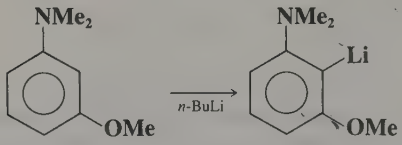
$$CH_2{=}CH{-}OMe \xrightarrow[-65^\circ]{t\text{-BuLi}} CH_2{=}\underset{\displaystyle Li}{\underset{|}{C}}{-}OMe$$

Ref. 206



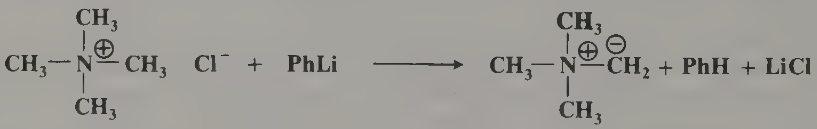
Ref. 207

In the second example, the lithium goes into the 2 position so as to be ortho to both substituents.[208] This regioselectivity can be quite valuable synthetically.

The mechanism involves a nucleophilic attack by R'^- (or a polar R′) on the *hydrogen*.[209] Evidence for this is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta and para (mostly meta).[210] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[211] The nature of R′ also has an effect on the rate. In the reaction between triphenylmethane and R′Li, the rate decreased in the order $R' = PhCH_2 >$ allyl > Bu > Ph > vinyl > Me.[212]

With respect to the reagent, this reaction is a special case of **2-22.**

A closely related reaction is formation of nitrogen ylides from quaternary ammonium salts (see **7-7**):



$$CH_3{-}\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{\overset{\oplus}{N}}}{-}CH_3\quad Cl^- + PhLi \longrightarrow CH_3{-}\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{\overset{\oplus}{N}}}{-}\overset{\ominus}{C}H_2 + PhH + LiCl$$

Phosphonium salts undergo a similar reaction (see **6-47**).

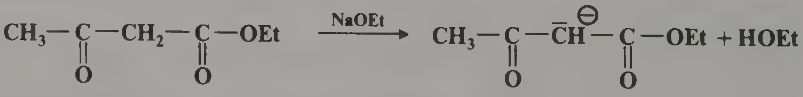
2-20 Metallation with Metals and Strong Bases

$$2RH + M \longrightarrow 2RM + H_2$$

Organic compounds can be metallated at suitably acidic positions by active metals and by strong bases. The reaction has been used to study the acidities of very weak acids (see p. 152). Synthetically, the most important use of the method is to convert ketones, esters, and similar compounds to their enolate forms,[213] e.g.,



$$CH_3{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}CH_2{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}OEt \xrightarrow{NaOEt} CH_3{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}\overset{\ominus}{\bar{C}H}{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}OEt + HOEt$$

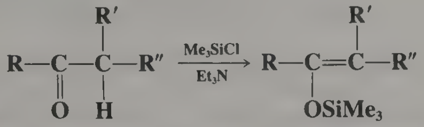
[213] For a review, see Caine, Ref. 142, vol. 1, pp. 95–145, 284–291.

for use in nucleophilic substitutions (**0-96, 0-97,** and **3-14**) and in additions to multiple bonds (**5-17** and **6-42**). Another important use is the conversion of terminal alkynes to acetylide ions.[214] The mechanism for the reaction between $ArCR_2H$ and RNHLi has been shown to be SEi.[215]

Mercuration of aromatic compounds can be accomplished with mercuric salts, most often $Hg(OAc)_2$[216] or $Hg(ClO_4)_2$ (to give ArHgOAc or $ArHgClO_4$, respectively). This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (p. 447).[217] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) $ArTl(OOCCF_3)_2$ by treatment with thallium(III) trifluoroacetate in trifluoroacetic acid.[218] These arylthallium compounds can be converted to phenols (**2-24**), aryl iodides or fluorides (**2-28**), aryl cyanides (**2-32**), aryl nitro compounds,[219] or aryl esters (**2-31**).

OS **I,** 70, 161, 490; **IV,** 473; **52,** 75; **54,** 19; **55,** 70; **57,** 18; **58,** 113. Conversions of ketones or esters to enolates are not listed.

2-21 Conversion of Enolates to Silyl Enol Ethers



Silyl enol ethers,[220] important reagents with a number of synthetic uses (see, for example, **0-97, 2-4, 5-17, 5-49, 6-40**), can be prepared by base treatment of a ketone (converting it to its enolate) followed by addition of a trialkylchlorosilane. Enolates prepared in other ways (e.g., as shown for **111** on p. 402) also give the reaction. The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.[221] A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane $(Me_3Si)_2NH$.[222]

Organometallic compounds react with acids in reactions in which the metal is replaced by hydrogen.[223] R may be aryl (see **1-47**). For Grignard reagents, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process RX → RMgX → RH. The reaction is often used to introduce deuterium or tritium into susceptible positions.

Other organometallic compounds that are hydrolyzed by water are those of sodium, potassium, lithium, zinc, etc.—the ones high in the electromotive series. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, though the latter can be cleaved with concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 react violently with water. However, BR_3 can be converted to RH with carboxylic acids.[224] For less active metals it is often possible to cleave just one R group from a multivalent metal. For example,

$$R_2Hg + HCl \longrightarrow RH + RHgCl$$

Organometallic compounds of less active metals and metalloids, such as silicon, antimony, bismuth, etc., are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[225] There is evidence that the reduction with $NaBH_4$ takes place by a free-radical mechanism.[226]

In the *Zerewittenoff process* the number of moles of active hydrogen in an unknown compound is determined by treatment of the compound with methylmagnesium bromide and measurement of the volume of methane evolved. An *active hydrogen* is defined as one that will react with this reagent. Usually it is a hydrogen connected to oxygen, nitrogen, sulfur, phosphorus, etc., but hydrogens attached to some carbons are acidic enough for the reaction.[227]

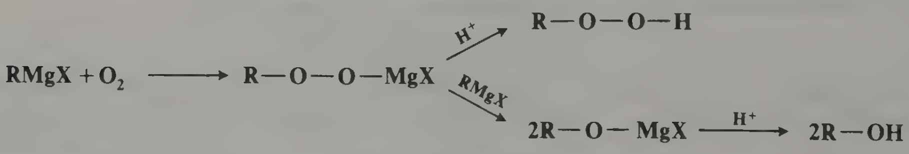
When the hydrogen of the HA is attached to carbon, this reaction is the same as **2-19.**

We do not list the many hydrolyses of sodium or potassium enolates, etc. found in *Organic Syntheses*. The hydrolysis of a Grignard reagent to give an alkane is found in OS **II,** 478.

B. Oxygen Electrophiles

2-23 The Reaction between Organometallic Reagents and Oxygen

Hydroperoxy-de-metallation; Hydroxy-de-metallation



Oxygen reacts with Grignard reagents to give either hydroperoxides or alcohols.[228] The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents yields are lower and only phenols are obtained, not hydroperoxides. It is because of the possibility of this reaction that oxygen must be excluded when Grignard reagents are desired for other purposes. A better procedure for the conversion of aryl Grignard reagents to phenols involves the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid[229] (see **2-26**).

[227] For a review, see Kharasch and Reinmuth, "Grignard Reactions of Nonmetallic Substances," pp. 1166–1198, Prentice-Hall, Englewood Cliffs, N.J., 1954.

[228] For a monograph, see Brilkina and Shushunov, "Reactions of Organometallic Compounds with Oxygen and Peroxides," Chemical Rubber Company Press, Cleveland, Ohio, 1969. For a review, see Ref. 227, pp. 1264–1274.

$$\mathrm{ArMgX} \xrightarrow{\mathrm{B(OMe)_3}} \mathrm{ArB(OMe)_2} \xrightarrow[\mathrm{H_2O_2}]{\mathrm{H^-}} \mathrm{ArOH}$$

Most other organometallic compounds also react with oxygen. Trialkylboranes and alkyldichloroboranes $RBCl_2$ can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.[230] Dilithiated carboxylic acids (see **0-98**) react with oxygen to give (after hydrolysis) α-hydroxy carboxylic acids.[231] There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.[232]

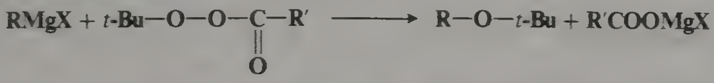
OS **V**, 918.

2-24 Conversion of Arylthallium Compounds to Phenols
Hydroxy-de-(bistrifluoroacetoxy)thallation

$$\mathrm{ArTl(OOCCF_3)_2} \xrightarrow[\substack{\text{2. PPh}_3 \\ \text{3. dil. NaOH}}]{\text{1. Pb(OAc)}_4} \mathrm{ArOH}$$

Arythallium bis(trifluoroacetates), which can be prepared by **2-20**, can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine and then dilute NaOH.[233] The entire process, including the thallation reaction, can be carried out in a single reaction vessel without isolation of any of the intermediate products, so that this is a method of accomplishing the conversion ArH → ArOH. Diarylthallium trifluoroacetates undergo the same reaction.[234]

2-25 Conversion of Grignard Reagents to *t*-Butyl Ethers
***t*-Butoxy-de-metallation**



$$\mathrm{RMgX} + t\text{-Bu}{-}\mathrm{O}{-}\mathrm{O}{-}\underset{\underset{\displaystyle\mathrm{O}}{\|}}{\mathrm{C}}{-}\mathrm{R'} \longrightarrow \mathrm{R}{-}\mathrm{O}{-}t\text{-Bu} + \mathrm{R'COOMgX}$$

A convenient method of preparation of *t*-butyl ethers consist of treating Grignard reagents with *t*-butyl acyl peroxides.[235] Both alkyl and aryl Grignard reagents may be used. The mechanism is probably of the cyclic, six-center type:

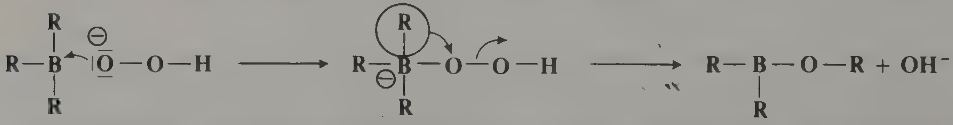
The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *t*-butyl ethers of cyclopropanols,[236] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by **0-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

OS **V,** 642, 924.

2-26 Oxidation of Trialkylboranes to Borates

$$R_3B \xrightarrow[NaOH]{H_2O_2} (RO)_3B \longrightarrow 3ROH + B(OH)_3$$

Trialkylboranes can be oxidized to esters of boric acid by alkaline H_2O_2.[237] This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles. The R group does not rearrange, and this reaction is a step in the hydroboration method of converting olefins to alcohols (**5-11**). The mechanism has been formulated as involving a rearrangement from boron to oxygen:[237]

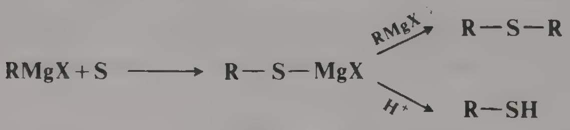


The other two R groups then similarly migrate. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen[238] and with trimethylamine oxide, either anhydrous[239] or in the form of the dihydrate.[240] The reaction with oxygen is free radical in nature.[241]

OS **V,** 918; **50,** 88; **52,** 59; **53,** 77.

C. Sulfur Electrophiles

2-27 Conversion of Grignard Reagents to Sulfur Compounds



Mercapto-de-metallation

Mercaptans and sulfides are occasionally prepared by treatment of Grignard reagents with sulfur.[242] Analogous reactions are known for selenium and tellurium compounds. Grignard reagents and other organometallic compounds react with sulfuryl chloride to give sulfonyl chlorides,[243] with esters of sulfinic acids to give (stereospecifically) sulfoxides,[244] with disulfides to give sulfides,[245] and with

SO_2 to give sulfinic acid salts[246] that can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.[247]

OS **III,** 771; **IV,** 667; **50,** 104; **59,** 141.

D. Halogen Electrophiles

2-28 Halogenation of Organometallic Compounds
Halo-de-metallation

$$\mathrm{RMgX + I_2 \longrightarrow RI + MgIX}$$

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[248] Alkyl, aryl, and vinyl Grignard reagents and lithium compounds can be converted to fluorides in moderate to high yields with perchloryl fluoride $FClO_3$.[249]

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[250] The reaction can be used to convert acetylide ions to 1-haloalkynes.[251] Since acetylide ions are easily prepared from alkynes (reaction **2-20**), this provides a means of making the conversion $\mathrm{RC{\equiv}CH \rightarrow RC{\equiv}CX}$. Trialkylboranes react rapidly with I_2[252] or Br_2[253] in the presence of NaOMe in methanol, or with NCl_3 in CCl_4[254] to give alkyl iodides, bromides, or chlorides, respectively. Combined with the hydroboration reaction (**5-13**), this is an indirect way of adding HBr or HI to a double bond to give products with an anti-Markovnikov orientation (see **5-1**). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free radical process.[255]

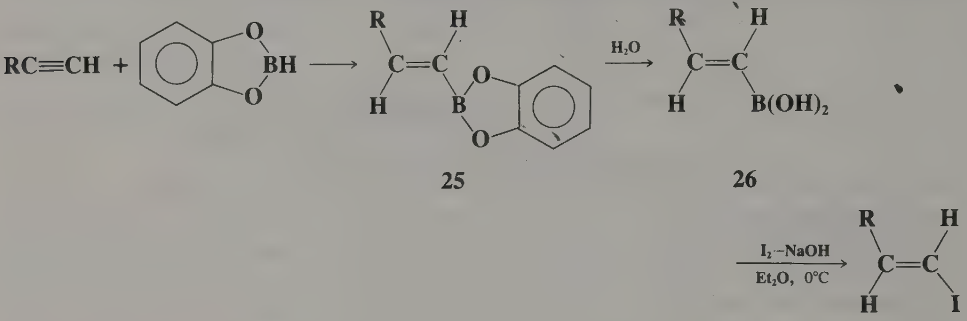
[254] Brown and De Lue, *J. Organomet. Chem.* **135,** C57 (1977). For other reagents, see Jigajinni, Paget, and Smith, *J. Chem. Res., Synop.* 376 (1981).

[255] Suzuki, Nozawa, Harada, Itoh, Brown, and Midland, *J. Am. Chem. Soc.* **93,** 1508 (1971). For reviews, see Brown and Midland, *Angew. Chem. Int. Ed. Engl.* **11,** 692–700 (1972), pp. 699–700 [*Angew. Chem.* **84,** 702–710]; Brown, "Boranes in Organic Chemistry," Ref. 224, pp. 442–446.

trans-1-Alkenylboronic acids **25**, prepared by hydroboration of terminal alkynes with catecholborane[256] (**5-13**) followed by hydrolysis, react with I_2 in the presence of NaOH at 0°C in ethereal solvents to give trans vinyl iodides.[257] This is an indirect way of accomplishing the anti-Markovnikov addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 moles of Br_2 must be used) followed by base to give the corresponding vinyl bromide, but in this case with *inversion* of configuration; so the product is the cis vinyl bromide.[258] Alkenylboronic acids also give vinyl bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.[258a] Vinyl halides can also be prepared from vinylaluminum[259] or vinylcopper reagents. The latter react with I_2 to give iodides,[260] and with N-chloro- or N-bromosuccinimide at −45°C to give chlorides or bromides.[261]



25

26

Aryl iodides and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see **2-20**), indirectly achieving the conversions ArH → ArI and ArH → ArF. The bis(trifluoroacetates) react with KI to give ArI in high yields.[262] The reaction with KF gives arylthallium(III) difluorides $ArTlF_2$, but these react with BF_3 to give ArF in moderate overall yields.[263] Aryl fluorides have also been prepared in low-to-moderate yields by treatment of arylmetal compounds such as Ph_4Sn and Ph_2Hg with F_2.[264]

For the reaction of lithium enolates of esters with I_2 or CX_4 see **2-5**.

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[265] In a number of cases the reaction has been shown to involve inversion of configuration (see p. 515), indicating an SE2 (back) mechanism, while in other cases retention of configuration has been shown,[266] implicating an SE2 (front) or SEi mechanism. In still other cases complete loss of configuration as well as other evidence have demonstrated the presence of a free-radical mechanism.[267]

E. Nitrogen Electrophiles

2-29 The Conversion of Organometallic Compounds to Amines
Amino-de-metallation

$$\mathrm{RLi} \xrightarrow[\mathrm{MeLi}]{\mathrm{CH_3ONH_2}} \mathrm{RNH_2}$$

Alkyl and aryllithium compounds can be converted to primary amines by treatment with methoxyamine and MeLi in ether at −78°C.[268] Grignard reagents give lower yields. The reaction can be extended to give secondary amines by the use of N-substituted methoxyamines CH_3ONHR'.[269] There is evidence[269a] that the mechanism involves the direct displacement of OCH_3 by R on an intermediate $CH_3O\bar{N}R'^-$ ($CH_3O\bar{N}R'^-\ Li^+ + RLi \rightarrow CH_3OLi + R\bar{N}R'^-\ Li^+$). Organoboranes react with a mixture of aqueous NH_3 and NaOCl to produce primary amines.[270] It is likely that the actual

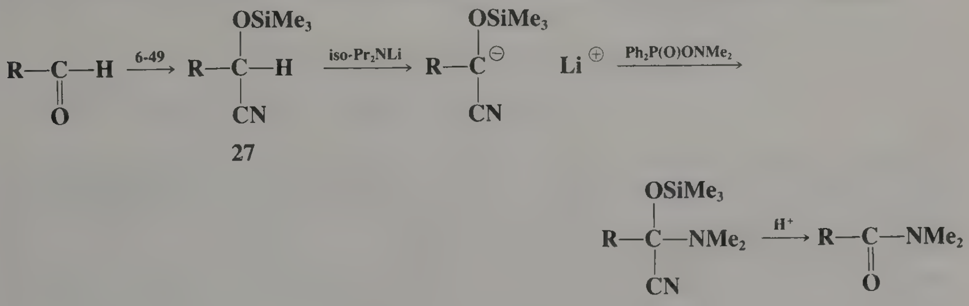
$$\mathrm{R_3B} \xrightarrow{\mathrm{NH_3\text{–}NaOCl}} \mathrm{2RNH_2 + RB(OH)_2}$$

reagent is chloramine NH_2Cl. Chloramine itself, and hydroxylamine-O-sulfonic acid in diglyme, also give the reaction.[271] Since the boranes can be prepared by the hydroboration of alkenes (**5-13**), this is an indirect method for the addition of NH_3 to a double bond with anti-Markovnikov orientation. Secondary amines can be prepared[272] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes (prepared as on p. 705) with alkyl or aryl azides.

$$\mathrm{RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[\mathrm{OH^-}]{\mathrm{H_2O}} RNHR'}$$

$$\mathrm{R_2BCl + R'N_3 \xrightarrow[\text{2. } \mathrm{H_2O}]{\text{1. } \mathrm{Et_2O}} RNHR'}$$

An indirect method for the conversion of aldehydes to N,N-disubstituted amides is based on the conversion of an O-(trimethylsilyl)aldehyde cyanohydrin **27** to the amine **28**.[273]



27

28

Secondary amines have been converted to tertiary by treatment with dialkylcopperlithium reagents: $R_2CuLi + NHR'_2 \rightarrow RNR'_2$.[274] The reaction was also used to convert primary amines to secondary, but yields were lower.[274]

[274] Yamamoto and Maruoka, *J. Org. Chem.* **45**, 2739 (1980).

Molecular nitrogen (N_2) reacts with aryllithium compounds in the presence of compounds of such transition metals as titanium, chromium, molybdenum, or vanadium (e.g., $TiCl_4$) to give (after hydrolysis) primary aromatic amines.[275]

$$\text{ArLi} + \text{N}_2 \xrightarrow[\text{2. H}_2\text{O}]{\text{1. MX}_n} \text{ArNH}_2 + \text{NH}_3$$

Another method for the conversion of ArM to $ArNH_2$ makes use of the reagent azidomethyl phenyl sulfide $PhSCH_2N_3$ to give triazenes that are hydrolyzed to the amines.[276]

$$\text{ArMgX} \xrightarrow{\text{PhSCH}_2\text{N}_3} \text{ArNHN{=}NCH}_2\text{SPh} \xrightarrow{\text{hydrolysis}} \text{ArNH}_2$$

OS **58**, 32.

2-30 The Conversion of Organometallic Reagents to Azides

Azido-de-metallation (Overall transformation)

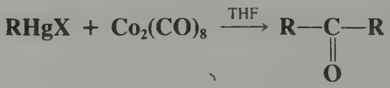
$$\text{ArMgX} + \text{TsN}_3 \longrightarrow (\text{ArNNNTs})\text{MgX} \xrightarrow[\text{pyrophosphate}]{\text{sodium}} \text{ArN}_3$$

Aryl Grignard reagents react with tosyl azide to give triazene salts that can be fragmented by treatment with aqueous sodium pyrophosphate to give moderate-to-good yields of aryl azides.[277] Alkyl Grignard reagents also give the reaction, but yields are poor. Alkyl azides RN_3 can be prepared by reaction of organoboranes R_3B with $Fe(N_3)_3$ in the presence of H_2O_2.[278]

F. Carbon Electrophiles

2-31 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Esters, or Amides

Acyl-de-metallation, etc.



$$\text{RHgX} + \text{Co}_2(\text{CO})_8 \xrightarrow{\text{THF}} \text{R}\text{—}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{—R}$$

Symmetrical ketones can be prepared in good yields by the reaction of organomercuric halides[279] with dicobalt octacarbonyl in THF,[280] or with nickel carbonyl in DMF or certain other solvents.[281] R may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $Co_2(CO)_8$ reaction, although the $Ni(CO)_4$ reaction seems to be free from such rearrangements.[281] Divinyl ketones have been prepared in high yields by treatment of vinylmercuric halides with CO and a rhodium catalyst.[282] When arylmercury halides are treated with nickel carbonyl in the presence of Ar′I, unsymmetrical diaryl ketones can be obtained.[281] In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds R_4Sn are treated with a halide R′X (R′ = aryl, vinyl, benzyl), CO, and a Pd complex catalyst.[283] A similar reaction used Grignard reagents, $Fe(CO)_5$, and an alkyl halide.[284]

[282] Larock and Hershberger, *J. Org. Chem.* **45,** 3840 (1980).

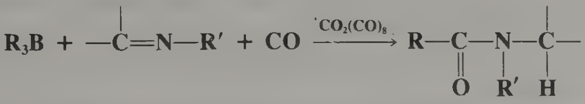
Grignard reagents react with formic acid to give good yields of aldehydes. Two moles of RMgX are used; the first converts HCOOH to $HCOO^-$, which reacts with the second mole to give RCHO.[285] Aryllithiums and Grignard reagents react with iron pentacarbonyl to give aldehydes ArCHO,[286] while alkyllithium reagents react with CO to give symmetrical ketones.[287] α,β-Unsaturated aldehydes can be prepared by treatment of vinylsilanes with dichloromethyl methyl ether and $TiCl_4$ at −90°C.[288] Vinylic aluminum compounds react with methyl chloroformate ClCOOMe to give α,β-unsaturated esters directly.[289] The latter compounds can also be prepared by treating **25** with CO, $PdCl_2$, and NaOAc in MeOH.[290]

Arylthallium bis(trifluoroacetates) (see **2-20**) can be carbonylated with CO, an alcohol, and a $PdCl_2$ catalyst to give esters of aryl carboxylic acids:[291]

$$ArTl(OOCCF_3)_2 + ROH + CO \xrightarrow{PdCl_2} ArCOOR$$

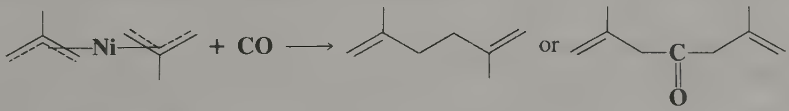
Alkyl and aryl Grignard reagents undergo a similar reaction with $Fe(CO)_5$ instead of CO.[292]

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl:[293]



$$R_3B + -\overset{|}{C}=N-R' + CO \xrightarrow{CO_2(CO)_8} R-\underset{O}{\underset{\|}{C}}-\underset{R'}{\underset{|}{N}}-\underset{H}{\underset{|}{\overset{|}{C}}}-$$

Treatment of bis-π-allylnickel complexes [which can be prepared from an allyl Grignard reagent and $NiBr_2$ or from a π-allylnickel bromide (p. 405)] with CO gives either a 1,5-hexadiene or a diallyl ketone, depending on the structure of the ligand.[294]



See also reactions **0-104, 5-20, 6-71,** and **8-26** to **8-28.**

2-32 Cyanation of Organometallic Compounds

Cyano-de-metallation

$$ArTl(OOCCF_3)_2 \xrightarrow[\text{aq. KCN}]{\text{excess}} ArTl(CN)_3^- \ K^+ \xrightarrow[\text{KCN}]{h\nu} ArCN$$

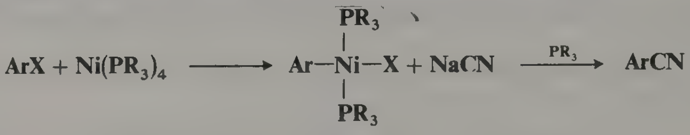
Arylthallium bis(trifluoroacetates) (see **2-20**) can be converted to aryl nitriles by treatment with excess aqueous KCN followed by photolysis of the resulting complex ion $ArTl(CN)_3^-$ in the presence of excess KCN.[233] Alternatively, arylthallium(III) salts react with $Cu(CN)_2$ or CuCN to give aryl nitriles without irradiation,[295] e.g.,

$$\mathbf{PhTl(OAc)(ClO_4) + Cu(CN)_2} \xrightarrow[\text{pyridine}]{115^\circ\text{C},\ 5\ \text{hr}} 75\%\ \mathbf{PhCN}$$

Yields from this procedure are variable, ranging from almost nothing to 90 or 100%. In another method, the arylnickel(0) complex **29** reacts with sodium cyanide to give aryl nitriles.[296] **29** are prepared by treatment of aryl halides with $Ni(PR_3)_4$ complexes.[297]



$$\mathbf{ArX + Ni(PR_3)_4 \longrightarrow Ar{-}\overset{\displaystyle PR_3}{\underset{\displaystyle PR_3}{\overset{|}{\underset{|}{Ni}}}}{-}X + NaCN \xrightarrow{PR_3} ArCN}$$

29

Vinylcopper reagents react with ClCN to give vinyl cyanides, though BrCN and ICN give the vinyl halide instead.[298] Vinyl cyanides have also been prepared by the reaction between vinyllithium compounds and phenyl cyanate PhOCN.[299] Alkyl cyanides RCN have been prepared, in varying yields, by treatment of sodium trialkylcyanoborates with NaCN and lead tetraacetate.[299a]

For other electrophilic substitutions of the type RM → RC, see **0-87** to **0-109,** which are discussed under nucleophilic substitutions in Chapter 10. See also **6-71.**

G. Metal Electrophiles

2-33 Transmetallation with a Metal

Metallo-de-metallation[300]

$$\mathbf{RM + M' \rightleftharpoons RM' + M}$$

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. RM′ can be successfully prepared only when M′ is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M′ is a metal more active than M. Most often, RM is R_2Hg, since mercury alkyls[279] are easy to prepare and mercury is far down in the electromotive series.[301] Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, etc. have been prepared this way. An important advantage of this method over **2-37** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls. If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

[300] This name also applies to reactions **2-34** and **2-35.**

[301] For a review of the reaction when M is mercury, see Makarova, Ref. 225, pp. 190–226. See also Ref. 279.

2-34 Transmetallation with a Metal Halide

$$\mathbf{RM + M'X \rightleftharpoons RM' + MX}$$

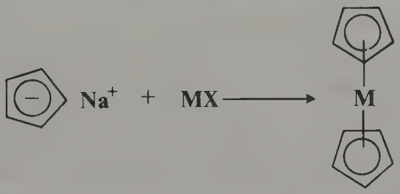
In contrast to **2-33** the reaction between an organometallic compound and a metal *halide* is successful only when M′ is *below* M in the electromotive series.[302] The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction the most common substrates are Grignard reagents and organolithium compounds. Among others, alkyls of Be, Zn, Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of Grignard reagents with the appropriate halide.[303] The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B, Ge, P, As, Sb, and Bi, can also be prepared in this manner.[304] Except for alkali-metal alkyls and Grignard reagents, the reaction between RM and M′X is the most common method for the preparation of organometallic compounds.[305]

If M′ has a valence higher than 1, it is often possible to stop the reaction before all the halogens have been replaced, e.g.,

$$\mathbf{RMgX + SiCl_4 \longrightarrow RSiCl_3}$$

However, it is not always possible: RMgX + BF_3 gives only BR_3, although $BRCl_2$ can be prepared from R_2Zn and BCl_3.

Metallocenes (see p. 44) are usually made by this method:



Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.[306]

Metal nitrates are sometimes used instead of halides.

OS **I,** 231, 550; **III,** 601; **IV,** 258, 473, 881; **V,** 211, 496, 727, 918, 1001; **55,** 127; **58,** 152; **59,** 122. Also see OS **IV,** 476

2-35 Transmetallation with an Organometallic Compound

$$\mathbf{RM + R'M' \rightleftharpoons RM' + R'M}$$

This type of metallic exchange is used much less often than **2-33** and **2-34.** It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,[307] e.g., vinyl- or allyllithium, most commonly from an organotin substrate. Examples are the preparation of vinyllithium from phenyllithium and tetravinyltin and the formation of α-dimethylamino organolithium compounds from the corresponding organotin compounds[308]

[307] For reviews, see Kauffmann, *Top. Curr. Chem.* **92,** 109–147 (1980), pp. 130–136; Seyferth, Vaughan, Raab, Welch, Cohen, and Alleston, *Bull. Soc. Chim. Fr.* 1364–1367 (1963).

$$\mathbf{RR'NCH_2SnBu_3 + BuLi \xrightarrow{0^\circ C} RR'NCH_2Li + Bu_4Sn}$$

The reaction has also been used to prepare 1,30dilithiopropanes from the corresponding mercury compounds.[309] In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (p. 152). The reaction proceeds with retention of configuration;[310] an SEi mechanism is likely.[311]

OS **V**, 452; **51**, 17.

Halogen as Leaving Group

A. Hydrogen as the Electrophile

2-36 Reduction of Alkyl Halides

Although this reaction can proceed by an electrophilic substitution mechanism, it is considered in Chapter 10 (**0-77**).

B. Metal Electrophiles

2-37 Replacement of a Halogen with a Metal

Metallo-de-halogenation[312]

$$\mathbf{RX + M \longrightarrow RM}$$

Alkyl halides react directly with certain metals to give organometallic compounds.[313] The most common metal is magnesium, and of course this is by far the most common method for the preparation of Grignard reagents.[314] The order of halide activity is I > Br > Cl. The reaction can be applied to many alkyl halides—primary, secondary, and tertiary—and to aryl halides, though aryl *chlorides* require the use of THF or another higher-boiling solvent instead of the usual ether, or special entrainment methods.[315] Aryl iodides and bromides can be treated in the usual manner. Allyl Grignard reagents can also be prepared in the usual manner (or in THF),[316] though in the presence of excess halide these may give Wurtz-type coupling products (see **0-88**). Like aryl chlorides, vinyl halides require higher-boiling solvents (see OS **IV**, 258). Ethynyl Grignard reagents are not generally prepared by this method at all. For these, **2-19** is used. Chemically activated magnesium can be used for difficult cases.[317] Dihalides[318] can be converted to Grignard reagents if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain dimagnesium compounds, e.g., $BrMg(CH_2)_4MgBr$.[319] 1,2-Dihalides give elimination instead of Grignard reagent formation (**7-29**), and the reaction is seldom successful with 1,1-dihalides, though the preparation of *gem*-disubstituted compounds, such as $CH_2(MgBr)_2$, has been accomplished with these substrates.[320] α-Halo Grignard reagents and α-halolithium reagents can be prepared by the method given in **2-38.**[321] Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in tetrahydrofuran for several days.[322]

[318] For a review of the preparation of Grignard reagents from dihalides, see Heaney, *Organomet. Chem. Rev.* **1,** 27–42 (1966).

The presence of other functional groups in the halide usually affects the preparation of the Grignard reagent. Groups that contain active hydrogen (as defined on p. 548), such as OH, NH_2, and COOH, may be present in the molecule, but only if they are converted to the salt form (O^-, NH^-, COO^-, respectively). Groups that react with Grignard reagents, such as C═O, C≡N, NO_2, COOR, etc., inhibit Grignard formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β-halo ethers generally give β-elimination when treated with magnesium (see **7-31**), and Grignard reagents from α-halo ethers[323] can only be formed in tetrahydrofuran or methylal at a low temperature, e.g.,[324]

$$\mathbf{EtOCH_2Cl + Mg \xrightarrow[-30^\circ C]{THF\ or\ CH_2(OMe)_2} EtOCH_2MgCl}$$

because such reagents immediately undergo α elimination (see **2-38**) at room temperature in ether solution.

Because Grignard reagents react with water (**2-22**) and with oxygen (**2-23**), it is generally best to prepare them in an anhydrous nitrogen atmosphere. Grignard reagents are generally neither isolated nor stored; solutions of Grignard reagents are used directly for the required synthesis. Grignard reagents can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX.[325] This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.[326]

Next to the formation of Grignard reagents, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,[327] but it has also been carried out with many other metals, e.g., Na, Be, Zn, Hg, As, Sb, and Sn.[328] With sodium, the Wurtz reaction (**0-87**) is an important side reaction. The reaction is not successful for potassium, complex mixtures being obtained in which RK is an unimportant constituent.[329] In some cases where the reaction between a halide and a metal is too slow, an alloy of the metal with potassium or sodium can be used instead. The most important example is the preparation of tetraethyllead from ethyl bromide and a Pb–Na alloy.

[329] Finnegan, *Tetrahedron Lett.* 1303 (1962), 851 (1963).

The efficiency of the reaction can often be improved by use of the metal in its powdered[330] or vapor[331] form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures.

The mechanism of Grignard reagent formation is not well known, though considerable work has been done in the area.[332] There is much evidence from CIDNP[333] (p. 163) and from stereochemical, rate, and product studies[334] that free radicals are intermediates. Further evidence is that free radicals have been trapped.[335] The following mechanism has been proposed:[333]

$$\begin{aligned} \mathrm{R{-}X} + \overline{\mathrm{Mg}} &\longrightarrow \mathrm{R{-}X}^{\dot{-}} + \mathrm{Mg}_s^{\dot{+}} \\ \mathrm{R{-}X}^{\dot{-}} &\longrightarrow \mathrm{R}\cdot + \mathrm{X}^- \\ \mathrm{X}^- + \mathrm{Mg}_s^{\dot{+}} &\longrightarrow \mathrm{XMg}_s^{\bullet} \\ \mathrm{R}\cdot + \mathrm{XMg}_s^{\bullet} &\longrightarrow \mathrm{RMgX} \end{aligned}$$

The species $\mathrm{R{-}X}^{\dot{-}}$ and $\mathrm{Mg}^{\dot{+}}$ are radical ions.[336] The subscript "s" is meant to indicate that the species so marked are bound to the surface of the magnesium.

There are too many preparations of Grignard reagents in *Organic Syntheses* for us to list here. Use of the reaction to prepare other organometallic compounds can be found in OS **I,** 228; **II,** 184, 517, 607; **III,** 413, 757; **52,** 19; **55,** 103. The preparation of unsolvated butylmagnesium bromide is described at OS **V,** 1141. The preparation of highly reactive (powdered) magnesium is given at OS **59,** 85.

2-38 Replacement of a Halogen by a Metal from an Organometallic Compound

$$\mathbf{RX + R'M \longrightarrow RM + R'X}$$

The exchange reaction between halides and organometallic compounds is almost entirely limited to the cases where M is lithium and X is bromide or iodide,[337] though it has been shown to occur with magnesium.[338] R′ is usually, although not always, alkyl, and often butyl; R is usually aromatic. Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give Wurtz coupling. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Vinylic halides react with retention of configuration.[339] The reaction can be used to prepare α-halo organolithium and α-halo organomagnesium compounds,[340] e.g.,[341]

[334] See, for example, Walborsky and Aronoff, *J. Organomet. Chem.* **51,** 31 (1973); Czernecki, Georgoulis, Gross, and Prevost, *Bull. Soc. Chim. Fr.* 3720 (1968); Rogers, Hill, Fujiwara, Rogers, Mitchell, and Whitesides, *J. Am. Chem. Soc.* **102,** 217 (1980); Barber and Whitesides, *J. Am. Chem. Soc.* **102,** 239 (1980).

[335] Lawrence and Whitesides, *J. Am. Chem. Soc.* **102,** 2493 (1980).

[336] For additional evidence for this mechanism, see Vogler, Stein, and Hayes, *J. Am. Chem. Soc.* **100,** 3163 (1978); Sergeev, Zagorsky, and Badaev, *J. Organomet. Chem.* **243,** 123 (1983).

[337] For a review, see Parham and Bradsher, *Acc. Chem. Res.* **15,** 300–305 (1982).

[338] See, for example, Zakharkin, Okhlobystin, and Bilevitch, *J. Organomet. Chem.* **2,** 309 (1964); Tamborski and Moore, *J. Organomet. Chem.* **26,** 153 (1971).

[339] For examples of exchange where R = vinyl, see Neumann and Seebach, *Chem. Ber.* **111,** 2785 (1978); Miller and McGarvey, *Synth. Commun.* **9,** 831 (1979).

$$\mathrm{CCl_4 + BuLi \xrightarrow[-105^\circ C]{THF} Cl_3C{-}Li}$$

Such compounds can also be prepared by hydrogen–metal exchange, e.g.,[342]

$$\mathrm{Br_3CH + iso\text{-}PrMgCl \xrightarrow[-95^\circ C]{THF{-}HMPT} Br_3C{-}MgCl + C_3H_8}$$

This is an example of **2-19.** However, these α-halo organometallic compounds are stable only at low temperatures (~ – 100°C) and only in tetrahydrofuran or mixtures of tetrahydrofuran and other solvents (e.g., HMPT). At ordinary temperatures they lose MX (α elimination) to give carbenes (which then react further) or carbenoid reactions. The α-chloro-α-magnesio sulfones $\mathrm{ArSO_2CH(Cl)MgBr}$ are exceptions, being stable in solution at room temperature and even under reflux.[343]

When the substrate has a halogen and a hydrogen on the same carbon, halogen–metal exchange is usually more rapid than hydrogen–metal exchange (the reaction of bromoform under the conditions shown above is an exception).[344] α-Halo sodium and α-halo potassium compounds have also been prepared by a hydrogen–metal exchange reaction.[345]

The mechanism[346] of the reaction of alkyllithium compounds with alkyl and aryl iodides has been shown to involve free radicals.[347]

$$\mathrm{RX + R'M \rightleftharpoons \underset{\text{Solvent cage}}{[R\cdot, X, M, R'\cdot]} \rightleftharpoons RM + R'X}$$

Evidence for this mechanism is the obtention of coupling and disproportionation products from R• and R′• and the observation of CIDNP (p. 163).[348]

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometallate ions, e.g.,

$$\mathrm{RX + R_3'SnLi \longrightarrow RSnR_3' + LiX}$$

These may be nucleophilic or free-radical substitutions.[349]

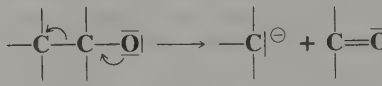
Carbon Leaving Groups

In these reactions (**2-39** to **2-47**) a carbon–carbon bond cleaves. We regard as the substrate that side which retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (**2-41**) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages,* though they do not always occur by mechanisms involving free carbanions (SE1). When they do, the reactions are facilitated by increasing stability of the carbanion.

A. Carbonyl-Forming Cleavages. These reactions follow the pattern

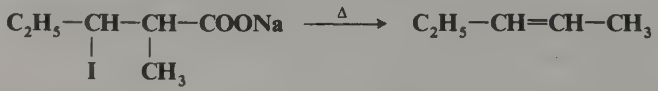


The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C=O bond. Retrograde aldol condensations (**6-40**) and cleavage of cyanohydrins (**6-49**) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in Chapter 17 (**7-46** and **7-47**).

2-39 Decarboxylation of Aliphatic Acids

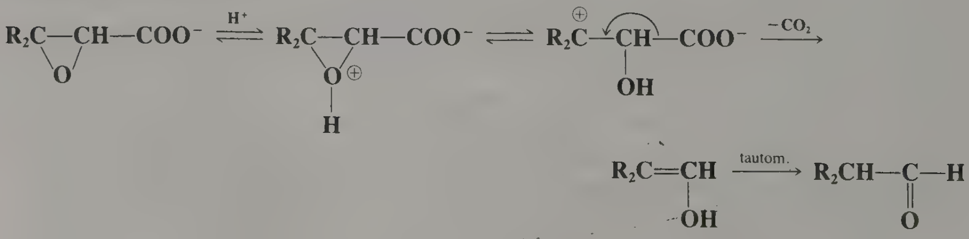
$$\mathrm{RCOOH} \longrightarrow \mathrm{RH} + \mathrm{CO_2}$$

Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple fatty acids.[350] An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or β position. Some of these are shown in Table 2. For decarboxylation of aromatic acids, see **1-41.** Decarboxylation of an α-cyano acid may give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 2, decarboxylation can also be carried out on α,β-unsaturated and α,β-acetylenic acids. β-Halo acids give decarboxylation accompanied by elimination:[351]



$$\mathrm{C_2H_5{-}\underset{\displaystyle I}{CH}{-}\underset{\displaystyle CH_3}{CH}{-}COONa} \xrightarrow{\Delta} \mathrm{C_2H_5{-}CH{=}CH{-}CH_3}$$

α,β-Unsaturated acids can also be decarboxylated with copper and quinoline in a manner similar to that discussed in **1-41.** Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:[352]



---

[350] March, *J. Chem. Educ.* **40,** 212 (1963).

[351] For a discussion of the mechanism of this elimination, see Vaughan, Cartwright, and Henzi, *J. Am. Chem. Soc.* **94,** 4978 (1972).

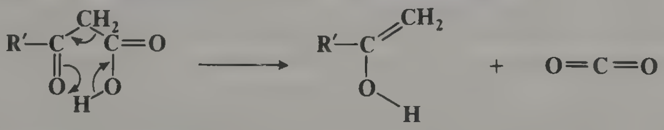
TABLE 2 Some acids which undergo decarboxylation fairly readily
Others are described in the text

	Acid type	Decarboxylation product
Malonic	$\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Cyano	$\mathrm{NC{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{NC{-}\overset{|}{\underset{|}{C}}{-}H}$ or $\mathrm{HOOC{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Nitro	$\mathrm{O_2N{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{O_2N{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Aryl	$\mathrm{Ar{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{Ar{-}\overset{|}{\underset{|}{C}}{-}H}$
α-Keto	$\mathrm{{-}\underset{\underset{O}{\|}}{C}{-}COOH}$	$\mathrm{{-}\underset{\underset{O}{\|}}{C}{-}H}$
α,α,α-Trihalo	$\mathrm{X_3C{-}COOH}$	$\mathrm{X_3CH}$
β-Keto	$\mathrm{{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}H}$
β,γ-Unsaturated	$\mathrm{{-}\underset{|}{C}{=}\underset{|}{C}{-}\overset{|}{\underset{|}{C}}{-}COOH}$	$\mathrm{{-}\underset{|}{C}{=}\underset{|}{C}{-}\overset{|}{\underset{|}{C}}{-}H}$

The direct product is an enol that tautomerizes to the aldehyde.[353] This is the usual last step in the Darzens reaction (**6-45**).

Decarboxylations can be regarded as reversals of the addition of carbanions to carbon dioxide (**6-33**), but free carbanions are not always involved.[354] When the carboxylate *ion* is decarboxylated, the mechanism may be either SE1 or SE2. In the case of the SE1 mechanism, the reaction is of course aided by the presence of electron-withdrawing groups, which stabilize the carbanion.[355] Decarboxylations of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.[356] But some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:



Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of β-keto acids,[357] but it is likely that malonic acids, α-cyano acids, α-nitro acids, and β,γ-unsaturated acids[358] behave similarly, since similar six-membered transition states can be written for them. Some α,β-unsaturated acids are also decarboxylated by this mechanism by isomerizing to the β,γ-isomers before they actually decarboxylate.[359] Evidence is that **30** and similar bicyclic β-keto acids resist decarboxylation.[360] In such compounds the six-membered cyclic transition state

---

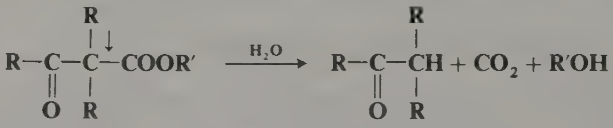
30

cannot form for steric reasons, and if it could, formation of the immediate enol product would violate Bredt's rule (p. 138). Some carboxylic acids which cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an SE1 or SE2 mechanism.[361] Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water[362]), and is not subject to acid catalysis.[363] The rate of decarboxylation of a β,γ-unsaturated acid was increased about 10^5–10^6 times by introduction of a β-methoxy group, indicating that the cyclic transition state has dipolar character.[364]

Although β-keto acids[365] are easily decarboxylated, this reaction is seldom performed because such acids are usually prepared from β-keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids. This decarboxylation of β-keto esters involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic,



$$\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{R-C}}-\overset{\substack{\mathrm{R}\\ |\,\downarrow}}{\underset{\substack{|\\ \mathrm{R}}}{\mathrm{C}}}-\mathrm{COOR'} \xrightarrow{\mathrm{H_2O}} \underset{\substack{\|\\ \mathrm{O}}}{\mathrm{R-C}}-\overset{\substack{\mathrm{R}\\ |}}{\underset{\substack{|\\ \mathrm{R}}}{\mathrm{CH}}} + \mathrm{CO_2} + \mathrm{R'OH}$$

neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (**2-42**). β-Keto esters can be decarbalkoxylated without passing through the free-acid stage by treatment with boric anhydride B_2O_3 at 150°C.[366] The alkyl portion of the ester (R′) is converted to an alkene or, if it lacks a β-hydrogen, to an ether R′OR′. Another method for the decarbalkoxylation of β-keto esters, malonic esters, and α-cyano esters consists of heating the substrate in wet dimethyl sulfoxide containing NaCl, Na_3PO_4, or some other simple salt.[367] In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. Ordinary carboxylic acids, containing no activating groups, can be decarboxylated by conversion to esters of 9-hydroxy-10-chlorodihydrophenanthrene and treatment of these with Bu_3SnH.[368] A free-radical mechanism is likely. Certain decarboxylations can also be accomplished photochemically.[369] See also the decarbonylation of acyl halides, mentioned in **4-40.**

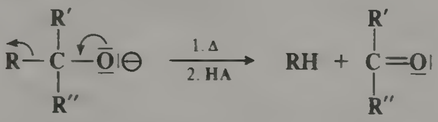
Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

With ester or nitrile hydrolysis: OS **I,** 290, 451, 523; **II,** 200, 391; **III,** 281, 286, 317, 326, 510, 513, 591; **IV,** 55, 93, 176, 441, 664, 708, 790, 804; **V,** 76, 288, 572, 687, 989; **53,** 70, 98; **57,** 80; **58,** 79; **61,** 56, 77.

Simple decarboxylations: OS **I,** 351, 401, 440, 473, 475; **II,** 21, 61, 93, 229, 302, 333, 368, 416, 474, 512, 523; **III,** 213, 425, 495, 705, 733, 783; **IV,** 234, 254, 278, 337, 555, 560, 597, 630, 731, 857; **V,** 251, 585; **51,** 73, 136; **61,** 59. Also see OS **IV,** 633.

