see Ingold, "Structure and Mechanism in Organic Chemistry," 2d ed., pp. 794–837, Cornell University Press, Ithaca, N.Y., 1969; Bell, "The Proton in Chemistry," 2d ed., pp. 171–181, Cornell University Press, Ithaca, N.Y., 1973; Bruice and Bruice, *J. Am. Chem. Soc.* **98,** 844 (1976).

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. If a full mole of base per mole of ketone is used, then the enolate ion (**14**) is formed and can be isolated. When enol ethers or esters are hydrolyzed, the enols initially formed immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to an asymmetric carbon α to a carbonyl group (as in **15**) is treated with acid or base, racemization results. If there is another asymmetric center in the molecule, the less stable epimer may be converted to the more stable one in this manner, and this is often done. For example, *cis*-decalone (**16**) may be equilibrated to the trans isomer. Isotopic exchange may also be accomplished at the α-position of an aldehyde or ketone in a similar manner. For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic.



$$C_2H_5-\underset{H}{\overset{CH_3}{C}}-\underset{O}{\underset{\|}{C}}-CH_3$$

15



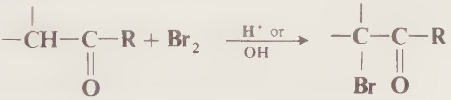
16

Enolizable hydrogens may be replaced by deuterium (and ^{16}O by ^{18}O) by passage of a sample through a deuterated (or ^{18}O-containing) gas-chromatography column.[68]

There are many enol-keto interconversions and acidifications of enolate ions to the keto forms listed in *Organic Syntheses*. No attempt is made to list them here.

B. Halogen Electrophiles

2-4 Halogenation of Aldehydes and Ketones



$$-\overset{|}{CH}-\underset{O}{\underset{\|}{C}}-R + Br_2 \xrightarrow[OH]{H^+\text{ or}} -\underset{Br}{\underset{|}{\overset{|}{C}}}-\underset{O}{\underset{\|}{C}}-R$$

Aldehydes and ketones may be halogenated in the α-position with bromine, chlorine, or iodine.[69] The reaction cannot be performed with fluorine, but active compounds, such as β-keto esters, have been fluorinated by treating the enolate ion with perchloryl fluoride ($FClO_3$).[70] However, if the

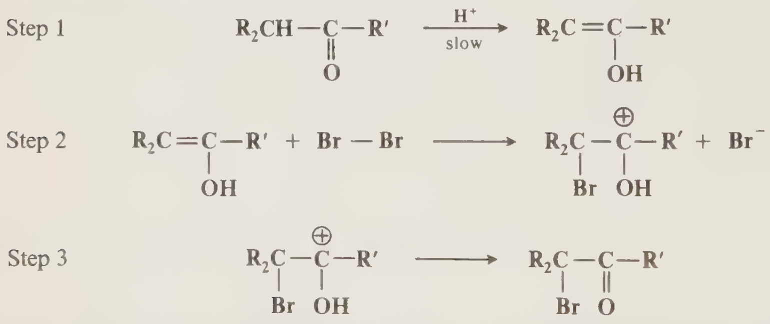
Mack Library
Bob Jones University
Greenville, SC

carbon attacked with $FClO_3$ has two hydrogens, then the reaction cannot be stopped until two fluorines have entered. Monofluorination can be accomplished indirectly, by treating an enamine, enol ether, or similar ketone derivative with $FClO_3$.[71] Trifluoromethyl hypofluorite CF_3OF and similar compounds behave similarly.[72] Sulfuryl chloride[73] and cupric chloride[74] have been used as reagents for chlorination, and N-bromosuccinimide for bromination (see reaction **4-2**). Pyrrolidone hydrotribromide is a reagent which can α-brominate a ketone without affecting a double bond also present.[75]

For unsymmetrical ketones the preferred position of halogenation is usually a CH group, then a CH_2 group, and then CH_3; however, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced (see reaction **4-3**). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one α-position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogens of the first carbon have been replaced (see below). If one of the groups is methyl, then the haloform reaction (**2-43**) takes place. With acid catalysts, it is easy to stop the reaction after only one halogen has entered, though a second halogen can be introduced by the use of excess reagent. In chlorination the second halogen generally appears on the same side as the first,[76] while in bromination the α,α′-dibromo product is found.[77] Actually, with both halogens it is the α,α-dihalo ketone which is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α′ isomer.[76] Sometimes acetals and ketals are brominated directly.

It is not the aldehyde or ketone itself which is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate. The reaction is often done without addition of acid or base, and even in the vapor state,[78] but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is



Step 1 $$R_2CH-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[\text{slow}]{H^+} R_2C{=}\underset{\underset{OH}{|}}{C}-R'$$

Step 2 $$R_2C{=}\underset{\underset{OH}{|}}{C}-R' + Br-Br \longrightarrow R_2\underset{\underset{Br}{|}}{C}-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R' + Br^-$$

Step 3 $$R_2\underset{\underset{Br}{|}}{C}-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-R' \longrightarrow R_2\underset{\underset{Br}{|}}{C}-\underset{\underset{O}{\|}}{C}-R'$$

The first step, as we have already seen (reaction **2-3**), actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (p. 672). There is a great deal of evidence for this mechanism: (1) the rate is first order in substrate; (2) the bromine does not appear in the rate expression at all, a fact consistent with a rate-determining first step,[79] (3) the rate of the reaction is the same for bromination, chlorination, and iodination under the same conditions;[80] and (4) the reaction shows an isotope effect. With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:[81]

---

[71] For example, see Gabbard and Jensen, *J. Org. Chem.* **23**, 1406 (1958); Nakanishi, Morita, and Jensen, *J. Am. Chem. Soc.* **81**, 5259 (1959); Nakanishi and Jensen, *J. Org. Chem.* **27**, 702 (1962).

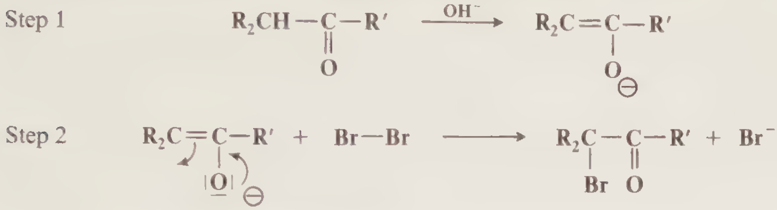
[74] For a review, see Nigh, in Trahanovsky, "Oxidation in Organic Chemistry," pt. B, pp. 67–81, Academic Press, Inc., New York, 1973. Cupric chloride has been used to chlorinate α,β-unsaturated aldehydes and ketones in the γ position: Dietl, Normark, Payne, Thweatt, and Young, *Tetrahedron Lett.* 1719 (1973).

[75] Awang and Wolfe, *Can. J. Chem.* **47**, 706 (1969).

[76] Rappe, *Ark. Kemi* **24**, 321 (1965). But see also Teo and Warnhoff, *J. Am. Chem. Soc.* **95**, 2728 (1973).

[77] Rappe and Schotte, *Acta Chem. Scand.* **16**, 2060 (1962); Rappe, *Acta Chem. Scand.* **16**, 2467 (1962), *Ark. Kemi* **21**, 503 (1964); Garbisch, *J. Org. Chem.* **30**, 2109 (1965).

[78] Dick, *J. Org. Chem.* **27**, 272 (1962).

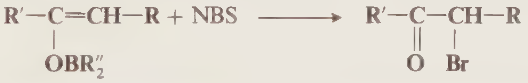


Step 1 $$R_2CH-\underset{\underset{\displaystyle O}{\|}}{C}-R' \xrightarrow{OH^-} R_2C=\underset{\underset{\displaystyle O^{\ominus}}{|}}{C}-R'$$

Step 2 $$R_2C=\underset{\underset{\displaystyle \overline{|O|}^{\ominus}}{|}}{C}-R' + Br-Br \longrightarrow R_2\underset{\underset{\displaystyle Br}{|}}{C}-\underset{\underset{\displaystyle O}{\|}}{C}-R' + Br^-$$

It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three α-halogens on the same side of the C=O group, then it is not possible to stop the reaction after just one halogen atom has entered. The reason for this is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogens: that is, a CHX group is more acidic than a CH_2 group, so that initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate. It has been reported that the halogen atom also increases the acidity of hydrogens in the α′ position, but generally to a lesser degree,[82] though it can be to a greater degree in cases where the approach of the base is sterically hindered.[83]

Regiospecificity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with N-bromo- or N-chlorosuccinimide.[84]



$$R'-\underset{\underset{\displaystyle OBR''_2}{|}}{C}=CH-R + NBS \longrightarrow R'-\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle Br}{|}}{CH}-R$$

The desired halo ketone is formed in high yield. In no case was the unwanted isomer found. Another method for achieving the same result involves bromination of the appropriate lithium enolate at a low temperature[85] (see p. 424 for the regiospecific formation of enolate ions). In a similar process, α-bromo and α-chloro aldehydes have been prepared in good yield by treatment of trimethylsilyl enol ethers $R_2C=CHOSiMe_3$ with Br_2 or Cl_2.[86]

---

[79] Under some conditions it is possible for step 2 to be rate-determining: Deno and Fishbein, *J. Am. Chem. Soc.* **95,** 7445 (1973).