2-40 Cleavage of Alkoxides

Hydro-de-(α-oxidoalkyl)-substitution

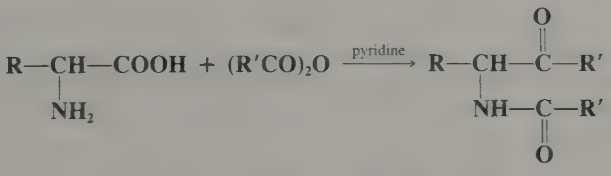


Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (**6-30**).[370] The reaction is unsuccessful when the R groups are simple unbranched alkyl groups, e.g., the alkoxide of triethylcarbinol. Cleavage is accomplished with branched alkoxides such as the alkoxides of diisopropylneopentylcarbinol or tri-*t*-butylcarbinol.[371] The reaction also takes place when R is aryl; for example, the alkoxide of triphenylcarbinol gives benzene and benzophenone. The reaction has been used for extensive mechanistic studies (see p. 517).

OS **51,** 70.

2-41 Replacement of a Carboxyl Group by an Acyl Group

Acyl-de-carboxylation



$$\underset{\substack{|\\ NH_2}}{R{-}CH}{-}COOH + (R'CO)_2O \xrightarrow{\text{pyridine}} \underset{\substack{|\\ NH{-}\underset{\substack{\|\\ O}}{C}{-}R'}}{R{-}CH}{-}\overset{\substack{O\\ \|}}{C}{-}R'$$

When an α-amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin–West reaction.* The mechanism involves formation of an oxazolone.[372] The reaction sometimes takes place on carboxylic acids even when an α-amino group is not present. In such cases, γ and δ amino groups facilitate the reaction.[373]

OS **IV,** 5; **V,** 27.

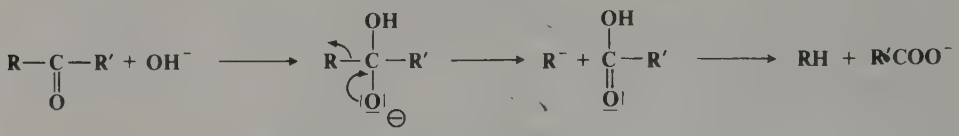
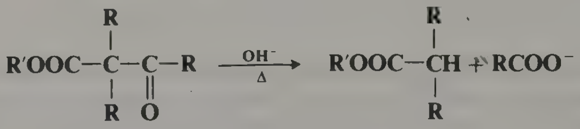
B. Acyl Cleavages. In these reactions (**2-42** to **2-45**) a carbonyl group is attacked by a hydroxide ion (or amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Chapter 10.



With respect to R of course this is electrophilic substitution. Indications are that the mechanism is usually SE1.

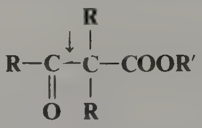
2-42 Basic Cleavage of β-Keto Esters and β-Diketones

Hydro-de-acylation[374]



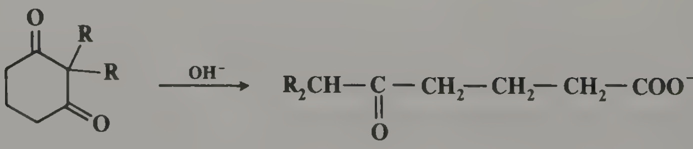
$$R'OOC-\underset{R}{\overset{R}{C}}-\underset{O}{\overset{}{\underset{\|}{C}}}-R \xrightarrow[\Delta]{OH^-} R'OOC-\underset{R}{\overset{R}{CH}} + RCOO^-$$

When β-keto esters are treated with concentrated base, cleavage occurs, but is on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned on page 564. The products are



$$R-\underset{O}{\underset{\|}{C}}\overset{\downarrow}{-}\underset{R}{\overset{R}{C}}-COOR'$$

an ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. β-Diketones behave similarly to give a ketone and the salt of a carboxylic acid. The reaction has often been applied to cyclic β-diketones:[375]



With both β-keto esters and β-diketones, OEt^- may be used instead of OH^-, in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of β-keto esters, this is the reverse of Claisen condensation (**0-111**).

OS **II**, 266, 531; **III**, 379; **IV**, 415, 957; **V**, 179, 187, 277, 533, 747, 767.

---

[374] This name also applies to reactions **2-44** and **2-45**.

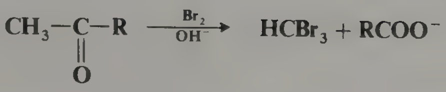
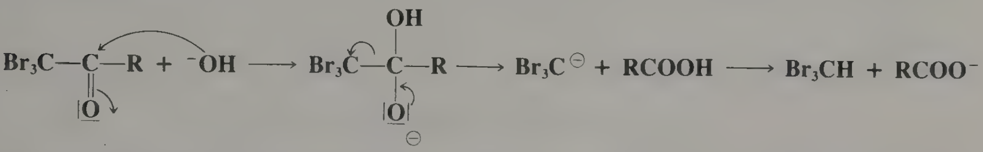
2-43 The Haloform Reaction



$$CH_3\text{—}\underset{\underset{O}{\|}}{C}\text{—}R \xrightarrow[OH^-]{Br_2} HCBr_3 + RCOO^-$$

In the *haloform reaction,* methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.[376] The halogen may be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of **2-4,** in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion:

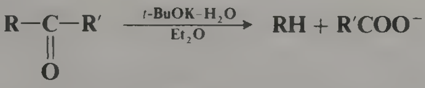


Primary or secondary methylcarbinols also give the reaction, since they are oxidized to the carbonyl compounds under the conditions employed. As with **2-4,** the rate-determining step is the preliminary enolization of the methyl ketone.[377] A side reaction is α halogenation of the nonmethyl R group. Sometimes these groups are also cleaved.[378] The reaction cannot be applied to F_2, but ketones of the form $RCOCF_3$ (R = alkyl or aryl) give fluoroform and $RCOO^-$ when treated with base.[379] The haloform reaction is often used as a test for methylcarbinols and methyl ketones. Iodine is most often used as the test reagent, since iodoform is an easily identifiable yellow solid. The reaction is also frequently used for synthetic purposes.

OS **I,** 526; **II,** 428; **III,** 302; **IV,** 345; **V,** 8. Also see OS **51,** 100.

2-44 Cleavage of Nonenolizable Ketones

Hydro-de-acylation



$$R\text{—}\underset{\underset{O}{\|}}{C}\text{—}R' \xrightarrow[Et_2O]{t\text{-BuOK-}H_2O} RH + R'COO^-$$

Ordinary ketones are generally much more difficult to cleave than trihalo ketones or β-diketones, because the carbanion intermediates in these cases are more stable than simple carbanions. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of *t*-BuOK-H_2O in an aprotic solvent such as ether, dimethyl sulfoxide, 1,2-dimethoxyethane (glyme), etc.,[380] or with solid *t*-BuOK in the absence of a solvent.[381] When the reaction is applied to monosubstituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of strain).[382] Combined with the preparation of diaryl ketones by Friedel–

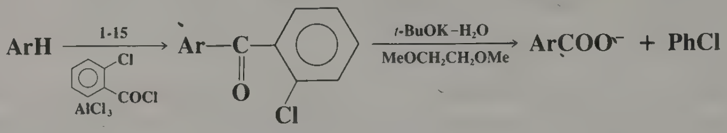
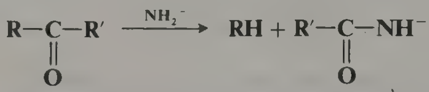
Crafts acylation (**1-15**), this reaction provides an indirect method for introducing a carboxyl group into an aromatic ring:[383]



2-Chlorobenzoyl chloride is the preferred reagent here, because a 2-chlorophenyl group cleaves much more readily than most other aryl groups. In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.[384]

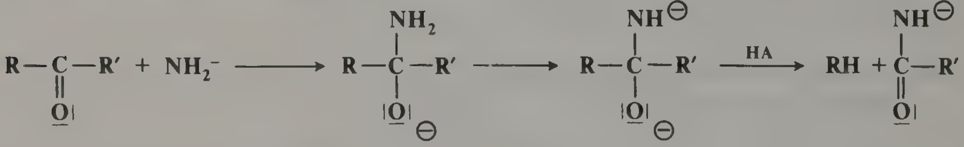
OS **56,** 28.

2-45 The Haller–Bauer Reaction



$$R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R' \xrightarrow{NH_2^-} RH + R'{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}NH^-$$

Cleavage of ketones with sodium amide is called the *Haller–Bauer reaction.*[385] As with **2-44,** which is exactly analogous, the reaction is usually applied only to nonenolizable ketones, most often to ketones of the form $ArCOCR_3$, where the products R_3CCONH_2 are not easily attainable by other methods. However, many other ketones have been used, though benzophenone is virtually unaffected. It has been shown that the configuration of optically active R is retained.[386] The NH_2 loses its proton *before* the R is cleaved:[387]



$$R{-}\underset{\underset{\displaystyle \underline{O}|}{\|}}{C}{-}R' + NH_2^- \longrightarrow R{-}\overset{\overset{\displaystyle NH_2}{|}}{\underset{\underset{\displaystyle |\underline{O}|^{\ominus}}{|}}{C}}{-}R' \longrightarrow R{-}\overset{\overset{\displaystyle NH^{\ominus}}{|}}{\underset{\underset{\displaystyle |\underline{O}|^{\ominus}}{|}}{C}}{-}R' \xrightarrow{HA} RH + \overset{\overset{\displaystyle NH^{\ominus}}{|}}{\underset{\underset{\displaystyle \underline{O}|}{\|}}{C}}{-}R'$$

OS **V,** 384, 1074.

C. Other Cleavages

2-46 The Cleavage of Alkanes
Hydro-de-*t*-butylation, etc.

$$(CH_3)_4C \xrightarrow{FSO_3H\text{-}SbF_5} CH_4 + (CH_3)_3C^+$$

The C—C bonds of alkanes can be cleaved by treatment with super acids[43] (p. 219). The reaction may be called *alkylolysis*. For example, neopentane in FSO_3H-SbF_5 can cleave to give methane and the *t*-butyl cation. C—H cleavage (see **2-1**) is a competing reaction and, for example, neopentane can give H_2 and the *t*-pentyl cation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C—H > C—C > secondary

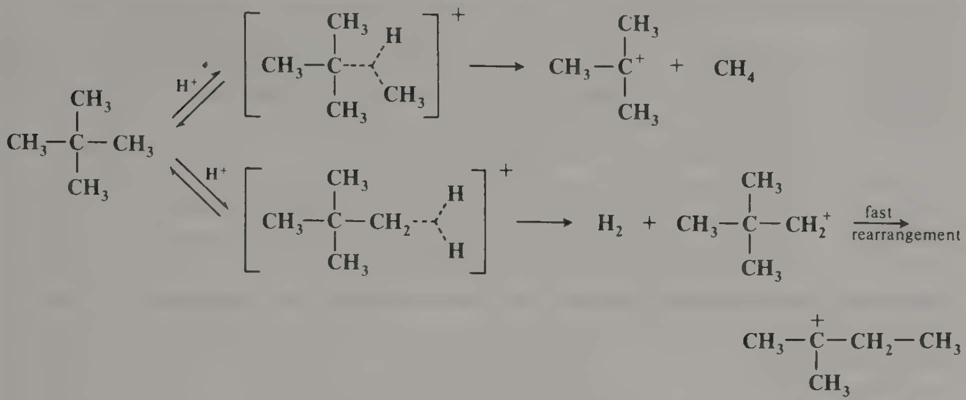
C—H ≫ primary C—H, though steric factors cause a shift in favor of C—C cleavage in such a hindered compound as tri-*t*-butylmethane. The mechanism is similar to that shown in **2-1** and **2-16** and involves attack by H^+ on the C—C bond to give a pentavalent cation. The two major pathways for neopentane may therefore be shown as:



t-Pentyl cation

Catalytic hydrogenation seldom breaks unactivated C—C bonds (i.e., $R—R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni-Al_2O_3 catalyst at about 250°C.[388] Certain C—C bonds have been cleaved by alkali metals.[388a]

2-47 **Decyanation** or **Hydro-de-cyanation**

$$\text{RCN} \xrightarrow[\text{Na-Fe(acac)}_3]{\text{Na-NH}_3 \text{ or}}$$

The cyano group of alkyl nitriles can be removed by treatment with metallic sodium, either in liquid ammonia,[389] or together with tris(acetylacetonato)iron(III) $Fe(acac)_3$[390] or, with lower yields, titanocene $C_{20}H_{20}Ti_2$. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na-NH_3 method gives high yields with R groups such as trityl, benzyl, phenyl, and tertiary alkyl, but lower yields (~35 to 50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na-$Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R· which would then be reduced to the carbanion R^-, which by abstraction of a proton from the solvent, would give RH. The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,[391] which is successful for R = primary, secondary, or tertiary, involves the use of highly dispersed K on Al_2O_3.[392]

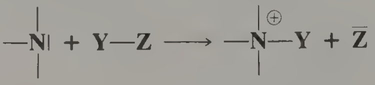
α-Amino and α-amido nitriles $RCH(CN)NR_2'$ and $RCH(CN)NHCOR'$ can be decyanated in high yield by treatment with $NaBH_4$.[393]

Electrophilic Substitution at Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:



$$-\overset{|}{\underset{|}{N}}| + Y-Z \longrightarrow -\overset{|\,\oplus}{\underset{|}{N}}-Y + \overline{Z}$$

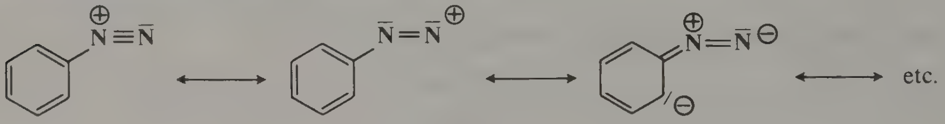
31

Further reaction of **31** depends on the nature of Y and of the other groups attached to the nitrogen.

2-48 Diazotization

$$Ar-NH_2 + HONO \longrightarrow Ar-\overset{\oplus}{N}\equiv\overline{N}$$

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.[394] The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see p. 313). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogens and the ring:



33

Incidentally, **32** contributes more to the hybrid than **33**, as shown by bond-distance measurements.[395] In benzenediazonium chloride, the C—N distance is ~1.42 Å, and the N—N distance ~1.08 Å,[396] which values fit more closely to a single and a triple bond than to two double bonds (see p. 19). Even aromatic diazonium salts are stable only at low temperatures, usually only below 5°C, though more stable ones, such as the diazonium salt obtained from sulfanilic acid, are stable up to 10 or 15°C. Diazonium salts are usually prepared in aqueous solution and used without isolation,[397] though it is possible to prepare solid diazonium salts if desired (see **3-25**). The stability of aryl diazonium salts can be increased by crown ether complexation.[398]

[397] For a review of reactions of diazonium salts, see Wulfman, in Patai, Ref. 395, pt. 1, pp. 247–339.

[398] Korzeniowski, Leopold, Beadle, Ahern, Sheppard, Khanna, and Gokel, *J. Org. Chem.* **46,** 2153 (1981) and references cited therein. For reviews, see Bartsch, in Patai and Rappoport, "The Chemistry of Functional Groups, Supplement C," pt. 1, pp. 889–915, Wiley, New York, 1983; Bartsch, *Prog. Macrocyclic Chem.* **2,** 1–39 (1981).

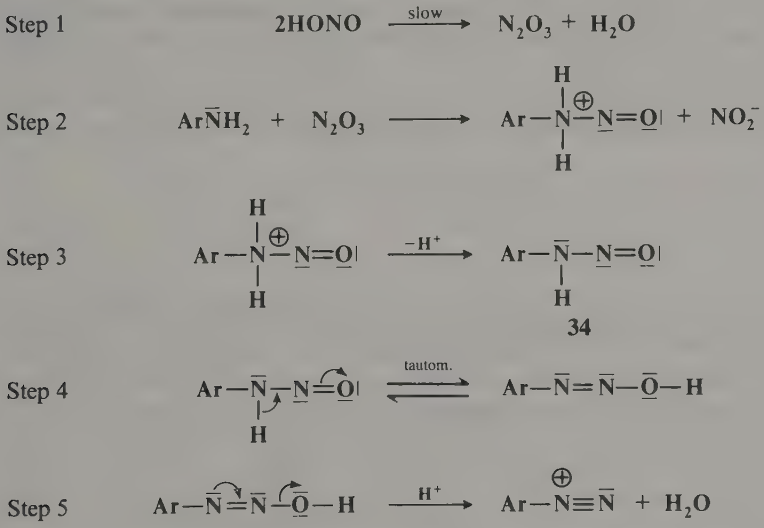
For aromatic amines, the reaction is very general.[399] Halogen, nitro, alkyl, aldehyde, sulfonic acid, etc., groups do not interfere. Since aliphatic amines do not react with nitrous acid below a pH of about 3, it is even possible, by working at a pH of about 1, to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.[400]

If an aliphatic amino group is α to a COOR, CN, CHO, COR, etc. and has an α-hydrogen, then treatment with nitrous acid gives not a diazonium salt, but a *diazo compound.*[401] Such diazo

$$\mathrm{EtOOC{-}CH_2{-}NH_2 + HONO \longrightarrow EtOOC{-}CH{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}}}$$

compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite and a small amount of acid.[402] Certain heterocyclic amines also give diazo compounds rather than diazonium salts.[399]

Despite the fact that diazotization takes place in acid solution, the actual species attacked is not the salt of the amine, but the small amount of free amine present.[403] It is because aliphatic amines are stronger bases than aromatic ones that at pH values below 3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid the actual attacking species is N_2O_3, which acts as a carrier of NO^+. Evidence for this is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.[404] Under these conditions the mechanism is



Step 1 $\mathrm{2HONO \xrightarrow{slow} N_2O_3 + H_2O}$

Step 2 $\mathrm{Ar\bar{N}H_2 + N_2O_3 \longrightarrow Ar{-}\overset{\oplus}{N}H_2{-}\underline{N}{=}\underline{O}| + NO_2^-}$

Step 3 $\mathrm{Ar{-}\overset{\oplus}{N}H_2{-}\underline{N}{=}\underline{O}| \xrightarrow{-H^+} Ar{-}\bar{N}H{-}\underline{N}{=}\underline{O}|}$

34

Step 4 $\mathrm{Ar{-}\bar{N}H{-}\underline{N}{=}\underline{O}| \overset{tautom.}{\rightleftharpoons} Ar{-}\bar{N}{=}\bar{N}{-}\underline{O}{-}H}$

Step 5 $\mathrm{Ar{-}\bar{N}{=}\bar{N}{-}\underline{O}{-}H \xrightarrow{H^+} Ar{-}\overset{\oplus}{N}{\equiv}\bar{N} + H_2O}$

There exists other evidence for this mechanism.[405] Other attacking species may be NOCl, $H_2NO_2^+$, and at high acidities even NO^+.

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. We do not list them here, but under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III,** 392; **IV,** 424. See also OS **52,** 53.

2-49 The Conversion of Hydrazines to Azides

$$RNHNH_2 + HONO \longrightarrow R{-}\overline{N}{=}\overset{\oplus}{N}{=}\overline{N}^{\ominus}$$

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction that is exactly analogous to the formation of aliphatic diazo compounds mentioned in **2-48.**

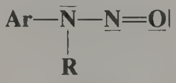
OS **III,** 710; **IV,** 819; **V,** 157.

2-50 *N*-Nitrosation or *N*-Nitroso-de-hydrogenation

$$R_2NH + HONO \longrightarrow R_2N{-}NO$$

When secondary amines are treated with nitrous acid, N-nitroso compounds are formed.[406] The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-N-substituted amides: RCONHR′ + HONO → RCON(NO)R′. Tertiary amines have also been N-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.[407] The group that cleaves appears as an aldehyde or ketone. Other reagents have also been used, for example NOCl, which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the N-nitroso compounds are highly reactive. N-Nitroso compounds are also formed by treatment of amines with gaseous N_2O_3 or N_2O_4.[408]

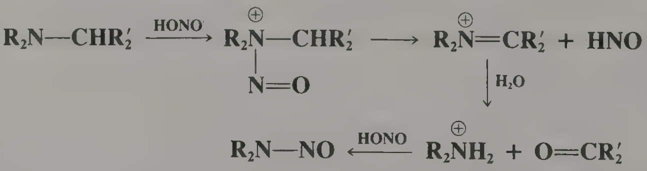
The mechanism of nitrosation is essentially the same as in **2-48** up to the point where **35** (analogous to **34**) is formed. Since this species cannot lose a proton, it is stable and the reaction



$$Ar{-}\underset{\displaystyle R}{\underset{|}{\overline{N}}}{-}\underline{N}{=}\underline{O}|$$

35

ends there. The attacking entity may be any of those mentioned in **2-48.** The following has been suggested as the mechanism for the reaction with tertiary amines:[409]



$$R_2N{-}CHR'_2 \xrightarrow{HONO} R_2\overset{\oplus}{N}(N{=}O){-}CHR'_2 \longrightarrow R_2\overset{\oplus}{N}{=}CR'_2 + HNO \xrightarrow{H_2O}$$
$$R_2N{-}NO \xleftarrow{HONO} R_2\overset{\oplus}{N}H_2 + O{=}CR'_2$$

The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by 2HNO → $H_2O + N_2O$) and that quinuclidine, where the nitrogen is at a bridgehead and therefore cannot give elimination, does not react.

Amines and amides can be N-*nitrated* with nitric acid,[410] N_2O_5,[411] or NO_2^+,[412] and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.[413] C-nitrosation is discussed at **1-3** and **2-8.**

2-51 Conversion of Amines to Azides

$$\mathbf{RNH^-} \xrightarrow[\text{base}]{\text{TsN}_3} \mathbf{RN_3}$$

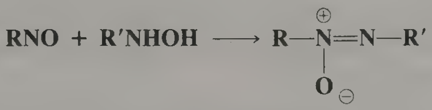
The treatment of the anion of a primary amine with tosyl azide produces the corresponding alkyl azide in low to moderate yields.[414] The reaction is analogous to the diazo transfer reaction (**2-9**) but takes place at a nitrogen rather than a carbon substrate. The conversion of amine anions to azides has also been effected with nitrous oxide N_2O.[415]

2-52 Conversion of Amines to Azo Compounds

$$\mathbf{ArNH_2 + Ar'NO} \xrightarrow{\text{HOAc}} \mathbf{Ar{-}N{=}N{-}Ar'}$$

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).[416] A wide variety of substituents may be present in both aryl groups.[417]

2-53 Conversion of Nitroso Compounds to Azoxy Compounds



$$\mathbf{RNO + R'NHOH \longrightarrow R{-}\overset{\oplus}{\underset{\underset{\ominus}{O}}{N}}{=}N{-}R'}$$

In a reaction similar to **2-52,** azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.[418] The position of the oxygen in the final product is determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R′ may be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr′, and Ar′NONAr′) are obtained[419] and the unsymmetrical product (ArNONAr′) is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction ($ArNO + Ar'NHOH \rightleftharpoons Ar'NO + ArNHOH$).[420] The mechanism[421] has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:

$$\mathrm{ArNO + ArNHOH \longrightarrow 2Ar{-}\overset{\bullet}{N}(\underline{O}^{\ominus}) \longrightarrow Ar{-}N(\underline{O}^{\ominus}){-}N(\overline{O}^{\ominus}){-}Ar \xrightarrow[H_2O]{-2OH^-} Ar{-}N{=}\overset{\oplus}{N}(\overline{O}^{\ominus}){-}Ar}$$

These radical anions have been detected by esr.[422] This mechanism is consistent with the following result: when nitrosobenzene and phenylhydroxylamine are coupled, ^{18}O and ^{15}N labeling show that the two nitrogens and the two oxygens become equivalent.[423] Unsymmetrical azoxy compounds can be prepared[424] by combination of a nitroso compound with an N,N-dibromoamine.

2-54 *N*-Halogenation or *N*-Halo-de-hydrogenation

$$\mathrm{RNH_2 + NaOCl \longrightarrow RNHCl}$$

Treatment with sodium hypochlorite or hypobromite converts primary amines into N-halo- or N,N-dihaloamines. Secondary amines may be converted to N-halo secondary amines. Similar reactions can be carried out on unsubstituted and N-substituted amides and on sulfonamides. With unsubstituted amides the N-halogen product is seldom isolated but usually rearranges (see **8-16**); however, N-halo-N-alkyl amides and N-halo imides are quite stable. The important reagent N-bromosuccinimide is made in this manner. N-Halogenation has also been accomplished with other reagents, e.g., *t*-BuOCl.[425] Unsubstituted amides can be N-brominated or N,N-dibrominated by treatment with dibromoisocyanuric acid.[426] The mechanisms of these reactions involve attack by a positive halogen and are probably similar to those of **2-48** and **2-50**.[427] N-Fluorination can be accomplished by direct treatment of amines[428] or amides[429] with F_2. Fluorination of N-alkyl-N-fluoro amides results in cleavage to N,N-difluoroamines.[430]

$$\mathrm{RNFCOR' \xrightarrow{F_2} RNF_2}$$

Three types of product can be obtained from the reaction of amines with carbon monoxide, depending on the catalyst. (1) Both primary and secondary amines react with CO in the presence of various catalysts [e.g., $Cu(CN)_2$, trimethylamine–hydrogen selenide, rhodium or ruthenium complexes] to give N-substituted and N,N-disubstituted formamides, respectively.[431] (2) Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO in the presence of selenium[432] or sulfur.[433] R may be alkyl or aryl. (3) When $PdCl_2$ is the catalyst, primary amines yield isocyanates.[434] Isocyanates can also be obtained by treatment of CO with azides: $RN_3 + CO \rightarrow RNCO$,[435] or with an aromatic nitroso or nitro compound and a rhodium complex catalyst.[436] A fourth type of product, a carbamate RNHCOOR′, can be obtained from primary or secondary amines, if these are treated with CO, O_2, and an alcohol R′OH in the presence of Pt and iodide ion.[437] Thiocarbamates RNHCOSR′ are formed on treatment of primary aliphatic amines RNH_2 with CO and a disulfide R′SSR′ in the presence of selenium.[438] See also **6-19.**

AROMATIC NUCLEOPHILIC SUBSTITUTION

On p. 300 it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and it is these exceptions that form the subject of this chapter.[1] Reactions that *are* successful at an aromatic substrate are largely of four kinds: (1) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (2) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (3) reactions initiated by electron donors; and (4) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile. However, not all the reactions discussed in this chapter fit into these categories.

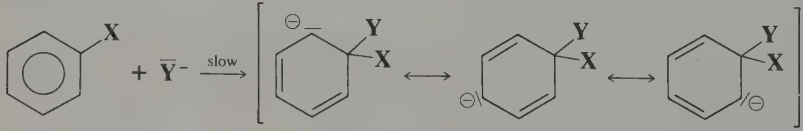
MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.[2] Three of them are similar to certain of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10. The fourth (SRN1) involves radical ions.

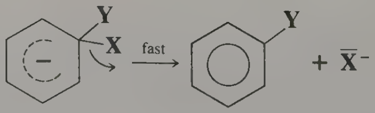
The SNAr Mechanism

By far the most important mechanism for nucleophilic aromatic substitution consists of two steps:

Step 1



Step 2



1

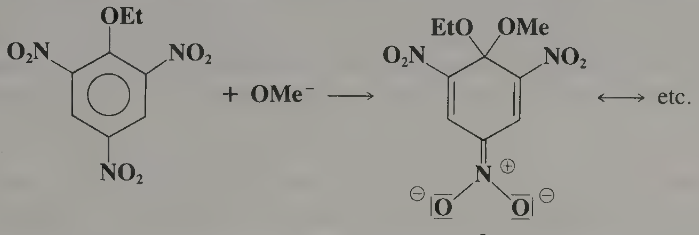
---

[1] For reviews of aromatic nucleophilic substitution, see Zoltewicz, *Top. Curr. Chem.* **59,** 33–64 (1975); Bunnett and Zahler, *Chem. Rev.* **49,** 273–412 (1951).

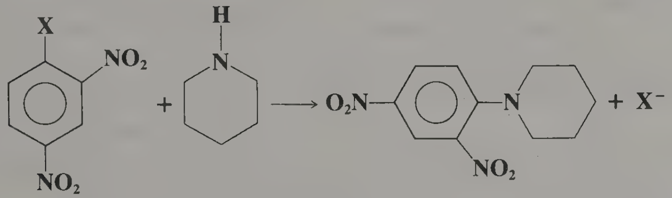
Educ.* **51,** 312–315 (1974); Ross, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 13, pp. 407–431, American Elsevier, New York, 1972, *Prog. Phys. Org. Chem.* **1,** 31–74 (1963); Buck, *Angew. Chem. Int. Ed. Engl.* **8,** 120–131 (1969) [*Angew. Chem.* **81,** 136–148]; Buncel, Norris, and Russell, *Q. Rev., Chem. Soc.* **22,** 123–146 (1968); Sauer and Huisgen, *Angew. Chem.* **72,** 294–315 (1960); Ref. 1.

The first step is usually, but not always, rate-determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 10 (p. 290) and, in another way, the arenium ion mechanism of electrophilic aromatic substitution (p. 448). In all three cases, the attacking species forms a bond with the substrate, giving an intermediate, and then the leaving group departs. We refer to this mechanism as the SNAr mechanism.[3]

There is a great deal of evidence for the mechanism; we shall discuss only some of it.[2] Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between ethyl picrate and methoxide ion.[4] Intermediates of this type are stable salts, called *Meisenheimer salts,* and many more of them have been isolated since 1902.[5] The structures of several of these intermediates have been proved by nmr[6] and by x-ray crystallography.[7] Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the SN1 or SN2 mechanisms described in Chapter 10, the Ar—X bond would be broken in the rate-determining step. In the SNAr mechanism this bond is not broken until after the rate-determining step (that is, if step 1 is rate-determining). We would predict from this that if the SNAr mechanism is operating, a change in leaving group should not have much effect on the rate of the reaction. In the reaction



2



when X was Cl, Br, I, SOPh, SO_2Ph, or *p*-nitrophenoxy, the rates differed only by a factor of about 5.[8] This behavior would not be expected in a reaction in which the Ar—X bond is broken in the rate-determining step. We do not expect the rates to be *identical,* because the nature of X affects the rate at which Y attacks. An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the SN1 and the SN2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (p. 296).

---

[3] The mechanism has also been called by other names, including the SN2Ar, the addition–elimination, and the intermediate complex mechanism.

[7] Destro, Gramaccioli, and Simonetta, *Acta Crystallogr.* **24,** 1369 (1968); Ueda, Sakabe, Tanaka, and Furusaki, *Bull. Chem. Soc. Jpn.* **41,** 2866 (1968); Messmer and Palenik, *Chem. Commun.* 470 (1969).

[8] Bunnett, Garbisch, and Pruitt, *J. Am. Chem. Soc.* **79,** 385 (1957).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. These reactions are catalyzed by bases only when a relatively poor leaving group (such as OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.[9] Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily but X does not, so that k_{-1} is large and step 2 is rate-determining. This is evidence for the SNAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low base concentrations: a plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see p. 449), is also evidence for the SNAr mechanism. At low base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high base concentration the process is virtually complete: there is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **3** followed by rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation step.[10] According to the other proposal, loss of X assisted by BH^+ is rate-determining.[11] For aprotic solvents like benzene, the situation seems to be more complicated.[12] Further evidence for the SNAr mechanism has been obtained from $^{18}O/^{16}O$ and $^{15}N/^{14}N$ isotope effects.[13]

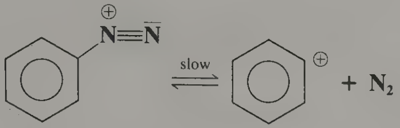
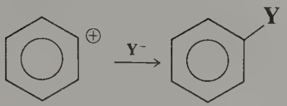
The SN1 Mechanism

For aryl halides and sulfonates,[14] even active ones, a unimolecular SN1 mechanism has never been observed with certainty. It is in reactions with diazonium salts that this mechanism is important:[15]

Step 1



Step 2



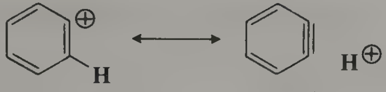
Among the evidence for the SN1 mechanism with aryl cations as intermediates,[16] is the following:[17]

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.

2. When high concentrations of halide salts are added, the product is an aryl halide but the rate is independent of the concentration of the added salts.

3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.[18]

4. When reactions were run with substrate deuterated in the ortho position, isotope effects of about 1.22 were obtained.[19] It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation, which is reduced



when hydrogen is replaced by deuterium.

5. That the first step is a reversible cleavage[20] was demonstrated by the observation that when $\mathrm{Ar}^{15}\overset{\oplus}{\mathrm{N}}\equiv\mathrm{N}$ was the reacting species, recovered starting material contained not only $\mathrm{Ar}^{15}\overset{\oplus}{\mathrm{N}}\equiv\mathrm{N}$ but also $\mathrm{Ar}\overset{\oplus}{\mathrm{N}}\equiv{}^{15}\mathrm{N}$.[21] This could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $\mathrm{PhN}\equiv{}^{15}\mathrm{N}$ with unlabeled N_2 at various pressures.

At 300 atm the recovered product had lost about 3% of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2.[22]

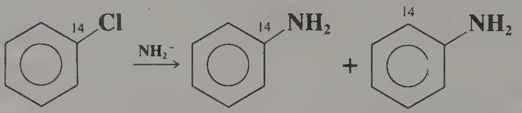
There is kinetic and other evidence[23] that step 1 is more complicated and involves two steps, both reversible:

$$ArN_2^+ \rightleftharpoons \underset{\mathbf{4}}{[Ar^+ \; N_2]} \rightleftharpoons Ar^+ + N_2$$

4 is probably some kind of a tight ion-molecule pair.

The Benzyne Mechanism[24]

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the SNAr mechanism (or the SN1 mechanism). These substitutions occur on aryl halides that have no activating groups; bases are required that are stronger than those normally used; and most interesting of all, the incoming group does not always take the position vacated by the leaving group. That the latter statement is true was elegantly demonstrated by the reaction of 1-^{14}C-chlorobenzene with potassium amide:

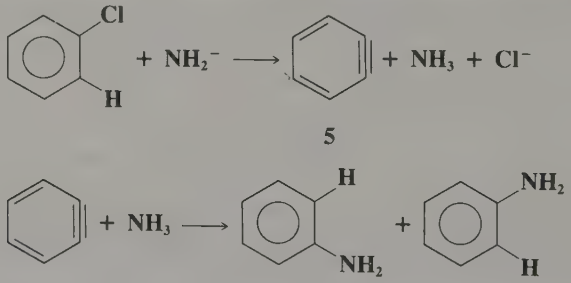


The product consisted of almost equal amounts of aniline labeled in the 1 position and in the 2 position.[25]

A mechanism that can explain all these facts involves elimination followed by addition:

Step 1

Step 2



5

The symmetrical intermediate **5** can be attacked by the NH_3 at either of two positions, which explains why about half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism is the following:

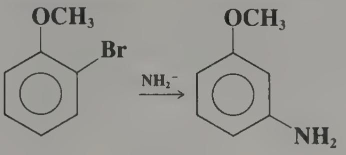
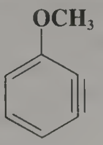
1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.[25]

2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution*[26] and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.[27] In this particular case, only the meta





6

isomer is formed. The reason a 1 : 1 mixture is not formed is that the intermediate **6** is not symmetrical and the methoxy group directs the incoming group meta but not ortho (see p. 586). However, not all cine substitutions proceed by this kind of mechanism (see **3-26**).[28]

3. The fact that the order of halide reactivity is $Br > I > Cl \gg F$ (when the reaction is performed with KNH_2 in liquid NH_3) shows that the SNAr mechanism is not operating here.[25]

In the conversion of the substrate to **6**, either proton removal or subsequent loss of halide ion can be rate-determining. In fact, the unusual leaving-group order just mentioned ($Br > I > Cl$) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate-determining and the rate order for this step is $F > Cl > Br > I$. When Cl or F is the leaving group, cleavage of the C—X bond is rate-determining and the order for this step is $I > Br > Cl > F$. Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with NH_2^-.[29] In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be $I > Br > Cl$.[29]

Species such as **5** and **6** are called *benzynes* (sometimes *dehydrobenzenes*), or, more generally, *arynes,* and the mechanism is known as the *benzyne mechanism.* Benzynes differ from the species discussed in Chapter 5 in that each carbon has a valence of 4. However, they are very reactive, as are the species in that chapter. Neither benzyne nor any other aryne has yet been isolated under ordinary conditions, but stable benzyne has been isolated in an argon matrix at 8 K,[30] where its ir spectrum could be observed. In addition, spectra of transient benzynes have been detected,[31] and benzynes can be trapped; e.g., they undergo the Diels–Alder reaction (see **5-47**). It should be noted that the extra pair of electrons does not affect the aromaticity. The original sextet still functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid. The ir spectrum, mentioned above, indicates that **A** contributes more than

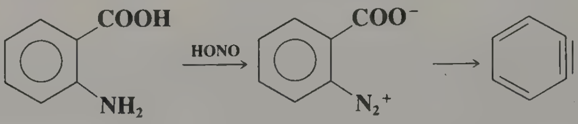
A **B**

B. Not only benzene rings but other aromatic rings[32] and even nonaromatic rings (p. 298) can react through this kind of intermediate. Of course, the nonaromatic rings do have a formal triple bond.

There are other ways to prepare benzyne intermediates.[33] Probably the most convenient method involves thermal or photolytic decomposition of the product of diazotization of anthranilic acid or its derivatives.[34]

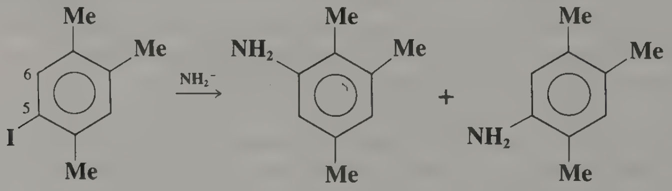


7

The zwitterion (**7**) decomposes to give the highly reactive benzyne.

The $S_{RN}1$ Mechanism

In several cases there is strong evidence that still another mechanism exists. For example, when 5-iodo-1,2,4-trimethylbenzene **8** was treated with KNH_2 in NH_3, **9** and **10** were formed in the ratio 0.63:1. From what we have already seen, the presence of an unactivated substrate, a strong base,



8 **9** **10**

and the occurrence of cine along with normal substitution would be strong indications of a benzyne mechanism. Yet if that were so, the 6-iodo isomer of **8** should have given **9** and **10** in the same ratio (because the same aryne intermediate should be formed in both cases), but in this case the ratio of **9** to **10** was 5.9:1 (the chloro and bromo analogs did give the same ratio, 1.46:1, showing that the benzyne mechanism may be taking place in this case).

[34] Stiles and Miller, *J. Am. Chem. Soc.* **82,** 3802 (1960); Stiles, Miller, and Burckhardt, *J. Am. Chem. Soc.* **85,** 1792 (1963); Gompper, Seybold, and Schmolke, *Angew. Chem. Int. Ed. Engl.* **7,** 389 (1968) [*Angew. Chem.* **80,** 404]; Logullo, Seitz, and Friedman, *Org. Synth.* **V,** 54.

To explain the iodo result, it has been proposed[35] that besides the benzyne mechanism, this free-radical mechanism is also operating here:

$$\mathrm{ArI} \xrightarrow[\text{donor}]{\text{electron}} [\mathrm{ArI}]^{\bullet -} \longrightarrow \mathrm{Ar}^{\bullet} + \mathrm{I}^{-}$$

$$\mathrm{Ar}^{\bullet} + \mathrm{NH_2}^{-} \longrightarrow \mathrm{ArNH_2}^{\bullet -} + \mathrm{ArI} \longrightarrow \mathrm{ArNH_2} + \mathrm{ArI}^{\bullet -}$$

Termination steps

This is called the SRN1 mechanism,[36] and several other aromatic examples have been found (see **3-5, 3-7, 3-14**), as well as aliphatic examples (see p. 415). Note that the last step of the mechanism produces $\mathrm{ArI}^{\cdot -}$ radical ions, so that the process is a chain mechanism[37] (see p. 609). An electron donor is required to initiate the reaction. In the case above it was solvated electrons from $\mathrm{KNH_2}$ in $\mathrm{NH_3}$. Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the cine substitution. Further evidence for the SRN1 mechanism was that addition of radical scavengers (which would suppress a free-radical mechanism) led to **9**:**10** ratios much closer to 1.46:1. Numerous other observations of SRN1 mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.[38] Further evidence for the SRN1 mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by $\mathrm{Ar}^{\cdot}$ of H from the solvent $\mathrm{NH_3}$. Besides initiation by solvated electrons, SRN1 reactions have been initiated photochemically,[39] electrochemically,[40] and even thermally.[41]

SRN1 reactions have a fairly wide scope. There is no requirement for activating groups or strong bases. Alkyl, alkoxy, aryl, and $\mathrm{COO^-}$ groups do not interfere, although $\mathrm{Me_2N}$, $\mathrm{O^-}$, and $\mathrm{NO_2}$ groups do interfere. Cine substitution is not found.

Other Mechanisms

There is no clear-cut proof that a one-step SN2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. Such a mechanism has been suggested[42] in cases where fluoro is a very poor leaving group, since this would be consistent with an SN2 process, but not with the SNAr mechanism as shown on p. 576. On the other hand, an SNAr mechanism in which the *second* step is rate-determining would be quite compatible with reactions in which fluoro is a poor leaving group, and some of them have been shown to operate by such a process.[43] The hypothetical aromatic SN2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* SNAr mechanism.

Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see **3-17**).

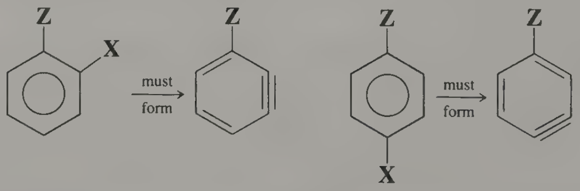
REACTIVITY

The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11) equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogens that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

Aromatic nucleophilic substitutions proceeding by the SNAr mechanism are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group[44] and hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Chapter 11 (p. 453). Table 1 contains a list of groups arranged approximately in order of activating or deactivating ability. Hetero nitrogen atoms are also strongly activating (especially to the α and γ positions) and are even more so when quaternized.[48] Thus 2- and 4-chloropyridine, for example, are often used as substrates. Heterocyclic N-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.[49] The N_2^+ group is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound such as *p*-nitroaniline or *p*-chloroaniline the group para to the diazonium group is replaced by OH from the solvent or by X from $ArN_2^+ X^-$, to the surprise and chagrin of the investigator, who was trying only to replace the diazonium group and to leave the para group untouched. By far the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).[50] Polyfluorobenzenes, e.g., C_6F_6, also undergo aromatic nucleophilic substitution quite well.[51] Benzene rings that lack activating substituents are generally not useful substrates for the SNAr mechanism, because the two extra electrons in **1** are in an antibonding orbital (p. 25). Activating groups, by withdrawing electron density, are able to stabilize the intermediates.

In reactions involving aryne intermediates, two factors affect the position of the incoming group, the first being the direction in which the aryne forms.[52] When there are groups ortho or para to the leaving group, there is no choice:



---

[44] The effect of meta substituents has been studied much less, but it has been reported that here too, electron-withdrawing groups increase the rate: See Nurgatin, Sharnin, and Ginzburg, *J. Org. Chem. USSR* **19,** 343 (1983).

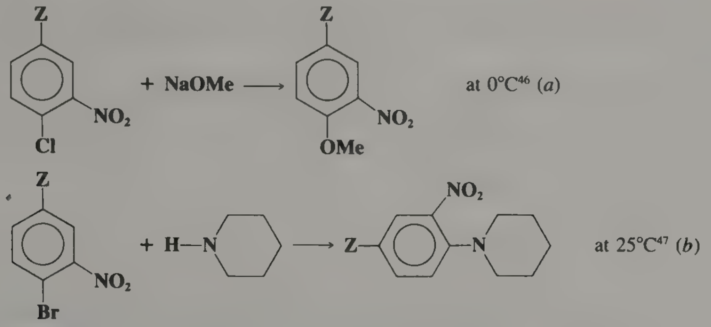
TABLE 1 Groups listed in approximate descending order of activating ability in the SNAr mechanism[45]

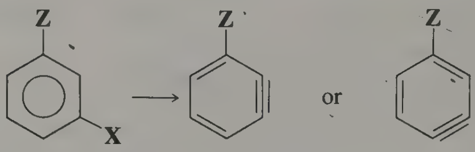


For reaction (a) the rates are relative to **H**; *for (b) they are relative to* **NH$_2$**

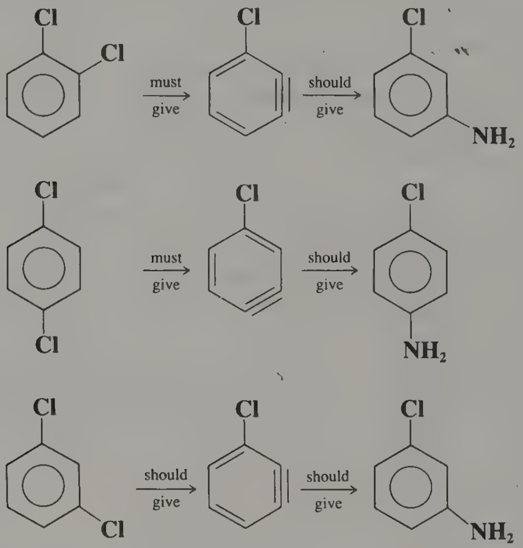
		Relative rate of reaction	
	Group Z	(*a*) **H = 1**[46]	(*b*) **NH$_2$ = 1**[47]
Activates halide exchange at room temperature	**N$_2^+$**		
Activates reaction with strong nucleophiles at room temperature	**N$^+$—R (heterocyclic)**		
Activate reactions with strong nucleophiles at 80–100°C	**NO**	5.22 × 10^6	
	NO$_2$	6.73 × 10^5	Very fast
	N (heterocyclic)		
With nitro also present, activate reactions with strong nucleophiles at room temperature	**SO$_2$Me**		
	NMe$_3^+$		
	CF$_3$		
	CN	3.81 × 10^4	
	CHO	2.02 × 10^4	
With nitro also present, activate reactions with strong nucleophiles at 40–60°C	**COR**		
	COOH		
	SO$_3^-$		
	Br		6.31 × 10^4
	Cl		4.50 × 10^4
	I		4.36 × 10^4
	COO$^-$		2.02 × 10^4
	H	1	8.06 × 10^3
	F		2.10 × 10^3
	CMe$_3$		1.37 × 10^3
	Me		1.17 × 10^3
	OMe		145
	NMe$_2$		9.77
	OH		4.70
	NH$_2$		1

The comments on the left are from Bunnett and Zahler, Ref. 1, p. 308.

but when a meta group is present, the aryne can form in two different ways:



In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate, and this in turn also depends on the field effect of Z. For $-I$ groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes with alkali-metal amides. The predicted products are



In each case the predicted product was the one chiefly formed.[53] The obtention of *m*-aminoanisole, mentioned on p. 581, is also in accord with these predictions.

Just as electrophilic aromatic substitutions were found more or less to follow the Hammett relationship (with σ^+ instead of σ; see p. 464), so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.[54]

As pointed out on p. 462, the position of attack at alternant hydrocarbons is the same for electrophiles, nucleophiles, and free radicals.

---

[53] Wotiz and Huba, *J. Org. Chem.* **24,** 595 (1959). Eighteen other reactions also gave products predicted by these principles. See also Caubère and Lalloz, *Bull. Soc. Chim. Fr.* 1983, 1989, 1996 (1974).

[54] For a discussion of linear free-energy relationships in this reaction, see Bartoli and Todesco, *Acc. Chem. Res.* **10,** 125–132 (1977). For a list of σ^- values, see p. 244.

The Effect of the Leaving Group[55]

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+, etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2, OR, OAr, SO_2R, and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.[56] An approximate order of leaving-group ability is[57] $F > NO_2 > OTs > SOPh > Cl, Br, I > N_3 > NR_3^+ > OAr, OR, SR, SO_2R, NH_2$. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $C_6Cl_5OCH_3$ treated with NH_2^- gives mostly $C_6Cl_5NH_2$; i.e., one methoxy group is replaced in preference to five chlorines.[58] As usual, OH can be a leaving group if it is converted to an inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually $Cl > Br > I$, but not always.[59] The leaving-group order is quite different from that for the SN1 or SN2 mechanisms. The most likely explanation is that the first step of the SNAr mechanism is usually rate-determining, and this step is promoted by groups with strong $-I$ effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the SNAr mechanism is rate-determining (p. 583) or when the benzyne mechanism is operating. The four halogens, as well as SPh, NMe_3^+, and $OPO(OEt)_2$, have been shown to be leaving groups in the SRN1 mechanism.[38] The only important leaving group in the SN1 mechanism is N_2^+.

The Effect of the Attacking Nucleophile[60]

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $NH_2^- > Ph_3C^- > PhNH^-$ (aryne mechanism) $> ArS^- > RO^- > R_2NH > ArO^- > OH^- > ArNH_2 > NH_3 > I^- > Br^- > Cl^- > H_2O > ROH$.[61] As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions, e.g., OH^-, a stronger base than ArO^-, is a poorer nucleophile. In a series of similar nucleophiles, such as substituted anilines,[62] nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts (**3-12**) and in the von Richter (**3-26**) and Rosenmund–von Braun (**3-11**) reactions, which are special cases.

REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+, which are treated subsequently. Finally, a few rearrangement reactions are discussed.

All Leaving Groups except Hydrogen and N_2^+

A. Oxygen Nucleophiles

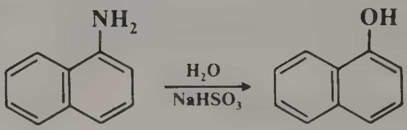
3-1 Replacement by OH
Hydroxy-de-halogenation

$$\mathrm{ArBr} + \mathrm{OH}^- \longrightarrow \mathrm{ArOH}$$

Aryl halides can be converted to phenols only if activating groups are present or if exceedingly strenuous conditions are employed.[63] Other leaving groups, including nitro,[64] azide, NR_3^+, etc., can also be replaced by OH groups. When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.[65] Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal such as lithium, followed by oxidation with alkaline H_2O_2.[66]

OS **I,** 455; **II,** 451; **V,** 632. Also see OS **V,** 918.

3-2 Replacement of an Amino Group by a Hydroxyl Group
Hydroxy-de-amination



The amino group of naphthylamines can be replaced by a hydroxyl group by treatment with aqueous bisulfite.[67] The scope is greatly limited; the amino group (which may be NH_2 or NHR) must be on a naphthalene ring, with very few exceptions. The reaction is reversible (see **3-7**), and both the forward and reverse reactions are called the *Bucherer reaction.* The mechanism is completely different from any outlined in the first section of this chapter and is discussed at **3-7.**

3-3 Alkali Fusion of Sulfonate Salts
Oxido-de-sulfonato-substitution

$$\mathrm{ArSO_3}^- \xrightarrow[\text{300–320°C}]{\text{NaOH fus.}} \mathrm{ArO}^-$$

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is obscure, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.[68]

OS **I,** 175; **III,** 288.

3-4 Replacement by OR or OAr

Alkoxy-de-halogenation

$$\text{ArBr} + \text{OR}^- \longrightarrow \text{ArOR}$$

This reaction is similar to **3-1** and, like that one, generally requires activated substrates.[63] With unactivated substrates, side reactions predominate, though aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPT.[69] This reaction gives better yields than **3-1** and is used more often. In addition to halides, leaving groups may be nitro, NR_3^+, other OR, etc., even OH.[70] The substrates Ar_2Br^+ are converted to ArOR in very high yields.[71] Acid salts, $RCOO^-$, are sometimes used as nucleophiles. Good yields of aryl benzoates can be obtained by the treatment of aryl halides with cuprous benzoate in diglyme or xylene at 140 to 160°C.[72] Unactivated substrates have been converted to esters in low-to-moderate yields under oxidizing conditions.[73] A mechanism similar to the SRN1 has been suggested for this.

For aroxide nucleophiles, the reaction is promoted by copper salts,[73a] and when these are used, activating groups need not be present. This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*[74] and should not be confused with the more important Ullmann coupling reaction (**3-16**). The reactivity order is typical of nucleophilic substitutions, despite the presence of the copper salts.[75] Because aryloxycopper(I) reagents ArOCu react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.[76] Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.[77] Diaryl ethers can be prepared from activated aryl halides by treatment with a triaryl phosphate $(ArO)_3PO$.[78]

OS **I,** 219; **II,** 445; **III,** 293, 566; **V,** 926; **51,** 82.

B. Sulfur Nucleophiles

3-5 Replacement by SH or SR

$$\text{ArBr} + \text{SH}^- \longrightarrow \text{ArSH} \qquad \textbf{Mercapto-de-halogenation}$$

$$\text{ArBr} + \text{SR}^- \longrightarrow \text{ArSR} \qquad \textbf{Alkylthio-de-halogenation}$$

Aryl thiols and thioethers can be prepared in reactions similar to **3-1** and **3-4.**[79] Activated aryl halides generally give good results, but side reactions are occasionally important. Diaryl sulfides can be prepared by the use of SAr^-. Even unactivated aryl halides react with SAr^- if polar aprotic solvents, e.g., DMF,[80] Me_2SO,[81] or HMPT,[82] are used, though the mechanism is still nucleophilic substitution. Unactivated aryl halides also give good yields of sulfides on treatment with SAr^- or SR^- in the presence of a catalytic amount of $(Ph_3P)_4Pd$.[83] Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS^- in liquid ammonia under irradiation.[84] The mechanism in this case is probably SRN1.

[75] Weingarten, *J. Org. Chem.* **29,** 977, 3624 (1964).

[76] Kawaki and Hashimoto, *Bull. Chem. Soc. Jpn.* **45,** 1499 (1972).

[77] Whitesides, Sadowski, and Lilburn, *J. Am. Chem. Soc.* **96,** 2829 (1974).

[78] Ohta, Iwasaki, and Akita, *Synthesis* 828 (1982). For another procedure, see Bates and Janda, *J. Org. Chem.* **47,** 4374 (1982).

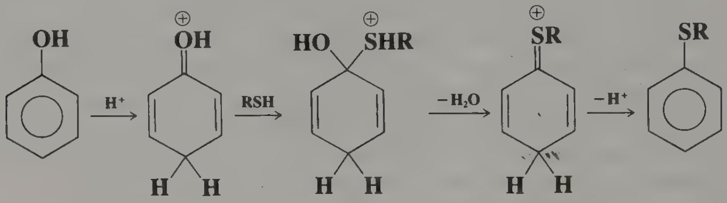
[79] For reviews of sulfur nucleophiles in aromatic substitution, see Peach, in Patai, "The Chemistry of the Thiol Group," pt. 2, pp. 735–744, Wiley, New York, 1974; Parker, in Kharasch, "Organic Sulfur Compounds," vol. 1, pp. 103–111, Pergamon, New York, 1961.

Other sulfur nucleophiles also react with activated aryl halides:

$$2ArX + S_2^{2-} \longrightarrow Ar\text{—}S\text{—}S\text{—}Ar \qquad ArX + SCN^- \longrightarrow ArSCN$$

$$ArX + SO_3^{2-} \longrightarrow Ar\text{—}SO_3^- \qquad ArX + RSO_2^- \longrightarrow Ar\text{—}SO_2\text{—}R$$

Hydroxyl groups can be replaced by SR groups in acid solution.[85] In this case the mechanism bears certain resemblances to that of the Bucherer reaction (**3-7**):



As with the Bucherer reaction, yields are highest with naphthols (50 to 60%), although in this case phenols also give the reaction (20 to 40% yields).

OS **I,** 220; **III,** 86, 239, 667; **V,** 107, 474; **50,** 75; **51,** 139. Also see OS **V,** 977.

C. Nitrogen Nucleophiles

3-6 Replacement by NH_2, NHR, or NR_2
Amino-de-halogenation

$$ArBr + NH_3 \longrightarrow ArNH_2$$

$$ArBr + RNH_2 \longrightarrow ArNHR$$

$$ArBr + R_2NH \longrightarrow ArNR_2$$

Activated aryl halides react quite well with ammonia and with primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine being especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2,4-Dinitrofluorobenzene is used to tag the amino end of a peptide or protein chain. Other leaving groups in this reaction may be NO_2, N_3, OSO_2R, OR, SR, and N═NAr (where Ar contains electron-withdrawing groups).[86] Activated halides can be converted to diethylamino compounds $ArX \rightarrow ArNMe_2$ by treatment with HMPT.[87]

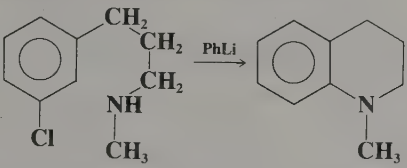
Unactivated aryl halides can be converted to amines by the use of $NaNH_2$, NaNHR, or $NaNR_2$.[88] With these reagents, the benzyne mechanism generally operates, and so cine substitution is often found. Ring closure has been effected by this type of reaction,[89] e.g.,



It has also proved possible to close larger rings in this manner: eight- and even twelve-membered. Triarylamines have been prepared in a similar manner from ArI and $Ar_2'NLi$, even with unactivated ArI.[90] Sulfonic acid salts can be fused with alkali-metal amides to give aromatic amines, a process similar to **3-3.** In the *Goldberg reaction,* an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an N-acetyldiarylamine, which can be hydrolyzed to a diarylamine: $ArBr + Ar'NHAc \rightarrow ArAr'NAc$.[91]

The reaction with ammonia or amines, which undoubtedly proceeds by the SNAr mechanism, is catalyzed by copper[73a] and nickel[92] salts, although these are normally used only with rather unreactive halides. The manner of catalysis is poorly understood.[93] Copper ion catalysts (especially cuprous oxide or iodide) also permit the Gabriel synthesis (**0-60**) to be applied to aromatic substrates. Aryl bromides or iodides are refluxed with potassium phthalimide and Cu_2O or CuI in dimethylacetamide to give N-aryl phthalimides, which can be hydrolyzed to primary aryl amines.[94] Copper catalysts also permit the reaction to be applied to amides and imides.[95]

In certain cases the SRN1 mechanism has been found (p. 582). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the SN(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.[96]

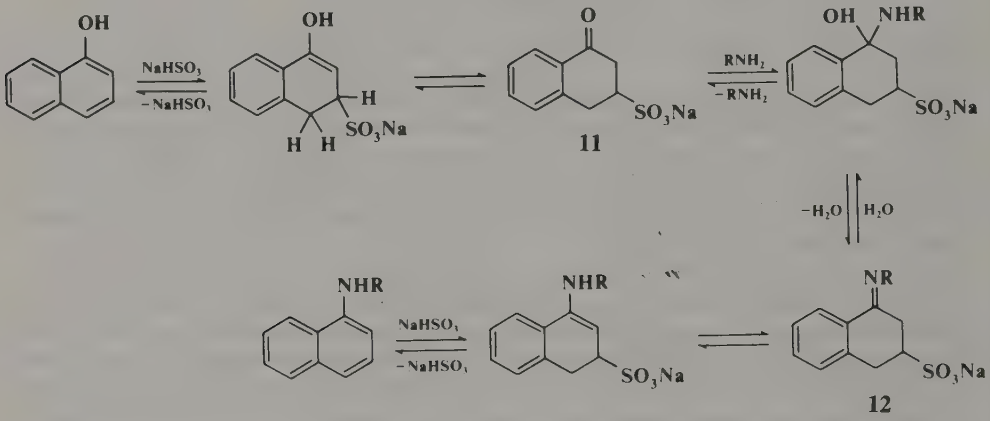
The reaction of naphthols with ammonia and sodium bisulfite is the reverse of **3-2** and has a similar scope.[67] It is also called the *Bucherer reaction*. Primary amines may be used instead of ammonia, in which case N-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary, by a transamination reaction:

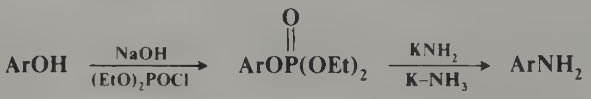
$$\mathrm{ArNH_2 + RNH_2 \xrightarrow{NaHSO_3} ArNHR}$$

The mechanism of the Bucherer reaction amounts to a kind of overall addition–elimination:[97]



The first step in either direction consists of addition of $NaHSO_3$ to one of the double bonds of the ring, which gives an enol (or enamine) that tautomerizes to the keto (or imine) form. The conversion of **11** to **12** (or vice versa) is an example of **6-14** (or **6-2**). Evidence for this mechanism was the isolation of **11**[98] and the demonstration that for β-naphthol treated with ammonia and HSO_3^-, the rate of the reaction depends only on the substrate and on HSO_3^-, indicating that ammonia is not involved in the rate-determining step.[99] If the starting compound is a β-naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so that the sulfur of the bisulfite in either case attacks meta to the OH or NH_2.[100]

Hydroxy groups on benzene rings can be replaced by NH_2 groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH_2 and potassium metal in liquid ammonia



$$\mathrm{ArOH \xrightarrow[(EtO)_2POCl]{NaOH} ArO\overset{O}{\overset{\|}{P}}(OEt)_2 \xrightarrow[K\text{-}NH_3]{KNH_2} ArNH_2}$$

gives the corresponding primary aromatic amines.[101] The mechanism of the second step is $S_{RN}1$.[102]

D. Halogen Nucleophiles

3-8 The Introduction of Halogens
Halo-de-halogenation, etc.

$$\mathrm{Ar{-}X + X'^{-} \longrightarrow Ar{-}X' + X^{-}}$$

It is possible to replace a halogen on a ring by another halogen if the ring is activated. There is an equilibrium, but it is usually possible to shift this in the desired direction by the use of an excess of added halide ion.[103] Another common leaving group is nitro, which can be replaced with chloro by use of NH_4Cl, PCl_5, $SOCl_2$, HCl, Cl_2, or CCl_4. Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. A nitro group can be replaced by a fluoro in activated rings by treatment with F^-.[104]

A phenolic hydroxy group can be replaced by chloro with PCl_5 or $POCl_3$, but only if activated. Unactivated phenols give phosphates when treated with $POCl_3$: $3ArOH + POCl_3 \rightarrow (ArO)_3PO$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2[105] (see **0-67**). However, when an ortho-*t*-butyl group is present, this group may be cleaved.[106]

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens.[107] Activated aryl chlorides give fluorides when treated with KF in DMF, Me_2SO, or dimethyl sulfone.[108] All six chlorines of hexachlorobenzene can be replaced by F by heating with KF at 450 to 500°C in the absence of a solvent.[109] The use of a crown ether allows the use of lower temperatures.[110] Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is $I > Br > Cl \gg F$, the SNAr mechanism is probably not operating.[111]

OS **III,** 194, 272, 475; **V,** 142, 478.

E. Hydrogen as Nucleophile

3-9 Reduction of Phenols and Phenolic Esters and Ethers
Hydro-de-hydroxylation or **Dehydroxylation,** etc.

$$\mathrm{ArOH \xrightarrow{Zn} ArH}$$

Phenols can be reduced by distillation over zinc dust or with HI and red phosphorus, but these methods are quite poor and are seldom feasible. Catalytic hydrogenation has also been used, but the corresponding cyclohexanol (see **5-13**) is a side product.[112]

[120] For a review, see Mowry, *Chem. Rev.* **42,** 189–283 (1948), pp. 207–209.

alkali cyanides do convert aryl halides to nitriles in DMF or HMPT in the presence of Pd(II) salts[121] or under phase-transfer conditions in the presence of a nickel complex.[122] Aromatic ethers ArOR[123] and some nitro compounds $ArNO_2$[124] have been photochemically converted to ArCN.

OS **III,** 212, 631.

3-12 Cyanide Fusion of Sulfonate Salts[125]
Cyano-de-sulfonato-substitution

$$ArSO_3^- \xrightarrow{\text{NaCN fus.}} ArCN$$

This reaction is very similar to **3-3.** Yields are usually low.

3-13 Coupling of Organometallic Compounds with Aryl Halides, Ethers, and Esters
Alkyl-de-halogenation, etc.

$$ArI + R_2CuLi \longrightarrow ArR$$

Aryl iodides, which need not be activated, couple with lithium dialkylcopper reagents. The reaction is discussed at **0-88.** Aryl halides, even when activated, generally do not couple with Grignard reagents, though certain transition-metal catalysts do effect this reaction in variable yields.[126] The reaction with Grignard reagents proceeds better when OR can be the leaving group, providing that activating groups are present in the ring.

Unactivated aryl halides react with copper acetylides to give good yields of arylacetylenes (*Stephens–Castro coupling*).[127]

$$ArI + RC{\equiv}CCu \longrightarrow ArC{\equiv}CR$$

R may be alkyl or aryl. A wide variety of aryl iodides has been used and the reaction is of considerable synthetic importance.

Unactivated aryl halides couple with alkyllithium reagents in tetrahydrofuran to give moderate-to-good yields of alkyl arenes.[128] Unactivated aryl triflates $ArOSO_2CF_3$ react with $R_2Cu(CN)Li_2$ to give ArR in good yields.[129]

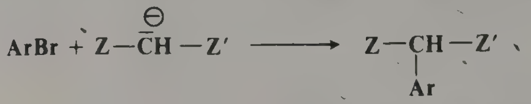
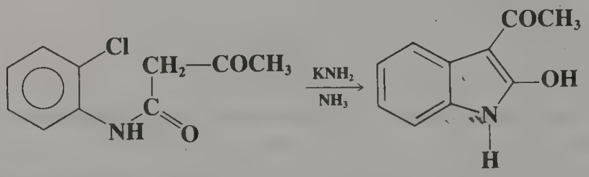
3-14 Arylation at a Carbon Containing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, etc.



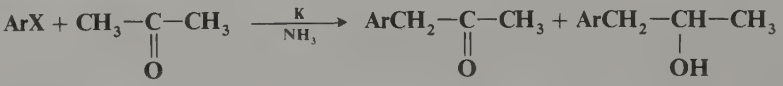
$$\mathrm{ArBr} + \mathrm{Z{-}\overset{\ominus}{C}H{-}Z'} \longrightarrow \mathrm{Z{-}\underset{\substack{|\\ Ar}}{C}H{-}Z'}$$

The arylation of compounds of the form ZCH_2Z' is analogous to **0-96,** and Z is as defined there. Activated aryl halides generally give good results.[130] Even unactivated aryl halides can be employed if the reaction is carried out in the presence of excess sodium amide.[131] Compounds of the form ZCH_2Z' and even simple ketones[132] and esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: it removes a proton from ZCH_2Z' and catalyzes the benzyne mechanism. The reaction has been used for ring closure:[133]



The reaction on unactivated halides can also be done with copper halide catalysts[73a] (the *Hurtley reaction*).[134]

Compounds of the form CH_3Z can be arylated by treatment with an aryl halide in liquid ammonia containing Na or K, e.g., [135]



$$\mathrm{ArX} + \mathrm{CH_3{-}\underset{\substack{\|\\ O}}{C}{-}CH_3} \xrightarrow[\mathrm{NH_3}]{\mathrm{K}} \mathrm{ArCH_2{-}\underset{\substack{\|\\ O}}{C}{-}CH_3} + \mathrm{ArCH_2{-}\underset{\substack{|\\ OH}}{C}H{-}CH_3}$$

The same products are obtained (though in different proportions) when Na or K is omitted but the solution is irradiated with near-uv light.[136] In either case other leaving groups may be used instead of halogens (e.g., NR_3^+, SAr) and the mechanism is the SRN1 mechanism. This reaction has also been used for ring closure.[137] In certain instances of the intermolecular reaction there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.[138] Malonic and β-keto esters can be arylated in high yields by treatment with aryllead tricarboxylates: RCOCHR′COOEt + $ArPb(OAc)_3 \rightarrow$ RCOCArR′COOEt.[139] Diaryliodonium salts have also been used to arylate ZCH_2Z', but the mechanism is apparently free radical.[140]

---

3-15 Carbalkoxylation, Carboxylation, and Acylation[141]

Alkoxycarbonyl-de-halogenation, etc.

$$\mathrm{ArI} \xrightarrow[\mathrm{Ni(CO)_4}]{\mathrm{ROH}} \mathrm{ArCOOR}$$

Aryl iodides can be converted directly to esters by treatment with nickel carbonyl in ROH as solvent[142] (see **0-105**). The yields are nearly quantitative. In aprotic solvents, such as tetrahydrofuran, the products are benzils, ArCOCOAr. The reaction is not successful for aryl chlorides, bromides, or fluorides. Aryl bromides can be carboxylated (ArBr → ArCOOH) in high yields by treatment with CO in the presence of water and either a catalytic amount of $Ni(CO)_4$ (provided that a salt such as KOAc is present to neutralize the HBr formed[143]) or a cobalt carbonyl $Co_2(CO)_8$ catalyst under irradiated phase transfer conditions.[144] Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: ArI + Ar′HgX + $Ni(CO)_4 \rightarrow$ ArCOAr′.[145]

3-16 The Ullmann Reaction

$$2\mathrm{ArI} \xrightarrow[\Delta]{\mathrm{Cu}} \mathrm{Ar{-}Ar}$$

The coupling of aryl halides with copper is called the *Ullmann reaction.*[146] The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.[147] When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. For example, picryl chloride and iodobenzene gave only 2,4,6-trinitrobiphenyl.[148] The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used.

The effects of other groups on the ring are unusual. The nitro group is strongly activating, but only in the ortho (not meta or para) position.[149] R and OR activate in all positions. Not only do OH, NH_2, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution, but so do COOH (but not COOR), SO_2NH_2, and similar group for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

[149] Forrest, *J. Chem. Soc.* 592 (1960).

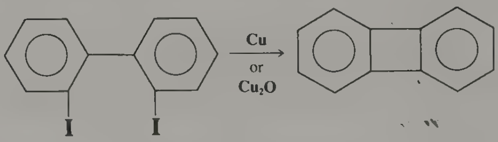
The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the Wurtz reaction (**0-87**), which can be represented schematically by:

Step 1 $$\mathrm{ArI + Cu \longrightarrow ArCu}$$

Step 2 $$\mathrm{ArCu + ArI \longrightarrow ArAr}$$

The species represented as ArCu may not actually have this structure, but some kind of a complex is formed.[150] Organocopper compounds have been trapped by coordination with organic bases.[151] In addition, arylcopper compounds (ArCu) have been independently prepared and shown to give biaryls (ArAr′) when treated with aryl iodides Ar′I.[152] An alternate possible second step is 2ArCu → ArAr, and indeed arylcopper compounds are known to dimerize in this fashion.[153] It is unlikely that free radicals intervene in step 1.[154] Step 2 may well be a nucleophilic attack by ArCu on ArI. Evidence is that a Meisenheimer salt could be isolated from treatment of 1,3,5-trinitrobenzene with an arylcopper compound[155] (in this case the leaving group is hydrogen).

A similar reaction has been used for ring closure:[156]



Aryl halides ArX can also be converted to Ar—Ar by treatment with certain nickel complexes,[157] with activated Ni metal,[158] with Zn and $NiBr_2$ in HMPT,[159] and with aqueous alkaline sodium formate, Pd-C, and a phase transfer catalyst.[160]

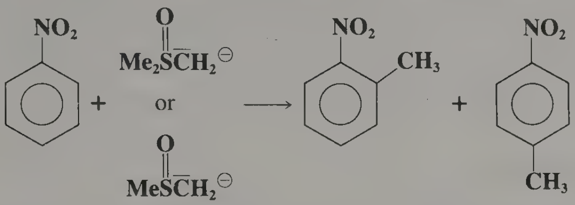
The alkylation of heterocyclic nitrogen compounds with alkyllithiums is called *Ziegler alkylation.* Aryllithiums give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.[162] Upon heating of the adduct, elimination of LiH occurs (see **7-17**) and an alkylated product is obtained. With respect to the 2-carbon the first step is the same as that of the SNAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so that the extra pair of ring electrons has a place to go: it becomes the new unshared pair on the nitrogen.

The reaction has been applied to nonheterocyclic aromatic compounds: benzene, naphthalene, and phenanthrene have been alkylated with alkyllithiums, though the usual reaction with these reagents is **2-19**,[163] and Grignard reagents have been used to alkylate naphthalene.[164] The addition–elimination mechanism apparently applies in these cases too.

Aromatic nitro compounds can be methylated by treatment with dimethyloxosulfonium methylide[165] or the methylsulfinyl carbanion (obtained by treatment of dimethyl sulfoxide with a strong base):[166]

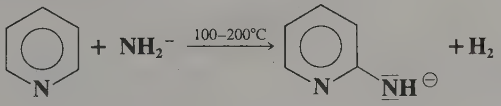


The latter reagent also methylates certain heterocyclic compounds, e.g., quinoline, and certain fused aromatic compounds, e.g., anthracene, phenanthrene.[167] The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the Friedel–Crafts procedure (**1-13**). It has been reported[168] that aromatic nitro compounds can also be alkylated, not only with methyl but with other alkyl and substituted alkyl groups as well, in ortho and para positions, by treatment with an alkyllithium compound (or, with lower yields, a Grignard reagent), followed by an oxidizing agent such as Br_2 or DDQ (p. 1053).

For the introduction of CH_2SR groups into phenols, see **1-28.** See also **4-21.**

OS **II,** 517.

3-18 Amination of Nitrogen Heterocycles
Amination or **Amino-de-hydrogenation**[169]



---

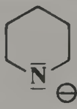
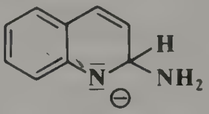
[169] These names also apply to reaction **3-19** and, in part, to **3-20.**

Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali-metal amides in a process called the *Chichibabin reaction.*[170] The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Nitro compounds do not give the reaction.[171] Substituted alkali-metal amides, e.g., sodium piperidide (**14**), have also been used. The mechanism is probably similar to that of reaction **3-17.** The existence of intermediate ions such as **15** (from quinoline) has been demonstrated by nmr spectra.[172] A pyridyne type of intermediate



14



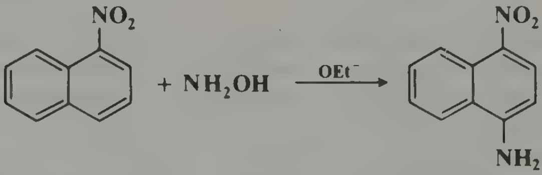
15

was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine[173] and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated.

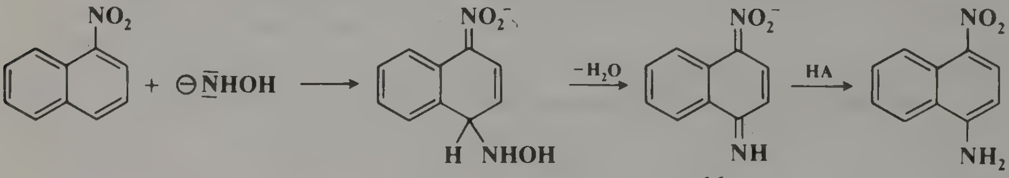
Analogous reactions have been carried out with hydrazide ions, $R_2N\overline{N}H^-$.[174] For other methods of aminating aromatic rings, see **1-6, 3-19,** and **3-20.**

There are no *Organic Syntheses* references, but see OS **V,** 977, for a related reaction.

3-19 Amination by Hydroxylamine



Activated aromatic compounds can be directly aminated with hydroxylamine in the presence of strong bases.[175] Conditions are mild and yields are high. Ions of the type **16** are intermediates:



16

OS **III,** 664.

3-20 Hydroxylation and Amination of Aromatic Acids
Hydroxylation or **Hydroxy-de-hydrogenation**

[175] See Ref. 161, p. 456.

When basic copper salts of aromatic acids are heated, hydroxylation occurs in the ortho position.[176] Better results are obtained by heating cupric carboxylates in protic solvents.[177] Phenols are also produced, by concomitant decarboxylation of the salicyclic acids or their esters.[178] In an analogous reaction, aromatic amines are produced by heating copper salts of aromatic acids with ammonia at 220°C under pressure.[179] See also **1-31, 4-5,** and **4-10.**

N_2^+ as Leaving Group

The diazonium group can be replaced by a number of groups.[180] Some of these are nucleophilic substitutions, with SN1 mechanisms (p. 579), but others are free-radical reactions and are treated in Chapter 14. The solvent in all these reactions is usually water. With other solvents it has been shown that the SN1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free-radical mechanisms.[181] (For *formation* of diazonium ions, see **2-48.**) The N_2^+ group can be replaced by Cl^-, Br^-, and CN^-, by a nucleophilic mechanism (see OS **IV,** 182), but the Sandmeyer reaction is much more useful (**4-24** and **4-27**). As mentioned on p. 584 it must be kept in mind that the N_2^+ group can activate the removal of another group on the ring.

3-21 Replacement by OH
Hydroxy-de-diazoniation

$$ArN_2^+ + H_2O \longrightarrow ArOH$$

Water is usually present whenever diazonium salts are made, but at these temperatures (0 to 5°C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, e.g., boiling with aqueous sulfuric acid or with trifluoroacetic acid containing potassium trifluoroacetate.[182] The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^-. A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $Cu(NO_3)_2$.[183] Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least partly involved when ordinary hydroxy-de-diazoniation is carried out in weakly alkaline aqueous solution.[184]

OS **I,** 404; **III,** 130, 453, 564; **V,** 1130.

3-22 Replacement by Sulfur-containing Groups
Mercapto-de-diazoniation, etc.

$$ArN_2^+ + HS^- \longrightarrow ArSH$$
$$ArN_2^+ + S^{2-} \longrightarrow ArSAr$$
$$ArN_2^+ + RS^- \longrightarrow ArSR$$
$$ArN_2^+ + SCN^- \longrightarrow ArSCN + ArNCS$$

[184] Dreher, Niederer, Rieker, Schwarz, and Zollinger, *Helv. Chim. Acta* **64,** 488 (1981).

These reactions are convenient methods for putting sulfur-containing groups onto an aromatic ring. With $Ar'S^-$, attack at the nitrogen takes precedence, so that the product is a diazosulfide ($Ar—N{=}N—S—Ar'$).[185] Thiophenols can be made as shown above, but more often the diazonium ion is treated with $EtO—CSS^-$ or S_2^{2-}, which give the expected products, and these are easily convertible to thiophenols. See also **4-26.**

OS **II,** 580; **III,** 809 (but see OS **V,** 1050). Also see OS **II,** 238.

3-23 Replacement by the Azido Group

Azido-de-diazoniation

$$ArN_2^+ + N_3^- \longrightarrow ArN_3$$

Diazonium salts can be converted to aryl azides by the addition of sodium azide to the acidic diazonium salt solution.[186]

OS **IV,** 75; **V,** 829.

3-24 Replacement by Iodine

Iodo-de-diazoniation

$$ArN_2^+ + I^- \longrightarrow ArI$$

One of the best methods for the introduction of iodine into aromatic rings is the reaction of diazonium salts with iodide ions. Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and **4-24** and **3-25** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products.

The actual attacking species is probably not only I^-, if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to I_3^-; this is the actual attacking species, at least partly. This was shown by isolation of $ArN_2^+ \; I_3^-$ salts, which, on standing, gave ArI.[187] From this, it can be inferred that the reason the other halide ions give poor results is not that they are poor nucleophiles but that they are poor reducing agents (compared with iodide). A free-radical mechanism has also been proposed.[188]

OS **II,** 351, 355, 604; **V,** 1120.

3-25 Replacement by Fluorine. The Schiemann Reaction

Fluoro-de-diazoniation (overall transformation)

$$ArN_2^+ \; BF_4^- \xrightarrow{\Delta} ArF + N_2 + BF_3$$

Heating of diazonium fluoroborates (the *Schiemann reaction*) is by far the best way of introducing fluorine into an aromatic ring.[189] In the most common procedure, the fluoroborate salts are prepared by diazotizing as usual with nitrous acid and HCl and then adding a cold aqueous solution of $NaBF_4$, HBF_4, or NH_4BF_4. A precipitate forms, which is then dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually quite successful. In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly[190] from primary aromatic amines with *t*-butyl nitrite and BF_3-etherate.[191] The reaction has also been carried out on ArN_2^+ PF_6^-, ArN_2^+ SbF_6^-, and ArN_2^+ AsF_6^- salts, in many cases with better yields.[192] The reaction has been extended to ArN_2^+ BCl_4^- and ArN_2^+ BBr_4^-,[193] but aryl chlorides and bromides are more commonly prepared by the Sandmeyer reaction (**4-24**). In an alternative procedure, aryl fluorides have been prepared by treatment of aryltriazenes Ar—N═N—NR_2 with 70% HF in pyridine.[194]

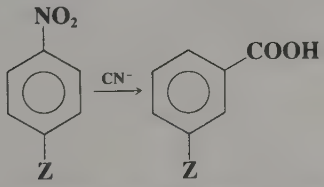
The mechanism is of the SN1 type. That phenyl cations are intermediates was shown by the following experiments:[195] aryl diazonium chlorides are known to arylate other aromatic rings by a free-radical mechanism (see **4-16**). In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species. If a phenyl free radical were an intermediate in the Schiemann reaction and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: mixtures of biaryls should be obtained in all cases. But if a phenyl cation is an intermediate in the Schiemann reaction, compounds containing meta-directing groups, i.e., meta-directing for *electrophilic* substitutions, should be meta-arylated and those containing ortho-para-directing groups should be ortho- and para-arylated, since a phenyl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown[196] that such orientation is observed, demonstrating that the Schiemann reaction has a positively charged intermediate. The attacking species, in at least some instances, is not F^- but BF_4^-.[197]

OS **II,** 188, 295, 299; **V,** 133.

Rearrangements

3-26 The von Richter Rearrangement



When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (p. 581), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement,* is variable.[198] As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually less than 20% and never more than 50%.

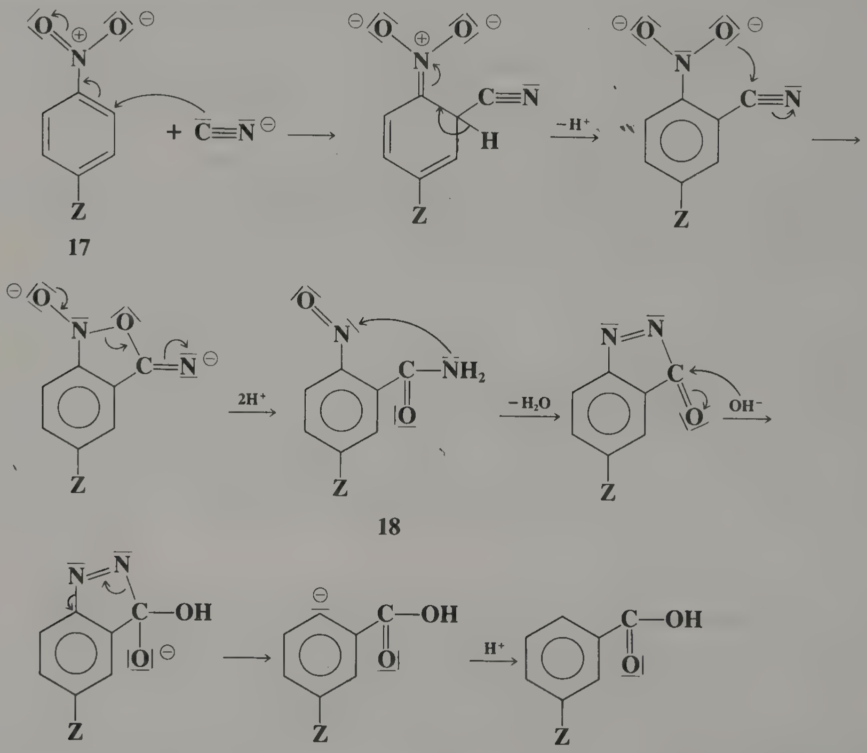
For many years, it was believed that a nitrile, ArCN, was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (**6-5**). However, a remarkable series of results have shown this belief to be in error. Bunnett and Rauhut demonstrated[199] that α-naphthyl cyanide is *not* hydrolyzable to α-naphthoic acid under conditions at which β-nitronaphthalene undergoes the von Richter rearrangement to give α-naphthoic acid. This proved that the nitrile cannot be an intermediate in this case and cast doubt on all other cases, since it is unlikely that different mechanisms would be operating. It was subsequently demonstrated that *elemental nitrogen* is a major product of the reaction.[200] It had previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^- is not a major product. The discovery of nitrogen indicated that a nitrogen–nitrogen bond must be formed during the course of the reaction. A mechanism in accord with all the facts was proposed by Rosenblum:[200]



17

18

It may be noted that **18** are stable compounds; hence it should be possible to prepare them independently and to subject them to the conditions of the von Richter rearrangement. This has been done and the correct products are obtained.[201] Further evidence for the mechanism is that when **17** (Z = Cl or Br) was treated with cyanide in $H_2{}^{18}O$, one-half of the oxygen in the product was labeled, showing that one of the oxygens of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.[202]

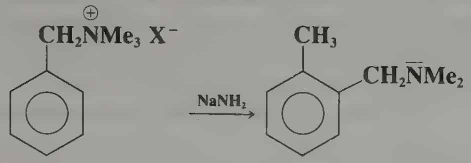
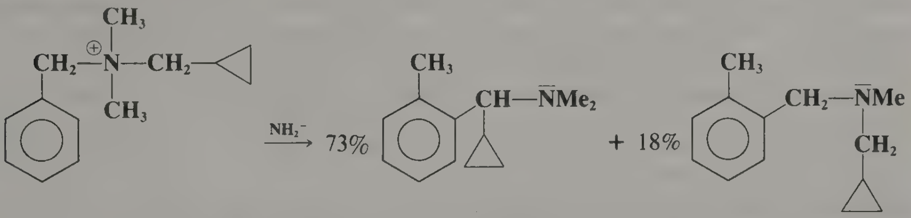
3-27 The Sommelet–Hauser Rearrangement



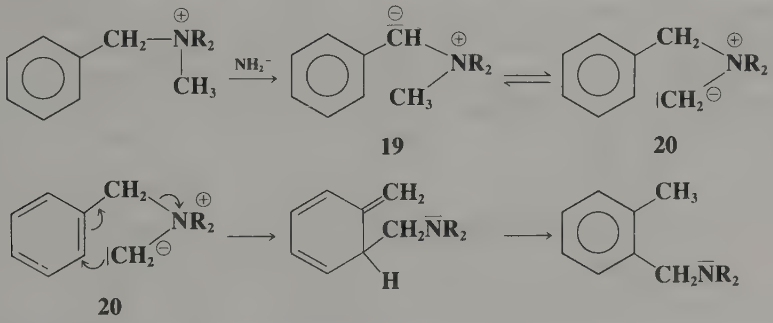
Benzyl quaternary ammonium salts, when treated with alkali-metal amides, undergo a rearrangement called the *Sommelet–Hauser rearrangement.*[203] Since the product is a benzyl tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.[204]

The rearrangement occurs with high yields and can be performed with various groups present in the ring.[205] The reaction is most often carried out with three methyl groups on the nitrogen, but other groups can also be used, though if a β-hydrogen is present, Hofmann elimination (**7-6**) can and often does compete. When the three groups are not the same, competing products may be obtained, e.g.,[206]



In any case, the Stevens rearrangement (**8-24**) is a competing process. When both rearrangements are possible, the Stevens is favored at high temperatures and the Sommelet–Hauser at low temperatures.[207] When the migrating group carries an α-SR′ group, the Sommelet–Hauser product is an aromatic aldehyde, formed by hydrolysis during the workup of the ArCH(SR′)NR$_2$ product.[208]

The mechanism is



The benzyl hydrogen is most acidic and is the one that first loses a proton to give the ylide **19.**

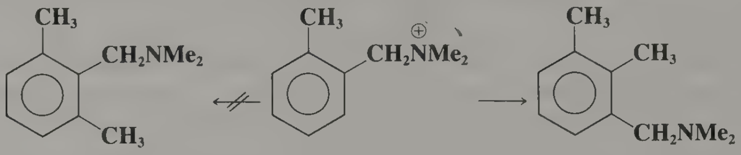
[208] Huynh, Julia, Lorne, and Michelot, *Bull. Soc. Chim. Fr.* 4057 (1972).

However, **20,** which is present in smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3] sigmatropic rearrangement (see **8-39**). Another mechanism which might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study and by labeling experiments.[209] If the second mechanism were true, **21** should give **22,** but the former mechanism predicts the formation of **23,**



22 **21** **23**

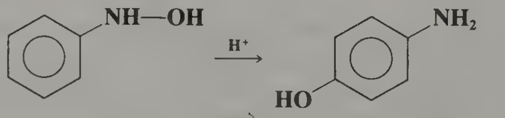
which is what was actually obtained.[210] In the labeling experiments, benzyltrimethylamine labeled with ^{14}C in the α position of the benzyl group gave a product labeled in the ring methyl group, as predicted by the first mechanism, and not in the methylene, as required by the second.[211]

The mechanism as we have pictured it can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.[212] A mechanism[206] in which there is a dissociation of the ArC—N bond (similar to the ion-pair mechanism of the Stevens rearrangement, p. 993) has been invoked to explain the obtention of the para products.

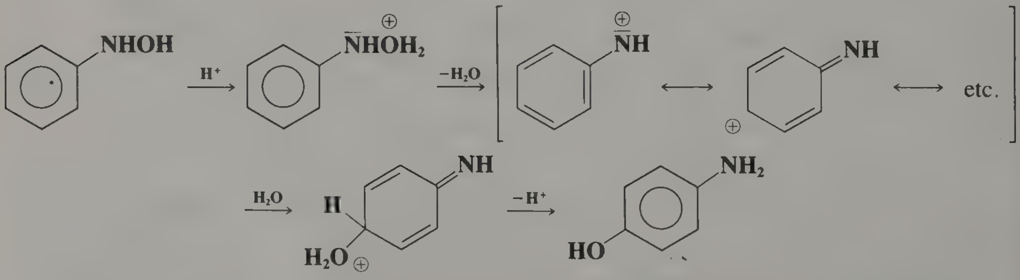
Sulfur ylides containing a benzylic group (analogous to **20**) undergo an analogous rearrangement.[213]

OS **IV,** 585.

3-28 Rearrangement of Aryl Hydroxylamines



Aryl hydroxylamines treated with acids rearrange to aminophenols.[214] Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to **1-34** to **1-38,** the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:



24

Among the evidence[215] for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles, e.g., *p*-ethoxyaniline when ethanol is present, and that when the para position is blocked, compounds similar to **24** are isolated.

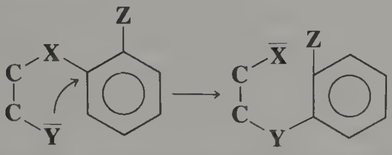
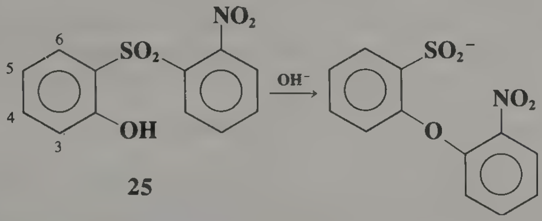
OS **IV,** 148.

3-29 The Smiles Rearrangement



The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern given above.[216] A specific example is

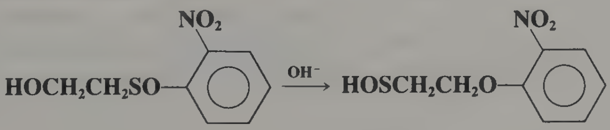


25

Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- the nucleophile, and the nitro group serves to activate its ortho position. The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. X is usually S, SO, SO_2,[217] O, or COO. Y is usually the conjugate base of OH, NH_2, NHR, or SH. The reaction has even been carried out with Y = CH_2^- (phenyllithium was the base here).[218]

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **25** caused the rate to be about 10^5 times faster than when the same groups were in the 4 position,[219] though electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation the molecule can adopt to suit the bulk of the 6-substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the Smiles rearrangement is usually carried out on compounds containing two rings, this need not be the case; e.g.,[220]



26

In this case the sulfenic acid (**26**) is unstable[221] and the actual products isolated were the corresponding sulfinic acid (RSO_2H) and disulfide (R_2S_2).

FREE-RADICAL SUBSTITUTION

MECHANISMS

Free-Radical Mechanisms in General[1]

A free-radical process consists of at least two steps. The first step involves the *formation* of free radicals, nearly always by homolytic cleavage of a bond, i.e., a cleavage in which each fragment retains one electron:

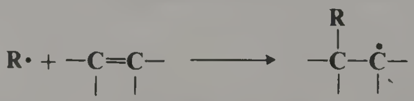
$$\mathrm{A{-}B} \longrightarrow \mathrm{A}\bullet + \mathrm{B}\bullet$$

This is called an *initiation* step. It may happen spontaneously or may be induced by heat or light (see the discussion on p. 168), depending on the type of bond. Peroxides, including hydrogen peroxide, dialkyl, diacyl, and alkyl acyl peroxides, and peracids are the most common source of free radicals induced spontaneously or by heat, but other organic compounds with low-energy bonds, such as azo compounds, are also used. Molecules that are cleaved by light are most often chlorine, bromine, and various ketones (see Chapter 7). Radicals can also be formed in another way, by a one-electron transfer (loss or gain), e.g., $\mathrm{A}^+ + e^- \rightarrow \mathrm{A}\bullet$. One-electron transfers usually involve inorganic ions or electrochemical processes.

The second step involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:

$$\mathrm{A}\bullet + \mathrm{B}\bullet \longrightarrow \mathrm{A{-}B}$$

This type of step is called *termination,*[2] and it ends the reaction as far as these particular radicals are concerned.[3] However, it is not often that termination follows *directly* upon initiation. The reason is that most radicals are very reactive and will react with the first available species with which they come in contact. In the usual situation, in which the concentration of radicals is low, this is much more likely to be a molecule than another radical. When a radical (which has an odd number of electrons) reacts with a molecule (which has an even number), the total number of electrons in the products must be odd. The product in a particular step of this kind may be one particle, e.g.,



$$\mathrm{R}\bullet + -\underset{|}{\mathrm{C}}{=}\underset{|}{\mathrm{C}}- \longrightarrow -\underset{|}{\overset{\overset{\mathrm{R}}{|}}{\mathrm{C}}}-\underset{|}{\dot{\mathrm{C}}}-$$

For reviews, see Huyser, in McManus, ''Organic Reactive Intermediates,'' pp. 1–59, Academic Press, New York, 1973; Lloyd, *Chem. Technol.* 176–180, 371–381, 687–696 (1971), 182–188 (1972). For a monograph on the use of free-radical reactions in synthesis, see Davies and Parrott, ''Free Radicals in Organic Synthesis,'' Springer-Verlag, New York, 1978.

[2] Another type of termination is disproportionation (see p. 169).