[80] Bell and Yates, *J. Chem. Soc.* 1927 (1962).

[81] It has been suggested that base-catalyzed halogenation may also take place by a mechanism which does not go through either enol or enolate [Rappe, *Acta Chem. Scand.* **20,** 1721 (1966), **21,** 857, 1823 (1967), **22,** 219 (1968)], but evidence against this view has been presented: Swain and Dunlap, *J. Am. Chem. Soc.* **94,** 7204 (1972); Thorpe and Warkentin, *Can. J. Chem.* **50,** 3229 (1972); Cox and Warkentin, *Can. J. Chem.* **50,** 3233 (1972); Cox, Thorpe, and Warkentin, *Can. J. Chem.* **50,** 3239 (1972); Knipe and Cox, *J. Org. Chem.* **38,** 3429 (1973), *J. Chem. Soc., Perkin Trans. 2* 1391 (1973).

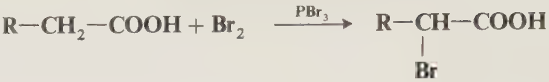
2-5 Halogenation of Acids and Acyl Halides



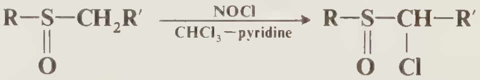
$$R{-}CH_2{-}COOH + Br_2 \xrightarrow{PBr_3} R{-}\underset{\displaystyle Br}{\underset{|}{CH}}{-}COOH$$

The α-hydrogens of carboxylic acids may be replaced by bromine or chlorine.[87] The reaction, known as the *Hell-Volhard-Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two α-hydrogens, one or both may be replaced, although it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed from the acid and the catalyst. Acids alone are inactive, except for those with relatively high enol content, such as malonic. Less than one full mole of catalyst (per mole of substrate) is required, because of the exchange reaction between acids and acyl halides (see reaction **0-75**). Each molecule of acid is α-halogenated while it is in the acyl halide stage. The halogen from the catalyst does not enter the α position. For example, the use of Cl_2 and PBr_3 results in α chlorination, not bromination. As expected from the foregoing, acyl halides undergo α halogenation without a catalyst. So do anhydrides and many compounds which enolize easily, e.g., malonic ester, aliphatic nitro compounds, etc. The mechanism is usually regarded as proceeding through the enol as in reaction **2-4.**[88]

A number of other methods exist for the α halogenation of acids or of their derivatives. Carboxylic acids or their chlorides or anhydrides can be α-chlorinated by treatment with $CuCl_2$ in polar inert solvents (e.g., sulfolane).[89] Acyl halides can be α-brominated or α-chlorinated by use of N-bromo- or N-chlorosuccinimide and HBr or HCl.[90] The latter is an ionic and not a free-radical halogenation (see reaction **4-2**). Acyl chlorides can be α-iodinated with I_2 and a trace of HI.[90] Esters can be α-iodinated by conversion to their enolate ions with lithium N-isopropylcyclohexylamide in tetrahyrofuran and addition of this solution at −78°C to a solution of I_2 in tetrahydrofuran.[91]

OS **I,** 115, 245; **II,** 74, 93; **III,** 347, 381, 495, 523, 623, 705, 848; **IV,** 254, 348, 398, 608, 616; **V,** 255; **50,** 31; **55,** 27. Also see OS **IV,** 877.

2-6 Halogenation of Sulfoxides and Sulfones



$$R{-}\underset{\displaystyle O}{\underset{\|}{S}}{-}CH_2R' \xrightarrow[CHCl_3-\text{pyridine}]{NOCl} R{-}\underset{\displaystyle O}{\underset{\|}{S}}{-}\underset{\displaystyle Cl}{\underset{|}{CH}}{-}R'$$

Sulfoxides can be chlorinated in the α position[92] by treatment with NOCl,[93] Cl_2,[94] TsCl,[95] or $PhICl_2$,[96] all in the presence of pyridine, or with N-chlorosuccinimide and K_2CO_3,[97] or *t*-BuOCl and KOAc (or pyridine).[98] All these methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2.[99] The bromination of sulfoxides with bromine[96] and with N-bromosuccinimide-bromine[100] have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases $RSO_2\overset{\ominus}{\bar{C}}HR'$ with various reagents, among them SO_2Cl_2, N-chlorosuccinimide,[101] and hexachloroethane.[102]

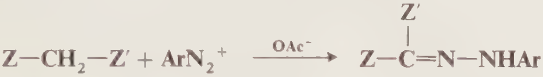
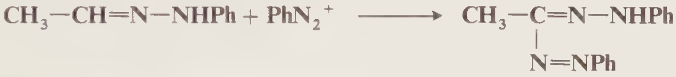
C. Nitrogen Electrophiles

2-7 Aliphatic Diazonium Coupling



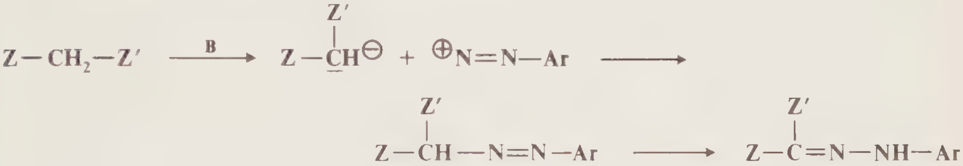
$$Z{-}CH_2{-}Z' + ArN_2^+ \xrightarrow{OAc^-} Z{-}\overset{\overset{\displaystyle Z'}{|}}{C}{=}N{-}NHAr$$

If a C—H bond is acidic enough, it couples with diazonium salts in the presence of a base, most often aqueous sodium acetate.[103] The reaction is commonly carried out on compounds of the form $Z{-}CH_2{-}Z'$, where Z and Z′ are as defined on p. 419, for example, β-keto esters, β-keto amides, malonic ester, nitroalkanes (in this case, only one Z is required), etc. However, certain compounds not of the form $Z{-}CH_2{-}Z'$ also give the reaction. Among these are conjugated dienes, where coupling takes place at the end of the conjugated system, and arylhydrazones, which give formazans:



$$CH_3{-}CH{=}N{-}NHPh + PhN_2^+ \longrightarrow CH_3{-}\underset{\underset{\displaystyle N{=}NPh}{|}}{C}{=}N{-}NHPh$$

The mechanism is probably of the simple SE1 type:



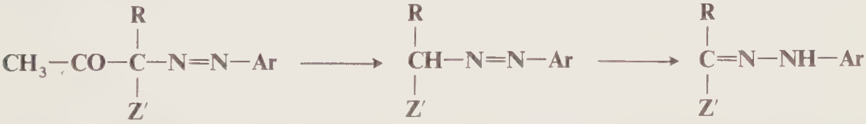
$$Z{-}CH_2{-}Z' \xrightarrow{B} Z{-}\overset{\overset{\displaystyle Z'}{|}}{\underline{C}}H^{\ominus} + {}^{\oplus}N{=}N{-}Ar \longrightarrow$$

$$Z{-}\overset{\overset{\displaystyle Z'}{|}}{C}H{-}N{=}N{-}Ar \longrightarrow Z{-}\overset{\overset{\displaystyle Z'}{|}}{C}{=}N{-}NH{-}Ar$$

17 **18**

Aliphatic azo compounds which contain a hydrogen at the carbon containing the azo group (**17**) are unstable and tautomerize to the isomeric hydrazones (**18**), which are therefore the products of the reaction.

When the reaction is carried out on a compound of the form $Z{-}CHR{-}Z'$, so that the azo compound does not have a tautomerizable hydrogen, if at least one Z is acyl or carboxyl, this group usually cleaves:



$$CH_3{-}CO{-}\overset{\overset{\displaystyle R}{|}}{\underset{\underset{\displaystyle Z'}{|}}{C}}{-}N{=}N{-}Ar \longrightarrow \overset{\overset{\displaystyle R}{|}}{\underset{\underset{\displaystyle Z'}{|}}{C}}H{-}N{=}N{-}Ar \longrightarrow \overset{\overset{\displaystyle R}{|}}{\underset{\underset{\displaystyle Z'}{|}}{C}}{=}N{-}NH{-}Ar$$

19

so that the product in this case too is the hydrazone, and not the azo compound. In fact, compounds of the type **19** are seldom isolable from the reaction, although this has been accomplished.[104] The cleavage step shown is actually an example of reaction **2-42** and, when a carboxyl group cleaves, of reaction **2-39.** The overall reaction in this case is called the *Japp-Klingemann reaction*[105] and involves conversion of a ketone (**20**) or an acid (**21**) to a hydrazone (**22**). When an acyl and a carboxyl group are both present, it is the carboxyl which preferentially cleaves. When

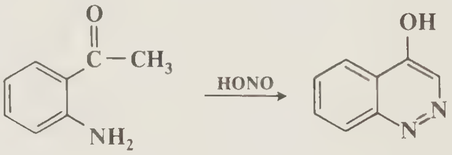
$$-\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{\underset{O}{\|}}{C}-R \longrightarrow -\underset{|}{C}=N-NHAr \longleftarrow -\overset{H}{\underset{|}{\overset{|}{C}}}-COOH$$

20 **22** **21**

there is no acyl or carboxyl group present, then the aliphatic azo compound is stable (for example, the formazan shown above).