[3] For a review of termination reactions, see Lapporte, *Angew. Chem.* **72,** 759–766 (1960).

in which case it must be another free radical; or it may consist of two particles, e.g.,

$$\mathbf{R\cdot + R'H \longrightarrow RH + R'\cdot}$$

in which case one must be a molecule and one a free radical, but in any case *a new radical is generated*. This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals do meet each other and terminate the process. The process just described is called a *chain reaction*, and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (1) cleavage of a radical into, necessarily, a radical and a molecule and (2) rearrangement of one radical to another (see Chapter 18). When free radicals are highly reactive, e.g., alkyl radicals, chains are long, since reactions occur with many molecules; but with radicals of low reactivity, e.g., aryl radicals, the radical may be unable to react with anything until it meets another radical, so that chains are short, or the reaction may be a nonchain process. In any particular chain process there is usually a wide variety of propagation and termination steps. Because of this, these reactions lead to many products and are often difficult to treat kinetically.[4]

The following are some general characteristics of free-radical reactions:

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, though solvation of free radicals in solution does cause some differences.[5]

2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.

3. They are initiated or accelerated by typical free-radical sources, such as the peroxides referred to, or by light. In the latter case the concept of quantum yield applies (p. 217). Quantum yields may be quite high, e.g., 1000, if each quantum generates a long chain, or low, in the case of nonchain processes.

4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals, e.g., nitric oxide, molecular oxygen, or benzoquinone. These substances are called *inhibitors*.

In this chapter are discussed free-radical substitution reactions. Free-radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. In addition, many of the oxidation–reduction reactions considered in Chapter 19 involve free-radical mechanisms. Several important types of free-radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book. Among these are polymerizations and high-temperature pyrolyses.

Free-Radical Substitution Mechanisms[6]

In a free-radical substitution reaction

$$\mathbf{R{-}X \longrightarrow R{-}Y} \qquad (1)$$

there must first be a cleavage of the substrate RX so that R• radicals are produced. This may happen by a spontaneous cleavage

$$\mathbf{R{-}X \longrightarrow R\cdot + X\cdot} \qquad (2)$$

---

[4] For a discussion of the kinetic aspects of free-radical chain reactions, see Huyser, "Free-Radical Chain Reactions," Ref. 1, pp. 39–65.

[5] For a discussion, see Mayo, *J. Am. Chem. Soc.* **89**, 2654 (1967).

[6] For a review, see Poutsma, in Kochi, "Free Radicals," vol. 2, pp. 113–158, Wiley, New York, 1973.

or it may be caused by light or heat, or, more often, there is no actual cleavage, but R• is produced by an *abstraction*

$$\mathrm{R{-}X + W\cdot \longrightarrow R\cdot + W{-}X} \tag{3}$$

W• is produced by adding a compound, such as a peroxide, which spontaneously forms free radicals. Such a compound is called an *initiator*. Once R• is formed, it may go to product in two ways, by abstraction

$$\mathrm{R\cdot + Y{-}W \longrightarrow R{-}Y + W\cdot} \tag{4}$$

or by coupling with another radical

$$\mathrm{R\cdot + Y\cdot \longrightarrow R{-}Y} \tag{5}$$

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (4) than by coupling (5). Cleavage steps like (2) have been called S_H1 (H for homolytic), and abstraction steps like (3) and (4) have been called S_H2; reactions can be classified as S_H1 or S_H2 on the basis of whether RX is converted to R by (2) or (3).[7] Most chain substitution mechanisms follow the pattern (3), (4), (3), (4). . . . Chains are long and reactions go well where both (3) and (4) are energetically favored (no worse than slightly endothermic, see pp. 614, 623).

It is known that with certain radicals the transition state in an abstraction reaction has some polar character. For example, consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. We can represent the transition state (assuming it is linear) as

$$\mathrm{PhCH_2{\text{------}}H{\text{-----}}Br}$$

Since bromine is more electronegative than carbon, it is reasonable to assume that in the transition state there is a separation of charge, with a partial negative charge on the halogen and a partial positive charge on the carbon. Another way to represent this is to draw canonical forms for the transition state. Evidence for the polar character of the transition state is that electron-withdrawing

$$\mathrm{Ph\overset{\delta+}{C}H_2{\text{----}}H{\text{-----}}\overset{\delta-}{Br}} \quad \text{or} \quad \mathrm{PhCH_2{-}H\cdot Br \leftrightarrow PhCH_2\cdot H{-}Br \leftrightarrow Ph\overset{+}{C}H_2\ \ \dot{H}\ \ \overset{-}{Br}}$$

groups in the para position of toluene (which would destabilize a positive charge) decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.[8] However, as we might expect, substituents have a smaller effect here ($\rho \approx -1.4$) than they do in reactions where a completely ionic intermediate is involved, e.g., the S_N1 mechanism (see p. 303). Other evidence for polar transition states in radical abstraction reactions is mentioned on p. 615. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen abstraction from ring-substituted toluenes by the methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.[9] Those radicals (e.g., Br•) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

When the reaction step R—X → R• takes place at a chiral carbon, racemization is almost always observed because free radicals do not retain configuration. Exceptions to this rule are found at cyclopropyl substrates, where both inversion[10] and retention[11] of configuration have been reported, and in the reactions mentioned on p. 612.

---

[7] Eliel, in Newman, "Steric Effects in Organic Chemistry," pp. 142–143, Wiley, New York, 1956.

[8] For example, see Pearson and Martin, *J. Am. Chem. Soc.* **85**, 354, 3142 (1963).

[9] For example, see Kalatzis and Williams, *J. Chem. Soc. B* 1112 (1966); Pryor, Tonellato, Fuller, and Jumonville, *J. Org. Chem.* **34**, 2018 (1969).

[10] Altman and Nelson, *J. Am. Chem. Soc.* **91**, 5163 (1969).

[11] Jacobus and Pensak, *Chem. Commun.* 400 (1969).

Certain stable compounds have unpaired electrons, and are hence free radicals (p. 166). When such a compound is used as a solvent, it may promote the homolytic cleavage of a weak bond that may be present in the solute molecules. Such a process is known as *homosolvolysis.*[12] An example is the reaction that takes place when bromotriphenylmethane is dissolved in di-*t*-butylnitroxide.

$$\mathbf{Ph_3CBr + (\mathit{t}\text{-}Bu)_2{-}N{-}O\bullet \longrightarrow Ph_3C\bullet + (\mathit{t}\text{-}Bu)_2{-}N{-}O{-}Br}$$

Mechanisms at an Aromatic Substrate[13]

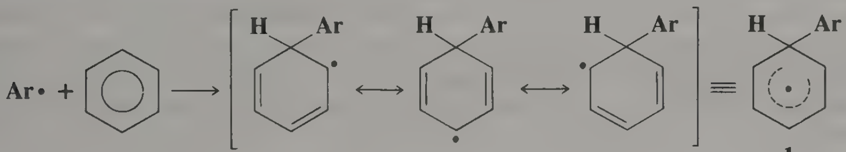
When the R in reaction (1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as the following (see **4-16, 4-19,** and **4-20**):

$$\mathbf{Ar\bullet + ArH \longrightarrow Ar{-}Ar} \tag{6}$$

which occur in solution, the coupling of two rings cannot be explained on the basis of a simple abstraction

$$\mathbf{Ar\bullet + ArH \longrightarrow Ar{-}Ar + H\bullet} \tag{7}$$

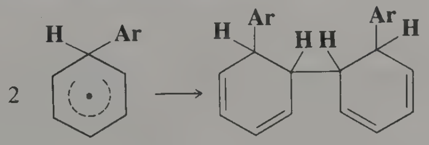
since, as discussed on p. 613, abstraction of an entire group such as phenyl by a free radical is very unlikely. The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a nucleophile:



1

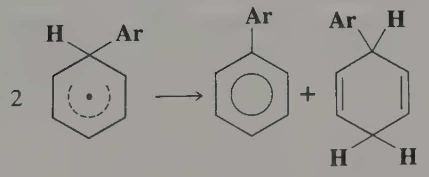
(8)

The intermediate is relatively stable because of the resonance. The reaction may terminate in three ways: by simple coupling, or by disproportionation



2

(9)



3

(10)

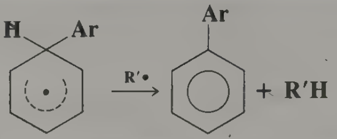
Rev.* **46,** 348–360 (1977); Perkins, in Kochi, Ref. 6, vol. 2, pp. 231–271; Bolton and Williams, *Adv. Free-Radical Chem.* **5,** 1–25 (1975); Nonhebel and Walton, Ref. 1, pp. 417–469; Minisci and Porta, *Adv. Heterocycl. Chem.* **16,** 123–180 (1974); Bass and Nababsing, *Adv. Free-Radical Chem.* **4,** 1–47 (1972); Hey, *Bull. Soc. Chim. Fr.* 1591 (1968); Norman and Radda, *Adv. Heterocycl. Chem.* **2,** 131–177 (1963).

or, if a species (R′•) is present which abstracts hydrogen, by abstraction[14]

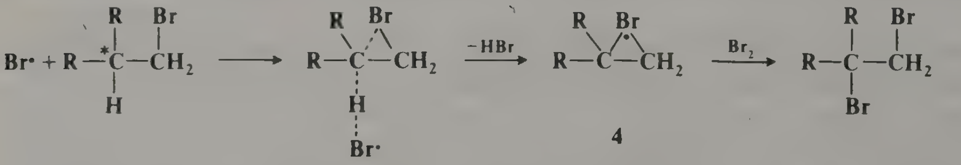


(11)

2 is a partially hydrogenated quaterphenyl. Of course, the coupling need not be ortho–ortho, and other isomers may also be formed. Among the evidence for steps (9) and (10) was isolation of compounds of types **2** and **3**,[15] although normally under the reaction conditions dihydrobiphenyls like **3** are oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **1** by CIDNP[16] (see p. 163) and the absence of isotope effects, which would be expected if the rate-determining step were (7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step (8) does not involve loss of hydrogen. A similar mechanism has been shown where the attacking radical was HO• (reaction **4-5**).

Neighboring-Group Assistance in Free-Radical Reactions

In a few cases it has been shown that cleavage steps (2) and abstraction steps (3) have been accelerated by the presence of neighboring groups. Photolytic halogenation (**4-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of alkyl bromides gave 84 to 94% substitution at the carbon adjacent to the bromine already in the molecule.[17] This result is especially surprising because, as we shall see (p. 615), positions close to a polar group such as bromine should actually be *deactivated* by the electron-withdrawing field effect of the bromine. The unusual regioselectivity is explained by a mechanism in which abstraction (3) is assisted by a neighboring bromine atom:[18]



(12)

In the normal mechanism, Br• abstracts a hydrogen from RH, leaving R•. When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **4**).[19] In the final step (very similar to R• + $Br_2 \rightarrow$ RBr + Br•) the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked *) should be retained. This has been shown to be the case: optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.[18] Furthermore, when this reaction was carried out in the presence of DBr, the "recovered" 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.[20] This is just what would be predicted if some of the **4** present abstracted D from DBr. There is evidence that Cl can form bridged radicals,[21] though esr spectra show that the bridging is not necessarily symmetrical.[22] Still more evidence for bridging by Br has been found in isotope effect and other studies.[23] However, evidence from CIDNP (p. 163) shows that the methylene protons of the β-bromoethyl radical are not equivalent, at least while the radical is present in the radical pair [PhCOO• •CH_2CH_2Br] within a solvent cage.[24] This evidence indicates that under these conditions $BrCH_2CH_2$• is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the Hunsdiecker reaction[25] (**4-39**), and in abstraction of iodine atoms by the phenyl radical.[26] Neighboring-group participation in cleavage reactions (2) has also been shown, in the case of decomposition of *t*-butyl peresters.[27] The neighboring group in this case was SR.

---

[14] **1** can also be oxidized to the arene Ar—Ph by atmospheric O_2. For a discussion of the mechanism of this oxidation, see Narita and Tezuka, *J. Am. Chem. Soc.* **104**, 7316 (1982).

The above facts support the neighboring-group mechanism for certain free-radical substitutions. However, the concept of anchimeric assistance in these reactions has been challenged by Tedder and co-workers[28] on the basis of results obtained in brominations in the gas phase. These workers distinguish between (1) interaction between a neighboring group and the half-filled orbital at the adjacent carbon (bridging) and (2) accelerated attack resulting from this bridging; they believe that bridging may be an important factor but that anchimeric assistance is not. However, anchimeric assistance approaching 10^3 in magnitude has been demonstrated in the bromination of alkyl bromides.[29] No such assistance was found in bromination of alkyl fluorides or chlorides.

REACTIVITY

Reactivity for Aliphatic Substrates[30]

In a chain reaction, the step that determines what the product will be is most often an abstraction step. What is abstracted by a free radical is almost never a tetra- or trivalent atom[31] (except in strained systems, see p. 679)[32] and seldom a divalent one.[33] Nearly always it is univalent, and so, for organic compounds, it is hydrogen or halogen. For example, a reaction between a chlorine atom and ethane gives an ethyl radical, not a hydrogen atom:

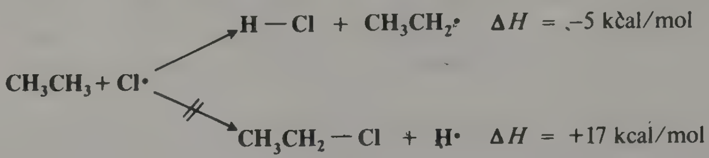
[32] For an example of an abstraction occurring to a small extent at an unstrained carbon atom, see Jackson and Townson, *J. Chem. Soc., Perkin Trans. 2* 1452 (1980). See also Johnson, *Acc. Chem. Res.* **16,** 343–349 (1983).

[33] For a monograph on abstractionsof divalent and higher-valent atoms, see Ingold and Roberts, "Free-Radical Substitution Reactions," Interscience, New York, 1971.



$$CH_3CH_3 + Cl\cdot \longrightarrow H{-}Cl + CH_3CH_2\cdot \quad \Delta H = -5 \text{ kcal/mol}$$

$$CH_3CH_3 + Cl\cdot \not\longrightarrow CH_3CH_2{-}Cl + H\cdot \quad \Delta H = +17 \text{ kcal/mol}$$

The principal reason for this is *steric*. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Another reason is that in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a C_2H_5—H bond is broken (D = 98 kcal/mol, from Table 3, Chapter 5, p. 166) whichever pathway is taken, but in the former case an H—Cl bond is formed (D = 103 kcal/mol) while in the latter case it is a C_2H_5—Cl bond (D = 81 kcal/mol). Thus the first reaction is favored because it is exothermic by 5 kcal/mol (98 − 103), while the latter is endothermic by 17 kcal/mol (98 − 81).[34] However, the steric reason is clearly more important, because even in cases where ΔH is not very different for the two possibilities, the univalent atom is chosen.

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.[35] In these reactions, every hydrogen in the substrate is potentially replaceable and mixtures are usually obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. We discuss the position of attack under several headings:[36]

1. *Alkanes.* The tertiary hydrogens of an alkane are the ones preferentially abstracted by almost any radical, with secondary hydrogens being next preferred. This is in the same order as D values for these types of C—H bonds (Table 2 in Chapter 5). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. Table 1 shows[37] that at high temperatures selectivity decreases, as might be expected. An example of the effect of radical selectivity may be noted in a comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1 : 1.4, while for the less reactive bromine atom this ratio is 1 : 1600. With certain large radicals there is a steric factor which may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H_2SO_4 with

TABLE 1 Relative susceptibility to attack by Cl• of primary, secondary, and tertiary positions at 100 and 600°C in the gas phase[37]

Temp., °C	Primary	Secondary	Tertiary
100	1	4.3	7.0
600	1	2.1	2.6

---

[34] ΔH for a free-radical abstraction reaction may be regarded simply as the difference in D values for the bond being broken and the one formed.

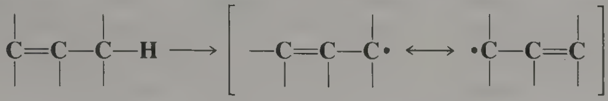
[35] For a review that lists many rate constants for abstraction of hydrogen at various positions of many molecules, see Hendry, Mill, Piszkiewicz, Howard, and Eigenmann, *J. Phys. Chem. Ref. Data* **3**, 937–978 (1974).

[36] For reviews, see Tedder, *Tetrahedron* **38**, 313–329 (1982); Kerr, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 18, pp. 39–109, Elsevier, New York, 1976; Russell, in Kochi, Ref. 6, vol. 2, pp. 275–331; Rüchardt, *Angew. Chem. Int. Ed. Engl.* **9**, 830–843 (1970) [*Angew. Chem.* **82**, 845–858]; Poutsma, *Methods Free-Radical Chem.* **1**, 79–193 (1969); Davidson, *Q. Rev., Chem. Soc.* **21**, 249–258 (1967); Pryor, Fuller, and Stanley, *J. Am. Chem. Soc.* **94**, 1632 (1972).

[37] Hass, McBee, and Weber, *Ind. Eng. Chem.* **28**, 333 (1936).

N-chloro-di-*t*-butylamine and N-chloro-*t*-butyl-*t*-pentylamine, the primary hydrogens are abstracted 1.7 times *faster* than the tertiary hydrogen.[38] In this case the attacking radicals (the radical ions $R_2NH\bullet^+$, see p. 622) are bulky enough for steric hindrance to become a major factor.

2. *Olefins.* When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution. However, for other free radicals (and even for chlorine or bromine atoms when they do abstract a hydrogen) the position of attack is perfectly clear. Vinylic hydrogens are practically never abstracted, and allylic hydrogens are greatly preferred to other positions of the molecule. This is generally attributed[39] to resonance stabilization of the allylic radical:



$$\mathrm{C{=}C{-}C{-}H} \longrightarrow \left[\, -\mathrm{C{=}C{-}C}\bullet \longleftrightarrow \bullet\mathrm{C{-}C{=}C} \,\right]$$

As might be expected, allylic rearrangements (see p. 287) are common in these cases.[40]

3. *Alkyl side chains of aromatic rings.* The preferential position of attack on a side chain is usually the one α to the ring. Both for active radicals such as chlorine and phenyl and for more selective ones such as bromine such attack is faster than that at a primary carbon, but for the active radicals benzylic attack is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogens even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:[41]

	Me—H	$MeCH_2$—H	Me_2CH—H	Me_3C—H	$PhCH_2$—H	Ph_2CH—H	Ph_3C—H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogens are seldom abstracted if there are aliphatic ones to compete (note from Table 3, Chapter 5, p. 166, that *D* for Ph—H is higher than that for any alkyl—H bond). A $\sigma^\bullet$ scale (similar to the σ, σ^+, and σ^- scales discussed in Chapter 9) has been developed for benzylic radicals.[42]

4. *Compounds containing electron-withdrawing substituents.* In halogenations electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type Z—CH_2—CH_3 are attacked predominantly or exclusively at the β position when Z is COOH, COCl, COOR, SO_2Cl, or CX_3. Such compounds as acetic acid and acetyl chloride are not attacked at all. This is in sharp contrast to electrophilic halogenations (**2-4** to **2-6**), where *only* the α position is substituted. This deactivation of α positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed on p. 610. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogens on carbon atoms next to electron-withdrawing groups have low electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior.

[40] For reviews, see Wilt, in Kochi, Ref. 6, vol. 1, pp. 458–466; Walling, in Mayo, "Molecular Rearrangements," pp. 431–438, Interscience, New York, 1963.

[41] Russell, Ref. 36, p. 289.

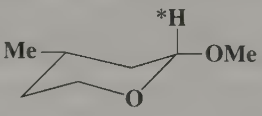
[42] Dinçtürk and Jackson, *J. Chem. Soc., Perkin Trans. 2* 1127 (1981).

For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the α and β carbons of propionic acid are:[43]

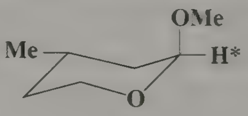
	CH_3-	CH_2-COOH
Me•	1	7.8
Cl•	1	0.03

Some free radicals, e.g., *t*-butyl,[44] benzyl,[45] and cyclopropyl,[46] are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms). The phenyl radical appears to have a very small degree of nucleophilic character.[47] For longer chains, the field effect continues, and the β position is also deactivated to attack by halogen, though much less so than the α position. We have already mentioned (p. 610) that abstraction of an α hydrogen atom from ring-substituted toluenes can be correlated by the Hammett equation. A similar correlation with Taft σ_I values (p. 245) has been found for abstraction of hydrogen from substituted adamantanes by the electrophilic radical $\cdot CCl_3$.[48]

5. *Stereoelectronic effects.* On p. 293, we saw an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle (~30°) with the unshared orbitals of the O or N much more easily than from those with a large angle (~90°). For example, the starred hydrogen of **5** was abstracted about 8 times faster than the starred hydrogen of **6**.[49]



5



6

Abstraction of a halogen has been studied much less,[50] but the order of reactivity is RI > RBr > RCl ⩾ RF.

Reactivity at a Bridgehead[51]

Many free-radical reactions have been observed at bridgehead carbons, e.g., (see **4-39**).[52]

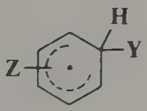
demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, although the bridgehead position is tertiary.[53] So, while bridgehead free-radical substitution is possible, it is not preferred, presumably because of the strain involved.[54]

Reactivity in Aromatic Substrates

Free-radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; i.e., we need to know which position on the ring will be attacked to give the intermediate



The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free-radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para but the intermediate from the para attack may go on to product while that from ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, although there has been much controversy over just how meaningful such conclusions are:[55]

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.

2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho-para-directing; none are deactivating or (chiefly) meta-directing.

3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.

4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds XC_6H_4Y showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).[56] The increase could be correlated with the Hammett σ_p values for X.

5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see p. 462) are not great. Partial rate factors for a few groups are given in Table 2.[57]

Cl	3.90	1.65	2.12
Br	3.05	1.70	1.92
MeO	5.6	1.23	2.31

6. Although hydrogen is the leaving group in most free-radical aromatic substitutions, ipso attack (p. 458) and ipso substitution (e.g., with Br, NO_2, or CH_3CO as the leaving group) have been found in certain cases.[58]

It should be remembered that in *alternant hydrocarbons*, the position of attack is the same for electrophilic, nucleophilic, and free-radical substitution (see p. 462).

Reactivity in the Attacking Radical[59]

We have already seen that some radicals are much more selective than others (p. 614). The bromine atom is so selective that when only primary hydrogens are available, as in neopentane or *t*-butylbenzene, the reaction is slow or nonexistent; and isobutane can be selectively brominated to give *t*-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes, e.g., ethylbenzene and cumene, takes place exclusively at the α position,[60] emphasizing the selectivity of Br• The dissociation energy *D* of the C—H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack α to an electron-withdrawing group because the energy of the C—H bond there is lower than in other places in the molecule.

Some free radicals, e.g., triphenylmethyl, are so unreactive that they abstract hydrogens very poorly if at all. Table 3 lists some common free radicals in approximate order of reactivity.[61]

It has been mentioned that some free radicals, e.g., chloro, are electrophilic and some, e.g., *t*-butyl, are nucleophilic. It must be borne in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

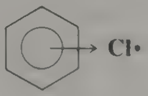
The Effect of Solvent on Reactivity[63]

As has been noted earlier, the solvent usually has little effect on free-radical substitutions in contrast to ionic ones: indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. The chlorination of 2,3-dimethylbutane in aliphatic solvents gave about 60% $(CH_3)_2CHCH(CH_3)CH_2Cl$ and 40% $(CH_3)_2CHCCl(CH_3)_2$, while in aromatic solvents the ratio became about 10:90.[64] This result is attributed to complex formation between the aromatic solvent and the chlorine atom



7

which makes the chlorine less reactive and more selective.[65] This type of effect is not found in cases where the differences in abstractability are caused by field effects of electron-withdrawing groups (p. 615). In such cases aromatic solvents make little difference.[66] The complex **7** has been detected as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl_4.[67] Differences caused by solvents have also been reported in reactions of other radicals.[68] Some of the anomalous results obtained in the chlorination of aromatic side chains (p. 615) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.[69]

REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (from the diazonium ion); these are considered first.[70]

Hydrogen as Leaving Group

A. Substitution by Halogen

4-1 Halogenation at an Alkyl Carbon
Halogenation or **Halo-de-hydrogenation**[71]

$$\mathbf{R{-}H + Cl_2 \xrightarrow{h\nu} R{-}Cl}$$

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or uv light.[72] The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariabily occur even if there is a large molar ratio of substrate to halogen. When functional groups are present, the principles are those outlined on p. 615; favored positions are those α to aromatic rings, while positions α to electron-withdrawing groups are least likely to be substituted. Tertiary carbons are most likely to be attacked and primary least. Positions α to an OR group are very readily attacked. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (**2-4** to **2-6**), which always takes place α to a carbonyl group (except when the reaction is catalyzed by $AgSbF_6$; see following). Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory and indeed it is of considerable industrial importance. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen, e.g., ethane, cyclohexane, neopentane. The most common are substrates with methyl groups on aromatic rings, since few cases are known where halogen atoms substitute at an aromatic position.[73] Of course, ring substitution *does* take place in the presence of a positive-ion-forming catalyst (**1-12**). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include hydrogen gas, olefins, higher alkanes, lower alkanes, and halogen derivatives of *them*.

The bromine atom is much more selective than the chlorine atom. As indicated on p. 618, it is often possible to brominate tertiary positions selectively.[74] High regioselectivity may also be obtained where the neighboring-group mechanism (p. 612) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,[75] but seldom, because it is too reactive and hard to control.[76] It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations too. Fluorination has been achieved by the use of fluoroxytrifluoromethane CF_3OF and uv light.[77] For example, cyclohexane gave 44% fluorocyclohexane ($CFCl_3$ solvent, $-78°C$). CF_3OF without uv light fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.[78] For example, adamantane gave 75% 1-fluoroadamantane. F_2 at $-70°C$, diluted with N_2, is also highly regioselective for tertiary positions.[79] These reactions probably have electrophilic (see p. 624), not free-radical mechanisms.

[76] However, there are several methods by which *all* the C—H bons in a molecule can be converted to C—F bonds. For reviews, see Lagow and Margrave, *Prog. Inorg. Chem.* **26,** 161–210 (1979); Burdon and Tatlow, *Adv. Fluorine Chem.* **1,**

Iodine can be used if the activating light has a wavelength of 184.9 nm,[80] but iodinations are seldom attempted, largely because the HI formed reduces the alkyl iodide. Iodinations have been accomplished in low-to-moderate yields with "*t*-BuOI," generated in situ from HgI_2 and *t*-BuOCl.[81]

Many other halogenation agents have been employed, the most common of which is sulfuryl chloride SO_2Cl_2.[82] The reaction in this case is more rapid and convenient than the one with chlorine itself. A mixture of Br_2 and HgO is a more active brominating agent than bromine alone.[83] The actual brominating agent in this case is believed to be bromine monoxide Br_2O. Other agents used have been N-bromosuccinimide (see **4-2**), CCl_4, N-chlorophthalimide,[84] dichlorine monoxide Cl_2O,[85] $BrCCl_3$,[86] PCl_5,[87] phosgene, *t*-butyl hypobromite[88] and hypochlorite,[89] N-haloamines and sulfuric acid,[90] and trichloromethanesulfonyl chloride and bromide.[91] In all these cases a chain-initiating catalyst is required, usually peroxides or uv light.

When chlorination is carried out with N-haloamines and sulfuric acid (catalyzed by either uv light or metal ions), selectivity is much greater than with other reagents.[90] In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the $\omega - 1$ position).[92] Some typical selectivity values are[93]

$$\begin{array}{lllllll} \mathrm{CH_3}- & \mathrm{CH_2}- & \mathrm{CH_2}- & \mathrm{CH_2}- & \mathrm{CH_2}- & \mathrm{CH_2}- & \mathrm{CH_3} \\ 1 & 56 & 29 & 14 & & & \end{array} \qquad \text{Ref. 94}$$

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,[97] and adamantane and bicyclo[2.2.2]octane at the bridgeheads[98] by this procedure. The reasons for the high ω − 1 specificity are not clearly understood.[93] Alkyl bromides can be regioselectively chlorinated one carbon away from the bromine (to give *vic*-bromochlorides) by treatment with PCl_5.[99] Alkyl chlorides can be converted to *vic*-dichlorides by treatment with $MoCl_5$.[100] For regioselective chlorination at certain positions of the steroid nucleus, see **9-2.**

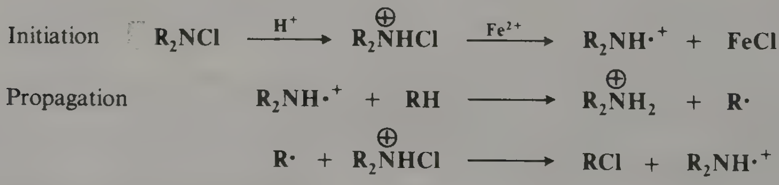
In almost all cases, the mechanism involves a free-radical chain:[101]

$$\begin{array}{lrl}
\text{Initiation} & X_2 \xrightarrow{h\nu} & 2X\cdot \\
\text{Propagation} & RH + X\cdot \longrightarrow & R\cdot + XH \\
 & R\cdot + X_2 \longrightarrow & RX + X\cdot \\
\text{Termination} & R\cdot + X\cdot \longrightarrow & RX
\end{array}$$

When the reagent is halogen, initiation occurs as shown above. When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *t*-BuOCl have been formulated as[102]

$$\begin{array}{rcl}
RH + t\text{-}BuO\cdot & \longrightarrow & R\cdot + t\text{-}BuOH \\
R\cdot + t\text{-}BuOCl & \longrightarrow & RCl + t\text{-}BuO\cdot
\end{array}$$

and the abstracting radicals in the case of N-haloamines are the aminium radical cations $R_2NH\cdot^+$ (p. 472), with the following mechanism (in the case of initiation by Fe^{2+}):[90]



$$\begin{array}{llcl}
\text{Initiation} & R_2NCl \xrightarrow{H^+} R_2\overset{\oplus}{N}HCl & \xrightarrow{Fe^{2+}} & R_2NH\cdot^+ + FeCl \\
\text{Propagation} & R_2NH\cdot^+ + RH & \longrightarrow & R_2\overset{\oplus}{N}H_2 + R\cdot \\
 & R\cdot + R_2\overset{\oplus}{N}HCl & \longrightarrow & RCl + R_2NH\cdot^+
\end{array}$$

This mechanism is similar to that of the Hofmann–Löffler reaction (**8-44**).

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine.

[102] Carlsson and Ingold, *J. Am. Chem. Soc.* **89,** 4885, 4891 (1967); Walling and Kurkov, *J. Am. Chem. Soc.* **89,** 4895 (1967); Walling and McGuiness, *J. Am. Chem. Soc.* **91,** 2053 (1969). See also Zhulin and Rubinshtein, *Bull. Acad. Sci. USSR* **26,** 2082 (1977).

Thus, products like hydrogen, higher alkanes, and alkyl halides can be accounted for by steps like these (these are for chlorination of methane, but analogous steps can be written for other substrates):

$$\begin{aligned}
Cl\cdot + HCl &\longrightarrow Cl{-}Cl + H\cdot \\
H\cdot + H\cdot &\longrightarrow H{-}H \\
CH_3\cdot + CH_3\cdot &\longrightarrow CH_3CH_3 \\
CH_3CH_3 + Cl\cdot &\longrightarrow CH_3CH_2\cdot + HCl \\
CH_3CH_2\cdot + Cl_2 &\longrightarrow CH_3CH_2Cl + Cl\cdot \\
CH_3CH_2\cdot + CH_3CH_2\cdot &\longrightarrow CH_3CH_3 + CH_2{=}CH_2 \\
CH_3CH_2\cdot + CH_3CH_2\cdot &\longrightarrow CH_3CH_2CH_2CH_3 \\
CH_3CH_2\cdot + HCl &\longrightarrow CH_3CH_3 + Cl\cdot
\end{aligned}$$

etc.

At least when methane is the substrate, the rate-determining step is

$$CH_4 + Cl\cdot \longrightarrow CH_3\cdot + HCl$$

since an isotope effect of 12.1 was observed at 0°C.[103] For chlorinations, chains are very long, typically 10^4 to 10^6 propagations before a termination step takes place.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, ΔH values for the two principal propagation steps are:

	kcal/mol			
	F_2	Cl_2	Br_2	I_2
$CH_4 + X\cdot \rightarrow CH_3\cdot + HX$	−32	+1	+17	+33
$CH_3\cdot + X_2 \rightarrow CH_3X + X\cdot$	−72	−26	−24	−20

In each case D for CH_3—H is 104 kcal/mol, while D values for the other bonds involved are given in Table 4.[104] F_2 is so reactive[105] that neither uv light nor any other initiation is needed (total $\Delta H = -104$ kcal/mol);[106] while Br_2 and I_2 essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br_2 and I_2. It is apparent that the most important single factor causing the order of halogen reactivity to be $F_2 > Cl_2 > Br_2 > I_2$ is the decreasing strength of the HX bond in the order HF > HCl > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in D values for R—H in the order primary > secondary > tertiary (Table 3 in Chapter 5, p. 166). (Note that for chlorination step 1 is exothermic for practically all substrates other than CH_4, since most other aliphatic C—H bonds are weaker than those in CH_4.)

[103] Wiberg and Motell, *Tetrahedron* **19,** 2009 (1963).

[104] Trotman-Dickenson and Kerr, in Weast, "Handbook of Chemistry and Physics," 60th ed. pp. F220–223, F241, CRC Press, Boca Raton, Fla., 1979.

[105] It has been reported that the reaction of F atoms with CH_4 at 25 K takes place with practically zero activation energy: Johnson and Andrews, *J. Am. Chem. Soc.* **102,** 5736 (1980).

[106] For F_2 the following initiation step is possible: $F_2 + RH \rightarrow R\cdot + F\cdot + HF$ [first demonstrated by Miller, Koch, and McLafferty, *J. Am. Chem. Soc.* **78,** 4992 (1956)]. ΔH for this reaction is equal to the small positive value of 5 kcal/mol. The possibility of this reaction (which does not require an initiator) explains why fluorination can take place without uv light (which would otherwise be needed to furnish the 37 kcal/mol necessary to break the F—F bond). Once the reaction has been initiated, the large amount of energy given off by the propagation steps is ample to cleave additional F_2 molecules. Indeed, it is the magnitude of this energy that is responsible for the cleavage of carbon chains by F_2.

TABLE 4 Some *D* values[104]

Bond	*D*, kcal/mol	Bond	*D*, kcal/mol	Bond	*D*, kcal/mol
H—F	136	F—F	37	CH_3—F	109
H—Cl	103	Cl—Cl	58	CH_3—Cl	84
H—Br	87	Br—Br	46	CH_3—Br	70
H—I	71	I—I	36	CH_3—I	56

Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by $AgSbF_6$.[107] Electrophilic fluorination has already been mentioned (p. 621).

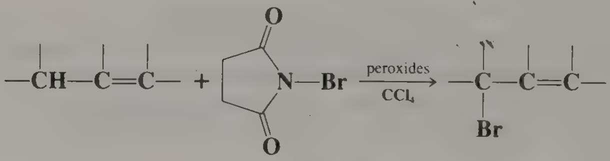
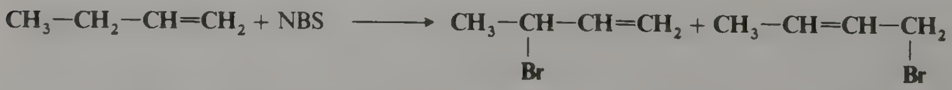
4-2 Allylic Halogenation



This reaction is actually a special case of **4-1,** but is important enough to be treated separately.[108] Olefins can be halogenated in the allylic position by a number of reagents, of which N-bromosuccinimide (NBS)[109] is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination.* A nonpolar solvent is used, most often CCl_4. Other N-bromo amides, including various N-bromohydantoins and N-bromocaprolactam,[110] have also been used. To a much lesser extent, allylic chlorination has been carried out, with N-chlorosuccinimide, N-chloro-N-cyclohexylbenzenesulfonamide,[111] or *t*-butyl hypochlorite.[112] With any reagent an initiator is needed; this is usually a peroxide or, less often uv light.

The reaction is usually quite specific at the allylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic shifts can take place, so that mixtures of both possible products are obtained, e.g.,



$$CH_3-CH_2-CH{=}CH_2 + NBS \longrightarrow CH_3-\underset{\displaystyle Br}{\underset{|}{CH}}-CH{=}CH_2 + CH_3-CH{=}CH-\underset{\displaystyle Br}{\underset{|}{CH_2}}$$

When a double bond has two different α positions, e.g., $CH_3CH{=}CHCH_2CH_3$, a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, although many substitutions at allylic tertiary positions have been performed.[113] It is possible to brominate both sides of the double bond.[114] Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than α to the first bromine.

[111] Theilacker and Wessel, *Liebigs Ann. Chem.* **703,** 34 (1967).

[112] Walling and Thaler, *J. Am. Chem. Soc.* **83,** 3877 (1961).

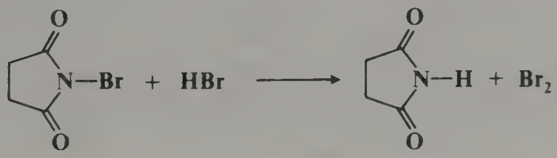
NBS is also a highly regioselective brominating agent at other positions, including positions α to a carbonyl group, to a C≡C triple bond, to a boron atom[115] (see p. 997), and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is α to the triple bond.[116] It has been shown that the regioselectivity of NBS can be substantially increased by changing the solvent.[117]

That the mechanism of allylic bromination is of the free-radical type was demonstrated by Dauben and McCoy,[118] who showed that the reaction is very sensitive to free-radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the substrate is the bromine atom.[119] The reaction is initiated by small amounts of Br•. Once it is formed, the main propagation steps are

Step 1 $\mathrm{Br}\cdot + \mathrm{RH} \longrightarrow \mathrm{R}\cdot + \mathrm{HBr}$

Step 2 $\mathrm{R}\cdot + \mathrm{Br_2} \longrightarrow \mathrm{RBr} + \mathrm{Br}\cdot$

The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:



The function of the NBS is therefore to provide a source of Br_2 in a low, steady-state concentration and to use up the HBr liberated in step 1.[120] The main evidence for this mechanism is that NBS and Br_2 show similar selectivity[121] and that the various N-bromo amides also show similar selectivity,[122] which is consistent with the hypothesis that the same species is abstracting in each case.[123]

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free-radical mechanism (see **5-27**). Apparently the concentration is too low.

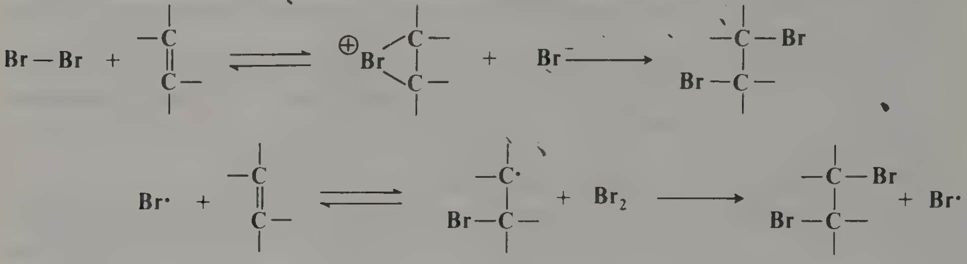
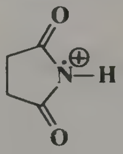
In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free-radical:



The other bromine comes from another bromine-containing molecule or ion. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an olefin in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.[124]

In polar solvents, the mechanism may be entirely different, involving electrophilic attack by Br^+. In protonating solvents the protonated radical **8** may be the abstracting species.[125]



8

Allylic chlorination has also been carried out[126] with N-chlorosuccinimide and either arylselenyl chlorides ArSeCl, aryl diselenides ArSeSeAr, or TsNSO as catalysts. Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. A free-radical mechanism is unlikely in these reactions.

OS **IV,** 108; **V,** 825; **56,** 49.

4-3 Halogenation of Aldehydes

$$\mathbf{RCHO + Cl_2 \longrightarrow RCOCl}$$

Aldehydes can be directly converted to acyl chlorides by treatment with chlorine; however, the reaction operates only when the aldehyde does not contain an α hydrogen and even then it is not very useful. When there is an α hydrogen, α halogenation (**2-4**) occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2[127] and *t*-BuOCl.[128] The mechanisms are probably of the free-radical type. NBS (with uv light)[129] has been used to convert aldehydes to acyl bromides.

B. Substitution by Oxygen

4-4 Hydroxylation at an Aliphatic Carbon
Hydroxylation or **Hydroxy-de-hydrogenation**[130]

$$R_3CH \xrightarrow[\text{silica gel}]{O_3} R_3COH$$

Compounds containing susceptible C—H bonds can be oxidized to alcohols.[131] Nearly always, the C—H bond involved is tertiary, so that the product is a tertiary alcohol. This is partly because tertiary C—H bonds are more susceptible to free-radical attack than primary and secondary bonds and partly because the reagents involved would oxidize primary and secondary alcohols further. In the best method the reagent is ozone and the substrate is adsorbed on silica gel.[132] Yields as high as 99% have been obtained by this method. Other reagents, which often give much lower yields, are chromic acid,[133] alkaline permanganate,[134] certain perbenzoic acids,[135] and peracetic acid with uv light.[136] Alkanes and cycloalkanes have been oxidized at secondary positions, to a mixture of alcohols and trifluoroacetates, by 30% aqueous H_2O_2 in trifluoroacetic acid.[137] This reagent does not oxidize the alcohols further and ketones are not found. As in the case of chlorination with N-haloamines and sulfuric acid (see **4-1**), the $\omega - 1$ position is the most favored.

When chromic acid is the reagent, the mechanism is probably as follows: a Cr^{6+} species abstracts a hydrogen to give $R_3C\bullet$, which is held in a solvent cage near the resulting Cr^{5+} species. The two species then combine to give R_3COCr^{4+}, which is hydrolyzed to the alcohol. This mechanism predicts retention of configuration; this is largely observed.[138] The oxidation by permanganate also involves predominant retention of configuration, and a similar mechanism has been proposed.[139]

Treatment of double-bond compounds with selenium dioxide introduces an OH group into the allylic position (see also **9-16**).[140] Allylic rearrangements are common. There is evidence that the mechanism does not involve free radicals but includes two pericyclic steps (**A** and **B**):[141]

[140] For reviews, see Rabjohn, *Org. React.* **24,** 261–415 (1976); Jerussi, *Sel. Org. Transform.* **1,** 301–326 (1970); Trachtenberg, in Augustine, Ref. 131, pp. 125–153.

[141] Sharpless and Lauer, *J. Am. Chem. Soc.* **94,** 7154 (1972); Arigoni, Vasella, Sharpless, and Jensen, *J. Am. Chem. Soc.* **95,** 7917 (1973); Woggon, Ruther, and Egli, *J. Chem. Soc., Chem. Commun.* 706 (1980). For other mechanistic proposals, see Schaefer, Horvath, and Klein, *J. Org. Chem.* **33,** 2647 (1968); Trachtenberg, Nelson, and Carver, *J. Org. Chem.* **35,** 1653 (1970); Bhalerao and Rapoport, *J. Am. Chem. Soc.* **93,** 4835 (1971). Stephenson and Speth, *J. Org. Chem.* **44,** 4683 (1979).

The step marked **A** is similar to the ene synthesis (**5-16**). The step marked **B** is a [2,3]sigmatropic rearrangement (see **8-39**). The reaction can also be accomplished with *t*-butyl hydroperoxide, if SeO_2 is present in catalytic amounts.[142] The SeO_2 is the actual reagent; the peroxide re-oxidizes the $Se(OH)_2$. This method makes work-up easier, but gives significant amounts of side products when the double bond is in a ring.[143] Alkynes generally give α,α'-dihydroxylation.[144]

Ketones and esters can be α-hydroxylated by treatment of their enolate forms (prepared by adding the ketone or ester to lithium diisopropylamide) with a molybdenum peroxide reagent (MoO_5–pyridine–HMPT) in tetrahydrofuran–hexane at −70°C[145] or by oxidation of their trimethylsilyl enol ethers with *m*-chloroperbenzoic acid,[146] or osmium tetroxide-N-methylmorpholine-N-oxide.[147] Yields in both methods are moderate to high. The enolate forms of amides and esters[148] and the enamine derivatives of ketones[149] can similarly be converted to their α-hydroxy derivatives by reaction with molecular oxygen. The MoO_5 method can also be applied to certain nitriles.[145]

Ketones can be α-hydroxylated in good yields, without conversion to the enolates, by treatment with *o*-iodosobenzoic acid[149a] or phenyliodoso acetate $PhI(OAc)_2$ in methanolic NaOH.[150] The latter reagent has also been used on carboxylic esters.[151]

4-5 Hydroxylation at an Aromatic Carbon[152]

$$\mathbf{ArH + H_2O_2 + FeSO_4 \longrightarrow ArOH}$$

A mixture of hydrogen peroxide and ferrous sulfate,[153] called *Fenton's reagent,*[154] can be used to hydroxylate aromatic rings, though yields are usually not high. Biaryls are usually side products. Among other reagents used have been H_2O_2 and titanous ion; H_2O_2 in SbF_5–HF;[155] a mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*);[156] α-azo hydroperoxides ArN═NCHPhOOH;[157] O_2 and KOH in liquid NH_3;[158] and peracids such as pernitrous and trifluoroperacetic acids.

Much work has been done on the mechanism of the reaction with Fenton's reagent, and it is known that free aryl radicals (formed by a process such as $HO\bullet + ArH \rightarrow Ar\bullet + H_2O$) are not intermediates. The mechanism is essentially that outlined on p. 611, with HO• as the attacking species,[159] formed by

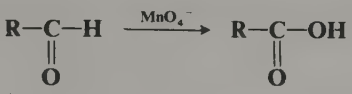
$$\mathrm{Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + HO\bullet}$$

The rate-determining step is formation of HO• and not its reaction with the aromatic substrate.

Another hydroxylation reaction is the *Elbs reaction.*[160] In this method phenols can be oxidized to *para*-diphenols with $K_2S_2O_8$ in alkaline solution.[161] Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boyland–Sims oxidation*. Yields are low with either phenols or amines, generally under 50%. The mechanisms are not clear but may involve attack by $S_2O_8{}^{2-}$ at the oxygen or nitrogen, followed by rearrangement to the products.[162]

See also **1-31** and **3-20.**

4-6 Oxidation of Aldehydes to Carboxylic Acids



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}H \xrightarrow{MnO_4^-} R{-}\underset{\underset{O}{\|}}{C}{-}OH}$$

Oxidation of aldehydes to carboxylic acids is one of the most common oxidation reactions in organic chemistry[163] and has been carried out with many oxidizing agents, the most popular of which is permanganate in acid, basic, or neutral solution. Chromic acid and bromine are other reagents frequently employed. Silver oxide is a fairly specific oxidizing agent for aldehydes and does not readily attack other groups. Benedict's and Fehling's solutions oxidize aldehydes,[164] and a test for aldehydes depends on this reaction, but the method is seldom used for preparative purposes and in any case gives very poor results with aromatic aldehydes. α,β-Unsaturated aldehydes can be oxidized by sodium chlorite without disturbing the double bond.[165] Aldehydes are also oxidized to carboxylic acids by atmospheric oxygen, but the actual direct oxidation product in this case is the peroxy acid RCO_3H,[166] which with another molecule of aldehyde disproportionates to give two molecules of acid (see **4-8**).[167]

Mechanisms of aldehyde oxidation[168] are not firmly established, but there seem to be at least two main types—a free-radical mechanism and an ionic one. In the free-radical process, the aldehydic hydrogen is abstracted to leave an acyl radical, which obtains OH from the oxidizing agent. In the ionic process, the first step is addition of a species OZ^- to the carbonyl bond to give

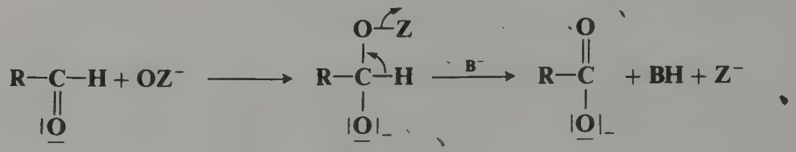
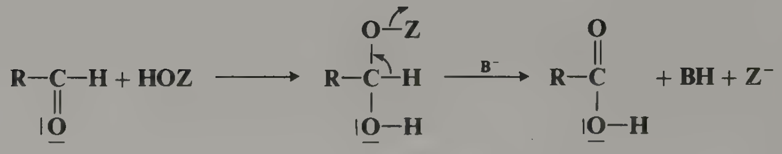
9 in alkaline solution and **10** in acid or neutral solution. The aldehydic hydrogen of **9** or **10** is then lost as a proton to a base, while Z leaves with its electron pair.



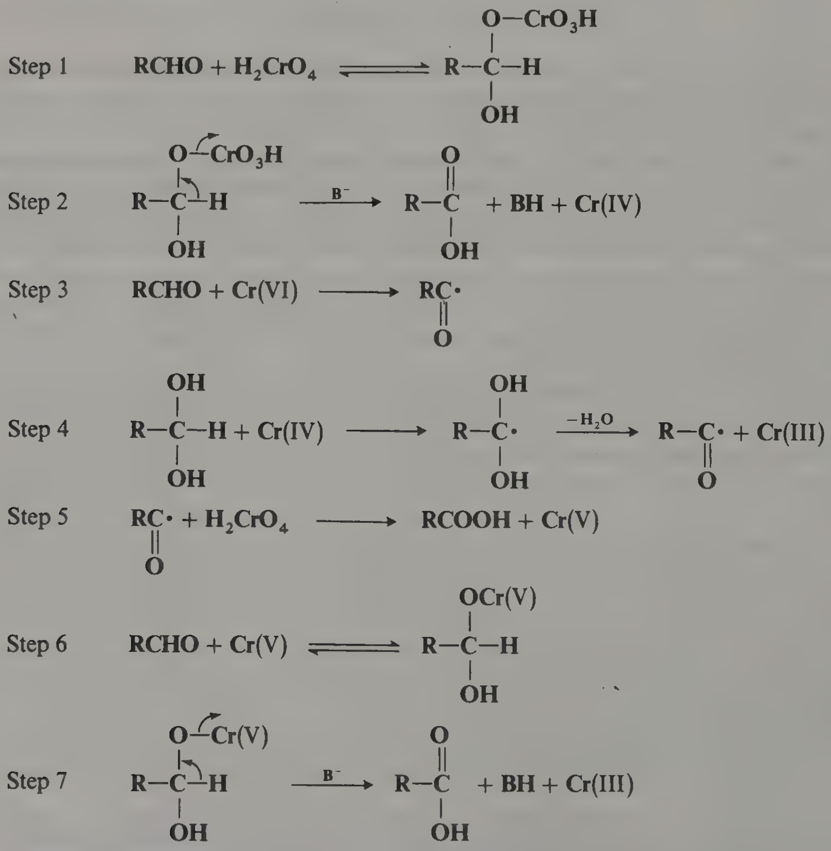
9



R—C—H + HOZ
B⁻
+ BH + Z⁻

10

For oxidation with acid dichromate the picture seems to be quite complex, with several processes of both types going on:[169]

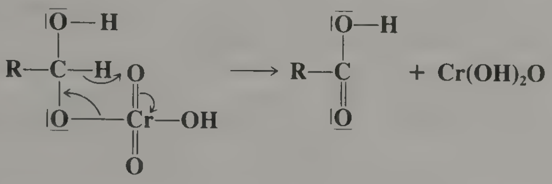


Step 1
RCHO + H₂CrO₄
Step 2
B⁻
+ BH + Cr(IV)
Step 3
RCHO + Cr(VI)
Step 4
+ Cr(IV)
−H₂O
+ Cr(III)
Step 5
+ H₂CrO₄
RCOOH + Cr(V)
Step 6
RCHO + Cr(V)
Step 7
B⁻
+ BH + Cr(III)

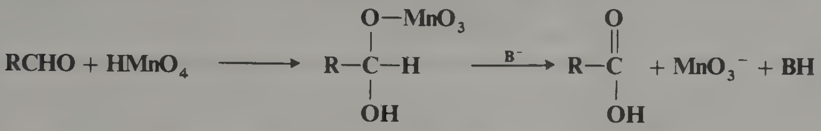
---

[169] Wiberg and Richardson, *J. Am. Chem. Soc.* **84**, 2800 (1962); Wiberg and Szeimies, *J. Am. Chem. Soc.* **96**, 1889 (1974). See also Roček and Ng, *J. Am. Chem. Soc.* **96**, 1522, 2840 (1974).

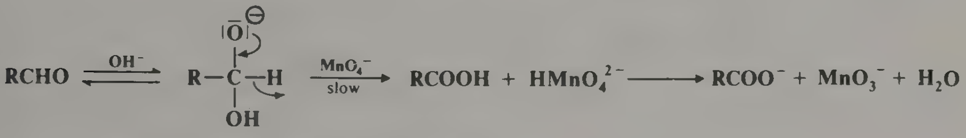
Steps 1 and 2 constitute an oxidation by the ionic pathway by Cr(VI), and steps 6 and 7 a similar oxidation by Cr(V), which is produced by an electron-transfer process. Either Cr(VI) (step 3) or Cr(IV) (step 4) [Cr(IV) is produced in step 2] may abstract a hydrogen and the resulting acyl radical is converted to carboxylic acid in step 5. Thus, chromium in three oxidation states is instrumental in oxidizing aldehydes. Still another possible process has been proposed in which the chromic acid ester decomposes as follows:[170]



The mechanism with permanganate is less well-known, but an ionic mechanism has been proposed[171] for neutral and acid permanganate, similar to steps 1 and 2 for dichromate:



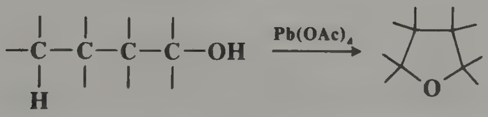
For alkaline permanganate, the following mechanism has been proposed:[172]



$$\text{Mn(V)} + \text{Mn(VII)} \longrightarrow 2\text{Mn(VI)}$$

OS **I,** 166; **II,** 302, 315, 538; **III,** 745; **IV,** 302, 493, 499, 919, 972, 974.

4-7 Formation of Cyclic Ethers



Alcohols with a hydrogen in the δ position can be cyclized with lead tetraacetate.[173] The reaction is usually carried out at about 80°C (most often in refluxing benzene) but can also be done at room temperature if the reaction mixture is irradiated with uv light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when γ and ε hydrogens are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),[174] and with ceric ammonium nitrate (CAN).[175] The following mechanism is likely for the lead tetraacetate reaction:[176]

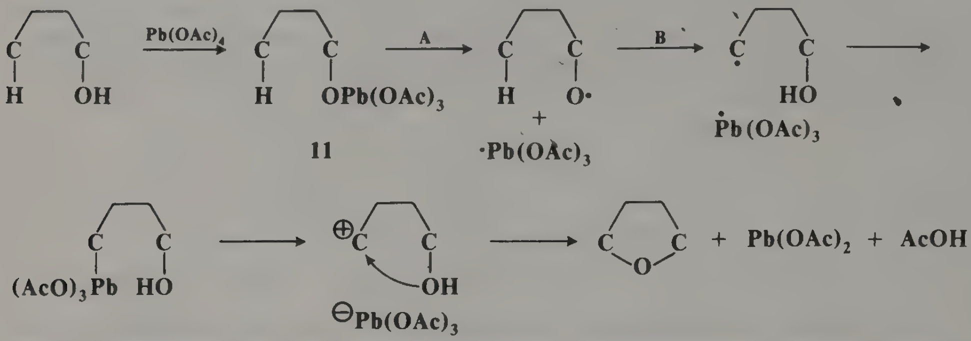
---

[170] See Roček and Ng, *J. Org. Chem.* **38,** 3348 (1973).

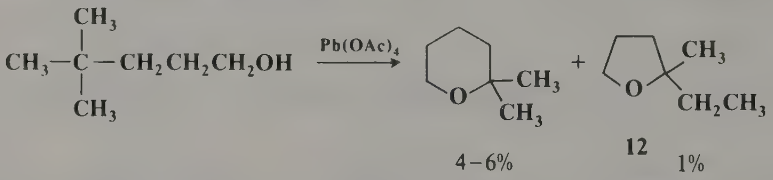
[171] See, for example, Freeman, Lin, and Moore, *J. Org. Chem.* **47,** 56 (1982); Jain and Banerji, *J. Chem. Res., Synop.* 60 (1983).

[172] Freeman, Brant, Hester, Kamego, Kasner, McLaughlin, and Paull, *J. Org. Chem.* **35,** 982 (1970).

[173] For reviews, see Mihailović and Partch, *Sel. Org. Transform.* **2,** 97–182 (1972); Mihailović and Čeković, *Synthesis* 209–224 (1970). For a review of the chemistry of lead tetraacetate, see Butler, in Pizey, Ref. 82, vol. 3, pp. 277–419, 1977.

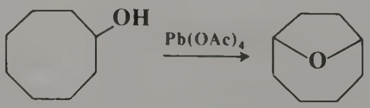


though **11** has never been isolated. The step marked **A** is a photochemical cleavage if irradiation is used; otherwise it is a thermal cleavage. The step marked **B** is a 1,5 internal hydrogen abstraction. Such abstractions are well-known (see p. 1044) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6 abstractions). Evidence for the intermediacy of a carbocation is that 4,4-dimethylpentanol, which cannot give a normal product since it has no δ hydrogen, gave 1% of the rearranged product 2-methyl-2-ethyltetrahydrofuran (**12**) in addition to 4 to 6% of the tetrahydropyran:[177]



12 could only have been produced by a 1,2-shift of a methyl in the carbocation intermediate $^+CH_2CMe_2CH_2CH_2CH_2OH$. Carbocations, but not free radicals, commonly rearrange in this manner (see Chapter 18).

Reactions that sometimes compete are oxidation to the aldehyde or acid (**9-3** and **9-22**) and fragmentation of the substrate into $H\text{—}\overset{|}{\underset{|}{C}}\text{—}\overset{|}{\underset{|}{C}}\text{—}\overset{|}{\underset{|}{C}}\text{—}OAc$ and $\text{—}\overset{|}{C}\text{=}O$. When the OH group is on a ring of at least seven members, a transannular product may be formed, e.g.,[178]



There are no references in *Organic Syntheses*, but see OS **V**, 692; **59**, 147, for related reactions.

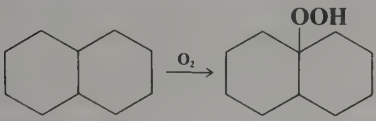
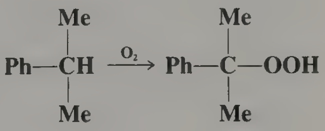
4-8 Formation of Hydroperoxides
Hydroperoxy-de-hydrogenation

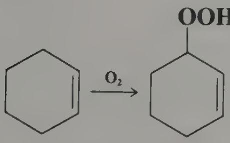
$$RH + O_2 \longrightarrow R—O—O—H$$

The slow atmospheric oxidation (*slow* meaning without combustion) of a C—H bond to a C—O—O—H group is called *autoxidation*.[179] The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so that unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. The hydroperoxides produced often react further to alcohols, ketones, and more complicated products, so that the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.[179a] It is because of autoxidation that foods, rubber, paint, lubricating oils, etc. deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free-radical reactions of C—H bonds, some bonds are attacked more readily than others,[180] and these are the ones we have seen before (pp. 614–616), although the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), allylic (though allylic rearrangements are common), and benzylic R.[181] The following are actual examples:

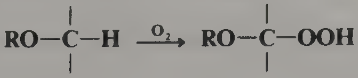




$$Ph—\overset{\overset{\large Me}{|}}{\underset{\underset{\large Me}{|}}{C}}H \xrightarrow{O_2} Ph—\overset{\overset{\large Me}{|}}{\underset{\underset{\large Me}{|}}{C}}—OOH$$



Another susceptible position is aldehydic C—H, but the peracids so produced are not easily isolated[166] since they are converted to the corresponding carboxylic acids (reaction **4-6**). The α positions of ethers are also easily attacked by oxygen:



$$RO—\overset{|}{\underset{|}{C}}—H \xrightarrow{O_2} RO—\overset{|}{\underset{|}{C}}—OOH$$

but the resulting hydroperoxides are almost never isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.[182]

Oxygen itself (a diradical) is too unreactive to be the species that actually abstracts the hydrogen.

---

[179] The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. For reviews, see Sheldon and Kochi, *Adv. Catal.* **25,** 272–413 (1976); Howard, in Kochi, Ref. 6, vol. 2, pp. 3–62; Lloyd, *Methods Free-Radical Chem.* **4,** 1–131 (1973); Betts, *Q. Rev., Chem. Soc.* **25,** 265–288 (1971); Huyser, "Free-Radical Chain Reactions," Ref. 1, pp. 306–312; Chinn, Ref. 131, pp. 29–39; Ingold, *Acc. Chem. Res.* **2,** 1–9 (1969); Mayo, *Acc. Chem. Res.* **1,** 193–201 (1968); Waters, "Mechanisms of Oxidation of Organic Compounds," pp. 6–16, Wiley, New York, 1964, *Prog. Org. Chem.* **5,** 1–46 (1961), pp. 17–26. For a monograph on these and similar reactions, see Sheldon and Kochi, Ref. 153.

[180] For a discussion, see Korcek, Chenier, Howard, and Ingold, *Can. J. Chem.* **50,** 2285 (1972), and previous papers in this series.

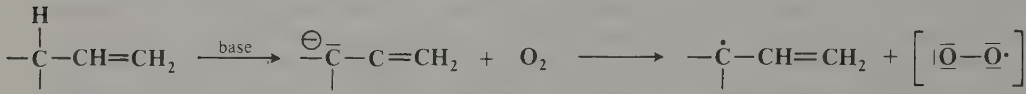
[181] For a review of autoxidation at allylic and benzylic positions, see Voronenkov, Vinogradov, and Belyaev, *Russ. Chem. Rev.* **39,** 944–952 (1970).

[182] For methods of detection and removal of peroxides from either solvents, see Gordon and Ford, "The Chemist's Companion," p. 437, Wiley, New York, 1972; Burfield, *J. Org. Chem.* **47,** 3821 (1982).

But if a trace of free radical (say R′•) is produced by some initiating process, *it* reacts with oxygen to give R′—O—O• ; since this type of radical *does* abstract hydrogen, the chain is

$$\mathrm{R'OO\cdot + RH \longrightarrow R\cdot + R'OOH}$$
$$\mathrm{R\cdot + O_2 \longrightarrow R{-}O{-}O\cdot}$$
$$\text{etc.}$$

In at least some cases (in alkaline media)[183] the radical R• can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, e.g.,[184]



$$-\underset{|}{\overset{\overset{H}{|}}{C}}-CH{=}CH_2 \xrightarrow{\text{base}} \overset{\ominus}{-\underset{|}{\bar{C}}}-C{=}CH_2 + O_2 \longrightarrow -\underset{|}{\dot{C}}-CH{=}CH_2 + \left[\,|\bar{O}-\bar{O}\cdot\,\right]$$

Autoxidations in alkaline media can also proceed by a different mechanism: R—H + base → R^- + O_2 → ROO^- [185]

When alkenes are treated with oxygen that has been photosensitized (p. 211), they are substituted by OOH in the allylic position in a synthetically useful reaction.[186] Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet) but an excited singlet state[187] (in which all electrons are paired), and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,[188] e.g., by the reaction between H_2O_2 and NaOCl[189] or between ozone and triphenyl phosphite.[190] The oxygen generated by either photochemical or nonphotochemical methods reacts with olefins in the same way;[191] this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free-radical mechanism, and further evidence that free radicals are not involved comes from the treatment of optically active limonene (**13**) with singlet oxygen. Among other products is the

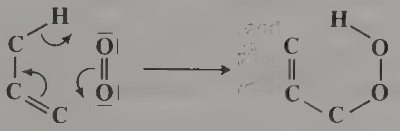
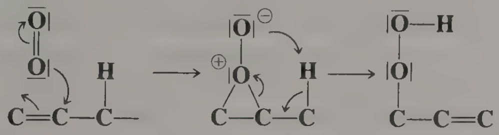
optically active hydroperoxide **14**, though if **15** were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.[192] In contrast, autoxidation of **13** gave optically inactive **14** (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more highly substituted than with less highly substituted alkenes (note that only the trisubstituted double bond of **13** was attacked). The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the olefin.[193] In simple trisubstituted olefins, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.[194] Several mechanisms have been proposed for the reaction with singlet oxygen.[195] One of these is a pericyclic mechanism, similar to that of the ene synthesis



(**5-16**) and to the first step of the reaction between alkenes and SeO_2 (**4-4**). Another involves addition of singlet oxygen to the double bond to give a peroxirane (**16**), followed by internal proton transfer.[196]



16

Still other proposed mechanisms involve diradicals or dipolar intermediates.[197]

OS **IV,** 895.

4-9 Formation of Peroxides
Alkyldioxy-de-hydrogenation

$$\mathbf{RH + R'OOH \xrightarrow{CuCl} ROOR'}$$

Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts, e.g., cobalt and manganese salts.[198] Very high yields can be obtained. The type of hydrogen replaced is similar to that with N-bromosuccinimide (reaction **4-2**), i.e., mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free-radical type, involving ROO• formed from ROOH and the metal ion.

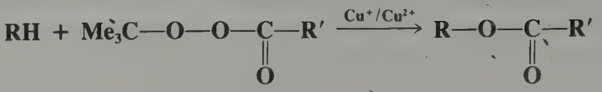
See also Stephenson, *Tetrahedron Lett.* **21,** 1005 (1980).

[196] For evidence in favor of this mechanism, at least with some kinds of substrates, see Jefford and Rimbault, *J. Am. Chem. Soc.* **100,** 6437 (1978); Okada and Mukai, *J. Am. Chem. Soc.* **100,** 6509 (1978); Paquette, Hertel, Gleiter, and Böhm, *J. Am. Chem. Soc.* **100,** 6510 (1978); Hurst and Schuster, *J. Am. Chem. Soc.* **104,** 6854 (1982).

[197] See, for example, Jefford, *Helv. Chim. Acta* **64,** 2534 (1981). See also Asveld and Kellogg, *J. Org. Chem.* **47,** 1250 (1982).

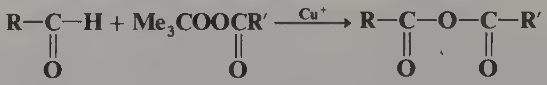
[198] For a review, see Sosnovsky and Rawlinson, Ref. 153, pp. 153–268. See also Ref. 179a.

4-10 **Acyloxylation** or **Acyloxy-de-hydrogenation**



$$\mathrm{RH} + \mathrm{Me_3C{-}O{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} \xrightarrow{\mathrm{Cu^+/Cu^{2+}}} \mathrm{R{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}$$

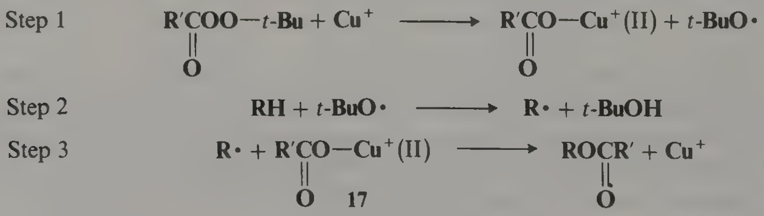
Susceptible positions of organic compounds can be directly acyloxylated by *t*-butyl peresters, the most frequently used being acetic and benzoic ($R' = \mathrm{Me}$ or Ph).[199] The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in **4-8**: benzylic, allylic, and the α position of ethers and sulfides. Terminal olefins are substituted almost entirely in the 3 position, i.e., with only a small amount of allylic rearrangement, but internal olefins generally give mixtures containing a large amount of allylic-shift product. If the reaction with olefins is carried out in an excess of another acid R″COOH, the ester produced is of *that* acid ROCOR″. Aldehydes give anhydrides:



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H} + \mathrm{Me_3COO\underset{\underset{\displaystyle O}{\|}}{C}R'} \xrightarrow{\mathrm{Cu^+}} \mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}$$

Acyloxylation has also been achieved with metallic acetates such as lead tetraacetate[200] and mercuric acetate.[201] In this case not only does the reaction take place at allylic and benzylic positions and at those α to an OR or SR group but also at positions α to the carbonyl groups of aldehydes, ketones, or esters and at those α to two carbonyl groups ($\mathrm{ZCH_2Z'}$). It is likely that in the latter cases it is the enol forms that react. Ketones can be α-acylated indirectly by treatment of various enol derivatives with metallic acetates, for example, enol silyl ethers with silver carboxylates–iodine,[202] enol thioethers with lead tetraacetate,[203] and enamines with lead tetraacetate[204] or thallium triacetate.[205] Methylbenzenes have been acetoxylated in the methyl group, in moderate yields, with sodium peroxydisulfate in boiling acetic acid in the presence of sodium acetate and Cu(II) acetate.[206] Palladium acetate converts alkenes to vinyl and/or allylic acetates.[207]

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following:[208]



Step 1 $$\mathrm{R'\underset{\underset{\displaystyle O}{\|}}{C}OO{-}\mathit{t}\text{-}Bu} + \mathrm{Cu^+} \longrightarrow \mathrm{R'\underset{\underset{\displaystyle O}{\|}}{C}O{-}Cu^+(II)} + \mathit{t}\text{-}\mathrm{BuO}\cdot$$

Step 2 $$\mathrm{RH} + \mathit{t}\text{-}\mathrm{BuO}\cdot \longrightarrow \mathrm{R}\cdot + \mathit{t}\text{-}\mathrm{BuOH}$$

Step 3 $$\mathrm{R}\cdot + \underset{\mathbf{17}}{\mathrm{R'\underset{\underset{\displaystyle O}{\|}}{C}O{-}Cu^+(II)}} \longrightarrow \mathrm{RO\underset{\underset{\displaystyle O}{\|}}{C}R'} + \mathrm{Cu^+}$$

This mechanism, involving a free radical R•, is compatible with the allylic shifts found.[209] The finding that *t*-butyl peresters labeled with ^{18}O in the carbonyl oxygen gave ester with 50% of the label in each oxygen[210] is in accord with a combination of R• with the intermediate **17,** in which the copper is ionically bound, so that the oxygens are essentially equivalent. Other evidence is that *t*-butoxy radicals have been trapped with dienes.[211] Much less is known about the mechanisms of the reactions with metal acetates.[212]

Free-radical acyloxylation of aromatic substrates has been accomplished with a number of reagents including cupric benzoate[213] (see also **3-20**), benzoyl peroxide–iodine,[214] silver(II) complexes,[215] and cobalt(III) trifluoroacetate.[216]

OS **III,** 3; **V,** 70, 151.

C. Substitution by Sulfur

4-11 **Chlorosulfonation** or **Chlorosulfo-de-hydrogenation**

$$\mathbf{RH + SO_2 + Cl_2 \xrightarrow{h\nu} RSO_2Cl}$$

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction*.[217] In scope and range of products obtained, the reaction is similar to **4-1.** The mechanism is also similar, except that there are two additional main propagation steps:

$$\mathbf{R\cdot + SO_2 \longrightarrow R{-}SO_2\cdot}$$

$$\mathbf{R{-}SO_2\cdot + Cl_2 \longrightarrow R{-}SO_2Cl + Cl\cdot}$$

Chlorosulfenation[218] can be accomplished by treatment with SCl_2 and uv light: $RH + SCl_2 \xrightarrow{h\nu} RSCl$.

D. Substitution by Nitrogen

4-12 Nitration of Alkanes
Nitration or **Nitro-de-hydrogenation**

$$\mathbf{RH + HNO_3 \xrightarrow{400°C} RNO_2}$$

Nitration of alkanes can be carried out in the gas phase at about 400°C or in the liquid phase.[219] The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.[220] The mechanism of the reaction has been the subject of considerable study. Titov has demonstrated[221] that nitric acid has no effect on alkanes in the absence of nitrogen dioxide, which suggests that the abstracting species is NO_2 (a stable free radical). The principal product-forming steps are

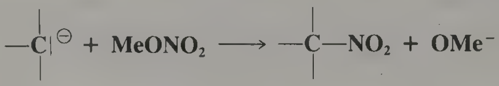
$$RH + \cdot NO_2 \longrightarrow R\cdot + HNO_2$$

$$R\cdot + \cdot NO_2 \longrightarrow RNO_2$$

The only purpose of the nitric acid is to furnish a supply of nitrogen dioxide.

Activated positions (e.g., ZCH_2Z' compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,[222] or by alkyl nitrates under alkaline conditions.[223] In the latter case it is the carbanionic form of the substrate that is actually nitrated. What is isolated under these alkaline conditions is the conjugate base of the nitro compound. Yields are not high.



$$-\overset{|}{\underset{|}{C}}|^{\ominus} + MeONO_2 \longrightarrow -\overset{|}{\underset{|}{C}}-NO_2 + OMe^-$$

Of course, the mechanism in this case is not of the free-radical type at all but is electrophilic substitution with respect to the carbon (similar to the mechanisms of **2-7** and **2-8**). Positions activated by only one electron-withdrawing group, e.g., α positions of simple ketones, nitriles, sulfones, or N,N-dialkyl amides, can be nitrated with alkyl nitrates if a very strong base, e.g., *t*-BuOK or $NaNH_2$, is present to convert the substrate to the carbanionic form.[224] Electrophilic nitration of alkanes has been performed with nitronium salts, e.g., $NO_2^+ PF_6^-$ and with HNO_3–H_2SO_4 mixtures, but mixtures of nitration and cleavage products are obtained and yields are generally low.[225]

Aliphatic nitro compounds can be α nitrated [$R_2CHNO_2 \longrightarrow R_2C(NO_2)_2$] by treatment of their conjugate bases $R\overset{\ominus}{\bar{C}}NO_2$ with NO_2^- and $K_3Fe(CN)_6$.[226]

OS **I,** 390; **II,** 440, 512.

4-13 The Direct Conversion of Aldehydes to Amides
Amination or **Amino-de-hydrogenation**

$$ArCHO \xrightarrow[\substack{\text{nickel peroxide} \\ -20°C}]{NH_3} ArCONH_2$$

Aromatic and α,β-unsaturated aldehydes can be directly converted to the corresponding amides by treatment with dry ammonia gas and nickel peroxide.[227] Best yields (80 to 90%) are obtained at −25 to −20°C. The reaction has also been performed with MnO_2 and NaCN along with ammonia or an amine at 0°C in isopropyl alcohol,[228] and with a secondary amine and a palladium acetate catalyst.[228a] In the nickel peroxide reaction the corresponding alcohols ($ArCH_2OH$) have also been used as substrates. For an indirect way of converting aldehydes to amides, see **2-29.**

E. Attack by Carbon In these reactions a new carbon–carbon bond is formed, and they may be given the collective title *coupling reactions*. In each case an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or olefin to give the coupling product.[229]

4-14 Simple Coupling at a Susceptible Position

$$2RH \xrightarrow{\text{peroxides}} R{-}R$$

In this reaction, the peroxide decomposes to give a radical that abstracts a hydrogen from RH to give R•, which dimerizes. Dialkyl and diacyl peroxides have been used, as well as Fenton's reagent (p. 628). This reaction is far from general, though in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,[230] as well as those α to a phenyl group (especially if there is also an α-alkyl or α-chloro group),[231] an ether group,[232] a carbonyl group,[233] a cyano group,[234] a dialkylamino group,[235] or a carboxylic ester group, either the acid or alcohol side.[236]

OS **IV,** 367; **V,** 1026; **60,** 78.

4-15 Coupling of Alkynes

$$2R{-}C{\equiv}C{-}H \xrightarrow[\text{pyridine}]{CuX_2} R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.[237] The large-ring annulenes of Sondheimer et al. (see p. 59) were prepared by rearrangement and hydrogenation of cyclic polyynes,[238] prepared by Eglinton coupling of terminal diynes, e.g.,[239]

18 is a cyclic trimer of 1,5-hexadiyne. The corresponding tetramers (C_{24}), pentamers (C_{30}), and hexamers (C_{36}) were also formed.

The Eglinton reaction is of wide scope. Many functional groups may be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen. Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent such as permanganate or hydrogen peroxide is required in the latter procedure. This method is not satisfactory for cyclic coupling. Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz* coupling:[240]

$$\text{R—C}\equiv\text{C—H} + \text{R}'\text{—C}\equiv\text{C—Br} \xrightarrow{\text{Cu}^+} \text{R—C}\equiv\text{C—C}\equiv\text{C—R}' + \text{HBr}$$

This may be regarded as a variation of **0-102** but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not. This is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. Propargyl halides also give the reaction.[241] A variation of the Cadiot–Chodkiewicz method consists of treating a haloalkyne ($R'C\equiv CX$) with a copper acetylide ($RC\equiv CCu$).[242] The Cadiot–Chodkiewicz procedure can be adapted to the preparation of diynes in which R′ = H by the use of $BrC\equiv CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.[243] This protecting group can also be used in the Eglinton or Glaser methods.[244]

The mechanism of the Eglinton and Glaser reactions probably begins with loss of a proton

$$\text{R—C}\equiv\text{C—H} \xrightarrow{\text{base}} \text{R—C}\equiv\text{C}^-$$

since there is a base present and acetylenic protons are acidic. The last step is probably the coupling of two free radicals:

$$2\text{R—C}\equiv\text{C}\cdot \longrightarrow \text{R—C}\equiv\text{C—C}\equiv\text{C—R}$$

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,[245] and depend on the oxidizing agent. It is known, of course, that cuprous ion can form complexes with triple bonds.

OS **V**, 517; **50**, 97; **54**, 1.

4-16 Arylation of Aromatic Compounds by Diazonium Salts
Arylation or **Aryl-de-hydrogenation**[246]

$$\text{ArH} + \text{Ar}'\text{N}_2^+\ \text{X}^- \xrightarrow{\text{OH}^-} \text{Ar—Ar}'$$

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,[247] it has been performed on several types of aromatic rings and on quinones.

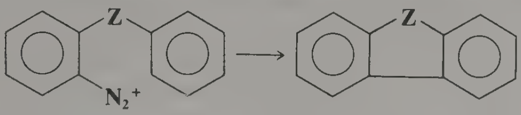
[245] See the discussions in Nigh, Ref. 164, pp. 27–31; Fedenok, Berdnikov, and Shvartsberg, *J. Org. Chem. USSR* **9**, 1908 (1973); Clifford and Waters, *J. Chem. Soc.* 3056 (1963).

[246] These names also apply to reactions **4-17** and **4-20**, and, in part, to **4-18** and **4-19.**

[247] For reviews, see Hey, *Adv. Free-Radical Chem.* **2**, 47–86 (1966); Williams, Ref. 13, pp. 27–34, 80–93. For a review applied to heterocyclic substrates, see Vernin, Dou, and Metzger, *Bull. Soc. Chim. Fr.* 1173–1203 (1972).

Yields are not high (usually under 40%) because of the many side reactions undergone by diazonium salts, though higher yields have been obtained under phase transfer conditions.[248] The conditions of the Meerwein reaction (**4-17**), treatment of the solution with a copper-ion catalyst, have also been used, as has the addition of sodium nitrite in Me_2SO (to benzene diazonium fluoroborate in Me_2SO).[249] When the Gomberg–Bachmann reaction is performed intramolecularly, either by the alkaline solution or by the copper-ion procedure, it is called the *Pschorr ring closure*[250] and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the Pschorr reaction electrochemically.[251] The Pschorr reaction has been carried out for Z = $CH{=}CH$, CH_2CH_2, NH, $C{=}O$, CH_2, and quite a few others. A rapid and convenient way to carry out the Pschorr synthesis is to diazotize the amine substrate with isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.[252]



Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are N-nitroso amides [Ar—N(NO)—COR], triazenes, and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.[253]

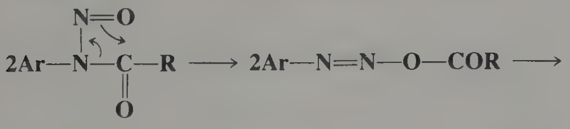
In each case the mechanism involves generation of an aryl radical from a *covalent* azo compound. In acid solution diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see p. 579). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals:

$$\mathbf{Ar{-}N{=}N{-}Z \longrightarrow Ar\bullet + N{\equiv}N + Z\bullet}$$

Under Gomberg–Bachmann conditions, the species that cleaves is the anhydride Ar—N=N—O—N=N—Ar:[254]

$$\mathbf{Ar{-}N{=}N{-}O{-}N{=}N{-}Ar \longrightarrow Ar\bullet + N_2 + \bullet O{-}N{=}N{-}Ar}$$

The aryl radical thus formed attacks the substrate to give the intermediate **1** (p. 611), from which the radical Ar—N=N—O• abstracts hydrogen to give the product. N-Nitroso amides probably rearrange to N-acyloxy compounds, which cleave to give aryl radicals:[255]



$$\mathbf{2Ar{-}\overset{\overset{\displaystyle N{=}O}{|}}{N}{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R \longrightarrow 2Ar{-}N{=}N{-}O{-}COR \longrightarrow Ar\bullet + Ar{-}N{=}N{-}O\bullet + N_2 + (RCO)_2O}$$

There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.[256]

The Pschorr reaction can take place by two different mechanisms, depending on conditions: (1)

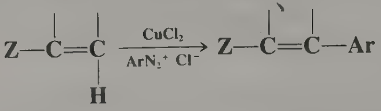
attack by an aryl radical (as in the Gomberg–Bachmann reaction) or (2) attack by an aryl cation (similar to the SN1 mechanism discussed on p. 579).[257] Under certain conditions the ordinary Gomberg–Bachmann reaction can also involve attack by aryl cations.[258]

OS **I,** 113; **IV,** 718.

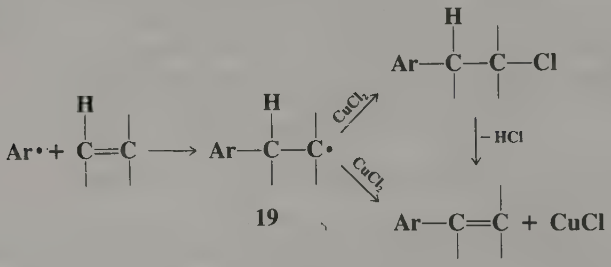
4-17 Arylation of Activated Olefins by Diazonium Salts. Meerwein Arylation



$$\text{Z—}\overset{|}{\text{C}}\text{=}\underset{\text{H}}{\overset{|}{\text{C}}} \xrightarrow[\text{ArN}_2^+\ \text{Cl}^-]{\text{CuCl}_2} \text{Z—}\overset{|}{\text{C}}\text{=}\overset{|}{\text{C}}\text{—Ar}$$

Olefins activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride[259] catalyst. This is called the *Meerwein arylation reaction.*[260] Addition of ArCl to the double bond (to give $\text{Z—}\underset{\text{Cl}}{\overset{|}{\text{C}}}\text{—}\underset{\text{H}}{\overset{|}{\text{C}}}\text{—Ar}$) is a side reaction (**5-34**). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN_2^+ in situ) and a copper(II) halide in the presence of the olefin.[260a]

The mechanism is probably of the free-radical type, with Ar• forming as in **4-24** and then[261]



The radical **19** can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl.[262]

OS **IV,** 15.

4-18 Arylation and Alkylation of Olefins by Organopalladium Compounds
Alkylation or **Alkyl-de-hydrogenation,** etc.[263]

$$\text{R}_2\text{C=CH}_2 + \text{“ArPdX”} \longrightarrow \text{R}_2\text{C=CH—Ar}$$

---

[262] For a discussion of the mechanism, see Zollinger, "Azo and Diazo Chemistry," pp. 162–165, Interscience, New York, 1961.

[263] These names also apply, in part, to reactions **4-19** and **4-21.**

Arylation of olefins can also be achieved[264] by treatment with an ''arylpalladium'' reagent that can be generated in situ by several[265] methods: (1) by treatment of an aryl bromide with a palladium–triarylphosphine complex (ArBr → ''ArPdBr'');[266] (2) by treatment of an aryl iodide with palladium acetate in the presence of a base such as tributylamine or potassium acetate (ArI → ''ArPdI'');[267] (3) by treatment of an arylmercury compound (either Ar_2Hg or ArHgX) with $LiPdCl_3$ (ArHgX → ''ArPdX'')[268] (in some cases other group VIII metal salts have been used); or (4) by the reaction of an aromatic compound with palladium acetate or palladium metal and silver acetate in acetic acid [in this case an aryl *hydrogen* is replaced (ArH → ''ArPdOAc'')].[269]

Unlike **4-17,** this reaction is not limited to activated substrates. The substrate may be a simple olefin, or it may contain a variety of functional groups, such as ester, carboxyl, phenolic, or cyano groups. Primary and secondary allylic alcohols give aldehydes or ketones that are products of double-bond migration,[270] e.g.,

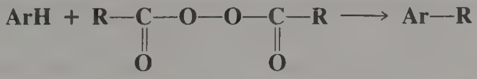
$$\mathbf{CH_2{=}CH{-}CH_2OH \xrightarrow{\text{"PhPdCl"}} PhCH_2CH_2CHO}$$

Ethylene is the most reactive olefin. Increasing substitution lowers the reactivity. Substitution therefore takes place at the less highly substituted side of the double bond.[271] Alkylation can also be accomplished, but only if the alkyl group lacks a β-hydrogen, e.g., the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.[272] However, vinyl groups, even those possessing β-hydrogens, have been successfully introduced (to give 1,3-dienes) by the reaction of the olefin with a vinyl halide in the presence of a trialkylamine and a catalyst composed of palladium acetate and a triarylphosphine at 100 to 150°C.[273]

The mechanisms are not completely known, but it is likely that an addition–elimination reaction (addition of ArPdX followed by elimination of HPdX) is involved in all the methods.[274] The reactions are stereospecific, yielding products expected from syn addition followed by syn elimination.[275]

OS **51,** 17; **61,** 82.

4-19 Alkylation and Arylation of Aromatic Compounds by Peroxides



$$\mathbf{ArH + R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}O{-}O{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R \longrightarrow Ar{-}R}$$

---

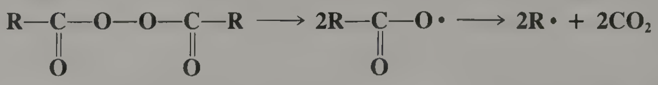
[275] Heck, Ref. 274; Moritani, Danno, Fujiwara, and Teranishi, *Bull. Chem. Soc. Jpn.* **44,** 578 (1971).

This reaction is most often carried out with R = aryl, so that the net result is the same as in **4-16,** though the reagent is different.[276] It is used less often than **4-16,** but the scope is similar. When R = alkyl, the scope is more limited.[277] Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown on p. 611 (CIDNP has been observed[278]); the radicals are produced by



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}O{-}O{-}\underset{\underset{O}{\|}}{C}{-}R \longrightarrow 2R{-}\underset{\underset{O}{\|}}{C}{-}O\bullet \longrightarrow 2R\bullet + 2CO_2}$$

Since no relatively stable free radical is present (such as Ph—N=N—O• in **4-16**), most of the product arises from dimerization and disproportionation.[279] The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts the hydrogen from **1** and reduces the extent of side reactions.[280]

Aromatic compounds can also be arylated by aryllead tricarboxylates.[281] Best yields (~70 to 85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely.

$$\mathbf{ArH + Ar'Pb(OAc)_3 \longrightarrow ArAr'}$$

OS **V,** 51. See also OS **V,** 952; **56,** 68.

4-20 Photochemical Arylation of Aromatic Compounds

$$\mathbf{ArH + Ar'I \xrightarrow{h\nu} ArAr'}$$

Another free-radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.[282] Yields are generally higher than in **4-16** or **4-19.** The aryl iodide may contain OH or COOH groups. The mechanism is similar to that of **4-16.** The aryl radicals are generated by the photolytic cleavage ArI → Ar• + I•. The reaction has been applied to intramolecular arylation (analogous to the Pschorr reaction).[283] A similar reaction is photolysis of an arylthallium bis(trifluoroacetate) (**2-20**) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.[284] In this case

$$\mathbf{Ar'Tl(OCOCF_3)_2 \xrightarrow[ArH]{h\nu} ArAr'}$$

it is the C—Tl bond which is cleaved to give aryl radicals.

---

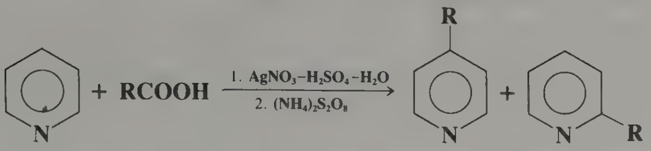
4-21 Alkylation and Acylation of Nitrogen Heterocycles[285]

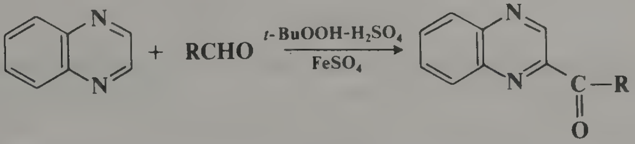


Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.[286] R may be primary, secondary, or tertiary. The attacking species is R•, formed by[287]

$$2Ag^+ + S_2O_8{}^{2-} \longrightarrow 2Ag^{2+} + 2SO_4{}^{2-}$$
$$RCOOH + Ag^{2+} \longrightarrow RCOO\cdot + H^+ + Ag^+$$
$$RCOO\cdot \longrightarrow R\cdot + CO_2$$

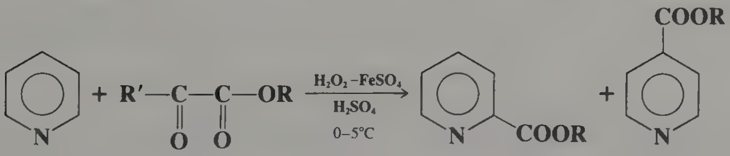
Similar alkylation can be accomplished with other reagents, including hydroperoxides and $FeSO_4$;[288] and carboxylic acids and lead tetraacetate. The reaction has also been applied to acetophenone and ferrocene.[289]

Protonated nitrogen heterocycles can be acylated by treatment with an aldehyde, *t*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, e.g.,[290]



These alkylation and acylation reactions are important because Friedel–Crafts alkylation and acylation (**1-13, 1-15**) cannot be applied to most nitrogen heterocycles. See also **3-17.**

4-22 Carbalkoxylation and Carboamidation of Nitrogen Heterocycles[291]
Alkoxycarbonyl-de-hydrogenation, etc.



---

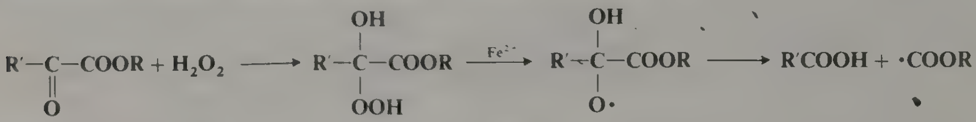
[291] For a review, see Minisci, *Top. Curr. Chem.*, Ref. 285, pp. 28–31.

In a reaction related to **4-21**, protonated nitrogen heterocycles can be carbalkoxylated[292] by treatment with •COOR radicals generated from esters of α-keto acids:



$$R'-\underset{\underset{O}{\|}}{C}-COOR + H_2O_2 \longrightarrow R'-\overset{\overset{OH}{|}}{\underset{\underset{OOH}{|}}{C}}-COOR \xrightarrow{Fe^{2+}} R'-\overset{\overset{OH}{|}}{\underset{\underset{O\cdot}{|}}{C}}-COOR \longrightarrow R'COOH + \cdot COOR$$

Similarly, a carbamoyl group can be introduced[293] by the use of the radicals $H_2N\underset{\underset{O}{\|}}{C}\cdot$ or $_2N\underset{\underset{O}{\|}}{C}\cdot$ generated from formamide or dimethylformamide and H_2SO_4, H_2O_2, and $FeSO_4$ or other oxidants.

N_2 as Leaving Group[294]

In these reactions diazonium salts are cleaved to aryl radicals,[295] in most cases with the assistance of copper salts. Reactions **4-16** and **4-17** may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts, see **3-21** to **3-25**.

4-23 Replacement of the Diazonium Group by Hydrogen
Dediazoniation or **Hydro-de-diazoniation**

$$ArN_2^+ + H_3PO_2 \longrightarrow ArH$$

Reduction of the diazonium group (*dediazoniation*) provides an indirect method for the removal of an amino group from a ring.[295a] The best and most common way of accomplishing this is by use of hypophosphorous acid H_3PO_2,[296] although many other reducing agents[297] have been used, among them ethanol, HMPT,[297] thiophenol,[298] and sodium stannite. Ethanol was the earliest reagent used, and it frequently gives good yields, but often ethers (ArOEt) are side products. When H_3PO_2 is used, 5 to 15 mol of this reagent is required per mole of substrate. Diazonium salts can be reduced in nonaqueous media by several methods,[299] including treatment with Bu_3SnH or Et_3SiH in ethers or MeCN[300] and by isolation as the BF_4^- salt and reduction of this with $NaBH_4$ in DMF.[301] Aromatic amines can be deaminated ($ArNH_2 \rightarrow ArH$) in one laboratory step by treatment with an alkyl nitrite in DMF[302] or boiling THF.[303] The corresponding diazonium salt is an intermediate.

Not many investigations of the mechanism have been carried out. It is generally assumed that the reaction of diazonium salts with ethanol to produce ethers takes place by an ionic (SN1) mechanism while the reduction to ArH proceeds by a free-radical process.[304] The reduction with H_3PO_2 is also believed to have a free-radical mechanism.[305] In the reduction with $NaBH_4$, an aryldiazene intermediate (ArN=NH) has been demonstrated,[306] arising from nucleophilic attack by BH_4^- on the β-nitrogen. Such diazenes can be obtained as moderately stable (half-life of several hours) species in solution by the decarboxylation of aryldiazenecarboxylate ions ($ArN{=}NCOO^-$).[307] It is not entirely clear how the aryldiazene decomposes, but there are indications that either the aryl radical Ar• or the corresponding anion Ar^- may be involved.[308]

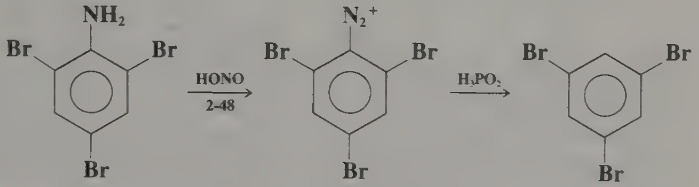
An important use of the dediazoniation reaction is to remove an amino group after it has been used to direct one or more other groups to ortho and para positions. For example, the compound 1,3,5-tribromobenzene cannot be prepared by direct bromination of benzene because the bromo group is ortho-para-directing; however, this compound is easily prepared by the following sequence:

$$C_6H_6 \xrightarrow[H_2SO_4 \atop 1\text{-}2]{HNO_3} PhNO_2 \xrightarrow[9\text{-}48]{Sn{-}HCl} PhNH_2 \xrightarrow[1\text{-}12]{3Br_2}$$



Many other compounds which would otherwise be difficult to prepare are easily synthesized with the aid of the dediazoniation reaction.