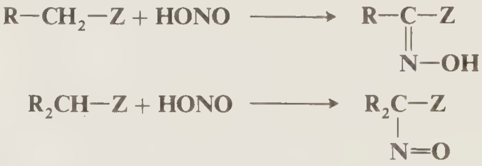
The reaction is occasionally used for ring closure:



In this case the ketone first formed tautomerizes to give the aromatic ring.

OS **III,** 660; **IV,** 633.

2-8 Nitrosation at a Carbon Bearing an Active Hydrogen



$$R-CH_2-Z + HONO \longrightarrow R-\underset{\underset{N-OH}{\|}}{C}-Z$$

$$R_2CH-Z + HONO \longrightarrow R_2\underset{\underset{N=O}{|}}{C}-Z$$

Carbons adjacent to a Z group (as defined on p. 419) may be nitrosated with nitrous acid or alkyl nitrites.[106] The initial product is always the C-nitroso compound, but these are stable only when there is no tautomerizable hydrogen. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds and hydrazones (reaction **2-7**). The mechanism is similar to that in reaction **2-7:**

$$R-H \rightarrow R^- + {}^+N=O \longrightarrow R-N=O$$

The attacking species is either NO^+ or a carrier of it. As in the Japp-Klingemann reaction, when Z is an acyl or carboxyl group (in the case of R_2CH-Z), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of reaction **2-4,** the trimethylsilyl enol ether of a ketone may be used instead of the ketone itself.[107]

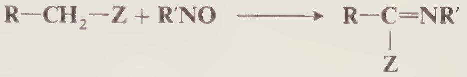
[107] Rasmussen and Hassner, *J. Org. Chem.* **39,** 2558 (1974).

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:

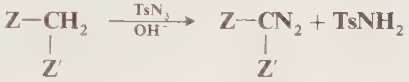


$$\mathrm{R{-}CH_2{-}Z + R'NO \longrightarrow R{-}\underset{\displaystyle Z}{\underset{|}{C}}{=}NR'}$$

Alkanes can be nitrosated photochemically, by treatment with NOCl and uv light.[108] For nitration at an activated carbon, see reaction **4-12.**

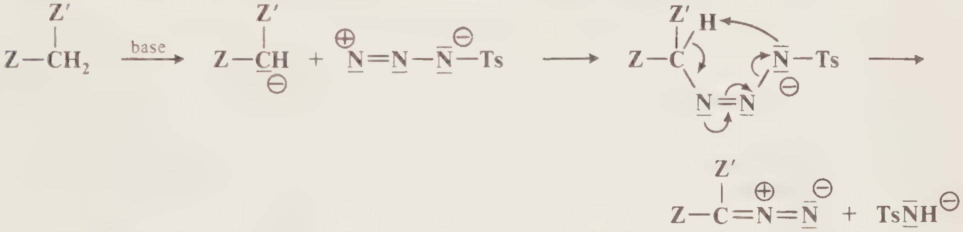
OS **II,** 202, 204, 223, 363; **III,** 191, 513; **V,** 32, 373; **52,** 53. Also see OS **V,** 650.

2-9 Direct Formation of Diazo Compounds

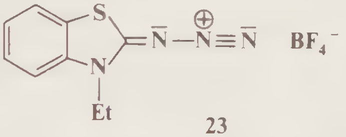


$$\mathrm{Z{-}\underset{\displaystyle Z'}{\underset{|}{C}}H_2 \xrightarrow[OH^-]{TsN_3} Z{-}\underset{\displaystyle Z'}{\underset{|}{C}}N_2 + TsNH_2}$$

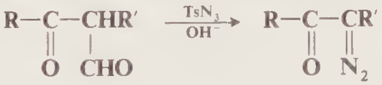
Compounds containing a CH_2 bonded to two Z groups (as defined on p. 419) may be converted to diazo compounds on treatment with tosyl azide in the presence of a base.[109] The use of phase-transfer catalysis (p. 358) increases the convenience of the method.[110] The reaction, which is called the *diazo transfer reaction*, can also be applied to other reactive positions, e.g., the 5 position of cyclopentadiene[110a] (to give **34** on p. 46). The mechanism is probably as follows:



Certain azidinium salts, e.g., 3-ethyl-2-azidobenzothiazolium fluoborate (**23**), may be used instead of tosyl azide. A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α-formyl ketone (reaction **0-111**) and then treating with tosyl azide. As in the similar case of reactions **2-7** and **2-8,** the formyl group is cleaved during the reaction.



23



$$\mathrm{R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}\underset{\displaystyle CHO}{\underset{|}{C}}HR' \xrightarrow[OH^-]{TsN_3} R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}\underset{\displaystyle N_2}{\underset{\|}{C}}R'}$$

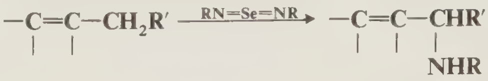
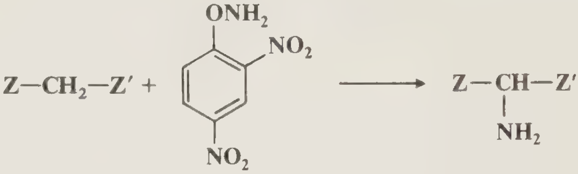
2-10 Direct Amination at an Activated Position



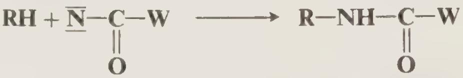
$$-\underset{|}{C}=\underset{|}{C}-CH_2R' \xrightarrow{RN=Se=NR} -\underset{|}{C}=\underset{|}{C}-\underset{\underset{NHR}{|}}{C}HR'$$

R = *t*-Bu, Ts

Alkenes can be aminated in the allylic position by treatment with solutions of imido selenium compounds R—N=Se=N—R.[111] The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see reaction **4-4**), has been performed with R = *t*-Bu and R = Ts. The imido sulfur compound TsN=S=NTs has also been used.[111a] In another reaction, compounds containing an active hydrogen can be converted to primary amines, in moderate yields, by treatment with O-(2,4-dinitrophenyl)hydroxylamine.[112]



2-11 Insertion by Nitrenes



$$RH + \underline{N}-\underset{\underset{O}{\|}}{C}-W \longrightarrow R-NH-\underset{\underset{O}{\|}}{C}-W$$

Carbonylnitrenes NCOX (W = R', Ar, or OR') are very reactive species (see p. 184) and insert into the C—H bonds of alkanes to give amides (W = R' or Ar) or carbamates (W = OR').[113] The nitrenes are generated as discussed on p. 185. The order of reactivity among alkane C—H bonds is tertiary > secondary > primary.[114] In cyclohexyl systems, equatorial C—H bonds are preferred to axial C—H bonds.[115] Indications are that in general it is only singlet and not triplet nitrenes which insert.[116] Retention of configuration is found at a chiral carbon.[117] The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (reaction **2-18**). Other nitrenes (e.g., cyanonitrene NCN[118] and arylnitrenes NAr) can also insert into C—H bonds, but alkylnitrenes usually undergo rearrangement before they can react with the alkane. The insertion reactions are not generally useful synthetically, since they usually lead to mixtures of products, but exceptions are known,[119] chiefly in cyclizations. For example, heating of 2-(2-methylbutyl)phenyl azide gave about 60% 2-ethyl-2-methylindoline.[117]

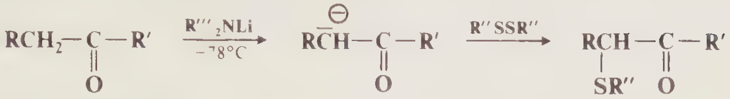
D. Sulfur Electrophiles

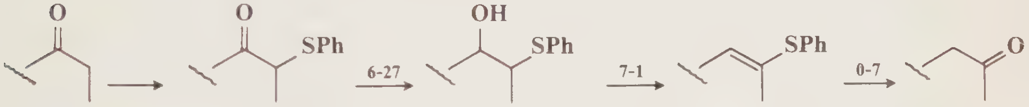
2-12 Sulfenylation and Selenylation of Ketones and Esters



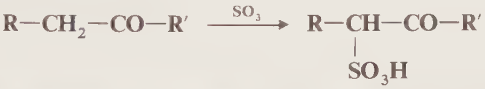
$$\mathrm{RCH_2{-}\underset{\overset{\|}{O}}{C}{-}R'} \xrightarrow[-78^\circ\mathrm{C}]{\mathrm{R'''_2NLi}} \mathrm{R\overset{\ominus}{\bar{C}}H{-}\underset{\overset{\|}{O}}{C}{-}R'} \xrightarrow{\mathrm{R''SSR''}} \mathrm{\underset{\overset{|}{SR''}}{RCH}{-}\underset{\overset{\|}{O}}{C}{-}R'}$$

Ketones and esters (including lactones) can be sulfenylated in the α position by conversion to the enolate ion with a base such as lithium N-isopropylcyclohexylamide and treatment of this with a disulfide.[120] The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. Analogously, α-phenylseleno ketones RCH(SePh)COR′ and α-phenylseleno esters RCH(SePh)-COOR′ can be prepared by treatment of the corresponding enolates with PhSeBr[121] or PhSeSePh.[122] Another method for the introduction of a phenylseleno group into the α position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.[123] This procedure is also successful for aldehydes but not for esters.