OS **I,** 133, 415; **II,** 353, 592; **III,** 295; **IV,** 947; **58,** 101.

4-24 Replacement of the Diazonium Group by Chlorine or Bromine
Chloro-de-diazoniation, etc.

$$ArN_2^+ + CuCl \longrightarrow ArCl$$

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case the reaction is called the *Sandmeyer reaction*. The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman reaction* (not to be confused with **1-18**). The Sandmeyer reaction is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is by no means known with certainty but is believed to take the following course:[309]

$$ArN_2^+ \quad X^- + CuX \longrightarrow Ar\cdot + N_2 + CuX_2$$
$$Ar\cdot + CuX_2 \longrightarrow ArX + CuX$$

---

[309] Dickerman, Weiss, and Ingberman, *J. Org. Chem.* **21,** 380 (1956), *J. Am. Chem. Soc.* **80,** 1904 (1958); Kochi, *J. Am. Chem. Soc.* **79,** 2942 (1957); Dickerman, DeSouza, and Jacobson, *J. Org. Chem.* **34,** 710 (1969); Galli, *J. Chem. Soc., Perkin Trans. 2* 1459 (1981), 1139 (1982).

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. CuX is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,[310] including treatment of the amine (1) with *t*-butyl nitrite and anhydrous $CuCl_2$ or $CuBr_2$ at 65°C,[311] and (2) with *t*-butyl thionitrite or *t*-butyl thionitrate and $CuCl_2$ or $CuBr_2$ at room temperature.[312] These procedures are, in effect, a combination of **2-48** and the Sandmeyer reaction. A further advantage is that cooling to 0°C is not needed.

For the preparation of fluorides and iodides from diazonium salts, see **3-25** and **3-24.**

OS **I,** 135, 136, 162, 170; **II,** 130; **III,** 185; **IV,** 160. Also see OS **III,** 136; **IV,** 182.

4-25 Replacement of the Diazonium Group by Nitro
Nitro-de-diazoniation

$$\mathrm{ArN_2^+ + NaNO_2 \xrightarrow{Cu^+} ArNO_2}$$

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the Sandmeyer reaction, although, like **4-24** and **4-27,** it was discovered by Sandmeyer. BF_4^- is often used as the negative ion to avoid competition from the chloride ion. The mechanism is probably like that of **4-24.**[313] If electron-withdrawing groups are present, the catalyst is not needed; $NaNO_2$ alone gives nitro compounds in high yields.[314]

OS **II,** 225; **III,** 341.

4-26 Replacement of the Diazonium Group by Sulfur-containing Groups
Chlorosulfo-de-diazoniation

$$\mathrm{ArN_2^+ + SO_2 \xrightarrow[HCl]{CuCl_2} ArSO_2Cl}$$

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.[315] The use of $FeSO_4$ and copper metal instead of $CuCl_2$ gives sulfinic acids $ArSO_2H$.[316] See also **3-22**.

OS **V,** 60; **60,** 121.

4-27 Replacement of the Diazonium Group by Cyano
Cyano-de-diazoniation

$$\mathrm{ArN_2^+ + CuCN \longrightarrow ArCN}$$

This reaction, also called the *Sandmeyer reaction*, is similar to **4-24** in scope and mechanism. It is usually conducted in neutral solution to avoid liberation of HCN.

OS **I,** 514.

---

[311] Doyle, Siegfried, and Dellaria, *J. Org. Chem.* **42,** 2426 (1977).

[312] Oae, Shinhama, and Kim, *Bull. Chem. Soc. Jpn.* **53,** 1065 (1980), *Chem. Lett.* 939 (1979).

[313] For discussions, see Opgenorth and Rüchardt, *Liebigs Ann. Chem.* 1333 (1974); Singh, Kumar, and Khanna, *Tetrahedron Lett.* **23,** 5191 (1982).

[314] Bagal, Pevzner, and Frolov, *J. Org. Chem. USSR* **5,** 1767 (1969).

[315] Gilbert, *Synthesis* 1–10 (1969), p. 6.

[316] Wittig and Hoffmann, *Org. Synth.* **V,** 60.

4-28 Aryl Dimerization with Diazonium Salts

$$2\mathrm{ArN_2}^+ \xrightarrow[\text{or Cu+H}^+]{\mathrm{Cu}^+} \mathrm{Ar{-}Ar} + 2\mathrm{N_2} \quad \text{or} \quad \mathrm{Ar{-}N{=}N{-}Ar} + \mathrm{N_2}$$

When diazonium salts are treated with cuprous ion (or with copper and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from **4-16** (and from **1-4**) in that *both* aryl groups in the product originate from $\mathrm{ArN_2}^+$, i.e., hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.[317]

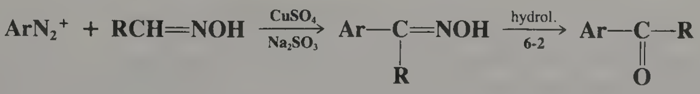
OS **I,** 222; **IV,** 872. Also see OS **IV,** 273.

4-29 Methylation and Vinylation of Diazonium Salts
Methyl-de-diazoniation, etc.

$$\mathrm{ArN_2}^+ + \mathrm{Me_4Sn} \xrightarrow[\mathrm{MeCN}]{\mathrm{Pd(OAc)_2}} \mathrm{ArMe}$$

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a palladium acetate catalyst.[318] The reaction has been performed with Me, Cl, Br, and $\mathrm{NO_2}$ groups on the ring. A vinyl group can be introduced with $\mathrm{CH_2{=}CHSnBu_3}$.

4-30 Conversion of Diazonium Salts to Aldehydes or Ketones
Acyl-de-diazoniation, etc.



$$\mathrm{ArN_2}^+ + \mathrm{RCH{=}NOH} \xrightarrow[\mathrm{Na_2SO_3}]{\mathrm{CuSO_4}} \mathrm{Ar{-}\underset{\displaystyle R}{\underset{|}{C}}{=}NOH} \xrightarrow[\text{6-2}]{\text{hydrol.}} \mathrm{Ar{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R}$$

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes (R = H) or ketones.[319] A copper sulfate–sodium sulfite catalyst is essential. In most cases higher yields (40 to 60%) are obtained when the reaction is used for aldehydes than for ketones. In another method[320] for achieving the conversion $\mathrm{ArN_2}^+ \rightarrow \mathrm{ArCOR}$, diazonium salts are treated with $\mathrm{R_4Sn}$ and CO with palladium acetate as catalyst.[321]

OS **V,** 139.

4-31 Conversion of Diazonium Salts to Carboxylic Acids
Carboxy-de-diazoniation

$$\mathrm{ArN_2}^+\ \mathrm{BF_4}^- + \mathrm{CO} \xrightarrow[\mathrm{NaOAc}]{\mathrm{Pd(OAc)_2}} \mathrm{ArCOOH}$$

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide, palladium acetate, and sodium acetate in MeCN.[322] The mixed anhydride ArCOOCOMe is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.[323] An arylpalladium compound is probably an intermediate.[323]

4-32 Replacement of the Diazonium Group by a Metal
Metallo-de-diazoniation

$$ArN_2^+\ BF_4^- + M \longrightarrow ArM$$

Aromatic organometallic compounds can be prepared by the treatment of diazonium salts (most often fluoroborates) with metals.[324] Among the metals used have been Hg, Tl, Sn, Pb, Sb, and Bi. Another method consists of treating the double salt of the diazonium salt and a metal chloride with a metallic powder, e.g.,

$$ArN_2Cl{\cdot}HgCl_2 \xrightarrow{Cu^+} ArHgCl + CuCl_2$$

Organometallic compounds of Hg, Ge, Sn, and As have been among those prepared by this method. The mechanisms are not clear and may be either homolytic or heterolytic.

OS **II,** 381, 432, 494; **III,** 665.

Metals as Leaving Groups

4-33 The Conversion of Boranes to Sulfides
Alkylthio-de-dialkylboration

$$R_3B + R'SSR' \xrightarrow[\text{or } h\nu]{O_2} RSR' + R_2BSR'$$

Unsymmetrical sulfides can be prepared in very high yields by treatment of a trialkylborane with a disulfide.[325] The reaction has been applied to R = primary or secondary alkyl and R′ = methyl or phenyl. The reaction rate is greatly accelerated by either light or air.

4-34 Coupling of Grignard Reagents

$$2RMgX \xrightarrow{TlBr} RR$$

Grignard reagents can be coupled to give symmetrical dimers by treatment with either thallium(I) bromide[326] or with a transition-metal halide such as $CrCl_2$, $CrCl_3$, $CoCl_2$, $CoBr_2$, or $CuCl_2$.[327] The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl Grignard reagents can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl Grignard reagents can also be dimerized by treatment with either 1,4-dichloro-2-butene or 1,4-dichloro-2-butyne.[328] Vinyl and alkynyl Grignard reagents can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.[329] Primary alkyl, vinyl, aryl, and benzylic Grignard reagents give symmetrical dimers in high yield (~90%) when treated with a silver(I) salt, e.g., $AgNO_3$, AgBr, $AgClO_4$, in the presence of a nitrogen-containing oxidizing agent such as lithium nitrate, methyl nitrate, or NO_2.[330] This method has been used to close rings of 4, 5, and 6 members.[331]

[327] For reviews, see Kauffmann, *Angew. Chem. Int. Ed. Engl.* **13,** 291–305 (1974) [*Angew. Chem.* **86,** 321–335]; Elsom, Hunt, and McKillop, *Organomet. Chem. Rev., Sect. A* **8,** 135–152 (1972); Nigh, Ref. 164, pp. 85–91.

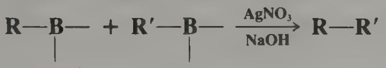
[328] Taylor, Bennett, Heinz, and Lashley, *J. Org. Chem.* **46,** 2194 (1981).

[329] Uchida, Nakazawa, Kondo, Iwata, and Matsuda, *J. Org. Chem.* **37,** 3749 (1972).

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (**2-34**), followed by its decomposition to free radicals.[332]

OS **55,** 48.

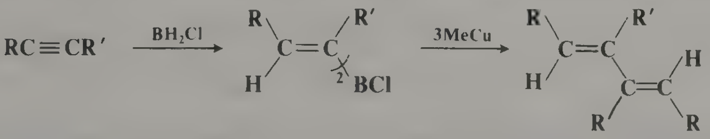
4-35 Coupling of Boranes
Alkyl-de-dialkylboration



$$R{-}\underset{|}{B}{-} + R'{-}\underset{|}{B}{-} \xrightarrow[\text{NaOH}]{\text{AgNO}_3} R{-}R'$$

Alkylboranes can be coupled by treatment with silver nitrate and base.[333] Since alkylboranes are easily prepared from olefins (**5-13**), this is essentially a way of coupling and reducing olefins; in fact, olefins can be hydroborated and coupled in the same flask. For symmetrical coupling ($R = R'$) yields range from 60 to 80% for terminal olefins and from 35 to 50% for internal ones. Unsymmetrical coupling has also been carried out,[334] but with lower yields. Arylboranes react similarly, yielding biaryls.[335] Dienes have been coupled intramolecularly to give cycloalkanes.[336] The mechanism is probably of the free-radical type.

Vinyl dimerization can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see **5-13**) with methylcopper. (*E*,*E*)-1,3-Dienes are prepared in high yields.[337]



In a similar reaction, symmetrical conjugated diynes RC≡C—C≡CR can be prepared by reaction of lithium dialkyldialkynylborates $Li^+ [R'_2B(C{\equiv}CR)_2]^-$ with iodine.[338]

4-36 Coupling of Other Organometallic Reagents

$$R_2CuLi \xrightarrow[-78°C, THF]{O_2} RR$$

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O_2 at −78°C in THF.[339] The reaction is successful for R = primary and secondary alkyl, vinyl, or aryl. Other oxidizing agents, e.g., nitrobenzene, can be used instead of O_2. Vinylcopper reagents dimerize on treatment with oxygen, or simply on standing at 0°C for several days or at 25°C for several hours, to yield 1,3-dienes.[340] The finding of retention of configuration for this reaction demonstrates that free-radical intermediates are not involved. Lithium organoaluminates $\mathrm{LiAlR_4}$ are dimerized to R—R by treatment with $\mathrm{Cu(OAc)_2}$.[341] Terminal vinylalanes (prepared by **5-14**) can be dimerized to 1,3-dienes with CuCl in THF.[342] Symmetrical 1,3-dienes can also be prepared in high yields by treatment of vinylmercury chlorides with LiCl and a rhodium catalyst.[343] Arylmercuric salts are converted to biaryls by treatment with copper and a catalytic amount of $\mathrm{PdCl_2}$.[344] Alkyl- and aryllithium compounds can be dimerized by transition-metal halides in a reaction similar to **4-34**.[345] Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents, e.g., $\mathrm{PhCH{=}CHHgCl + Me_2CuLi \rightarrow PhCH{=}CHMe}$.[346]

Halogen as Leaving Group

The conversion of RX to RH may occur by a free-radical mechanism but is treated at **0-77.**

Sulfur as Leaving Group

4-37 Desulfurization with Raney Nickel
Hydro-de-mercapto-substitution, etc.

$$\mathbf{RSH \xrightarrow[Ni]{H_2} RH}$$

$$\mathbf{RSR' \xrightarrow[Ni]{H_2} RH + R'H}$$

Thiols and thioethers,[347] both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.[348] The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them:

Disulfides	$\mathbf{RSSR' \longrightarrow RH + R'H}$
Thiono esters[349]	$\mathbf{RCSOR' \longrightarrow RCH_2OR'}$
Thioamides	$\mathbf{RCSNHR' \longrightarrow RCH_2NHR}$
Sulfoxides	$\mathbf{RSOR' \longrightarrow RH + R'H}$
Thioacetals	$\mathbf{RS\overset{\vert}{\underset{\vert}{C}}SR' \longrightarrow \overset{\vert}{\underset{\vert}{CH_2}}}$

---

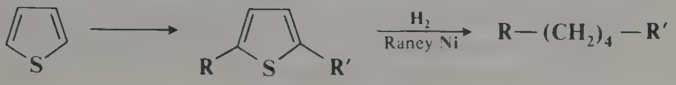
[348] For reviews, see Pettit and van Tamelen, *Org. React.* **12,** 356–529 (1962); Hauptmann and Walter, *Chem. Rev.* **62,** 347–404 (1962).

[349] See Baxter and Bradshaw, *J. Org. Chem.* **46,** 831 (1981).

The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see **9-38**), can also give the olefin if an α-hydrogen is present.[350] In most of the examples given, R may also be aryl. Other reagents have also been used.[351]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many otherwise difficultly accessible compounds have been made by alkylation of thiophene, followed by reduction:



20

Thiophenes can also be desulfurized to alkenes ($RCH_2CH{=}CHCH_2R'$ from **20**) with a nickel boride catalyst prepared from nickel(II) chloride and $NaBH_4$ in methanol.[352] Phenyl selenides RSePh can be reduced to RH with Ph_3SnH.[353]

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free-radical type.[354] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through butyl mercaptan or other sulfur compounds, i.e., the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the olefins and the failure to isolate any potential sulfur-containing intermediates.[355]

Carbon as Leaving Group

4-38 Decarboxylative Dimerization. The Kolbe Reaction

$$2RCOO^- \xrightarrow{\text{electrol.}} R{-}R$$

Electrolysis of carboxylate ions, which results in decarboxylation and combination of the resulting radicals, is called the *Kolbe reaction*.[356] It is used to prepare symmetrical R—R, where R is straight- or branched-chained, except that little or no yield is obtained when there is α branching. When R is aryl, the reaction fails. Many functional groups may be present, though many others inhibit the reaction.[356] Unsymmetrical R—R′ have been made by coupling mixtures of acid salts.

A free-radical mechanism is involved:

$$RCOO^- \xrightarrow[\text{oxidation}]{\text{electrolytic}} RCOO\cdot \xrightarrow{-CO_2} R\cdot \longrightarrow R{-}R$$

There is much evidence[357] for a free-radical mechanism, including side products (RH, alkenes) characteristic of free-radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see p. 667).

When the reaction is carried out in the presence of 1,3-dienes, additive dimerization may occur:[358]

$$2RCOO^- + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow RCH_2CH{=}CHCH_2CH_2CH{=}CHCH_2R$$

The radical R• adds to the conjugated system to give $RCH_2CH{=}CHCH_2\bullet$, which dimerizes. Another possible product is $RCH_2CH{=}CHCH_2R$, from coupling of the two kinds of radicals.[359]

Arylacetic acids can be converted to *vic*-diaryl compounds $2ArCR_2COOH \longrightarrow ArCR_2CR_2Ar$ without electrolysis by treatment with sodium persulfate $Na_2S_2O_8$ and a catalytic amount of $AgNO_3$.[360] This also involves dimerization of free radicals.

4-39 Decarboxylative Bromination. The Hunsdiecker Reaction
Bromo-de-carboxylation

$$RCOOAg + Br_2 \longrightarrow RBr + CO_2 + AgBr$$

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction* and is a way of decreasing the length of a carbon chain by one unit.[361] The reaction is of wide scope, giving good results for normal-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not α-substituted. R may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine and iodine have also been used.

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt to iodine gives the alkyl halide, as above. A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini reaction* and is sometimes used to prepare esters. A 3:2 ratio gives both products—1 mole of ester and 1 mole of halide from 3 moles of salt. The Simonini reaction can also be carried out with lead salts of acids.[362] A more convenient way to perform the Hunsdiecker reaction is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.[363]

Other methods for accomplishing this reaction are: (1) treatment of thallium(I) carboxylates (which are easy to prepare and purify) with bromine;[364] (2) treatment of carboxylic acids with lead tetraacetate and halide *ions* (Cl^-, Br^-, or I^-);[365] (3) reaction of the acids with lead tetraacetate and N-chlorosuccinimide, which gives tertiary and secondary chlorides in good yields but is not good for R = primary or phenyl;[366] (4) the reaction between an acyl peroxide and $CuCl_2$, $CuBr_2$, or

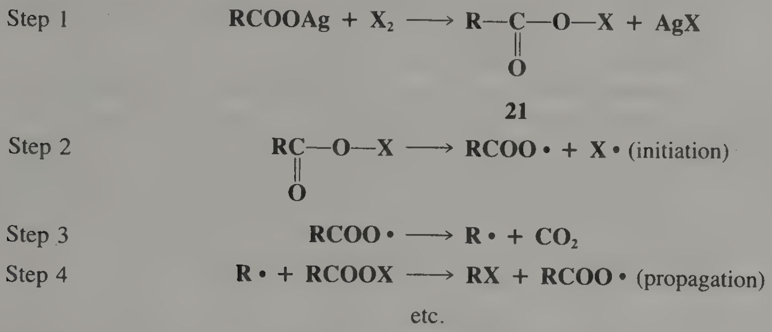
[366] Becker, Geisel, Grob, and Kuhnen, *Synthesis* 493 (1973).

CuI_2[367] [this reaction also takes place with $Cu(SCN)_2$, $Cu(N_3)_2$, and $Cu(CN)_2$]; (5) treatment of acyl chlorides with a sodium salt of N-hydroxypyridine-2-thione in CCl_4 ($RCOCl \rightarrow RCl$), $BrCCl_3$ ($RCOCl \rightarrow RBr$), or benzene containing CHI_3 ($RCOCl \rightarrow RI$), and an amine catalyst.[367a] Alkyl fluorides can be prepared in moderate to good yields by treating carboxylic acids with XeF_2 and HF.[368]

The mechanism of the Hunsdiecker reaction is believed to be as follows:



Step 1 $$RCOOAg + X_2 \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}O{-}X + AgX$$

21

Step 2 $$R\underset{\underset{O}{\|}}{C}{-}O{-}X \longrightarrow RCOO\bullet + X\bullet \text{ (initiation)}$$

Step 3 $$RCOO\bullet \longrightarrow R\bullet + CO_2$$

Step 4 $$R\bullet + RCOOX \longrightarrow RX + RCOO\bullet \text{ (propagation)}$$

etc.

The first step is not a free-radical process, and its actual mechanism is not known. **21** is an acyl hypohalite and is presumed to be an intermediate, although it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see p. 613); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably R—R, are consistent with a free-radical mechanism. There is evidence that the Simonini reaction involves the same mechanism as the Hunsdiecker reaction but that the alkyl halide formed then reacts with excess RCOOAg (**0-26**) to give the ester.[369] See also reaction **9-13**.

4-40 Decarbonylation of Aldehydes and Acyl Halides

$$RCHO \xrightarrow{RhCl(Ph_3P)_3} RH$$

Aldehydes, both aliphatic and aromatic, can be decarbonylated[370] by heating with chlorotris(triphenylphosphine)rhodium[371] or other catalysts such as palladium.[372] $RhCl(Ph_3P)_3$ is often called *Wilkinson's catalyst*.[373] In an older reaction aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*t*-butyl peroxide or other peroxides,[374] usually in a solution containing a hydrogen donor, such as a mercaptan. The reaction has also been initiated with light, and thermally (without an initiator) by heating at about 500°C.

[372] For a review, see Rylander, Ref. 207, pp. 260–267.

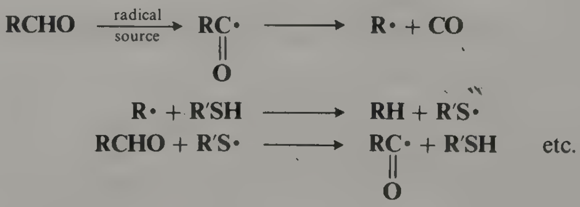
[373] For a review of this catalyst, see Jardine, *Prog. Inorg. Chem.* **28,** 63–202 (1981).

[374] For reviews of free-radical aldehyde decarbonylations, see Vinogradov and Nikishin, *Russ. Chem. Rev.* **40,** 916–932 (1971); Schubert and Kinter, in Patai, Ref. 168, pp. 711–735.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180°C (ArCOCl → ArCl).[375] This reaction has been carried out with acyl iodides,[376] bromides, and chlorides. Aliphatic acyl halides that lack an α-hydrogen also give this reaction,[377] but if an α-hydrogen is present, elimination takes place instead (**7-19**). Aromatic acyl cyanides give aryl cyanides (ArCOCN → ArCN).[378] Aromatic acyl chlorides can also be decarbonylated with palladium catalysts.[379]

It is possible to decarbonylate acyl halides in another way, to give alkanes (RCOCl → RH). This is done by heating the substrate with tripropylsilane Pr_3SiH in the presence of *t*-butyl peroxide.[380] Yields are good for R = primary or secondary and poor for R = tertiary or benzyl. There is no reaction when R = aryl.

The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of mercaptans):[381]



$$\mathrm{RCHO} \xrightarrow[\text{source}]{\text{radical}} \mathrm{R}\underset{\overset{\|}{\mathrm{O}}}{\mathrm{C}}\cdot \longrightarrow \mathrm{R}\cdot + \mathrm{CO}$$

$$\mathrm{R}\cdot + \mathrm{R'SH} \longrightarrow \mathrm{RH} + \mathrm{R'S}\cdot$$

$$\mathrm{RCHO} + \mathrm{R'S}\cdot \longrightarrow \mathrm{R}\underset{\overset{\|}{\mathrm{O}}}{\mathrm{C}}\cdot + \mathrm{R'SH} \qquad \text{etc.}$$

The reaction of aldehydes with Wilkinson's catalyst goes through complexes of the form **22** and **23**, which have been trapped.[382] The reaction has been shown to give retention of configuration at a chiral R;[383] and deuterium labeling demonstrates that the reaction is intramolecular: RCOD gave RD.[384] Free radicals are not involved.[385] The mechanism with acyl halides appears to be more complicated.[386] The tripropylsilane reaction has been postulated to go through a free-radical chain mechanism.[380]

15

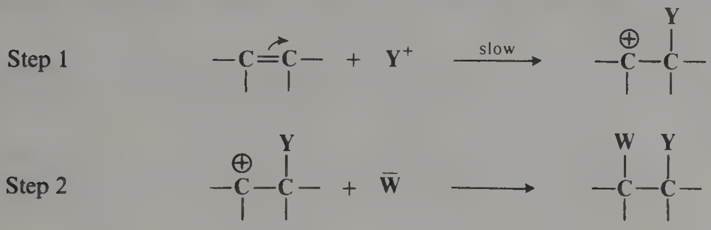
ADDITION TO CARBON–CARBON MULTIPLE BONDS

There are basically four ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, an electrophile, or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous. Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanisms.

MECHANISMS

Electrophilic Addition[1]

In this mechanism a positive species approaches the double or triple bond and in the first step forms a bond by converting the π pair of electrons into a σ pair:

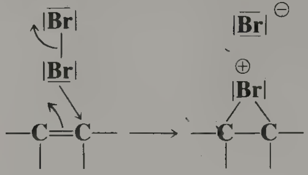


1

As in electrophilic substitution (p. 448), Y need not actually be a positive ion but can be the positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. In any case, **1** has a positive charge on the other carbon. The second step is a combination of **1** with a species carrying an electron pair and usually bearing a negative charge. This step is the same as the second step of the SN1 mechanism. There is evidence that **1** is not the actual intermediate ion in all cases. In many brominations it is fairly certain that **1**, if formed at all, very rapidly cyclizes to a bromonium ion (**2**):

---

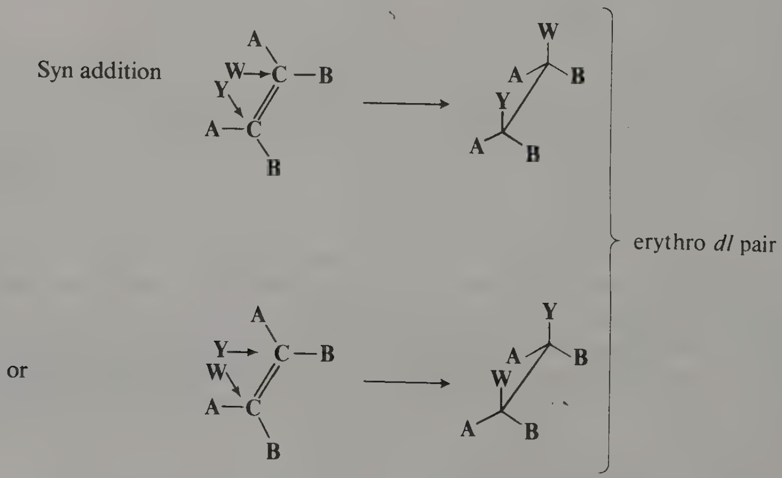
[1] For a monograph, see de la Mare and Bolton, "Electrophilic Additions to Unsaturated Systems," 2d ed., Elsevier, New York, 1982. For reviews, see V'yunov and Ginak, *Russ. Chem. Rev.* **50,** 151–163 (1981); Schmid and Garratt, in Patai, "The Chemistry of Functional Groups: Supplement A," pt. 2, pp. 725–912, Wiley, New York, 1977; Freeman, *Chem. Rev.* **75,** 439–490 (1975); Bolton, in Bamford and Tipper, "Comprehensive Chemical Kinetics," vol. 9, pp. 1–86, American Elsevier, New York, 1973; Dolbier, *J. Chem. Educ.* **46,** 342–344 (1969).



2

This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see p. 268). The attack of $\overline{W}$ on an intermediate like **2** is a nucleophilic substitution. Whether the intermediate is **1** or **2**, the mechanism is called AdE2 (electrophilic addition, bimolecular).

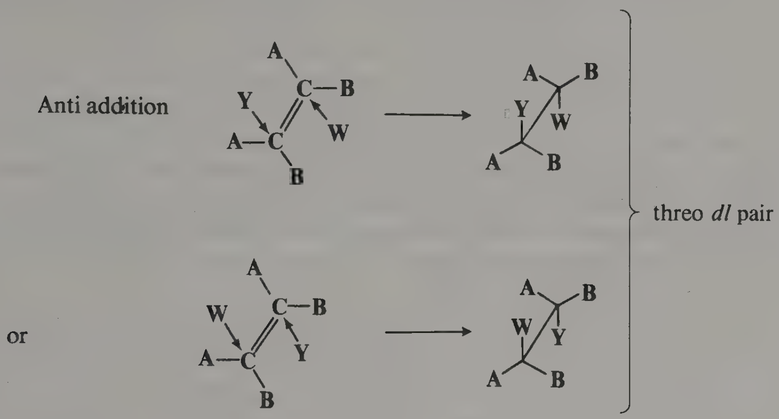
In investigating the mechanism of addition to a double bond, perhaps the most useful type of information is the stereochemistry of the reaction.[2] The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (p. 9); there are thus three possibilities. Y and W may enter from the same side of the plane, in which case the addition is stereospecific and *syn;* they may enter from opposite sides for stereospecific *anti* addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the cis and trans isomers of an olefin of the form ABC=CBA. We may use the cis olefin as an example. If the addition is syn, the product will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:



---

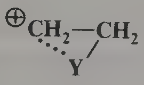
[2] For a review of the stereochemistry of electrophilic additions to double and triple bonds, see Fahey, *Top. Stereochem.* **3,** 237–342 (1968). For a review of the synthetic uses of stereoselective additions, see Bartlett, *Tetrahedron* **36,** 2–72 (1980), pp. 3–15.

On the other hand, if the addition is anti, the threo *dl* pair will be formed:



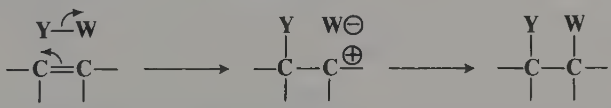
Of course, the trans isomer will give the threo pair if the addition is syn and the erythro pair if it is anti. The threo and erythro isomers have different physical properties. In the special case where Y = W (as in the addition of Br_2), the "erythro pair" is a meso compound. In addition to triple-bond compounds of the type AC≡CA, syn addition results in a cis olefin and anti addition in a trans olefin. By the definition given on p. 119, addition to triple bonds cannot be stereospecific, though it can be, and often is, stereoselective.

It can easily be seen that in reactions involving cyclic intermediates like **2** addition must be anti, since the second step must occur from the backside. It is not so easy to predict the stereochemistry for reactions involving **1.** If **1** has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. On the other hand, there may be some factor that maintains the configuration, in which case W may come in from the same side or the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve a full bond:



3

The second group would then come in anti. A circumstance that would favor syn addition would be the formation of an ion pair after the addition of Y:[3]

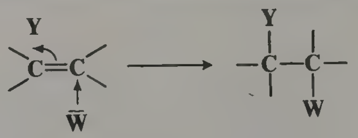


Since W is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

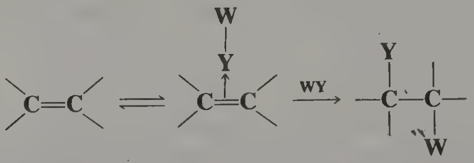
Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially simultaneous but from opposite sides:

---

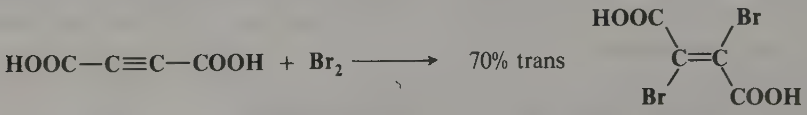
[3] Dewar, *Angew. Chem. Int. Ed. Engl.* **3,** 245–249 (1964) [*Angew. Chem.* **76,** 320–325]; Heasley, Bower, Dougharty, Easdon, Heasley, Arnold, Carter, Yaeger, Gipe, and Shellhamer, *J. Org. Chem.* **45,** 5150 (1980).



This mechanism, which is called the AdE3 mechanism (*termolecular addition*), has the disadvantage that three molecules must come together in the transition state. However, it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (p. 874). Another third-order reaction (also called AdE3) has also been proposed. In this case one molecule of YW forms a π complex (Chapter 3) with the substrate,[4] while a second molecule attacks from the rear, leading to anti addition.[5]



There is much evidence that when the attack is by Br^+ (or a carrier of it), the bromonium ion **2** is often an intermediate and the addition is anti. As long ago as 1912, McKenzie showed that treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, while fumaric acid (the trans isomer) gave the meso compound.[6] Many similar experiments have been performed since with similar results. For triple bonds, stereoselective anti addition was shown even earlier. Bromination of dicarboxyacetylene gave 70% of the trans isomer.[7]



$$HOOC—C{\equiv}C—COOH + Br_2 \longrightarrow \text{70\% trans}$$

There is other evidence for mechanisms involving **2.** We have already mentioned (p. 271) that bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.[8] The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some

1-chloro-2-bromoethane along with the dibromoethane.[9] Similar results are found when the reaction is carried out in the presence of nitrate ions and of water.

However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-1-phenylpropenes in CCl_4 was nonstereospecific.[10] Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90 to 100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until, at a dielectric constant of about 35, the addition was completely nonstereospecific.[11] Likewise in the case of triple bonds, stereoselective anti addition was found in bromination of 3-hexyne, but both cis and trans products were obtained in bromination of phenylacetylene.[12] These results indicate that a bromonium ion is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1-phenylpropene gives the ion $Ph\overset{\oplus}{C}HCHBrCH_3$, which is a relatively stable benzylic cation) and that there is probably a spectrum of mechanisms between complete bromonium ion (**2,** no rotation) formation and completely open-cation (**1,** free rotation) formation, with partially bridged bromonium ions (**3,** restricted rotation) in between.[13] We have previously seen cases (e.g., p. 276) where cations require more stabilization from outside sources as they become intrinsically less stable themselves.[14]

Attack by Cl^+,[15] I^+,[16] and RS^+[17] is similar to that by Br^+; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected, iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. For example, when *trans*-1,2-di-*t*-butylethene was treated with chlorine the product was not the simple addition product, but **5.**[18] This compound could only have been formed by a carbocation rearrangement, which is, of course, evidence for the open cation intermediate **4.**

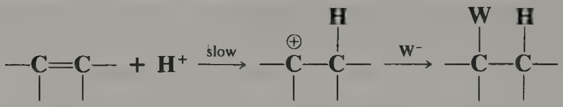
5

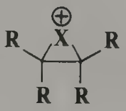
When the electrophile is a proton,[19] a cyclic intermediate is not possible, and the mechanism is

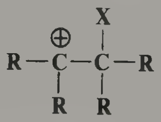


This is an A-SE2 mechanism (p. 331). There is a great deal of evidence[20] for it, including:

1. The reaction is general-acid, not specific-acid-catalyzed, implying rate-determining proton transfer from the acid to the double bond.[21]

2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects[22] with that found in brominations, where cyclic intermediates are involved. In the latter case substitution of alkyl groups on $H_2C{=}CH_2$ causes a cumulative rate acceleration until all four hydrogens have been replaced by alkyl groups, because each group helps to stabilize the positive charge.[23] In addition of HX the effect is not cumulative. Replacement of the two hydrogens on one carbon causes great rate increases (primary → secondary → tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.[24] This is evidence for open cations when a proton is the electrophile.





3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O.[25]

It may also be recalled that vinyl ethers react with proton donors in a similar manner (see **0-7**).

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (**6**) with HBr gave predominant anti addition,[26] while addition of water to **4** gave equal amounts of the cis and trans alcohols:[27]

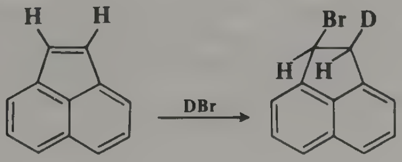
6

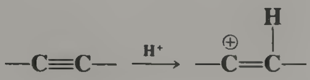
On the other hand, addition of DBr to acenaphthylene (**7**) and to indene and 1-phenylpropene gave predominant syn addition.[28]



7

In fact it has been shown that the stereoselectivity of HCl addition can be controlled by changing the reaction conditions. Addition of HCl to **6** in CH_2Cl_2 at −98°C gave predominantly syn addition, while in ethyl ether at 0°C, the addition was mostly anti.[29]

Addition of HX to triple bonds has the same mechanism, though the intermediate in this case is a vinyl cation:[30]



$$-C\equiv C- \xrightarrow{H^+} -\overset{\oplus}{C}=\overset{\overset{H}{|}}{C}-$$

In all these cases (except for the AdE3 mechanisms) we have assumed that formation of the intermediate (**1**, **2**, or **3**) is the slow step and attack by the nucleophile on the intermediate is rapid, and this is probably true in most cases. However, some additions have been found in which the second step is rate-determining.[31]

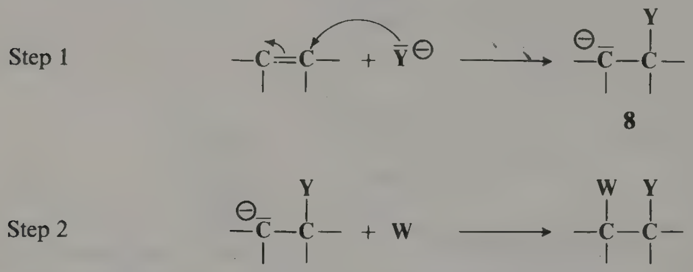
Nucleophilic Addition[32]

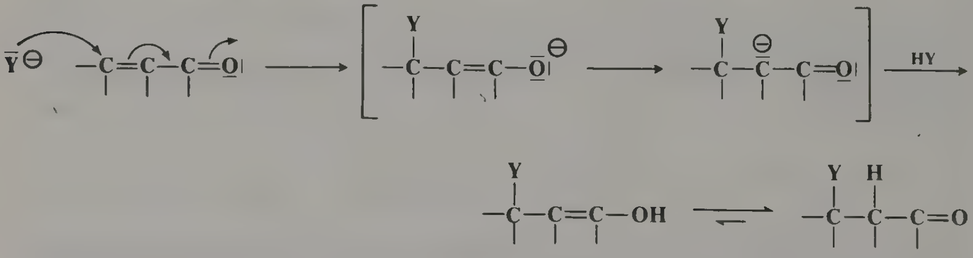
In the first step of nucleophilic addition a nucleophile brings its pair of electrons to one carbon atom of the double or triple bond, forcing the π electrons to become centered on the other carbon, creating a carbanion. The second step is combination of this carbanion with a positive species:



8

This mechanism is the same as the simple electrophilic one shown on page 657 except that the charges are reversed. When the olefin contains a good leaving group (as defined for nucleophilic substitution, p. 310), substitution is a side reaction (this is nucleophilic substitution at a vinyl substrate, see p. 295). There are at least five other types of side reactions that intermediates like **8** can undergo.[33]

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR (including quinones[34]), COOR, $CONH_2$, CN, NO_2, SOR, SO_2R, etc., addition nearly always follows a nucleophilic mechanism, with Y^- bonding with the carbon *away* from the Z group, e.g.,



9

Protonation of the enolate ion is chiefly at the oxygen, which is more negative than the carbon, but this produces the enol **9**, which tautomerizes. So although the net result of the reaction is addition to a carbon–carbon double bond, the *mechanism* is 1,4 nucleophilic addition to the C=C—C=O (or similar) system and is thus very similar to the mechanism of addition to carbon–oxygen double and similar bonds (see Chapter 16). When Z is CN or a C=O group, it is also possible for Y^- to attack at *this* carbon, and this reaction sometimes competes. When it happens, it is called 1,2 addition. 1,4 addition to these substrates is also known as *conjugate addition*. Y^-

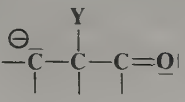
never attacks at the 3 position, since the resulting carbanion would have no resonance stabilization:



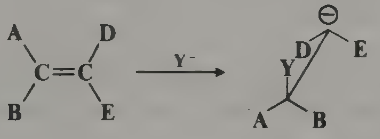
$$-\overset{\ominus}{\underset{|}{\bar{C}}}-\overset{Y}{\underset{|}{C}}-\underset{|}{C}=\underline{O}|$$

An important substrate of this type is acrylonitrile, and 1,4 addition to it is called *cyanoethylation* because the Y is cyanoethylated:

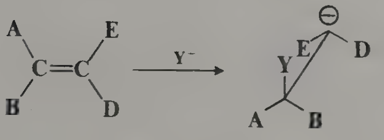
$$H_2C=CH-CN + HY \longrightarrow Y-CH_2-CH_2-CN$$

With any substrate, when Y is an ion of the type $Z-\overset{\ominus}{\bar{C}}R_2$ (Z is as defined above; R may be alkyl, aryl, hydrogen, or another Z), the reaction is called the *Michael reaction* (see **5-17**). In this book we shall call all other reactions that follow this mechanism *Michael-type additions*. Systems of the type C=C—C=C—Z may give 1,2, 1,4, or 1,6 addition. Michael-type reactions are reversible, and compounds of the type YCH_2CH_2Z can often be decomposed to YH and $CH_2=CHZ$ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined on p. 664, the addition should be nonstereospecific, though it might well be stereoselective (see p. 119 for the distinction). For example, the cis and trans forms of an olefin ABC=CDE would give, respectively, **10** and **11**:



10



11

If the carbanion has even a short lifetime, **10** and **11** will assume the most favorable conformation before the attack of W. This is of course the same for both of them, and when W attacks, the same product will result from each. This will be one of two possible diastereomers, so the reaction will be stereoselective; but since the cis and trans isomers do not give rise to different isomers, it will not be stereospecific. Unfortunately, this prediction has not been tested on open-chain olefins. Except for Michael-type substrates, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the cis isomer exists. In these cases the reaction has been shown to be stereoselective, with syn addition reported in some cases[35] and anti addition in others.[36] When the reaction is performed on a Michael-type substrate, C=C—Z, the hydrogen does not arrive at the carbon directly but only through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. For obvious reasons, additions to triple bonds cannot be stereospecific.[37] As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and anti,[38] though syn addition[39] and nonstereoselective addition[40] have also been reported.

Free-Radical Addition[41]

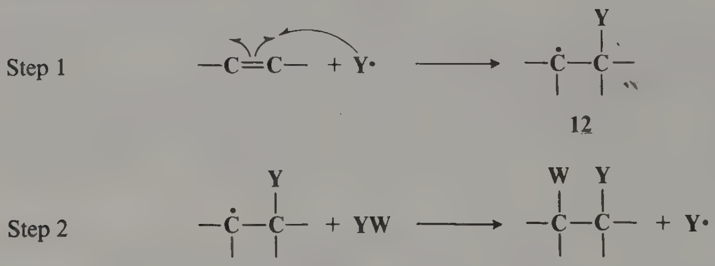
The mechanism of free-radical addition follows the pattern discussed in Chapter 14 (pp. 608–609). A radical is generated by

$$\mathrm{YW} \xrightarrow[\text{dissociation}]{h\nu\text{ or spontaneous}} \mathrm{Y}\cdot + \mathrm{W}\cdot$$

or

$$\mathrm{R}\cdot\ \text{(from some other source)} + \mathrm{YW} \longrightarrow \mathrm{RW} + \mathrm{Y}\cdot$$

Propagation then occurs by



Step 2 is an abstraction, so that W is nearly always univalent, either hydrogen or halogen (p. 613). Termination of the chain may occur in any of the ways discussed in Chapter 14. If **12** adds to another olefin molecule,

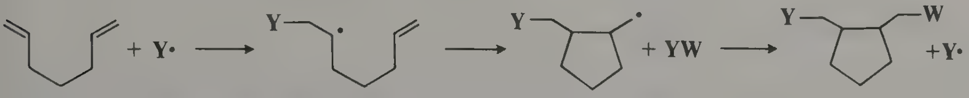
a dimer is formed. This may now add to still another, and chains, long or short, may be built up. This is the mechanism of free-radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free-radical addition reactions.

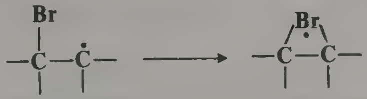
When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical can add intramolecularly to the other double bond, leading to a cyclic product, e.g.,[42]



13

Free radicals of the type **13,** generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed in these reactions (see p. 674).

The free-radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if **12** has any but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed for nucleophilic addition on p. 665.[43] Many free-radical additions have been found to be stereoselective, though not all. For example, addition of HBr to 1-bromocyclohexene gave only *cis*-1,2-dibromocyclohexane and none of the trans isomer (anti addition),[44] and propyne (at −78 to −60°C) gave only *cis*-1-bromopropene (anti addition).[45] However, stereospecificity has been found only in a few cases. The most important of these is addition of HBr to 2-bromo-2-butene under free-radical conditions at −80°C. Under these conditions, the cis isomer gave 92% of the meso addend, while the trans isomer gave mostly the *dl* pair.[46] This stereospecificity disappeared at room temperature, where both olefins gave the same mixture of products (about 78% of the *dl* pair and 22% of the meso compound), so that the addition was still stereoselective but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned on p. 612:



$$-\overset{\overset{\displaystyle Br}{|}}{\underset{|}{C}}-\overset{\bullet}{\underset{|}{C}}- \longrightarrow -\underset{|}{C}\overset{\overset{\bullet}{Br}}{\frown}\underset{|}{C}-$$

This species is similar to the bromonium ion, which is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged radicals was obtained by addition of Br• to olefins at 77 K. Esr spectra of the resulting species were consistent with bridged structures.[47]

For many radicals step 1 ($C{=}C + Y\bullet \rightarrow \bullet C{-}C{-}Y$) is reversible. In such cases free radicals can cause cis → trans isomerization of a double bond by the pathway[48]

---

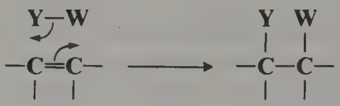
Cyclic Mechanisms

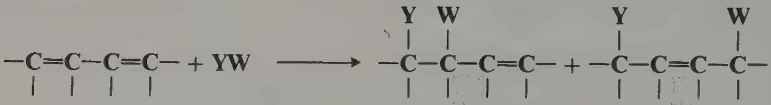
There are some addition reactions where the initial attack is not at one carbon of the double bond, but both carbons are attacked simultaneously. Some of these are four-center mechanisms, which follow this pattern:



In others there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be syn. The most important reaction of this type is the Diels–Alder reaction (**5-47**).

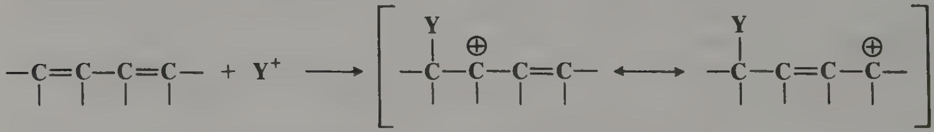
Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (**14**) is often obtained, but in most cases there is also a 1,4-addition product (**15**), often in larger yield:

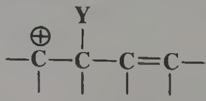


14 **15**

If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack by Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:



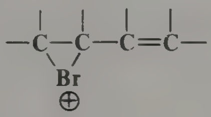
W^- may then attack either position. The original attack of Y^+ is always at the end of the conjugated system because an attack at a middle carbon would give a cation unstabilized by resonance:



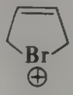
---

[48] Benson, Egger, and Golden, *J. Am. Chem. Soc.* **87**, 468 (1965); Golden, Furuyama, and Benson, *Int. J. Chem. Kinet.* **1**, 57 (1969).

In the case of electrophiles like Br^+, which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an intermediate like **16.** Direct nucleophilic attack by W^- would give the 1,2-product, while the 1,4-product could be formed by attack at the 4 position, by an SN2′-type mechanism (see p. 288). Intermediates like **17** have been postulated but ruled out for Br and Cl by the observation that chlorination or bromination of butadiene gives trans 1,4-products.[49] If an ion like **17** were the intermediate, the 1,4-products would have to have the cis configuration.



16

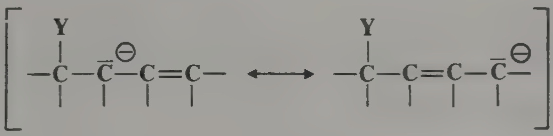


17

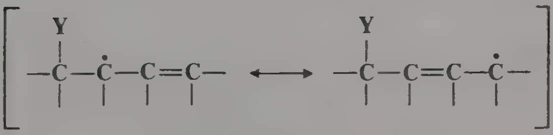
In most cases more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic. In most cases, under the reaction conditions, **14** is converted to a mixture of **14** and **15** which is richer in **15.** That is, either isomer gives the same mixture of both, which contains more **15.** It was found that at low temperatures, butadiene and HCl gave only 20 to 25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.[50] 1,2-Addition predominated over 1,4- in the reaction between DCl and 1,3-pentadiene, where the intermediate was the symmetrical (except for the D label) $\mathrm{CH_3CH{\cdots}\overset{\oplus}{C}H{\cdots}CHCH_2D}$.[51] Ion pairs were invoked to explain this result, since a free ion would be expected to be attacked by Cl^- equally well at both positions, except for the very small isotope effect.

Another aspect of the stereochemistry of 1,4 addition, besides the configuration (cis or trans) of the new double bond, is the question of whether the groups Y and W both come in from the same face of the conjugated system or from opposite faces. This can be determined only for dienes of the type XZC=CR—CR=CUV (where X can be the same as U and Z can be the same as V but X ≠ Z and U ≠ V). Electrophilic bromination and chlorination of such systems has shown that the addition is primarily syn, with both bromines or chlorines entering mostly from the same face of the plane.[52]

Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case there is competition between 1,2 and 1,4 addition. In the case of nucleophilic or free-



$$\left[-\underset{|}{\overset{\overset{Y}{|}}{C}}-\underset{|}{\overset{\ominus}{\bar{C}}}-\underset{|}{C}=\underset{|}{C}- \longleftrightarrow -\underset{|}{\overset{\overset{Y}{|}}{C}}-\underset{|}{C}=\underset{|}{C}-\underset{|}{\overset{\ominus}{\bar{C}}}-\right]$$



$$\left[-\underset{|}{\overset{\overset{Y}{|}}{C}}-\underset{|}{\dot{C}}-\underset{|}{C}=\underset{|}{C}- \longleftrightarrow -\underset{|}{\overset{\overset{Y}{|}}{C}}-\underset{|}{C}=\underset{|}{C}-\underset{|}{\dot{C}}-\right]$$

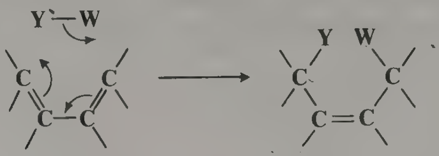
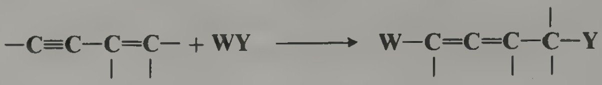
radical attack,[53] the intermediates are resonance hybrids (p. 669) and behave like the intermediate from electrophilic attack. Dienes can give 1,4 addition by a cyclic mechanism in this way:



Other conjugated systems, including trienes, enynes, diynes, etc., have been studied much less but behave similarly.[54] 1,4 addition to enynes is an important way of making allenes:[55]



$$-C\equiv C-\underset{|}{C}=\underset{|}{C}- + WY \longrightarrow W-\underset{|}{C}=C=\underset{|}{C}-\overset{|}{\underset{|}{C}}-Y$$

ORIENTATION AND REACTIVITY

Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 1 and 2.[56] As a further illustration it may be mentioned that the reactivity toward electrophilic addition of a group of olefins increased in the order $CCl_3CH{=}CH_2 < Cl_2CHCH{=}CH_2 < ClCH_2CH{=}CH_2 < CH_3CH_2{=}CH_2$.[57] For nucleophilic addition the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $F_2C{=}CF_2$[58] and $(NC)_2C{=}C(CN)_2$.[59]

TABLE 1 Relative reactivity of some olefins toward bromine in acetic acid at 24°C[56]

Olefin	Relative rate
$PhCH{=}CH_2$	Very fast
$PhCH{=}CHPh$	18
$CH_2{=}CHCH_2Cl$	1.6
$CH_2{=}CHCH_2Br$	1.0
$PhCH{=}CHBr$	0.11
$CH_2{=}CHBr$	0.0011

TABLE 2 Relative reactivity of some olefins toward bromine in methanol[56]

Olefin	Relative rate
$CH_2{=}CH_2$	3.0×10^1
$CH_3CH_2CH{=}CH_2$	2.9×10^3
cis-$CH_3CH_2CH{=}CHCH_3$	1.3×10^5
$(CH_3)_2C{=}C(CH_3)_2$	2.8×10^7

The effect of substituents is so great that it is possible to make the statement that *simple olefins do not react by the nucleophilic mechanism, and polyhalo or polycyano olefins do not generally react by the electrophilic mechanism.*[60] There are some reagents that attack only as nucleophiles, e.g., ammonia, and these add only to substrates susceptible to nucleophilic attack. Other reagents attack only as electrophiles, and, for example, $F_2C{=}CF_2$ does not react with these. In still other cases, the same reagent reacts with a simple olefin by the electrophilic mechanism and with a polyhalo olefin by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(NC)_2C{=}CHCN$ with initial attack by Cl^-[61] and that HF adds to $F_2C{=}CClF$ with initial attack by F^-.[62] Compounds that have a double bond conjugated with a Z group (as defined on p. 664) nearly always react by a nucleophilic mechanism. These are actually 1,4 additions, as discussed on p. 664. A number of studies have been made of the relative activating abilities of various Z groups.[63] On the basis of these studies, the following order of decreasing activating ability has been suggested: Z = NO_2, COAr, CHO, COR, SO_2Ar, CN, COOR, SOAr, $CONH_2$, CONHR.[64] When Michael-type reactions are performed on $ZCH{=}CHZ'$, then, in general, the more activating Z controls the position of attack[65] so that, for example, $PhCOCH{=}CHCN$ is attacked at the carbon adjacent to the CN.[66] However, exceptions are known.

It seems obvious that electron-withdrawing groups enhance nucleophilic substitution and inhibit electrophilic substitution because they lower the electron density of the double bond. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.[67] There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and yet triple bonds are *less* subject to electrophilic attack and *more* subject to nucleophilic attack than double bonds.[68] This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.[69] In fact, all reagents that form bridged intermediates like **2** react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, **5-2;** addition of hydrogen halides, **5-1**) takes place at about the same rates for alkenes as for corresponding alkynes.[70]

Still, it is true that in general triple bonds are more susceptible to nucleophilic and less to electrophilic attack than double bonds, in spite of their higher electron density. One explanation for this is that the electrons in the triple bond are held more tightly because of the smaller carbon–carbon distance; it is thus harder for an attacking electrophile to pull out a pair. There is evidence from far-uv spectra to support this conclusion.[71] Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π^* orbital of bent alkynes

---

[60] Such reactions can take place under severe conditions. For example, electrophilic addition could be accomplished with $F_2C{=}CHF$ in super-acid solutions [Olah and Mo, *J. Org. Chem.* **37,** 1028 (1972)] although $F_2C{=}CF_2$ did not react under these conditions. For reviews of electrophilic additions to fluoroolefins, see Dyatkin, Mochalina, and Knunyants, *Russ. Chem. Rev.* **35,** 417–427 (1966), *Fluorine Chem. Rev.* **3,** 45–71 (1969); Ref. 58, pp. 77–81.

[71] Walsh, *Q. Rev., Chem. Soc.* **2,** 73–91 (1948).

(such as cyclooctyne) has a lower energy than the π^* orbital of alkenes, and it has been suggested[72] that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**18**) are more strained than the corresponding **19** and furthermore are antiaromatic systems (see p. 53), which **19** are not. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, etc., is slower for triple than for double bonds.[73] As might be expected, triple bonds connected to a Z group (C≡C—Z) undergo nucleophilic addition especially well.[74]

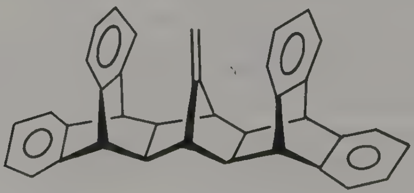
18

19

Although alkyl groups in general increase the rates of electrophilic addition, we have already mentioned (p. 662) that there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation.

Free-radical additions can occur with any type of substrate. The determining factor is the presence of a free-radical attacking species. Some reagents, e.g., HBr, RSH, attack by ionic mechanisms if no initiator is present, but in the presence of a free-radical initiator, the mechanism changes and the addition is of the free-radical type. Nucleophilic radicals (see p. 616) behave like nucleophiles, in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.[75] However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,[76] which is contrary to what might have been expected.

Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon **20**, in which the double bond is entombed between the benzene rings, does not react with Br_2, H_2SO_4, O_3, BH_3, CBr_2, or other reagents that react with most double bonds.[77] A similarly inactive compound is tetra-*t*-butylallene $(t\text{-Bu})_2C{=}C{=}C(t\text{-Bu})_2$, which is inert to Br_2, Cl_2, O_3, and catalytic hydrogenation.[78]



20

---

[72] Ng, Jordan, Krebs, and Rüger, *J. Am. Chem. Soc.* **104,** 7414 (1982).

[73] Nevertheless, bridged ions **18** have been implicated in some additions to triple bonds. See, for example, Pincock and Yates, Ref. 12; Mauger and Berliner, *J. Am. Chem. Soc.* **94,** 194 (1972); Bassi and Tonellato, *J. Chem. Soc., Perkin Trans. 1* 669 (1973); Schmid, Modro, Lenz, Garratt, and Yates, *J. Org. Chem.* **41,** 2331 (1976).

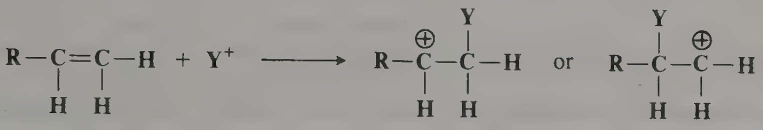
Orientation

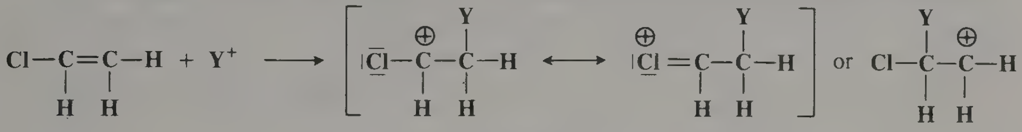
When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? For electrophilic attack, the answer is given by *Markovnikov's rule: the positive portion of the reagent goes to the side of the double or triple bond that has more hydrogens.*[79] A number of explanations have been suggested for this regioselectivity, but the most probable is that Y^+ adds to that side that will give the more stable carbocation. Thus, when an alkyl group is present, secondary carbocations are more stable than primary:



$$R-\underset{H}{C}=\underset{H}{C}-H + Y^+ \longrightarrow R-\underset{H}{\overset{\oplus}{C}}-\underset{H}{\overset{Y}{C}}-H \quad \text{or} \quad R-\underset{H}{\overset{Y}{C}}-\underset{H}{\overset{\oplus}{C}}-H$$

More stable

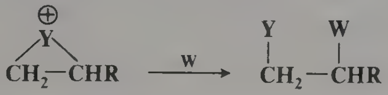
We may ask: How does Y^+ "know" which side will give the more stable carbocation? As in the similar case of electrophilic aromatic substitution (p. 454), we invoke the Hammond postulate and say that the lower energy carbocation is preceded by the lower energy transition state. Markovnikov's rule also applies for halogen substituents because the halogen stabilizes the carbocation by resonance:



$$Cl-\underset{H}{C}=\underset{H}{C}-H + Y^+ \longrightarrow \left[|\overline{\underline{Cl}}-\underset{H}{\overset{\oplus}{C}}-\underset{H}{\overset{Y}{C}}-H \longleftrightarrow \overset{\oplus}{|\underline{Cl}}=\underset{H}{C}-\underset{H}{\overset{Y}{C}}-H \right] \quad \text{or} \quad Cl-\underset{H}{\overset{Y}{C}}-\underset{H}{\overset{\oplus}{C}}-H$$

More stable

Markovnikov's rule is also usually followed where bromonium ions or other three-membered rings are intermediates.[80] This means that in these cases attack by W must resemble the SN1 rather than the SN2 mechanism (see p. 326), though the overall stereospecific anti addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration.



Olefins containing strong electron-withdrawing groups may violate Markovnikov's rule. For example, attack at the Markovnikov position of $Me_3\overset{\oplus}{N}-CH=CH_2$ would give an ion with positive charges on adjacent atoms. The compound $CF_3CH=CH_2$ has been reported to give electrophilic addition with acids in an anti-Markovnikov direction, but it has been shown[81] that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently anti-Markovnikov products are formed by other pathways.

For nucleophilic addition the direction of attack has been studied very little, except for Michael-type addition, with compounds of the type C=C—Z. Here the negative part of the reagent *always* attacks regioselectively at the carbon that does not carry the Z (see p. 664).

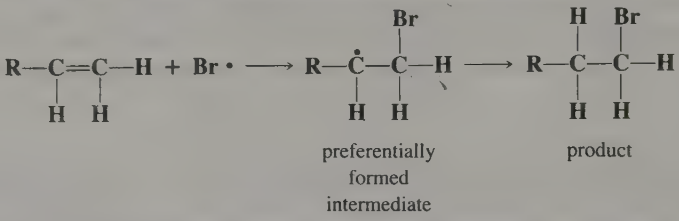
---

[79] For discussions of Markovnikov's rule, see Isenberg and Grdinic, *J. Chem. Educ.* **46,** 601 (1969); Grdinic and Isenberg, *Intra-Sci. Chem. Rep.* **4,** 145–162 (1970).

[80] This has been graphically demonstrated by direct treatment of stabilized bromonium ions by nucleophiles: Dubois and Chrétien, *J. Am. Chem. Soc.* **100,** 3506 (1978).

[81] Myhre and Andrews, *J. Am. Chem. Soc.* **92,** 7595, 7596 (1970).

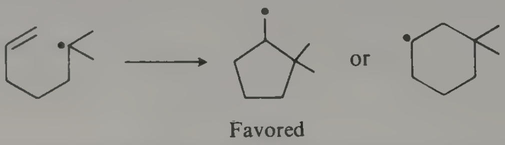
In free-radical addition[82] the main effect seems to be steric. All substrates $CH_2{=}CHX$ are preferentially attacked at the CH_2, regardless of the identity of X or of the attacking radical.[83] With a reagent such as HBr, this means that the addition is anti-Markovnikov:



$$\mathrm{R{-}\underset{H}{C}{=}\underset{H}{C}{-}H} + \mathrm{Br}\cdot \longrightarrow \mathrm{R{-}\underset{H}{\dot{C}}{-}\overset{Br}{\underset{H}{C}}{-}H} \longrightarrow \mathrm{R{-}\overset{H}{\underset{H}{C}}{-}\overset{Br}{\underset{H}{C}}{-}H}$$

Thus the observed orientation in both kinds of HBr addition (Markovnikov electrophilic and anti-Markovnikov free radical) is caused by formation of the secondary intermediate. In the electrophilic case it forms because it is more stable than the primary; in the free-radical case because it is sterically preferred. The stability order of the free-radical intermediates is also usually in the same direction: 3° > 2° > 1° (p. 164), but this factor is apparently less important than the steric factor. Internal olefins with no groups present to stabilize the radical usually give approximately a 1:1 mixture.

In *intramolecular* additions of radicals containing a 5,6 double bond, both five- and six-membered rings may be formed, but in most cases the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.[84] Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case the smaller ring (exo addition) is preferred to the larger (endo addition).[85]



For conjugated dienes, attack by a positive ion, a negative ion, or a free radical is always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is the one that is formed. For example, isoprene $CH_2{=}CMeCH{=}CH_2$, treated with HCl gives only $Me_2CClCH{=}CH_2$ and $Me_2C{=}CHCH_2Cl$, with none of the product arising from attack at the other end. $PhCH{=}CHCH{=}CH_2$ gives only $PhCH{=}CHCHClCH_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack by H^+ at an end of the conjugated system.

---

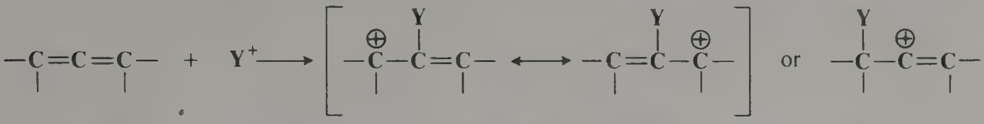
[82] For reviews of orientation in free-radical additions, see Tedder and Walton, *Tetrahedron* **36,** 701–707 (1980); *Adv. Phys. Org. Chem.* **16,** 51–86 (1978); *Acc. Chem. Res.* **9,** 183–191 (1976). See also Giese, Ref. 41; Tedder, *J. Chem. Educ.* **61,** 237 (1984).

[83] It has been contended that this regioselectivity is caused by an electronic effect: Poblet, Canadell, and Sordo, *Can. J. Chem.* **61,** 2068 (1983).

[84] For discussions, see Beckwith, *Tetrahedron* **37,** 3073–3100 (1981); Verhoeven, *Recl. Trav. Chim. Pays-Bas* **99,** 143 (1980).

[85] See Beckwith, Easton, and Serelis, *J. Chem. Soc., Chem. Commun.* 482 (1980).

When allenes are attacked by electrophilic reagents,[86] Markovnikov's rule would predict that the attack should be at the end of the system, since there are no hydrogens in the middle. Attack at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect the three p orbitals must be parallel, and it requires a rotation about the C—C bond for this to happen.[87] Therefore, the stability of the allyl cation has no effect on the transition state, which still has a geometry similar to that of the original allene (p. 90). Probably because of this, attack on the unsubstituted $CH_2{=}C{=}CH_2$ is most often at the end carbon, to give a vinyl cation,[30] though center attack has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, attack at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $RCH{=}C{=}CH_2$ are still attacked most often at the end, but with $RCH{=}C{=}CHR'$ center attack is more prevalent. Tetramethylallene is also attacked predominantly at the center carbon.[88] Free radicals[89] attack allenes most often at the end,[90] though attack at the middle has also been reported. As with electrophilic attack and for the same reason, the stability of the allyl radical has no effect on the transition state of the reaction between a free radical and an allene. Again, as with electrophilic attack, the presence of alkyl groups increases the extent of attack by a free radical at the middle carbon.[91]



$$-\underset{|}{C}=C=\underset{|}{C}- \quad + \quad Y^{+} \longrightarrow \left[-\underset{|}{\overset{\oplus}{C}}-\overset{Y}{\overset{|}{C}}=\underset{|}{C}- \longleftrightarrow -\underset{|}{C}=\overset{Y}{\overset{|}{C}}-\underset{|}{\overset{\oplus}{C}}-\right] \quad \text{or} \quad -\underset{|}{\overset{Y}{\overset{|}{C}}}-\overset{\oplus}{C}=\underset{|}{C}-$$

Stereochemical Orientation

It has already been pointed out that some additions are syn, with both groups, approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds there are further aspects of steric orientation. In syn addition to an unsymmetrical cyclic olefin, the two groups can come in from the more-hindered side or from the less-hindered side of the double bond. The rule is that syn addition is usually, though not always, from the less-hindered side.[92] For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered side.[93]

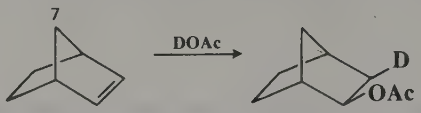
[93] Henbest and McCullough, *Proc. Chem. Soc.* 74 (1962).

In anti addition to a cyclic substrate, the initial attack by the electrophile is also from the less-hindered side. However, many (though not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.[94] In these cases attack is always from the exo side, e.g.,[95]



unless the exo side is blocked by substituents in the 7 position, in which case endo attack may predominate; e.g., 7,7-dimethylnorbornene undergoes syn–endo epoxidation (**5-37**) and hydroboration[96] (**5-13**). However, addition of DCl and F_3CCOOD to, and oxymercuration (**5-2**) of, 7,7-dimethylnorbornene proceed syn–exo in spite of the methyl groups in the 7 position.[97] Similarly, free-radical additions to norbornene and similar molecules are often syn–exo, though anti additions and endo attacks are also known.[98]

It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free-radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.[99] This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.[100] However, the initial diaxial product may then pass over to the diequatorial conformer (see p. 125) unless other groups on the ring render the latter less stable than the former. In free-radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial attack by the radical is also usually from the axial direction,[101] resulting in a diaxial initial product if the overall addition is anti.

Addition to Cyclopropane Rings[102]

We have previously seen (p. 131) that in some respects, cyclopropane rings resemble double bonds.[103] It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, e.g. (the reaction numbers of the analogous addition reactions are given in parentheses),

$+ \ \mathrm{HBr} \longrightarrow \mathrm{CH_3CH_2CH_2Br}$ **(5-1)**

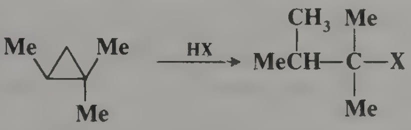
Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves electrophilic attack.[106] For substituted cyclopropanes, these reactions usually follow Markovnikov's rule, though exceptions are known and the degree of regioselectivity is often small. The application of Markovnikov's rule to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.[107] The rule predicts that the electrophile (in this case H^+) goes to the carbon with the most hydrogens and the nucleophile



goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions—the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,[108] 100% inversion,[109] and with mixtures of retention and inversion[110] At the carbon that becomes connected to the nucleophile the result is usually inversion, though retention has also been found,[111] and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for attack by HX, but analogous mechanisms can be written for other electrophiles).

Mechanism *a*

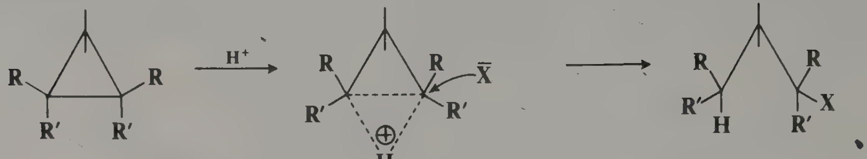
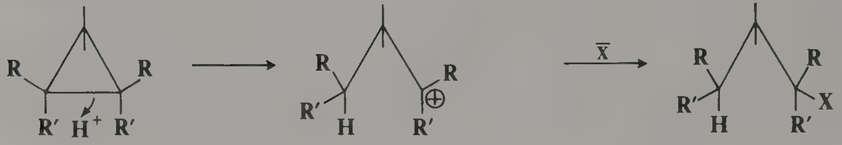
Mechanism *b*



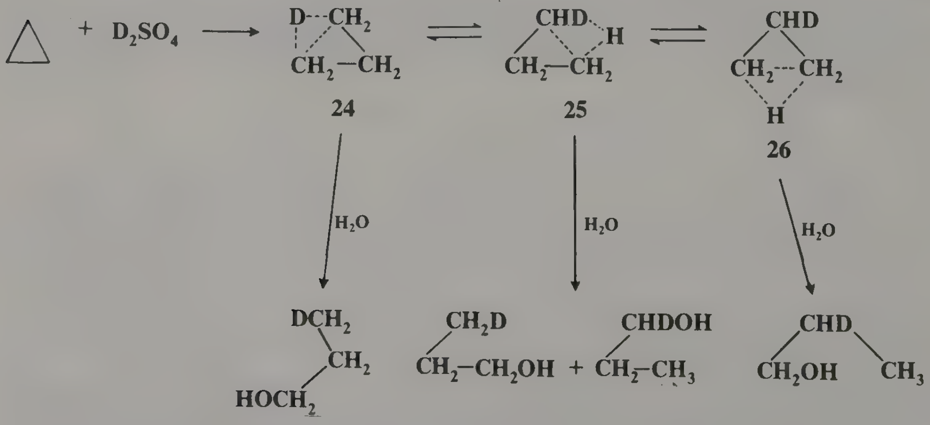
22

Mechanism *c*



23

Mechanism *a* involves a corner-protonated cyclopropane[112] (**21**); we have already seen examples of such ions in the 2-norbornyl and 7-norbornenyl cations (pp. 282, 274). Mechanism *b* involves an edge-protonated cyclopropane (**22**). Mechanism *c* consists of a one-step SE2-type attack by H^+ to give the classical cation **23**, which then reacts with the nucleophile. Although the three mechanisms as we have drawn them show retention of configuration at the carbon that becomes attached to the proton, mechanisms *a* and *c* at least can also lead to inversion at this carbon. Unfortunately, the evidence on hand at present does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. When cyclopropane was treated with D_2SO_4 (reaction **5-2**), the deuterium was found at all three carbons of the resulting 1-propanol.[113] This result can be explained by an equilibrium among the three edge-protonated species **24** to **26**.



---

Soc.* **92,** 3700 (1970).

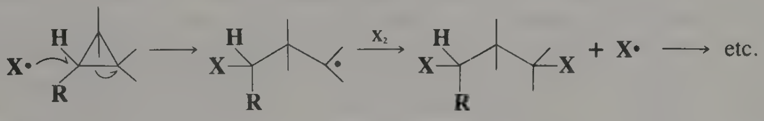
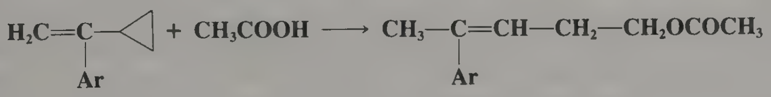
A similar equilibrium (with CH_3CO^+ instead of D^+) can explain the reaction of cyclopropane with CH_3COCl to give $CH_3COCH_2CH_2CH_2Cl$, $CH_3COCHMeCH_2Cl$, and $CH_3COCHEtCl$ (as well as $CH_3COCMe{=}CH_2$, formed by elimination of HCl from $CH_3COCHMeCH_2Cl$).[114] There are also the possibilities that three corner-protonated cyclopropanes might be in equilibrium with each other (corner-to-corner hydrogen shifts) and with the edge-protonated species and that in some cases **21** or **22** might form first and then be converted to **23.**

Free-radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free-radical mechanism in the presence of uv light. The addition follows Markovnikov's rule, with the initial radical attacking the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.[115] A mechanism that accounts for this behavior is



In some cases conjugate addition has been performed on systems where a double bond is "conjugated" with a cyclopropyl ring. An example is[116]



(5-5)

REACTIONS

Reactions are classified by type of reagent. All reactions where hydrogen adds to one side of the double bond are treated first.

Reactions in Which Hydrogen Adds to One Side

Any of the four hydrogen halides may be added to double bonds. HI, HBr, and HF[117] add at room temperature. The addition of HCl usually requires heat.[19] The reaction can be carried out with a large variety of double-bond compounds, including conjugated systems, where both 1,2 and 1,4 addition are possible. A convenient method for the addition of HF involves the use of a polyhydrogen fluoride–pyridine solution.[118] When the substrate is mixed with this solution in a solvent such as tetrahydrofuran at 0°C, alkyl fluorides are obtained in moderate-to-high yields.

The addition of hydrogen halides to simple olefins, in the absence of peroxides, take place by an electrophilic mechanism, and the orientation is in accord with Markovnikov's rule.[119] When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is anti-Markovnikov (p. 674).[120] It must be emphasized that this is true only for HBr. Free-radical addition of HF and HI has never been observed, even in the presence of peroxides, and of HCl only rarely. In the rare cases where free-radical addition of HCl was noted, the orientation was still Markovnikov, presumably because the more stable *product* was formed.[121] Free-radical addition of HF, HI, and HCl is energetically unfavorable (see the discussions on pp. 614, 623). It has often been found that anti-Markovnikov addition of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (**4-8**). Markovnikov addition can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve, and it is more common to add inhibitors, e.g., phenols or quinones, which suppress the free-radical pathway. The presence of free-radical precursors such as peroxides does not inhibit the ionic mechanism, but the radical reaction, being a chain process, is much more rapid than the electrophilic reaction. In most cases it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free-radical addition, or inhibitors to achieve complete electrophilic addition, though there are some cases where the ionic mechanism is fast enough to compete with the free-radical mechanism and complete control cannot be attained. Markovnikov addition of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase transfer catalysis.[122] For alternative methods of adding HBr (or HI) with anti-Markovnikov orientation, see **2-28.**

It is also possible to add one[123] or two moles of any of the four hydrogen halides to triple bonds.

$$-\mathrm{C}{\equiv}\mathrm{C}- \xrightarrow{\mathrm{HX}} -\mathrm{CH}{=}\mathrm{CX}- \xrightarrow{\mathrm{HX}} -\mathrm{CH_2}-\mathrm{CX_2}-$$

Markovnikov's rule ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of two moles.

HX are electrophilic reagents, and many polyhalo and polycyano alkenes, e.g., $\mathrm{Cl_2C{=}CHCl}$, do not react with them at all in the absence of free-radical conditions. When such reactions do occur, however, they take place by a nucleophilic addition mechanism, i.e., initial attack is by X^-. This type of mechanism also occurs with Michael-type substrates C=C—Z,[124] where the orientation is always such that the halogen goes to the carbon that does not bear the Z, so that the product is of the form X—C—CH—Z, even in the presence of free-radical initiators. HI adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:[125]

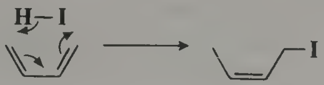
[121] Mayo, *J. Am. Chem. Soc.* **84,** 3964 (1962).

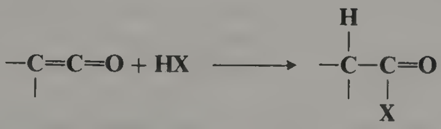
[122] Landini and Rolla, *J. Org. Chem.* **45,** 3527 (1980).

[123] For a convenient method of adding one mole of HCl or HBr to a triple bond, see Cousseau and Gouin, *J. Chem Soc., Perkin Trans. 1* 1797 (1977); Cousseau, *Synthesis* 805 (1980).

[124] For an example, see Marx, *Tetrahedron* **39,** 1529 (1983).



HX can be added to ketenes[126] to give acyl halides:[127]

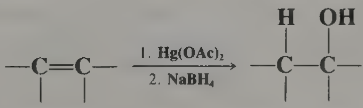


$$\underset{|}{-\mathrm{C}}{=}\mathrm{C}{=}\mathrm{O} + \mathrm{HX} \longrightarrow \underset{|}{\overset{\overset{\mathrm{H}}{|}}{-\mathrm{C}}}-\underset{\underset{\mathrm{X}}{|}}{\mathrm{C}}{=}\mathrm{O}$$

OS **I,** 166; **II,** 137, 336; **III,** 576; **IV,** 238, 543; **57,** 26.

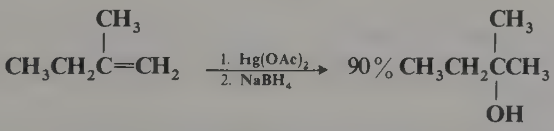
B. Oxygen on the Other Side

5-2 Hydration of Double bonds
Hydro-hydroxy-addition



$$\underset{|}{-\mathrm{C}}{=}\underset{|}{\mathrm{C}-} \xrightarrow[\text{2. NaBH}_4]{\text{1. Hg(OAc)}_2} \underset{|}{\overset{\overset{\mathrm{H}}{|}}{-\mathrm{C}}}-\underset{|}{\overset{\overset{\mathrm{OH}}{|}}{\mathrm{C}}}-$$

Olefins can be hydrated quickly under mild conditions in high yields without rearrangement products by the use of *oxymercuration*[128] (addition of oxygen and mercury) followed by in situ treatment with sodium borohydride[129] (**2-22**). For example, 2-methyl-1-butene treated with mercuric acetate,[130] followed by $NaBH_4$, gave 90% 2-methyl-2-butanol:



$$\mathrm{CH_3CH_2}\overset{\overset{\mathrm{CH_3}}{|}}{\mathrm{C}}{=}\mathrm{CH_2} \xrightarrow[\text{2. NaBH}_4]{\text{1. Hg(OAc)}_2} 90\%\ \mathrm{CH_3CH_2}\underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{\mathrm{CH_3}}{|}}{\mathrm{C}}}\mathrm{CH_3}$$

This method, which is applicable to mono-, di-, tri-, and tetraalkyl as well as phenyl-substituted olefins, gives almost complete Markovnikov addition. Hydroxy, methoxy, acetoxy, and halo groups may be present in the substrate without, in general, causing difficulties.[131]

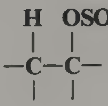
[130] For a review of this reagent, see Butler, in Pizey, "Synthetic Reagents," vol. 4, pp. 1–145, Wiley, New York, 1981.

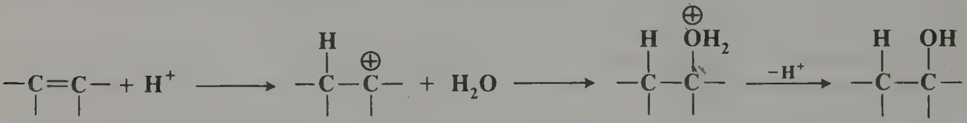
Double bonds can also be hydrated by treatment with water and an acid catalyst. The most common catalyst is sulfuric acid, but other acids, such as nitric or perchloric can also be used. The mechanism is electrophilic and begins with attack by a proton (see p. 662). The negative attacking species may be HSO_4^- (or similar ion in the case of other acids) to give the initial product



$$\underset{|}{\overset{\overset{\textstyle H}{|}}{-C}}-\underset{|}{\overset{\overset{\textstyle OSO_2OH}{|}}{C}}-$$

27

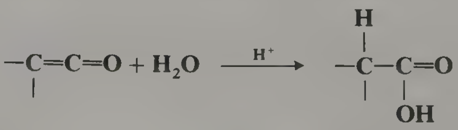
which can be isolated but, under the conditions of the reaction, is usually hydrolyzed to the alcohol (reaction **0-4**). However, the conjugate base of the acid is not the only possible species that attacks the initial carbocation. The attack may also be by water:



$$-\underset{|}{C}=\underset{|}{C}- + H^+ \longrightarrow -\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}-\underset{|}{\overset{\oplus}{C}}- + H_2O \longrightarrow -\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}-\underset{|}{\overset{\overset{\textstyle \overset{\oplus}{O}H_2}{|}}{C}}- \xrightarrow{-H^+} -\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}-\underset{|}{\overset{\overset{\textstyle OH}{|}}{C}}-$$

When the reaction proceeds by this pathway, **27** and similar intermediates are not involved and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of E1 elimination of alcohols (**7-1**).[132] It is likely that the mechanism involves both pathways. Sometimes the initial carbocation rearranges to a more stable one. For example, hydration of $CH_2{=}CHCH(CH_3)_2$ gives $CH_3CH_2COH(CH_3)_2$. With ordinary olefins the addition predominantly follows Markovnikov's rule. Water can be added indirectly, with anti-Markovnikov orientation, by treatment of the alkene with a 1:2 mixture of $TiCl_4$ and $NaBH_4$ in 1,2-dimethoxyethane, followed by addition of water.[133] For another method of anti-Markovnikov hydration, see **5-13.** With substrates of the type C=C—Z (Z is as defined on p. 664) the product is always HO—C—CH—Z and the mechanism is usually nucleophilic,[134] although electrophilic addition gives the same product[135] since a cation $CH—\overset{\oplus}{C}—Z$ would be destabilized by the positive charges (full or partial) on two adjacent atoms. Conjugated dienes are seldom hydrated.

The addition of water to vinyl ethers causes hydrolysis to aldehydes or ketones (**0-7**). Ketenes add water to give carboxylic acids in a reaction catalyzed by acids:[136]



$$-\underset{|}{C}=C=O + H_2O \xrightarrow{H^+} -\underset{|}{\overset{\overset{\textstyle H}{|}}{C}}-\underset{\underset{\textstyle OH}{|}}{C}=O$$

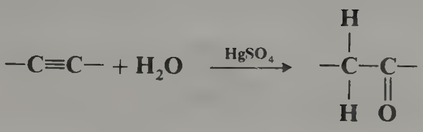
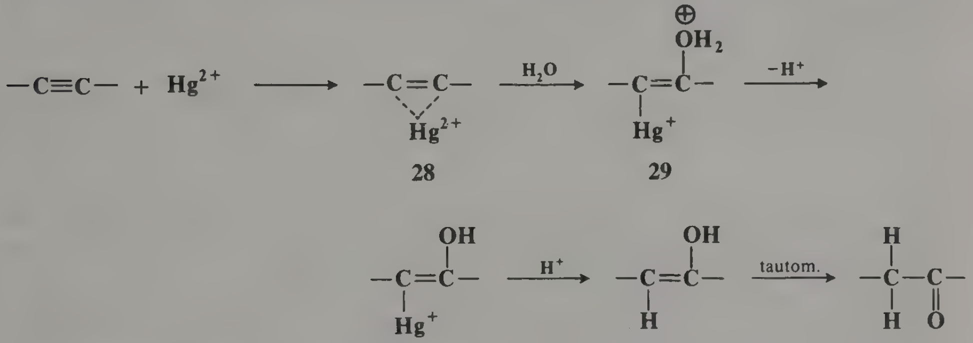
5-3 Hydration of Triple Bonds
Dihydro-oxo-biaddition



$$-C{\equiv}C- + H_2O \xrightarrow{HgSO_4} -\underset{H}{\overset{H}{\underset{|}{\overset{|}{C}}}}-\underset{O}{\underset{\|}{C}}-$$

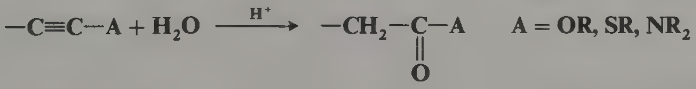
The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate) as catalysts.[137] Since the addition follows Markovnikov's rule, only acetylene gives an aldehyde. All other triple-bond compounds give ketones (for a method of reversing the orientation for terminal alkynes, see **5-13**). With alkynes of the form RC≡CH methyl ketones are formed almost exclusively, but with RC≡CR′ both possible products are usually obtained. However, if R is primary and R′ secondary or tertiary, the carbonyl group is formed preferentially next to the secondary or tertiary carbon.[138] The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid).[139]

The first step of the mechanism is formation of a complex (**28**) (ions like Hg^{2+} form complexes with alkynes—p. 75). Water then attacks in an SN2-type process to give the intermediate **29,** which loses a proton to give **30.** Hydrolysis of **30** (an example of **2-22**) gives the enol, which tautomerizes to the product.



28 **29** **30**

Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,[140] and ynamines, without a mercuric catalyst:[141]



$$-C{\equiv}C-A + H_2O \xrightarrow{H^+} -CH_2-\underset{O}{\underset{\|}{C}}-A \qquad A = OR, SR, NR_2$$

This is ordinary electrophilic addition, with rate-determining protonation as the first step.[142] Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts. These include $ArC{\equiv}CCOOH$,[143] $ArC{\equiv}CCH_3$,[144] and 3-hexyne.[145]

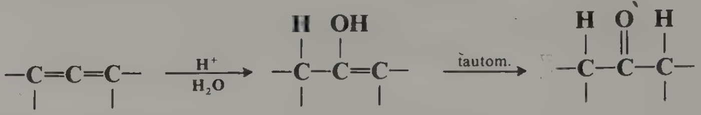
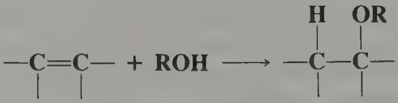
Allenes can also be hydrolyzed to ketones, with an acid catalyst:[146]



$$-C{=}C{=}C- \xrightarrow[H_2O]{H^+} -\overset{H}{C}-\overset{OH}{C}{=}C- \xrightarrow{\text{tautom.}} -\overset{H}{C}-\overset{\overset{O}{\|}}{C}-\overset{H}{C}-$$

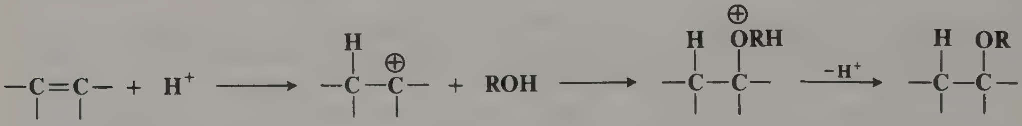
OS **III,** 22; **IV,** 13; **V,** 1024.

5-4 Addition of Alcohols and Phenols
Hydro-alkoxy-addition



$$-C{=}C- + ROH \longrightarrow -\overset{H}{C}-\overset{OR}{C}-$$

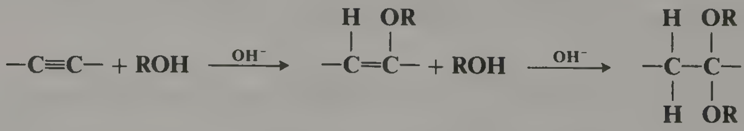
The addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid-catalyzed, the mechanism is electrophilic, with H^+ as the attacking species. The resulting carbocation combines with a molecule of alcohol:



$$-C{=}C- + H^+ \longrightarrow -\overset{H}{C}-\overset{\oplus}{C}- + ROH \longrightarrow -\overset{H}{C}-\overset{\overset{\oplus}{ORH}}{C}- \xrightarrow{-H^+} -\overset{H}{C}-\overset{OR}{C}-$$

The addition, therefore, follows Markovnikov's rule. Primary alcohols give better results than secondary, and tertiary alcohols are very inactive. This is a convenient method for the preparation of tertiary ethers by the use of a suitable olefin such as $Me_2C{=}CH_2$.

For those substrates more susceptible to nucleophilic attack, e.g., polyhalo olefins and olefins of the type $C{=}C{-}Z$, it is better to carry out the reaction in basic solution, where the attacking species is RO^-.[147] The reactions with $C{=}C{-}Z$ are of the Michael type, and OR always goes to the side away from the Z. Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction:[148]



$$-C{\equiv}C- + ROH \xrightarrow{OH^-} -\overset{H}{C}{=}\overset{OR}{C}- + ROH \xrightarrow{OH^-} -\underset{H}{\overset{H}{C}}-\underset{OR}{\overset{OR}{C}}-$$

Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids. One utilization of this reaction involves the compound dihydropyran (**31**), which is often used to protect the OH groups of primary and secondary

31 **32**

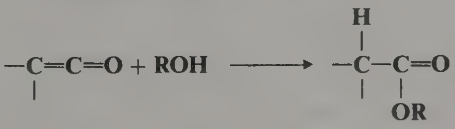
alcohols and phenols.[149] The tetrahydropyranyl acetal formed by this reaction (**32**) is stable to bases, Grignard reagents, $LiAlH_4$, and oxidizing agents, any of which may be used to react with functional groups located within the R group. When the reactions are completed, **32** is easily cleaved by treatment with dilute acids (**0-7**).

In base-catalyzed addition to triple bonds the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions. Other catalysts, namely, BF_3 and mercuric salts, have also been used in addition of ROH to triple bonds.

Alcohols can be added to certain double-bond compounds (cyclohexenes, cycloheptenes) photochemically in the presence of a photosensitizer such as benzene. The mechanism is electrophilic and Markovnikov orientation is found. The olefins react in their first excited triplet states.[150]

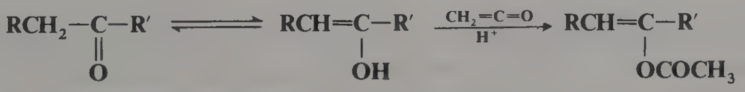
The oxymercuration–demercuration procedure mentioned in **5-2** can be adapted to the preparation of ethers (Markovnikov orientation) if the oxymercuration is carried out in an alcohol ROH as solvent, e.g., 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.[151] Primary and secondary alcohols give good yields when mercuric acetate is used, but for tertiary alcohols it is necessary to use mercuric trifluoroacetate. However, even with this reagent the method fails where the product would be a ditertiary ether. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with $NaBH_4$) is an alkyl peroxide (peroxymercuration).[152]

Both alcohols and phenols add to ketenes to give esters:[153]



$$-\underset{|}{C}{=}C{=}O + ROH \longrightarrow -\overset{\overset{H}{|}}{\underset{|}{C}}-\underset{\underset{OR}{|}}{C}{=}O$$

Similarly, carbon suboxide gives malonic esters: $O{=}C{=}C{=}C{=}O + 2ROH \rightarrow ROOCCH_2COOR$.[154] In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates:



$$RCH_2-\underset{\underset{O}{\|}}{C}-R' \rightleftharpoons RCH{=}\underset{\underset{OH}{|}}{C}-R' \xrightarrow[H^+]{CH_2=C=O} RCH{=}\underset{\underset{OCOCH_3}{|}}{C}-R'$$

Alcohols can also add to olefins in a different way (see **5-21**).

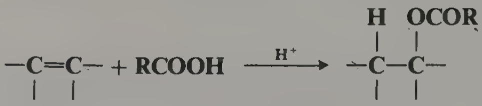
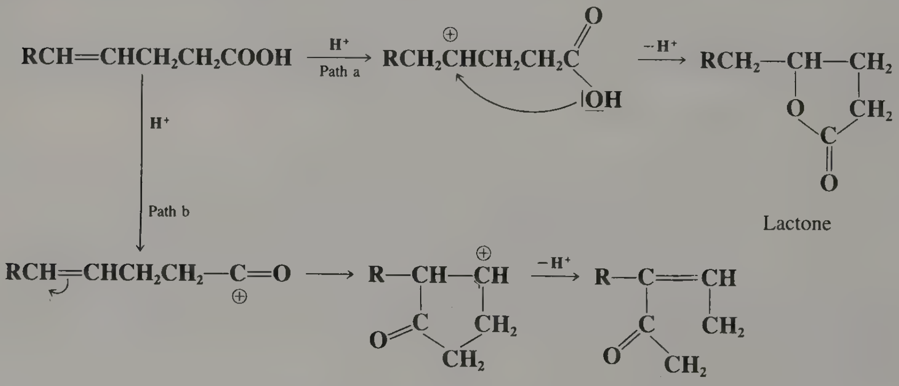
5-5 Addition of Carboxylic Acids
Hydro-acyloxy-addition



$$-\underset{|}{C}=\underset{|}{C}- + RCOOH \xrightarrow{H^+} -\underset{|}{\overset{\overset{\displaystyle H}{|}}{C}}-\underset{|}{\overset{\overset{\displaystyle OCOR}{|}}{C}}-$$

Carboxylic esters are produced by the addition of carboxylic acids to olefins, a reaction that is usually acid-catalyzed (by proton or Lewis acids[155]) and similar in mechanism to **5-4.** Since Markovnikov's rule is followed, hard-to-get esters of tertiary alcohols can be prepared from olefins of the form $R_2C{=}CHR$.[156] *t*-Butyl alcohol is a particularly good solvent for this reaction.[157] When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the addition occurs internally and the product is a γ- and/or a δ-lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double-bond shifts (**2-2**).[158] The double bond always migrates to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. However, another reaction competes, in which the product is a cyclopentenone or a cyclohexenone. This is essentially an example of **2-14.** In either case, the double bond first migrates into the proper position,



Cyclopentenone

and then whether path a or b predominates depends mainly on which type of acid is used as catalyst. Proton-donating acids, e.g., H_2SO_4, HCOOH, and HF, give mostly lactones, while Lewis acids like acetic anhydride, $ZnCl_2$ in HOAc, P_2O_5, etc., are among those which give mostly ketones. Since carbocations are involved, rearrangements take place in both reactions.