The α-seleno and α-sulfenyl carbonyl compounds prepared by this reaction can be converted to α,β-unsaturated carbonyl compounds (reaction **7-12**). The sulfenylation reaction has also been used as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon[124] (see also reaction **7-8**):



2-13 Sulfonation of Aldehydes, Ketones, and Acids

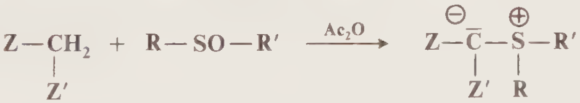


$$\mathrm{R{-}CH_2{-}CO{-}R'} \xrightarrow{\mathrm{SO_3}} \mathrm{R{-}\underset{\overset{|}{SO_3H}}{CH}{-}CO{-}R'}$$

Aldehydes, ketones, and carboxylic acids containing α hydrogens can be sulfonated with sulfur trioxide.[125] The mechanism is presumably similar to that of reaction **2-4**. Sulfonation has also been accomplished at vinylic hydrogen.

OS **IV**, 846, 862.

2-14 Formation of Sulfur Ylides from Sulfoxides and Active Methylene Compounds



$$\mathrm{Z{-}\underset{\overset{|}{Z'}}{CH_2}} + \mathrm{R{-}SO{-}R'} \xrightarrow{\mathrm{Ac_2O}} \mathrm{Z{-}\underset{\overset{|}{Z'}}{\overset{\ominus}{\bar{C}}}{-}\underset{\overset{|}{R}}{\overset{\oplus}{S}}{-}R'}$$

Compounds containing a CH_2 connected to two Z groups (as defined on p. 419) react with sulfoxides (most often dimethyl sulfoxide) in the presence of acetic anhydride,[126] or of dicyclohexylcarbodiimide in polyphosphoric acid,[127] thionyl chloride, P_2O_5, or protonic acids, to give stable sulfur ylides.[128]

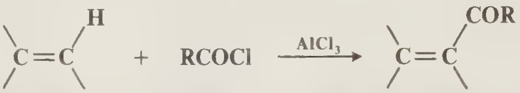
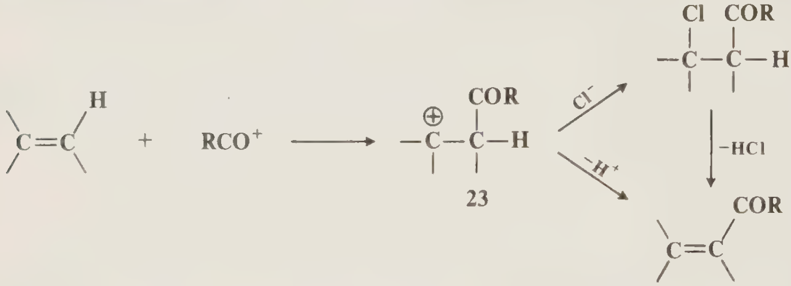
E. Carbon Electrophiles With respect to the attacking molecule, these are nucleophilic substitutions.

2-15 Acylation at an Aliphatic Carbon



Olefins can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a Friedel-Crafts reaction at an aliphatic carbon.[129] The product can arise by two paths. The initial attack is by the acyl cation RCO^+ (or by the acyl halide free or complexed; see reaction **1-15**) on the olefin to give a carbonium ion:



The carbonium ion (**23**) may either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone, and the mechanism is similar to the tetrahedral mechanism of Chapter 10, but with the charges reversed. If it combines with chloride, the product is a β-halo ketone, which can be isolated, so that the result is addition to the double bond (see reaction **5-38**). On the other hand, the β-halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition-elimination mechanism. In the case of unsymmetrical olefins, the attacking ion prefers the position at which there are more hydrogens, following Markovnikov's rule (p. 687). Anhydrides and carboxylic acids (the latter with a proton acid such as anhydrous HF, H_2SO_4, or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. Even alkanes can be acylated with acyl halides and a Friedel-Crafts catalyst if there is present a trace of a compound, such as an olefin, which can give rise to carbonium ions. With some substrates and catalysts double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.[130]

Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π-alkyl carbonyl derivatives.[131] The reaction is very general and seems to be applicable to all alkyl- and acylcobalt tetracarbonyls and all

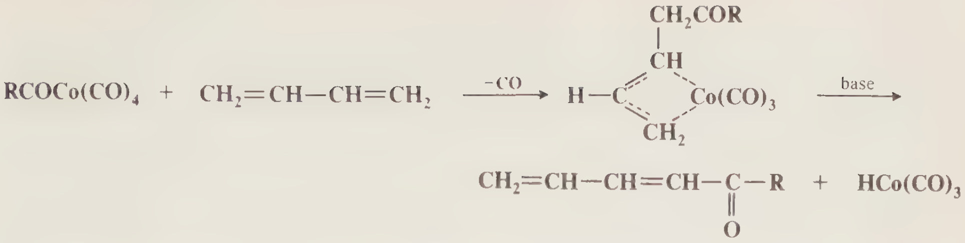
Rev.* **1,** 73–97 (1972); House, Ref. 69, pp. 786–797; Satchell and Satchell, in Patai, "The Chemistry of the Carbonyl Group," vol. 1, pp. 259–266, 270–273, Interscience Publishers, New York, 1966; Nenitzescu and Balaban, in Olah, "Friedel-Crafts and Related Reactions," vol. 3, pp. 1033–1152, Interscience Publishers, New York, 1964.

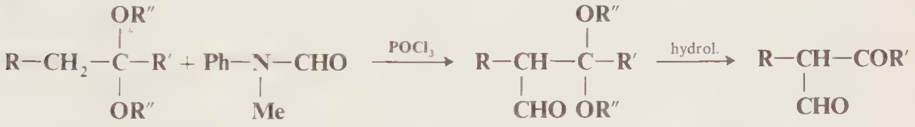
[130] Deno and Chafetz, *J. Am. Chem. Soc.* **74,** 3940 (1952); Groves and Jones, *J. Chem. Soc. C* 2215 (1968).

[131] For a review, see Heck, in Wender and Pino, "Organic Syntheses via Metal Carbonyls," vol. 1, pp. 388–397, Interscience Publishers, New York, 1968.



conjugated dienes and higher conjugated polyenes which have an appropriately situated hydrogen atom and which are not excessively hindered or constrained to unfavorable configurations. With unsymmetrical dienes, the acyl group generally substitutes most readily at a cis double bond, next at a terminal olefinic group, and least readily at a trans double bond. If both ends are trans, the acyl group prefers the less substituted side. The most useful bases are strongly basic, hindered amines such as dicyclohexylethylamine. The reaction may be performed by treating the diene with an acyl or alkyl halide and $Co(CO)_4^-$ (see p. 437) in the presence of CO and a base, in which case the entire process takes place in one synthetic step. Both an alkyl halide RX and an acyl halide RCOX lead to the same acylated olefin. In the case of an alkyl halide (or an alkylcobalt tetracarbonyl) the carbonyl group in the product arises from the carbon monoxide (or from a carbonyl group of the alkylcobalt tetracarbonyl).

Formylation of olefins can be accomplished with N-disubstituted formamides and $POCl_3$.[132] This is an aliphatic Vilsmeier reaction (see reaction **1-16**). Vilsmeier formylation may also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:[133]



$$R-CH_2-\underset{OR''}{\overset{OR''}{C}}-R' + Ph-\underset{Me}{N}-CHO \xrightarrow{POCl_3} R-\underset{CHO}{CH}-\underset{OR''}{\overset{OR''}{C}}-R' \xrightarrow{\text{hydrol.}} R-\underset{CHO}{CH}-COR'$$

Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3-etherate.[134] The mechanism with acetals or ketals also involves attack at an olefinic carbon, since enol ethers are intermediates.[134] Ketones can be formylated in the α position by treatment with CO and a strong base.[135] A carbalkoxy group can be introduced by treatment of an olefin with a reagent prepared from ClHgCOOR or $Hg(COOR)_2$ and $LiPdCl_3$ (see reaction **4-18**).[136]

OS **IV**, 555, 560; **51**, 109. Also see OS **52**, 1.

2-16 Alkylation of Alkanes

$$RH + R'^+ \longrightarrow R-R' + H^+$$

Alkanes can be alkylated by treatment with solutions of stable carbonium ions[137] (p. 152), though the reaction has not been used for synthetic purposes. Mixtures are generally obtained.

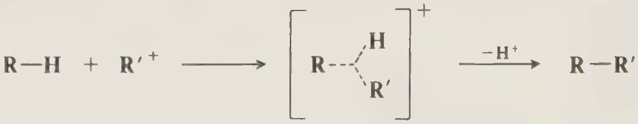
[134] Youssefyeh, *J. Am. Chem. Soc.* **85**, 3901 (1963).

[135] See, for example, van der Zeeuw and Gersmann, *Recl. Trav. Chim. Pays-Bas* **84**, 1535 (1965).

[136] Heck, *J. Am. Chem. Soc.* **90**, 5518 (1968).

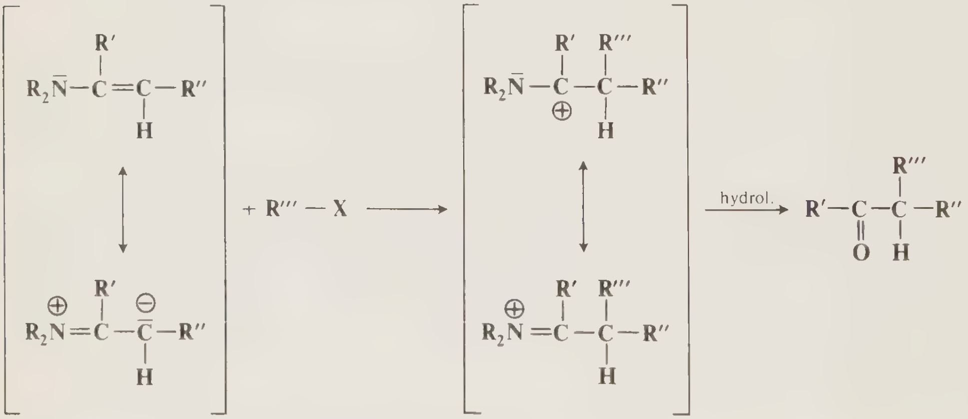
[137] Olah, Mo, and Olah, *J. Am. Chem. Soc.* **95**, 4939 (1973). For a review, see Baker, *Chem. Ind.* (*London*) 877 (1973).

For example, in a typical experiment, the treatment of propane with isopropyl fluoroantimonate (Me_2C^+ SbF_6^-) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by reaction **2-46**), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($RH + R'^+ \rightleftharpoons R^+ + R'H$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbonium ions formed in the exchange reaction. Furthermore, the carbonium ions present are subject to rearrangement (Chapter 18), giving rise to new carbonium ions. Products result from all the hydrocarbons and carbonium ions present in the system, so that mixtures are to be expected. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *t*-butyl cation does not alkylate methane or ethane, though it does react with isobutane to give a small amount of 2,2,3,3-tetramethylbutane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or C_2H_5F and SbF_5.[138] The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with super acids, reaction **2-1**) as



It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *t*-butyl cations in super-acid solutions (p. 154).[139]

2-17 The Stork Enamine Reaction



When enamines are treated with alkyl halides, an alkylation occurs which is analogous to the first step of reaction **2-15**. Hydrolysis of the imine salt gives a ketone. Since the enamine is normally formed from a ketone (reaction **6-15**), the net result is alkylation of the ketone at the α position. The method is known as the *Stork enamine reaction*[140] and represents an alternative to the ketone alkylation considered at reaction **0-97**. The Stork method has the advantage that it generally leads almost exclusively to monoalkylation of the ketone, while reaction **0-97,** when applied to ketones, is difficult to stop with the introduction of just one alkyl group. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine. There is evidence that at least in some cases the alkylation takes place on the nitrogen, and the quaternary salt thus formed rearranges to the C-alkylated product.[141]

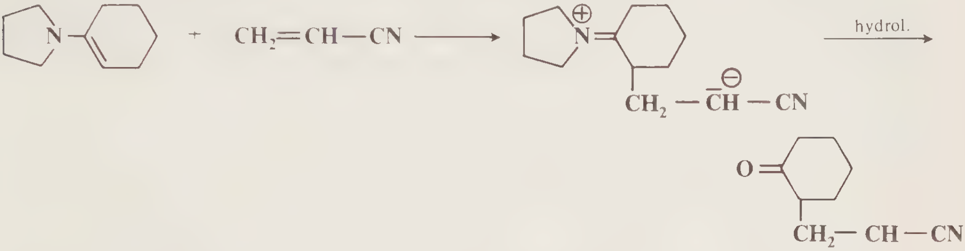
[138] Olah, DeMember, and Shen, *J. Am. Chem. Soc.* **95,** 4952 (1973).

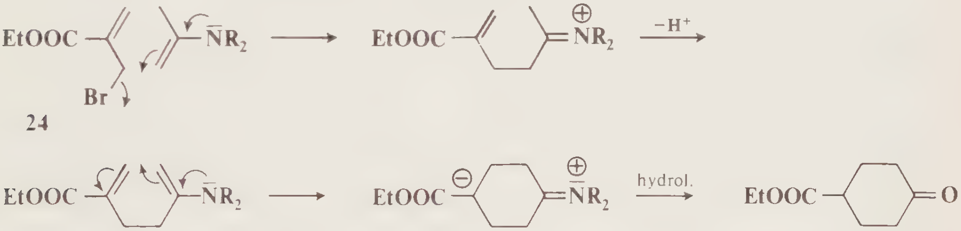
[139] For example, see Hogeveen and Roobeek, *Recl. Trav. Chim. Pays-Bas* **91,** 137 (1972).

[140] Stork, Brizzolara, Landesman, Szmuszkovicz, and Terrell, *J. Am. Chem. Soc.* **85,** 207 (1963). For reviews, see Kuehne, *Synthesis* 510-537 (1970); House, Ref. 69, pp. 570-582, 766-772; Bláha and Červinka, *Adv. Heterocycl. Chem.* **6,** 147-227 (1966), pp. 186-204; Szmuszkovicz, *Adv. Org. Chem.* **4,** 1-113 (1963), pp. 25-92; in Cook, "Enamines," Marcel Dekker, Inc., New York, 1969, the articles by Alt, pp. 115-168; and by Kuehne, pp. 313-468.

The method is quite useful for particularly active alkyl halides such as allyl, benzyl, and propargyl halides, and for α-halo ethers and esters, but is not very serviceable for ordinary primary and secondary halides. Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction may also be applied to activated aryl halides (such as 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,[142] and to activated olefins such as acrylonitrile, e.g.,



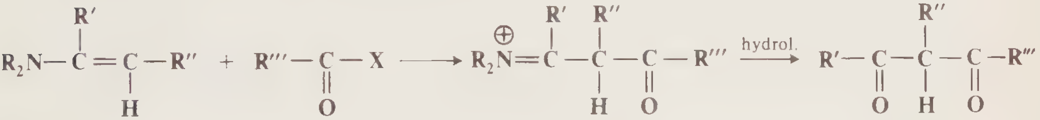
The latter is a Michael-type reaction (p. 679) with respect to the olefin. The compound ethyl α-(bromomethyl)acrylate (**24**), which is both an allylic halide and an activated olefin, reacts in a double fashion with enamines which have an α-hydrogen in the R′ group to give (after hydrolysis) a cyclohexanone:[143]



24

The application of this reaction to the enamine of cyclopentanone gives bicyclo[3.2.1]octanones.

Acylation[144] can be accomplished with acyl halides:



$$R_2N-\overset{R'}{\overset{|}{C}}=\underset{\underset{H}{|}}{C}-R'' + R'''-\underset{\underset{O}{\|}}{C}-X \longrightarrow R_2\overset{\oplus}{N}=\overset{R'}{\overset{|}{C}}-\overset{R''}{\overset{|}{\underset{\underset{H}{|}}{C}}}-\underset{\underset{O}{\|}}{C}-R''' \xrightarrow{\text{hydrol.}} R'-\underset{\underset{O}{\|}}{C}-\overset{R''}{\overset{|}{\underset{\underset{H}{|}}{C}}}-\underset{\underset{O}{\|}}{C}-R'''$$

25

---

[141] For example, see Elkik, *Bull. Soc. Chim. Fr.* 903 (1969).

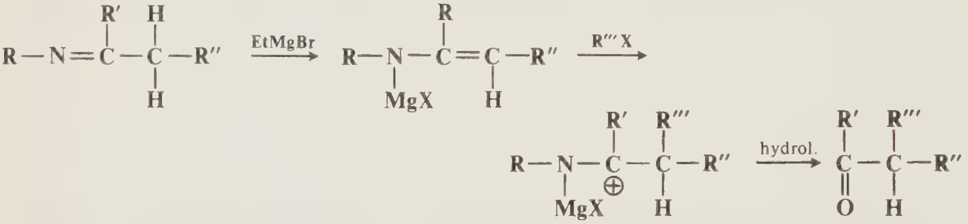
[142] Britten, Owen, and Went, *Tetrahedron* **25,** 3157 (1969).

[143] Nelson, McEuen, and Lawton, *J. Org. Chem.* **34,** 1225 (1969). For a similar reaction, see Hargreaves, Hickmott, and Hopkins, *J. Chem. Soc. C* 592 (1969); Hickmott, Hopkins, and Yoxall, *Tetrahedron Lett.* 2519 (1970).

[144] For reviews, see Hickmott, *Chem. Ind. (London)* 731 (1974); Hünig and Hoch, *Fortschr. Chem. Forsch.* **14,** 235 (1970).

or with anhydrides. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate ClCOOEt,[145] a CN group with cyanogen chloride[146] (not cyanogen bromide or iodide, which leads to halogenation of the enamine), and a CHO group with the mixed anhydride of formic and acetic acids[145] or with dimethylformamide and phosgene.[147] The acylation of the enamine can take place by the same mechanism as alkylation, but in this case another mechanism is also possible, if the acyl halide has an α-hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene (reaction **7-14**) which adds to the enamine to give a cyclobutanone (reaction **5-52**). This compound can be cleaved in the solution to form the same acylated imine salt (**25**) which would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.[148]

Primary and secondary halides do not perform well, mostly because N-alkylation becomes important, particularly with enamines derived from aldehydes. An alternative method, which does give good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in tetrahydrofuran:[149]



The imines are prepared by reaction **6-15**. The enamine salt method has also been used to give good yields of mono α-alkylation of α,β-unsaturated ketones.[150] Enamines prepared from aldehydes and butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.[151] N-alkylation in this case is presumably prevented by steric hindrance.

Ketenimines (these can be formed by the Meyers method, p. 430) react with alkyllithium

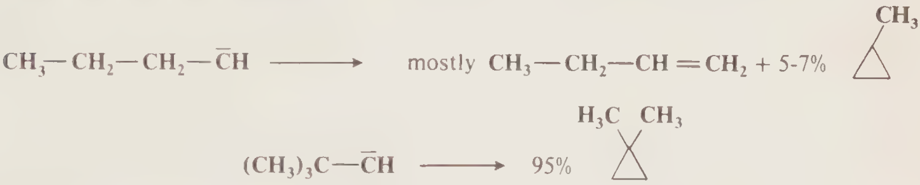
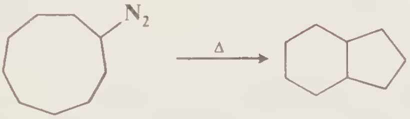
2-18 Insertion by Carbenes

$$RH + \bar{C}H_2 \longrightarrow RCH_3$$

The highly reactive species methylene inserts into C—H bonds,[153] both aliphatic and aromatic,[154] though with aromatic compounds ring expansion is also possible (see reaction **5-53**). The reaction is useless for synthetic purposes because of its nonselectivity (see p. 183). Alkylcarbenes usually rearrange rather than give insertion (p. 183), but, when this is impossible, *intramolecular* insertion is found rather than intermolecular:[155]



Transannular insertion is also known:[156]



CH_2 generated by photolysis of CH_2N_2 in the liquid phase is indiscriminate—totally nonselective—in its reactivity (p. 183). CH_2 generated in other ways, and other carbenes, are less reactive and insert in the order tertiary > secondary > primary.[157] Halocarbenes insert much less readily, though a number of instances have been reported[158] (an unusual example is that of adamantane, which gives a good yield of 1-dichloromethyladamantane with dichlorocarbene[159]).

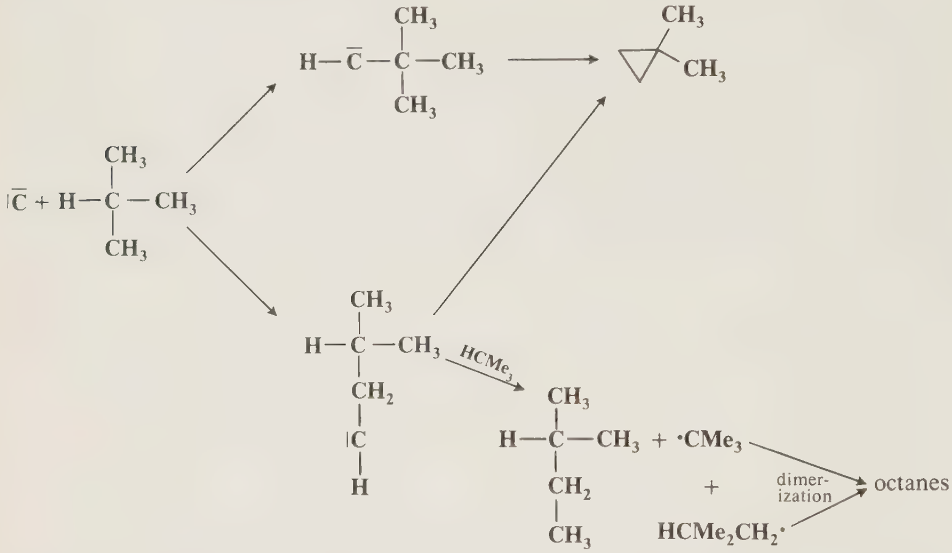
Nevertheless, even for less reactive carbenes, the insertion reaction has seldom been used for synthetic purposes. The carbenes can be generated in any of the ways mentioned in Chapter 5 (p. 181). Carbon atoms (which can be considered a type of carbene) also insert into C—H bonds. The reaction between carbon atoms and isobutane gave 1,1-dimethylcyclopropane, 2-methylbutane, and octanes, which were presumed to arise in this manner:[160]



CH₃
H—C̄—C—CH₃
CH₃
CH₃
CH₃
|C̄ + H—C—CH₃
CH₃

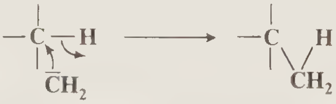
HCMe₂CH₂·
dimer-ization
octanes

For the similar insertion of nitrenes, see reaction **2-11.**

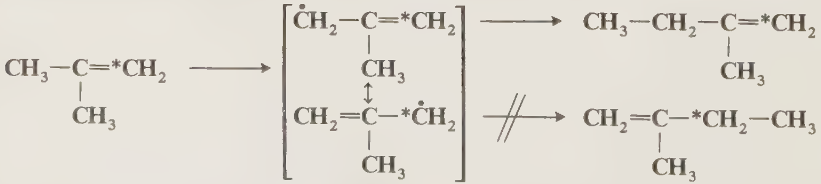
The mechanism[161] of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:



—C—H
C̄H₂
—C H
CH₂

The most convincing evidence for this mechanism is that in the reaction between isobutylene-1-^{14}C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.[162] This rules out a free radical or other free intermediate such as a carbonium ion or carbanion. If **30** (or a corresponding ion) were an intermediate, then resonance would ensure that some carbene attacked at the 1 position:



CH₃—C=*CH₂
CH₃
ĊH₂—C=*CH₂
CH₃
CH₂=C—*ĊH₂
CH₃
CH₃—CH₂—C=*CH₂
CH₃
CH₂=C—*CH₂—CH₃
CH₃

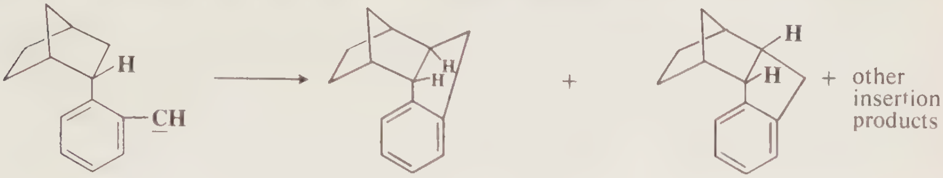
[161] For a discussion, see Bethell, *Adv. Phys. Org. Chem.* **7**, 153–209 (1969), pp. 190–194.

[162] Doering and Prinzbach, *Tetrahedron* **6**, 24 (1959).

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.[163] The fact that carbene **31** inserted intramolecularly to give primarily **32** (about 50%) and only 8% of the *less strained* isomer **33** (as well as other intramolecular insertion products) was interpreted to mean that there is a preferred pathway of attack of the carbene on the C—H bond: midway between the C and H atoms and perpendicular to the C—H bond,[164] though this is contrary to theoretical predictions.[165]



31 **32** **33**

2. A free-radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

$$\mathrm{RH + CH_2 \longrightarrow R\cdot + CH_3\cdot}$$
$$\mathrm{R\cdot + CH_3\cdot \longrightarrow RCH_3}$$

One fact supporting this mechanism is that among the products obtained (besides butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,[166] which could arise, respectively, by

$$\mathrm{2CH_3CH_2CH_2\cdot \longrightarrow CH_3CH{=}CH_2 + CH_3CH_2CH_3} \qquad \text{(disproportionation)}$$

and

$$\mathrm{CH_3CH_2CH_3 + \overline{C}H_2 \longrightarrow CH_3CH_2CH_2\cdot + CH_3\cdot}$$
$$\mathrm{2CH_3\cdot \longrightarrow CH_3CH_3}$$

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling[167] and by other means.[168] However, the obtention of disproportionation and dimerization products does not always mean that the free-radical abstraction process takes place. In some cases these products arise in a different manner.[169] We have seen that the product of the reaction between a carbene and a molecule may have excess energy (p. 180). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

$$\underset{\text{Excited}}{\mathrm{CH_3CH_2CH_2CH_3}} \longrightarrow \underset{\text{disproportionation}}{\underset{\downarrow}{\mathrm{CH_3CH_2CH_2\cdot}}} + \underset{\text{dimerization}}{\underset{\downarrow}{\mathrm{CH_3\cdot}}}$$

It has been suggested[170] that singlet carbenes insert by the one-step direct-insertion process, and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free-radical process. In support of this suggestion is that CIDNP signals (p. 171) were observed in the ethylbenzene produced from toluene and triplet CH_2, but not from the same reaction with singlet CH_2.[171]

The reaction in which aldehydes are converted to methyl ketones, $RCHO + CH_2N_2 \rightarrow RCOCH_3$, while apparently similar, does not involve a free carbene intermediate. It is considered in Chapter 18 (reaction **8-10**).

F. Metal Electrophiles

2-19 Metalation with Organometallic Compounds

$$RH + R'M \longrightarrow RM + R'H$$

Many organic compounds can be metalated by treatment with an organometallic compound.[172] Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid. For example, fluorene reacts with butyllithium to give butane and 9-fluoryllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is butyllithium. Normally, only active aromatic rings react with butyllithium. Benzene itself is not reactive enough, though benzene can be metalated by butyllithium in the presence of *t*-BuOK,[173] or by butyllithium coordinated with various diamines such as N,N,N′,N′-tetramethylethylenediamine.[174] Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allyl, benzyl, etc.) or when the negative charge is at an *sp* carbon (at triple bonds). In certain cases *gem*-dialkali metal compounds can be prepared. An example is the conversion of phenylacetonitrile to 1,1-dilithiophenylacetonitrile $PhCLi_2CN$ by treatment with excess butyllithium.[175]

In general, the reaction can be performed only with organometallics of active metals such as lithium, sodium, and potassium, but Grignard reagents abstract protons from a sufficiently acidic C—H bond, as in $R—C\equiv C—H \rightarrow R—C\equiv C—MgX$. This is the best method for the preparation of ethynyl Grignard reagents.[176]

The reaction may be used to determine relative acidities of very weak acids by allowing two R—H compounds to compete for the same R′M, and to determine which proton in a molecule is the most acidic. The reaction is often remarkably specific, for example,[177]

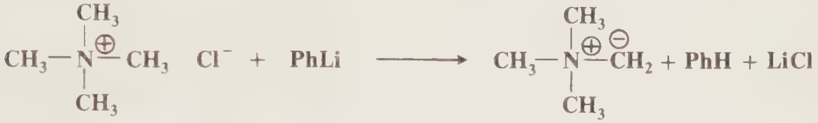
[177] Shirley and Gilmer, *J. Org. Chem.* **27,** 4421 (1962). For other uses of this reaction to determine position of maximum acidity, see Broaddus, Logan, and Flautt, *J. Org. Chem.* **28,** 1174 (1963); Finnegan and McNess, *J. Org. Chem.* **29,** 3234 (1964); Shirley, Johnson, and Hendrix, *J. Organomet. Chem.* **11,** 209 (1968); Shirley and Hendrix, *J. Organomet. Chem.* **11,** 217 (1968).

The mechanism involves a nucleophilic attack by R′ (or a polar R′) on the *hydrogen.*[178] Evidence for this is that mesomeric effects of substituents in R seem to make little difference. Only field effects are important. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta and para (mostly meta).[179] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects. All this implies that attack occurs at the hydrogen and not at R. Only the acidity seems to be important. Resonance factors would influence an intermediate or transition state. Since resonance factors in R are not important, R is involved very little in the transition state. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[180] The nature of R′ also has an effect on the rate. In the reaction between triphenylmethane and R′Li, the rate decreased in the order $R' = PhCH_2 > allyl > Bu > Ph > vinyl > Me$.[181]

With respect to the reagent, this reaction is a special case of reaction **2-21.**

A closely related reaction is formation of nitrogen ylides from quaternary ammonium salts (see reaction **7-7**):[182]



$$\mathrm{CH_3{-}\overset{CH_3}{\underset{CH_3}{\overset{\oplus}{N}}}{-}CH_3\quad Cl^- + PhLi \longrightarrow CH_3{-}\overset{CH_3}{\underset{CH_3}{\overset{\oplus}{N}}}{-}\overset{\ominus}{C}H_2 + PhH + LiCl}$$

Phosphonium salts undergo a similar reaction (see reaction **6-47**).

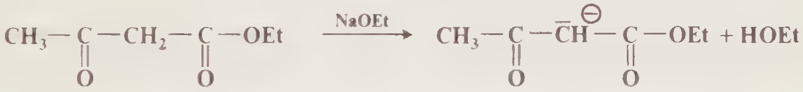
2-20 Metalation with Metals and Strong Bases

$$2RH + M \longrightarrow 2RM + H_2$$

Organic compounds can be metalated at suitably acidic positions by active metals and by strong bases. The reaction has been used to study the acidities of very weak acids (see p. 161). Synthetically, the most important use of the method is to convert activated ketones, esters, and similar compounds to their enolate forms, e.g.,



$$\mathrm{CH_3{-}\underset{\overset{\|}{O}}{C}{-}CH_2{-}\underset{\overset{\|}{O}}{C}{-}OEt \xrightarrow{NaOEt} CH_3{-}\underset{\overset{\|}{O}}{C}{-}\overset{\ominus}{\bar{C}H}{-}\underset{\overset{\|}{O}}{C}{-}OEt + HOEt}$$

for use in nucleophilic substitutions (reactions **0-96** and **3-14**) and in additions to multiple bonds (reactions **5-19** and **6-42**). Another important use is the conversion of terminal alkynes to acetylide ions.[183] The mechanism for the reaction between $ArCR_2H$ and RNHLi has been shown to be SEi.[184] Ethyl acetate has been converted to ethyl lithioacetate $LiCH_2COOEt$ by treatment with lithium bis(trimethylsilyl)amide $LiN(SiMe_3)_2$ in tetrahydrofuran at −78 C.[185]

Mercuration of aromatic compounds can be accomplished with mercuric salts, most often $Hg(OAc)_2$ or $Hg(ClO_4)_2$ (to give ArHgOAc or $ArHgClO_4$, respectively). This is ordinary electrophilic aromatic substitution and takes place by the arenium-ion mechanism (p. 453).[186] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) $ArTl(OOCCF_3)_2$ by treatment with thallium(III) trifluoroacetate in trifluoroacetic acid.[187] These arylthallium compounds can be converted to phenols (reaction **2-23**), aryl iodides (reaction **2-28**), or aryl nitriles (reaction **2-32**).

OS **I,** 70, 161, 490; **IV,** 473; **52,** 75; **54,** 19; **55,** 70. We do not list conversions of ketones or esters to enolates.

Metals as Leaving Groups

A. Hydrogen as the Electrophile

2-21 Replacement of Metals by Hydrogen

$$\mathbf{RM + HA \longrightarrow RH + MA}$$

Organometallic compounds react with acids in reactions in which the metal is replaced by hydrogen.[188] R may be aryl (see reaction **1-50**). For Grignard reagents, water is usually a strong enough acid, but stronger acids are also used. Hydrogen (H_2) has been used as an acid to convert Grignard reagents and other organometallic compounds to hydrocarbons.[189] An important method for the reduction of alkyl halides consists of the process

$$\mathbf{RX \longrightarrow RMgX \longrightarrow RH}$$

Other organometallic compounds that are hydrolyzed by water are those of sodium, potassium, lithium, zinc, etc.: the ones high in the electromotive series. When the metal is farther down in the series, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, though the latter may be cleaved with concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 react violently with water. However, BR_3 can be converted to RH with carboxylic acids.[190] For less active metals it is often possible to cleave just one R group from a multivalent metal. For example,

$$\mathbf{R_2Hg + HCl \longrightarrow RH + RHgCl}$$

Organometallic compounds of less active metals and metalloids, such as silicon, antimony, bismuth, etc., are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[191] There is evidence that the reduction with $NaBH_4$ takes place by a free-radical mechanism.[192] Vinylsilanes $RR'C{=}CR''SiMe_3$ give alkenes $RR'C{=}CR''H$ with retention of configuration when treated with HI.[192a]

[191] For a review, see Makarova, *Organomet. React.* **1,** 119–348 (1970), pp. 251–270, 275–300.

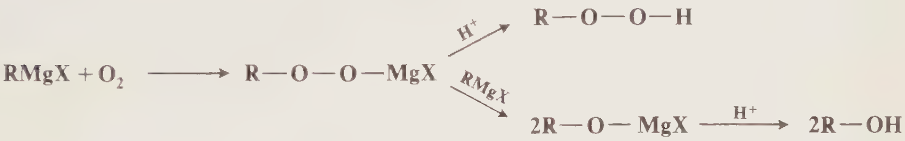
In the *Zerewittenoff process* the number of moles of active hydrogen in an unknown compound is determined by treatment of the compound with methylmagnesium bromide and measurement of the volume of methane evolved. An *active hydrogen* is defined as one which will react with this reagent. Usually it is a hydrogen connected to oxygen, nitrogen, sulfur, phosphorus, etc., but hydrogens attached to some carbons are acidic enough for the reaction.[193]

When the hydrogen of the HA is attached to carbon, this reaction is the same as reaction **2-19.**

We do not list the many hydrolyses of sodium or potassium enolates, etc., found in *Organic Syntheses*. The hydrolysis of a Grignard reagent to give an alkane is found in OS **II,** 478.

B. Oxygen Electrophiles

2-22 The Reaction between Organometallic Reagents and Oxygen



Oxygen reacts with Grignard reagents to give either hydroperoxides or alcohols.[194] The reaction is useful to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents yields are lower, and only phenols are obtained, not hydroperoxides. It is because of the possibility of this reaction that oxygen must be excluded when Grignard reagents are desired for other purposes. A better procedure for the conversion of aryl Grignard reagents to phenols involves the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid[195] (see reaction **2-26**).

$$\mathrm{ArMgX} \xrightarrow{\mathrm{B(OMe)_3}} \mathrm{ArB(OMe)_2} \xrightarrow[\mathrm{H_2O_2}]{\mathrm{H^+}} \mathrm{ArOH}$$

Most other organometallic compounds also react with oxygen. Trialkylboranes and alkyldichloroboranes $RBCl_2$ can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.[196] Dilithiated carboxylic acids (see reaction **0-98**) react with oxygen to give (after hydrolysis) α-hydroxy carboxylic acids.[197] There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.[198]

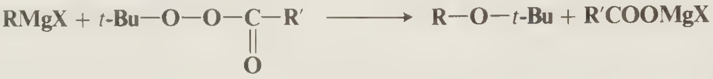
2-23 Conversion of Arylthallium Compounds to Phenols

$$\mathrm{ArTl(OOCCF_3)_2} \xrightarrow[\text{2. PPh}_3\ \ \text{3. dil. NaOH}]{\text{1. Pb(OAc)}_4} \mathrm{ArOH}$$

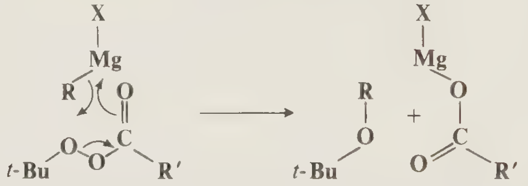
Arythallium bis(trifluoroacetates), which can be prepared by reaction **2-20**, can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine and then dilute NaOH.[199] The entire process, including the thallation reaction, can be carried out in a single reaction vessel without isolation of any of the intermediate products, so that this is a method of accomplishing the conversion ArH → ArOH. Diarylthallium trifluoroacetates undergo the same reaction.[199a]

2-24 Conversion of Grignard Reagents to *t*-Butyl Ethers



$$\mathrm{RMgX} + t\text{-Bu}{-}\mathrm{O}{-}\mathrm{O}{-}\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}{-}\mathrm{R'} \longrightarrow \mathrm{R}{-}\mathrm{O}{-}t\text{-Bu} + \mathrm{R'COOMgX}$$

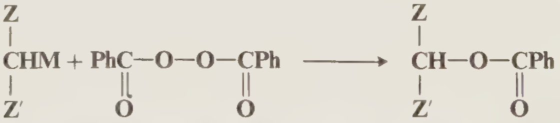
A convenient method of preparation of *t*-butyl ethers consists of treating Grignard reagents with *t*-butyl acyl peroxides.[200] Both alkyl and aryl Grignard reagents may be used. The mechanism is probably of the cyclic, six-center type:



The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *t*-butyl ethers of cyclopropanols,[201] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by reaction **0-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

OS V, 642, 924.

2-25 Esterification of Enolates



$$\underset{\mathrm{Z'}}{\overset{\mathrm{Z}}{\mathrm{CHM}}} + \mathrm{Ph}\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}{-}\mathrm{O}{-}\mathrm{O}{-}\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}\mathrm{Ph} \longrightarrow \underset{\mathrm{Z'}}{\overset{\mathrm{Z}}{\mathrm{CH}}}{-}\mathrm{O}{-}\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}\mathrm{Ph}$$

β-Keto esters and other compounds of the form Z—CHR—Z′ (see p. 419 for the definition of Z) can be esterified through their enolate salts by treatment with acyl peroxides.[202]

OS V, 379.

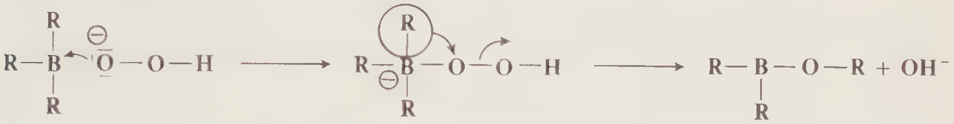
2-26 Oxidation of Trialkylboranes to Borates

$$R_3B \xrightarrow[NaOH]{H_2O_2} (RO)_3B$$

Trialkylboranes can be oxidized to esters of boric acid by alkaline H_2O_2.[203] This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles. The R group does not rearrange, and this reaction is a step in the hydroboration method of converting olefins to alcohols (reaction **5-13**). The mechanism has been formulated as involving a rearrangement from boron to oxygen:[203]



The other two R groups then similarly migrate. Retention of configuration in the R group has been observed in a similar reaction.[204] Boranes can also be oxidized to borates in good yields with oxygen[205] and with trimethylamine oxide, either anhydrous[206] or in the form of the dihydrate.[206a] The reaction with oxygen is free-radical in nature.[207]

D. Halogen Electrophiles

2-28 Halogenation of Organometallic Compounds

$$\mathrm{RMgX} + \mathrm{I_2} \longrightarrow \mathrm{RI} + \mathrm{MgIX}$$

Grignard reagents react with halogens to give alkyl halides. The reaction represents a useful method for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[212] Alkyl, aryl, and vinyl Grignard reagents and lithium compounds can be converted to fluorides in moderate to high yields by treatment with perchloryl fluoride $FClO_3$.[213]

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[214] The reaction can be used to convert acetylide ions to 1-haloalkynes.[215] Since acetylide ions are easily prepared from alkynes (reaction **2-20**), this provides a means of making the conversion $RC{\equiv}CH \rightarrow RC{\equiv}CX$. Trialkylboranes react rapidly with I_2[216] or Br_2[217] in the presence of NaOMe in methanol to give alkyl iodides or bromides, respectively (see also reaction **4-32**). Combined with the hydroboration reaction (**5-15**), this is an indirect way of adding HBr or HI to a double bond to give products with an anti-Markovnikov orientation (see reaction **5-1**). An alternative procedure for achieving this result for HBr consists of treating the R_3B with $Hg(OAc)_2$ or HgO, which produces RHgOAc or R_2Hg, respectively, either of which, when treated with Br_2, gives RBr.[218]

trans-1-Alkenylboronic acids **34,** prepared by hydroboration of terminal alkynes with catecholborane (reaction **5-15**) followed by hydrolysis, react with I_2 in the presence of NaOH at 0°C in ethereal solvents to give trans vinyl iodides.[219] This is an indirect way of accomplishing the

anti-Markovnikov addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 moles of Br_2 must be used) followed by base to give the corresponding vinyl bromide, but in this case with *inversion* of configuration; so the product is the cis vinyl bromide.[220] Vinylaluminum compounds react with Br_2 and I_2 to give vinyl bromides and iodides with retention of configuration.[221] Vinyl iodides can also be prepared by treatment of vinylcopper reagents with I_2.[222] This reaction is not applicable to bromides, but divinylmercury compounds (which can be prepared from vinylcopper compounds) give vinyl bromides when treated with Br_2.[222]

Aryl iodides can be prepared in high yield by the reaction of arylthallium bis(trifluoroacetates) (see reaction **2-20**) with KI.[223] This procedure affords an indirect method for achieving still another conversion, that of ArH → ArI. For the reaction of lithium enolates of esters with I_2, see reaction **2-5.**

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[224] In a number of cases the reaction has been shown to involve inversion of configuration (see p. 523), indicating an SE2 (back) mechanism, while in other cases retention of configuration has been shown,[225] implicating an SE2 (front) or SEi mechanism. In still other cases complete loss of configuration as well as other evidence have demonstrated the presence of a free-radical mechanism.[226]

E. Nitrogen Electrophiles

2-29 The Conversion of Organometallic Compounds to Amines

$$R_3B \xrightarrow[NH_2OSO_2OH]{NH_2Cl\ \text{or}} 2RNH_2 + RB(OH)_2$$

Organoboranes react with chloramine or with hydroxylamine-O-sulfonic acid in diglyme to produce primary amines.[227] Only two of the three alkyl groups of the borane are converted to amine molecules. Since the boranes can be prepared by the hydroboration of alkenes (reaction **5-15**), this is an indirect method for the addition of NH_3 to a double bond with anti-Markovnikov orientation. Alkyl Grignard reagents also react with chloramine and with hydroxylamine derivatives to give moderate yields of primary amines.[228] Secondary amines can be prepared[229] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes (prepared as on p. 720) with alkyl or aryl azides. Trialkylboranes also give this reaction, but are less

$$RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[OH^-]{H_2O} RNHR'$$

$$R_2BCl + R'N_3 \xrightarrow[2.\ H_2O]{1.\ Et_2O} RNHR'$$

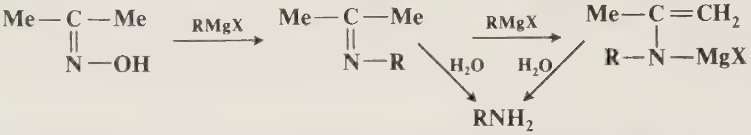
satisfactory because higher temperatures are required, and the reaction fails when R or R′ is bulky.[230]

It has been reported that alkyl or aryl Grignard reagents in toluene react with acetoxime to give (after hydrolysis) primary amines.[231] An imine intermediate is assumed.



Molecular nitrogen (N_2) reacts with aryllithium compounds in the presence of compounds of such transition metals as titanium, chromium, molybdenum, or vanadium (e.g., $TiCl_4$) to give (after hydrolysis) primary aromatic amines.[232]

$$\mathrm{ArLi} + \mathrm{N_2} \xrightarrow[\text{2. } \mathrm{H_2O}]{\text{1. } \mathrm{MX}_n} \mathrm{ArNH_2} + \mathrm{NH_3}$$

2-30 The Conversion of Grignard Reagents to Azides

$$\mathrm{ArMgX} + \mathrm{TsN_3} \longrightarrow \mathrm{(ArNNNTs)MgX} \xrightarrow[\text{pyrophosphate}]{\text{sodium}} \mathrm{ArN_3}$$

Aryl Grignard reagents react with tosyl azide to give triazene salts which can be fragmented by treatment with aqueous sodium pyrophosphate to give moderate to good yields of aryl azides.[233] Alkyl Grignard reagents also give the reaction, but yields are poor.

F. Carbon Electrophiles

2-31 The Conversion of Organometallic Compounds to Ketones or Aldehydes