Triple bonds can give enol esters or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts, and vinylmercury compounds $-\underset{\underset{\displaystyle HgX}{|}}{C}=\overset{|}{C}-OCOR$ are intermediates.[159] With

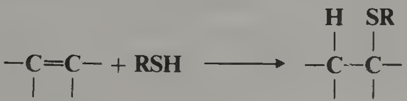
C. Sulfur on the Other Side

5-6 Addition of H_2S and Mercaptans
Hydro-alkylthio-addition



$$-\underset{|}{C}=\underset{|}{C}- + RSH \longrightarrow -\underset{|}{\overset{H}{\overset{|}{C}}}-\underset{|}{\overset{SR}{\overset{|}{C}}}-$$

H_2S and mercaptans add to olefins by electrophilic, nucleophilic, or free-radical mechanisms.[162] In the absence of initiators the addition to simple olefins is by an electrophilic mechanism, similar to that in **5-4,** and Markovnikov's rule is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless an acid catalyst is used. For example, the reaction can be performed in concentrated H_2SO_4.[163] In the presence of free-radical initiators, H_2S and mercaptans add to double and triple bonds by a free-radical mechanism and the orientation is anti-Markovnikov.[164] In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free-radical addition can be done with H_2S, RSH (R may be primary, secondary, or tertiary), ArSH, or RCOSH.[165] R may contain various functional groups. The olefins may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, COOH, COOR, NO_2, RSO_2, etc. With acetylenes it is possible to add 1 or 2 moles of RSH.

When mercaptans are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the Michael type[166] or may be polyhalo olefins or alkynes.[148] As with the free-radical mechanism, alkynes may give either vinyl thioethers or thioacetals:

---

[160] For discussions of the mechanism, see Briody, Lillford, and Satchell, *J. Chem. Soc. B* 885 (1968); Corriu, Guenzet, Camps, and Reye, *Bull. Soc. Chim. Fr.* 3679 (1970); Ref. 126; Blake and Vayjooee, *J. Chem. Soc., Perkin Trans. 2* 1533 (1976).

[161] Kharasch and Fono, *J. Org. Chem.* **24,** 606 (1959); Kochi, *J. Am. Chem. Soc.* **84,** 1572 (1962).

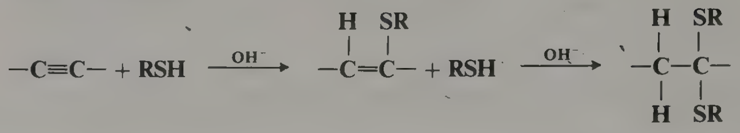
[162] For reviews, see Prilezhaeva and Shostakovskii, *Russ. Chem. Rev.* **32,** 399–426 (1963); Wardell, in Patai, "The Chemistry of the Thiol Group," pt. 1, pp. 169–178, Wiley, New York, 1974.

[163] Shostakovskii, Kul'bovskaya, Gracheva, Laba, and Yakushina, *J. Gen. Chem. USSR* **32,** 707 (1962).

[164] For reviews of free-radical addition of H_2S and RSH, see Griesbaum, *Angew. Chem. Int. Ed. Engl.* **9,** 273–287 (1970) [*Angew. Chem.* **82,** 276–290]; Oswald and Griesbaum, in Kharasch and Meyers, "Organic Sulfur Compounds," vol. 2, pp. 233–256, Pergamon, New York, 1966; Stacey and Harris, *Org. React.* **13,** 150–376 (1963), pp. 165–196, 247–324; Sosnovsky, Ref. 41, pp. 62–97.

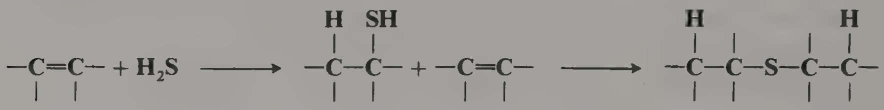
[165] For a review of the addition of thio acids, see Janssen, in Patai, "The Chemistry of Carboxylic Acids and Esters," pp. 720–723, Interscience, New York, 1969.

[166] Michael substrates usually give the expected orientation. For a method of reversing the orientation for RS groups (the RS group goes α to the C=O bond of a C=C—C=O system), see Gassman, Gilbert, and Cole, *J. Org. Chem.* **42,** 3233 (1977).



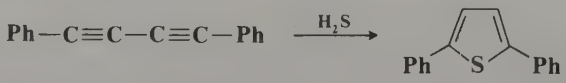
$$-C{\equiv}C- + RSH \xrightarrow{OH^-} -\overset{H}{\overset{|}{C}}{=}\overset{SR}{\overset{|}{C}}- + RSH \xrightarrow{OH^-} -\underset{H}{\underset{|}{\overset{H}{\overset{|}{C}}}}-\underset{SR}{\underset{|}{\overset{SR}{\overset{|}{C}}}}-$$

By any mechanism, the initial product of addition of H_2S to a double bond is a mercaptan, which is capable of adding to a second molecule of olefin, so that sulfides are often produced:

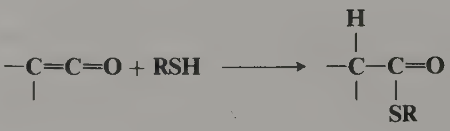


$$-\underset{|}{C}{=}\underset{|}{C}- + H_2S \longrightarrow -\underset{|}{\overset{H}{\overset{|}{C}}}-\underset{|}{\overset{SH}{\overset{|}{C}}}- + -\underset{|}{C}{=}\underset{|}{C}- \longrightarrow -\underset{|}{\overset{H}{\overset{|}{C}}}-\underset{|}{\overset{|}{C}}-S-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{H}{\overset{|}{C}}}-$$

Additions to conjugated dienes have been rare. For electrophilic (acid-catalyzed) conditions, 1,4-addition has been reported.[167] For free-radical addition, both 1,2[167] and 1,4 addition[168] have been demonstrated. Conjugated diynes, treated with H_2S, give thiophenes:[169]



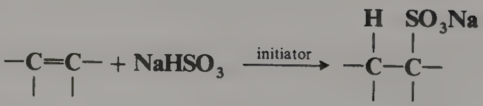
Ketenes add mercaptans to give thiol esters:



$$-\underset{|}{C}{=}C{=}O + RSH \longrightarrow -\underset{|}{\overset{H}{\overset{|}{C}}}-\underset{SR}{\underset{|}{C}}{=}O$$

OS **III,** 458; **IV,** 669.

5-7 Addition of Sodium Bisulfite **Hydro-sulfonato-addition**



$$-\underset{|}{C}{=}\underset{|}{C}- + NaHSO_3 \xrightarrow{\text{initiator}} -\underset{|}{\overset{H}{\overset{|}{C}}}-\underset{|}{\overset{SO_3Na}{\overset{|}{C}}}-$$

Salts of aliphatic sulfonic acids can be prepared by addition of bisulfite salts to olefins in the presence of free-radical initiators.[170] The orientation is anti-Markovnikov.

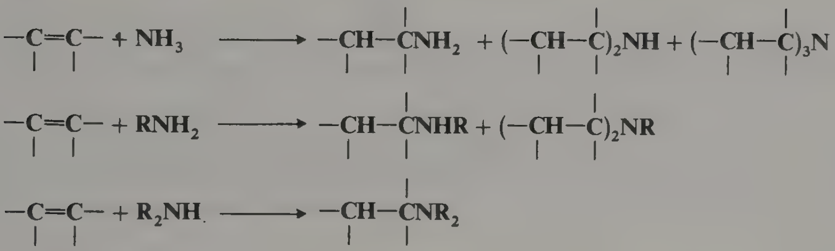
[168] Oswald, Griesbaum, Thaler, and Hudson, *J. Am. Chem. Soc.* **84,** 3897 (1962); Claisse and Davies, *J. Chem. Soc.* 4894 (1965), obtained both 1,2 and 1,4 products.

[169] Schulte, Reisch, and Hörner, *Chem. Ber.* **95,** 1943 (1962).

[170] For a review, see Gilbert, "Sulfonation and Related Reactions," pp. 148–156, Interscience, New York, 1965.

D. Nitrogen on the Other Side

5-8 Addition of Ammonia and Amines
Hydro-amino-addition

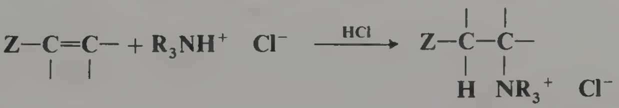


$$-\underset{|}{C}=\underset{|}{C}- + NH_3 \longrightarrow -\underset{|}{CH}-\overset{|}{\underset{|}{C}}NH_2 + (-\underset{|}{CH}-\overset{|}{\underset{|}{C}})_2NH + (-\underset{|}{CH}-\overset{|}{\underset{|}{C}})_3N$$

$$-\underset{|}{C}=\underset{|}{C}- + RNH_2 \longrightarrow -\underset{|}{CH}-\overset{|}{\underset{|}{C}}NHR + (-\underset{|}{CH}-\overset{|}{\underset{|}{C}})_2NR$$

$$-\underset{|}{C}=\underset{|}{C}- + R_2NH \longrightarrow -\underset{|}{CH}-\overset{|}{\underset{|}{C}}NR_2$$

Ammonia and primary and secondary amines add to olefins that are susceptible to nucleophilic attack.[171] Ammonia gives three possible products, since the initial product is a primary amine, which may add to a second molecule of olefin, etc. Similarly, primary amines give both secondary and tertiary products. In practice it is usually possible to control which product predominates. Since ammonia and amines are much weaker acids than water, alcohols, and mercaptans (see **5-2, 5-4, 5-6**) and since acids could hardly catalyze the reaction (because they would turn NH_3 into NH_4^+), this reaction does not occur by an electrophilic mechanism and so gives very low yields, if any, with ordinary olefins, unless extreme conditions are used (e.g., 178–200°C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH_3 and ethylene[172]). The mechanism is nearly always nucleophilic, and the reaction is generally performed on polyhalo olefins,[173] Michael-type substrates, and alkynes. As expected, on Michael-type substrates the nitrogen goes to the carbon that does not carry the Z. Other nitrogenous compounds, among them hydroxylamine, hydrazines, amides[174] ($RCONH_2$ and $RCONHR'$ including imides and lactams), and sulfonamides, also add to olefins. In the case of amides, basic catalysts are required, since amides are not good enough nucleophiles for the reaction and must be converted to $RCONH^-$. Even with amines, basic catalysts are sometimes used, so that RNH^- or R_2N^- is the actual nucleophile. Tertiary amines (except those that are too bulky) add to Michael-type substrates in a reaction that is catalyzed by acids like HCl or HNO_3 to give the corresponding quaternary ammonium salts.[175]



$$Z-\underset{|}{C}=\underset{|}{C}- + R_3NH^+ \quad Cl^- \xrightarrow{HCl} Z-\overset{|}{\underset{\underset{H}{|}}{C}}-\overset{|}{\underset{\underset{NR_3^+}{|}}{C}}- \quad Cl^-$$

The tertiary amine may be aliphatic, cycloalkyl, or heterocyclic (including pyridine).

Primary amines add to triple bonds[176] to give enamines, which have a hydrogen on the nitrogen and (analogously to enols) tautomerize to the more stable imines:

---

[171] For reviews, see Gasc, Lattes, and Périé, *Tetrahedron* **39,** 703–731 (1983); Pines and Stalick, "Base-Catalyzed Reactions of Hydrocarbons and Related Compounds," pp. 423–454, Academic Press, New York, 1977; Suminov and Kost, *Russ. Chem. Rev.* **38,** 884–899 (1969); Gibson, in Patai, "The Chemistry of the Amino Group," pp. 61–65, Interscience, New York, 1968.

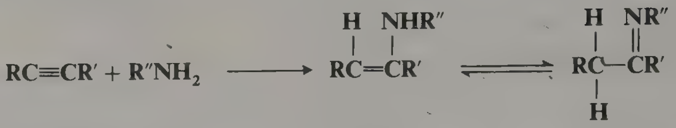
[172] Howk, Little, Scott, and Whitman, *J. Am. Chem. Soc.* **76,** 1899 (1954).

[173] For a review with respect to fluoroolefins, see Chambers and Mobbs, *Adv. Fluorine Chem.* **4,** 51–112 (1965), pp. 62–68.

[174] See for example Batty, Howes, and Stirling, *J. Chem. Soc., Perkin Trans. 1* 1543 (1976).

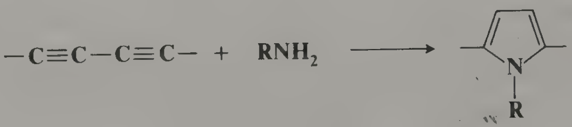
[175] Le Berre and Delacroix, *Bull. Soc. Chim. Fr.* 640, 647 (1973).

[176] For a review of addition of ammonia and amines to triple bonds, see Chekulaeva and Kondrat'eva, *Russ. Chem. Rev.* **34,** 669–680 (1965).



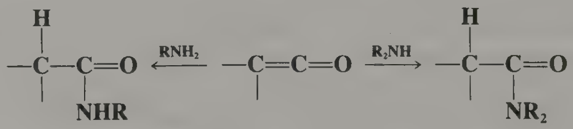
$$RC\equiv CR' + R''NH_2 \longrightarrow R\overset{H}{\overset{|}{C}}=\overset{NHR''}{\overset{|}{C}}R' \rightleftharpoons R\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{C}}-\overset{NR''}{\overset{\|}{C}}R'$$

These are often stable enough for isolation.[177] When ammonia is used instead of a primary amine, the corresponding $RCH_2-\overset{\overset{NH}{\|}}{C}R'$ is not stable enough for isolation, but polymerizes. Secondary amines give enamines $RCH=CR'NR_2''$, which, lacking a hydrogen on the nitrogen, are quite stable. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles:[178]



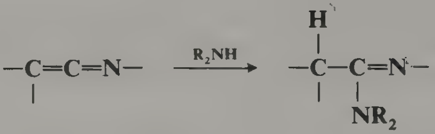
This is not 1,4 addition but 1,2 addition twice.

Primary and secondary amines add to ketenes to give, respectively, N-substituted and N,N-disubstituted amides:[179]



$$-\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{NHR}{\underset{|}{C}}=O \xleftarrow{RNH_2} -\underset{|}{C}=C=O \xrightarrow{R_2NH} -\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{NR_2}{\underset{|}{C}}=O$$

and to ketenimines to give amidines:[180]



$$-\underset{|}{C}=C=N- \xrightarrow{R_2NH} -\overset{H}{\underset{|}{\overset{|}{C}}}-\underset{NR_2}{\underset{|}{C}}=N-$$

R = H or alkyl

Secondary amines can be added to certain nonactivated olefins if palladium(II) complexes are used as catalysts.[181] Markovnikov orientation is observed.

NH_3 can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (**5-13**) followed by treatment with NH_2Cl or NH_2OSO_2OH (**2-29**). This produces a primary amine with anti-Markovnikov orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration followed by reduction (see

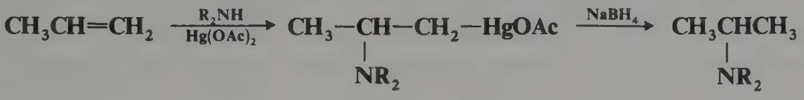
5-2 for the analogous oxymercuration–demercuration procedure), e.g.,[182]



$$CH_3CH{=}CH_2 \xrightarrow[Hg(OAc)_2]{R_2NH} \underset{\displaystyle NR_2}{CH_3{-}\overset{}{CH}}{-}CH_2{-}HgOAc \xrightarrow{NaBH_4} \underset{\displaystyle NR_2}{CH_3CHCH_3}$$

33

The addition of a secondary amine (shown above) produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows Markovnikov's rule. Amido- and sulfamidomercuration–demercuration[183] and nitromercuration[184] have also been accomplished (see also **6-56**). For conversion of **33** to other products, see **5-40** and **5-41.**

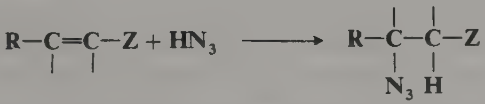
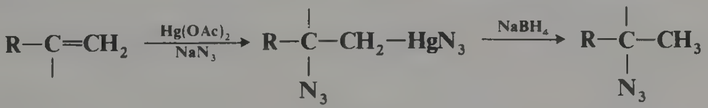
5-9 Addition of Hydrazoic Acid
Hydro-azido-addition



$$R{-}\underset{|}{C}{=}\underset{|}{C}{-}Z + HN_3 \longrightarrow R{-}\overset{|}{\underset{N_3}{C}}{-}\overset{|}{\underset{H}{C}}{-}Z$$

Hydrazoic acid can be added to certain Michael-type substrates (Z is as defined on p. 664) to give β-azido compounds.[185] The reaction apparently fails if R is phenyl. HN_3 can be added indirectly to ordinary olefins by azidomercuration, followed by demercuration,[186] analogous to the similar

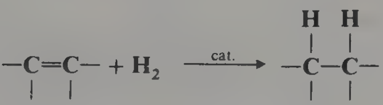


$$R{-}\underset{|}{C}{=}CH_2 \xrightarrow[NaN_3]{Hg(OAc)_2} R{-}\overset{|}{\underset{N_3}{C}}{-}CH_2{-}HgN_3 \xrightarrow{NaBH_4} R{-}\overset{|}{\underset{N_3}{C}}{-}CH_3$$

procedures mentioned in **5-2, 5-4,** and **5-8.** The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene) but fails for unstrained internal alkenes.

E. Hydrogen on Both Sides

5-10 Hydrogenation of Double and Triple Bonds[187]
Dihydro-addition



$$-\underset{|}{C}{=}\underset{|}{C}- + H_2 \xrightarrow{cat.} -\overset{H}{\underset{|}{C}}{-}\overset{H}{\underset{|}{C}}-$$

Most carbon–carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.[188] Almost all known alkenes add hydrogen at temperatures between 0 and 275°C. Many functional groups may be present in the molecule, e.g., OH, COOH, NH_2, CHO, COR, COOR, or CN. Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions under which double bonds can be reduced selectively[189] (see Table 2 in Chapter 19, p. 1093). The catalysts used can be divided into two broad classes, both of which mainly consist of transition metals and their compounds: (1) catalysts insoluble in the reaction medium (*heterogeneous catalysts*). These have been the ones traditionally used. Among the most effective are Raney nickel,[190] palladium-on-charcoal (perhaps the most common), $NaBH_4$-reduced nickel[191] (also called nickel boride), platinum metal or its oxide, rhodium, ruthenium, NaH-RONa-$Ni(OAc)_2$,[192] and zinc oxide,[193] (2) Catalysts soluble in the reaction medium (*homogeneous catalysts*).[194] These are of more recent discovery. The most important is chlorotris(triphenylphosphine)rhodium $RhCl(Ph_3P)_3$,[195] (*Wilkinson's catalyst*),[196] which catalyzes the hydrogenation of many olefinic compounds without disturbing such groups as COOR, NO_2, CN, or COR present in the same molecule.[197] Even unsaturated aldehydes can be reduced to saturated aldehydes,[198] though in this case decarbonylation (**4-40**) may be a side reaction. Among other homogeneous catalysts are chlorotris(triphenylphosphine)hydridoruthenium(II) $(Ph_3P)_3RuClH$,[199] which is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all), and pentacyanocobaltate(II) $Co(CN)_5^{3-}$, which is effective for double and triple bonds only when they are part of conjugated systems[200] (the conjugation may be with C=C, C=O, or an aromatic ring). Homogeneous catalysts often have the advantages of better catalyst reproducibility and better selectivity. They are also less susceptible to catalyst poisoning[201] (heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by sulfur-containing compounds such as mercaptans and sulfides). On the other hand, heterogeneous catalysts are usually easier to separate from the reaction mixture. Optically active homogeneous (as well as heterogeneous) catalysts have been used to achieve partially asymmetric (enantioselective) hydrogenations.[202] In recent years these have been developed to such a point that optical purities greater than 90% have been achieved in certain cases.[203]

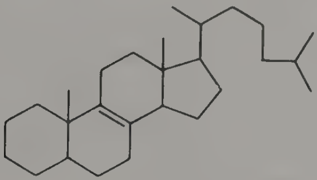
Hydrogenations in most cases are carried out at room temperature and just above atmospheric pressure, but some double bonds are more resistant and require higher temperatures and pressures. The resistance is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25°C and 100 atm, while tetrasubstituted double bonds may require 275°C and 100 atm. Among the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings, as in the steroid shown.



Hydrogenations, even at about atmospheric pressure, are ordinarily performed in a special hydrogenator, but this is not always necessary. Both the catalyst and the hydrogen may be generated in situ, by treatment of H_2PtCl_6 or $RhCl_3$ with $NaBH_4$;[204] ordinary glassware may then be used.

Although catalytic hydrogenation is the method most often used, double bonds can be reduced by other reagents, as well. Among these are sodium in ethanol, sodium and *t*-butyl alcohol in HMPT,[205] lithium and aliphatic amines[206] (see also **5-11**), chromous ion,[207] zinc and acids, sodium hydrogen telluride NaTeH,[208] water and precipitated nickel,[209] trifluoroacetic acid and triethylsilane Et_3SiH,[210] hydrazine (if a small amount of oxidizing agent, such as air, H_2O_2, or cupric ion is present),[211] hydroxylamine and ethyl acetate,[212] and NH_2OSO_3H.[213] However, metallic hydrides, such as lithium aluminum hydride and sodium borohydride, do not in general reduce carbon–carbon double bonds,[214] although this can be done in special cases where the double bond is polar, as in 1,1-diarylethenes.[215] In certain cases[216] these reagents may also reduce double bonds in conjugation with C=O bonds, as well as reducing the C=O bonds, e.g.,[217]

$NaBH_4$ has a greater tendency than $LiAlH_4$ to effect this double reduction, though even with $NaBH_4$ the product of single reduction (of the C=O bond) is usually formed in larger amount than the doubly reduced product. $LiAlH_4$ gives significant double reduction only in cinnamyl systems, e.g., with PhCH=CHCOOH.[218]

The double reduction can also be avoided by the use of AlH_3,[219] $NaBH_4$ in the presence of lanthanide chlorides (e.g., $LaCl_3$, $CeCl_3$, $SmCl_3$),[220] 9-BBN (see p. 704),[221] Et_3SiH,[222] lithium *n*-butylborohydride,[223] or diisobutylaluminum hydride,[224] which selectively reduce C=O groups in the presence of conjugated C=C bonds (see also p. 809). On the other hand, C=C bonds can be selectively reduced in the presence of conjugated C=O bonds by hydrogenation with $RhCl(PPh_3)_3$ as catalyst,[225] as well as[226] by a number of other methods.[227] $LiAlH_4$ also reduces the double bonds of allylic alcohols.[228] Furthermore, both $LiAlH_4$ and $NaBH_4$, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts, such as $FeCl_2$ or $CoBr_2$.[229]

The inertness of ordinary double bonds toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chapter 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,[230] although it does reduce alkynes, allenes, conjugated dienes,[231] and aromatic rings (**5-11**).

Another hydrogenation method is called *transfer hydrogenation*.[232] In this method the hydrogen comes from another organic molecule, which is itself oxidized. A transition-metal catalyst is frequently employed. A common reducing agent is cyclohexene, which, when a palladium catalyst is used, is oxidized to benzene, losing 2 moles of hydrogen.

Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned. The comparative reactivity of triple and double bonds depends on the catalyst.[233] With most catalysts, e.g., Pd, triple bonds are hydrogenated more easily, and therefore it is possible to add just 1 mole of hydrogen and reduce a triple bond to a double bond (usually a stereoselective syn addition) or to reduce a triple bond without affecting a double bond present in the same molecule.[234] A particularly good catalyst for this purpose is the Lindlar catalyst ($Pd\text{-}CaCO_3\text{-}PbO$).[235] Triple bonds can also be selectively reduced to double bonds with diisobutylaluminum hydride[236] or a zinc–copper couple[237] (usually a stereoselective syn addition) or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine (a stereoselective anti addition). Terminal alkynes are not reduced by the $Na\text{-}NH_3$ procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the addition to the $Na\text{-}NH_3$ solution of $(NH_4)_2SO_4$, which liberates the free ethynyl group.[238]

An indirect method[239] of double-bond reduction involves hydrolysis of boranes (prepared by **5-13**). Trialkylboranes can be hydrolyzed by refluxing with carboxylic acids,[240] while monoalkylboranes RBH_2 can be hydrolyzed with base.[241] Triple bonds can be similarly reduced, to cis olefins.[242]

Conjugated dienes can add hydrogen by 1,2 or 1,4 addition. Selective 1,4 addition can be achieved by hydrogenation in the presence of carbon monoxide, with bis(cyclopentadienyl)chromium as catalyst.[243] With allenes catalytic hydrogenation usually reduces both double bonds, but reduction of just one double bond, to give an olefin, has been accomplished by treatment with $Na\text{-}NH_3$[244] or with diisobutylaluminum hydride,[245] and by hydrogenation with $RhCl(PPh_3)_3$ as catalyst.[246]

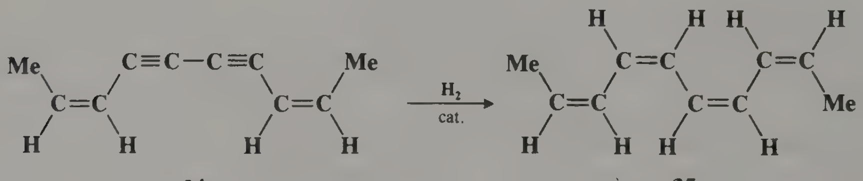
Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be syn, with the hydrogens entering from the less-hindered side of the molecule.[247] Stereospecificity can be investigated only for tetrasubstituted olefins (except when the reagent is D_2), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80 to 100% syn, though some of the anti addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes nearly always is stereoselective, giving the cis olefin (usually at least 80%), even when it is thermodynamically less stable. For example, **34** gave **35**, even though the steric hindrance is such that a planar molecule is impossible.[248] This is thus a useful method for preparing such cis olefins.[249] However, when steric hindrance is too great, the trans olefin may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogens takes place, as can be shown by hydrogenation with deuterium. Thus deuterogenation of ethylene produced all the possible deuterated ethylenes and ethanes (even C_2H_6), as well as HD.[250] With 2-butene, it was found that double-bond migration, cis–trans isomerization, and even exchange of hydrogen with groups not on the double bond could occur; e.g., $C_4H_2D_8$ and C_4HD_9 were detected on treatment of *cis*-2-butene with deuterium and a catalyst.[251] Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,[252] and even without deuterium, i.e., $CH_4 + CD_4 \rightarrow CHD_3 + CH_2D_2$ in the gas phase, with a catalyst. All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.



34

35

It was mentioned that catalytic hydrogenation of triple bonds and the reaction with diisobutylaluminum hydride usually give the cis olefin. Most of the other methods of triple-bond reduction lead to the more thermodynamically stable trans olefin. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with hydrazine or NH_2OSO_3H, which also give the cis products.

The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly

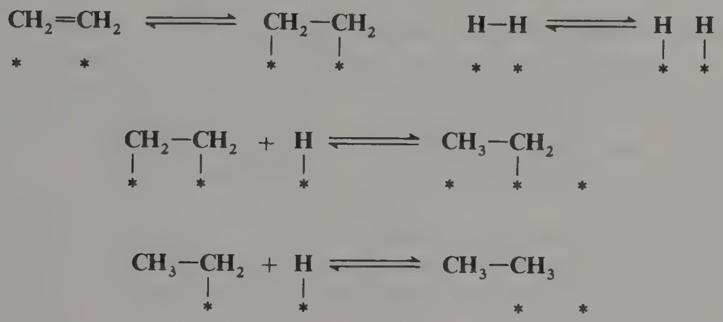
understood because it is a very difficult reaction to study.[253] Because the reaction is heterogeneous, kinetic data, though easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.[254] According to this, the olefin is adsorbed onto the surface of the metal, though the nature of the actual bonding is unknown,[255] despite many attempts to elucidate it.[256] The metallic site is usually indicated by an asterisk. For steric reasons it is apparent that adsorption of the olefin takes place with its less-hindered side attached to the catalyst surface. The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the olefin. It is likely that the H_2 molecule is cleaved to hydrogen atoms in the act of being adsorbed. It has been shown that platinum catalyzes homolytic cleavage of hydrogen molecules.[257] In the second step one of the adsorbed hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical (which is still bound to the catalyst though only by one bond) and two vacant catalyst sites. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and two more vacant sites. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process. For example, the scheme at the top of p. 698 shows the steps that may be occurring in hydrogenation of 1-butene.[258] In this scheme the normal reaction is represented by **36** → **37** → **38** → **39**, double-bond migration by **36** → **37** → **38** → **40** → **42**, cis–trans isomerization by **43** → **41** → **38** → **40** → **42**, and hydrogen exchange by **36** → **37** → **38** → **40** → **44** → **45**. Although this mechanism is satisfactory as far as it goes, there are still questions it does not answer, among them questions involving the nature of the asterisk, the nature of the bonding, and the differences caused by the differing nature of each catalyst.[259]



$$\underset{*}{CH_2}{=}\underset{*}{CH_2} \rightleftharpoons \underset{\overset{|}{*}}{CH_2}-\underset{\overset{|}{*}}{CH_2} \qquad \underset{*}{H}-\underset{*}{H} \rightleftharpoons \underset{\overset{|}{*}}{H}\;\;\underset{\overset{|}{*}}{H}$$

$$CH_3-\underset{\overset{|}{*}}{CH_2} + \underset{\overset{|}{*}}{H} \rightleftharpoons CH_3-CH_3 \quad * \quad *$$

The mechanism of homogeneous hydrogenation catalyzed by $RhCl(Ph_3P)_3$[260] involves reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (**46**), which rapidly transfers two hydrogen atoms to the alkene. The intermediate **46** can be isolated. If a mixture of H_2 and D_2

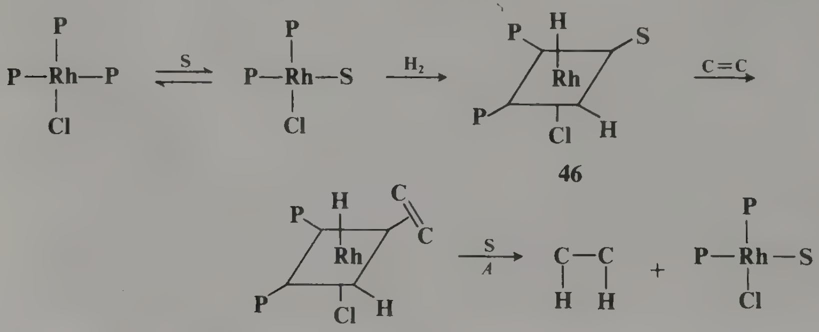
is used, the product contains only dideuterated and nondeuterated compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one olefin molecule and that no exchange takes place.[260] Although the addition is syn, there is evidence that the actual addition of the two hydrogens to the double bond (the step marked *A*) is not concerted but takes place in a stepwise fashion, at least in some cases.[261]



P = PPh_3
S = solvent

In the above-mentioned reactions with hydrazine and hydroxylamine, the actual reducing species is diimide NH=NH, which is formed from N_2H_4 by the oxidizing agent and from NH_2OH by the

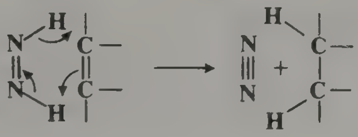
ethyl acetate.[262] Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,[263] at least in part by a cyclic mechanism:[264]



The addition is therefore stereospecifically syn[265] and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, though not much discrimination in this respect is observed where the difference in bulk effects is small.[266] Diimide reductions are most successful with symmetrical multiple bonds (C═C, C≡C, N═N) and are more difficult for those inherently polar (C≡N, C═N, C═O, etc.). Diimide is not stable enough for isolation at ordinary temperatures, although it has been prepared[267] as a yellow solid at − 196°C. Diimide can also be generated by acid treatment of potassium azodicarboxylate (KOOC—N═N—COOK)[268] and by base-catalyzed or thermal elimination of a proton and the substituent from an acyl or sulfonyl hydrazide.[269]

When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the Birch reduction (**5-11**). The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.[210] In accord with this mechanism, the reaction can be applied only to those olefins which when protonated can form a tertiary carbocation or one stabilized in some other way, e.g., by α-OR substitution.[270] It has been shown, by the detection of CIDNP, that reduction of α-methylstyrene by hydridopentacarbonylmanganese(I) $HMn(CO)_5$ involves free-radical addition.[271]

The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling[272] or by the use of one of the diimide methods.[265] Deuterium can also be regioselectively added by the hydroboration–reduction procedure previously mentioned.

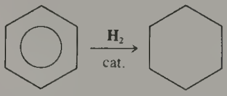
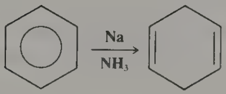
5-11 Hydrogenation of Aromatic Rings



Hexahydro-teraddition



1/4/Dihydro-addition

Aromatic rings can be reduced by catalytic hydrogenation,[273] but higher temperatures (100 to 200°C) are required than for ordinary double bonds. Though the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.[274] Mild conditions are also successful in hydrogenations with phase transfer catalysts.[275] Many functional groups, such as OH, O^-, COOH, COOR, NH_2, etc., do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH_2OH groups, which undergo hydrogenolysis to CH_3 (**0-79**). Phenols may be reduced to *cyclohexanones,* presumably through the enol. Heterocyclic compounds are often reduced. Thus furan gives tetrahydrofuran. With benzene rings it is usually impossible to stop the reaction after only one or two bonds have been reduced, since olefins are more easily reduced than aromatic rings. Thus, 1 mole of benzene, treated with 1 mole of hydrogen, gives no cyclohexadiene or cyclohexene but $\frac{1}{3}$ mole of cyclohexane and $\frac{2}{3}$ mole of recovered benzene. This is not true for all aromatic systems. With phenanthrene, for example, it is easy to stop after only the 9,10-bond has been reduced (see p. 40).

When aromatic rings are reduced by sodium (or potassium or lithium) in liquid ammonia (such reductions are known as *dissolving metal reductions*), usually in the presence of an alcohol (often ethyl, isopropyl, or *t*-butyl alcohol), 1,4 addition of hydrogen takes place and nonconjugated cyclohexadienes are produced. This reaction is called the *Birch reduction.*[276] Ammonia obtained commercially often has iron salts as impurities that lower the yield in the Birch reduction. Therefore it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the Birch reduction, electron-donating groups such as alkyl or alkoxyl decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups such as COOH or $CONH_2$ increase the reaction rate and are found on the reduced positions of the product.[277] The mechanism involves direct transfer of electrons from the metal:[278]

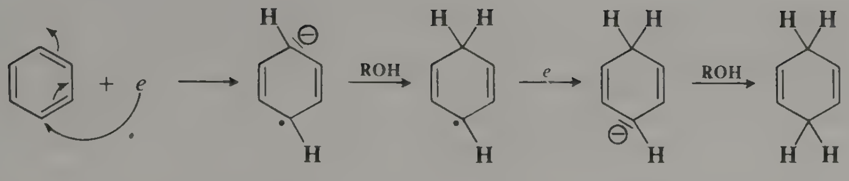
[276] For a monograph, see Akhrem, Reshotova, and Titov, "Birch Reduction of Aromatic Compounds," Plenum, New York, 1972. For reviews, see Birch and Subba Rao, *Adv. Org. Chem.* **8,** 1–65 (1972); Kaiser, *Synthesis* 391–415 (1972); Harvey, *Synthesis* 161–172 (1970); House, Ref. 128, pp. 145–150, 173–209; Hückel, *Fortschr. Chem. Forsch.* **6,** 197–250 (1966); Smith, Ref. 273, pp. 95–170.

[277] These regioselectivities have generally been explained by molecular-orbital considerations regarding the intermediates involved. For example, see Birch, Hinde, and Radom, *J. Am. Chem. Soc.* **102,** 3370, 4074, 6430 (1980); **103,** 284 (1981).

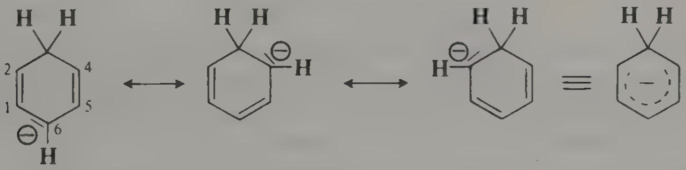


47 **48**

The sodium transfers an electron to the ring, becoming oxidized to Na^+ and creating a radical ion (**47**).[279] There is a great deal of evidence from esr spectra for these species.[280] The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **48** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **47** are frequently obtained. There is evidence[281] at least with some substrates, e.g., biphenyl, that the radical ion corresponding to **47** is converted to the carbanion corresponding to **48** by a different pathway, in which the order of the steps is reversed: first a second electron is gained to give a dianion,[279] which then acquires a proton, producing the intermediate corresponding to **48.**

Ordinary olefins are usually unaffected by Birch-reduction conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However, phenylated olefins, internal alkynes (p. 695), and conjugated olefins (with C=C or C=O) are reduced under these conditions.

It may be noted that **48** is a resonance hybrid; i.e., we can write two additional canonical forms:



The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?[281a] An answer to this question has been proposed by Hine, who has suggested that this case is an illustration of the operation of the *principle of least motion.*[282] According to this principle, "those elementary reactions will be favored that involve the least change in atomic position and electronic configuration."[282] The principle can be applied to the case at hand in the following manner (simplified): The valence-bond bond orders (p. 24) for the six carbon–carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:

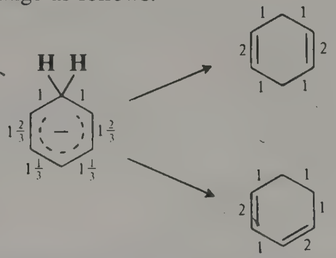
Soc.* **91,** 7144 (1969); Jochum, Gasteiger, and Ugi, *Angew. Chem. Int. Ed. Engl.* **19,** 495–505 (1980) [*Angew. Chem.* **92,** 503–513].



It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3} + \frac{1}{3} + \frac{1}{3} + \frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3} + \frac{2}{3} + \frac{2}{3} + \frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C nmr spectrum of **48** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.[283]

Reduction of aromatic rings with lithium[284] or calcium[285] in amines (instead of ammonia) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced. Another reagent reported to reduce aromatic rings to cyclohexanes is $NaBH_4$ with a rhodium chloride catalyst in ethanol.[286]

5-12 Reductive Cleavage of Cyclopropanes

Cyclopropanes can be cleaved by catalytic hydrogenolysis.[287] Among the catalysts used have been Ni, Pd, and Pt. The reaction can often be run under mild conditions.[288] Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,[289] can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.[290]

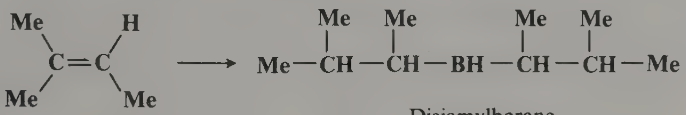
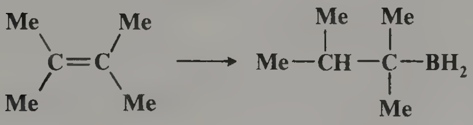
When olefins are treated with borane[291] in ether solvents, BH_3 adds across the double bond.[292] Borane cannot be prepared as a stable pure compound[293] (it dimerizes to diborane B_2H_6), but it is commercially available in the form of complexes with tetrahydrofuran, dimethyl sulfide,[294] or tertiary amines. The olefins can be treated with a solution of one of these complexes (THF-BH_3 reacts at 0°C and is the most convenient to use; R_3N-BH_3 generally require temperatures of about 100°C; however, the latter can be prepared as air-stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture in air) or with a mixture of $NaBH_4$ and BF_3 etherate (or $NaBH_4$ and acetic acid[295]), which generates borane in situ. Ordinarily, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of olefin to give R_2BH, which in turn adds to a third olefin molecule, so that the isolated product is a trialkylborane R_3B. The reaction can be performed on alkenes with one to four substituents, including cyclic olefins, but when the olefin is moderately hindered,[296] the product *is* the dialkylborane R_2BH or even the monoalkylborane RBH_2.[297] For example, **49** (*disiamylborane*), **50** (*thexylborane*),[298] and **52** have been prepared in this manner:



Disiamylborane

49



Thexylborane

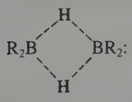
[296] Hydroboration of hindered olefins can be performed under high pressure: Rice and Okamoto, *J. Org. Chem.* **47,** 4189 (1982).

[297] Unless coordinated with a strong Lewis base such as a tertiary amine, mono and dialkylboranes actually exist as dimers, e.g.,

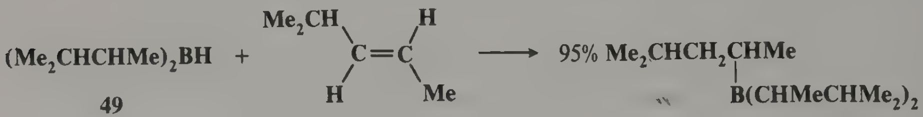


: Brown and Klender, *Inorg. Chem.* **1,** 204 (1962).

[298] For a review of the chemistry of thexylborane, see Negishi and Brown, *Synthesis* 77–89 (1974).

Monoalkylboranes RBH_2 (which can be prepared from hindered olefins, as above) and dialkylboranes R_2BH also add to olefins, to give the mixed trialkylboranes $RR_2'B$ and $R_2R'B$,[299] respectively.[300]

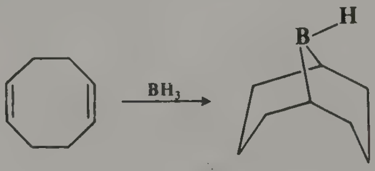
In all cases the boron goes to the side of the double bond that has more hydrogens, whether the substituents are aryl or alkyl.[301] Thus the reaction of **51** with BH_3 gives 98% **52** and only 2% of the other product. This actually follows Markovnikov's rule, since boron is more positive than hydrogen. However, the regioselectivity is caused mostly by steric factors, though electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of substituted styrenes showed that the attack by boron has electrophilic character.[302] When both sides of the double bond are monosubstituted or both disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large attacking molecule. For example, treatment of iso-PrCH═CHMe with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with disiamylborane (**49**) gave 95% of **53** and only 5% of the other isomer.[303]



49

53

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN), which is prepared by hydroboration of 1,5-cyclooctadiene:[304]



9-BBN

9-BBN has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are far more selective and will preferentially attack less-hindered bonds, so that it is often possible to hydroborate one double bond in a molecule selectively and leave others unaffected or to hydroborate one olefin in the presence of a less reactive olefin.[305] For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a cis olefin can be selectively hydroborated in a mixture of the cis and trans isomers.

Another hydroboration reagent with even greater regioselectivity than BH_3 (for terminal alkenes or those of the form $R_2C{=}CHR$) is monochloroborane[306] BH_2Cl coordinated with dimethyl sulfide (the hydroboration product is a dialkylchloroborane R_2BCl).[307] For example, 1-hexene gave 94% of the anti-Markovnikov product with BH_3-THF, but 99.2% with BH_2Cl-SMe_2. Treatment of alkenes with dichloroborane-dimethyl sulfide $BHCl_2$-SMe_2 in the presence of BF_3 gives alkyldichloroboranes $RBCl_2$.[308]

An important use of the hydroboration reaction is that alkylboranes, when oxidized with hydrogen peroxide and NaOH, are converted to alcohols (**2-26**). This is therefore an indirect way of adding H_2O across a double bond in an anti-Markovnikov manner. However, boranes undergo other reactions as well. Among other things, they react with α-halo carbonyl compounds to give alkylated products (**0-101**), with α,β-unsaturated carbonyl compounds to give Michael-type addition of R and H (**5-19**), with CO to give alcohols and ketones (**8-26** to **8-28**); they can be reduced with carboxylic acids, providing an indirect method for reduction of double bonds (reaction **5-10**), or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketones[309] or aldehydes (from terminal olefins),[310] dimerized with silver nitrate and NaOH (**4-35**), isomerized (**8-13**), or converted to amines (**2-29**) or halides (**2-28**). They are thus useful intermediates for the preparation of a wide variety of compounds.

Besides alkyl and aryl groups, such functional groups as OR, OH, NH_2, SMe, halogen, and COOR may be present in the molecule,[311] but not groups that are reducible by borane.

Use of the reagent diisopinocampheylborane **54** (prepared by treating optically active α-pinene with BH_3) results in enantioselective hydroboration–oxidation.[312] Alcohols with optical purities as high as 98% have been obtained in this way.[313] However, **54** does not give good results with even moderately hindered alkenes; better reagents for these compounds are isopinocampheylborane[314] and dilongifolyborane,[315] though optical yields are lower. The method has been improved[315a] by synthesizing the chiral isopinocampheylborane in the presence of tetramethylenediamine (TMED), whereupon a TMED–isopinocampheylborane adduct is formed. This adduct, in Et_2O, reacts with a prochiral alkene to give a dialkylborane RBHR′ (R′ = isocampheyl). The RBHR′ crystallizes from THF in 99–100% optical purity (the other diastereomer remains in solution). The optically

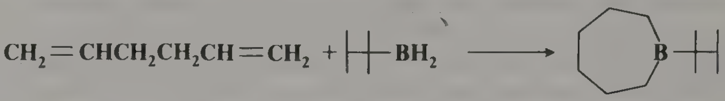
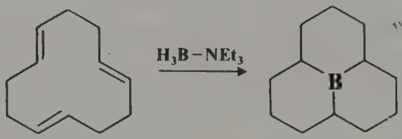
pure RBHR′ is treated with acetaldehyde to produce α-pinene and optically pure R_2BH, which can be converted to optically pure alcohols or to other products. Since both (+) and (−) α-pinene are readily available, both enantiomers can be prepared.

The double bonds in a conjugated diene are hydroborated separately, i.e., there is no 1,4 addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane[298] (**50**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated,[316] e.g.,



50

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.[317] One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene:[318]



Triple bonds[319] can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to cis alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed at **5-3.** However, terminal alkynes give vinylic boranes[320] (and hence aldehydes) only when treated with a hindered borane such as **49, 50,** or catecholborane (p. 552),[321] or with $BHBr_2$-SMe_2.[322] The reaction between terminal alkynes and BH_3 produces 1,1-dibora compounds, which can be oxidized either to primary alcohols (with NaOH-H_2O_2) or to carboxylic acids (with

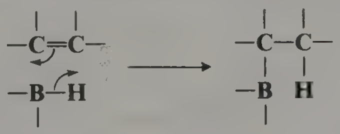
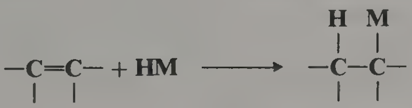
m-chloroperbenzoic acid).[323] Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.[324] On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.[325]

The addition in hydroboration has been shown to be stereospecific and syn, with attack taking place from the less-hindered side.[326] The mechanism[327] may be a cyclic four-center one:[328]



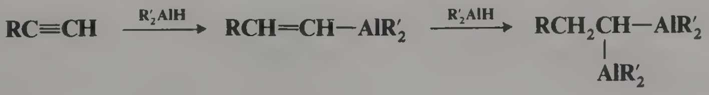
OS **50,** 88; **52,** 59; **53,** 77; **58,** 32; **61,** 103.

5-14 Other Hydrometalation
Hydro-metallo-addition



$$-\underset{|}{C}=\underset{|}{C}- + HM \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{M}{|}}{C}}-$$

Metal hydrides of groups IIIA and IVA of the periodic table (e.g., AlH_3, GaH_3) as well as many of their alkyl and aryl derivatives (e.g., R_2AlH, Ar_3SnH) add to double bonds to give organometallic compounds.[329] The hydroboration reaction (**5-13**) is the most important example, but other important metals in this reaction are aluminum, silicon, tin,[330] and zirconium[331] (a group IVB metal). The mechanism with group IIIA hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with group IVA hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesiums have been obtained by adding MgH_2 to double bonds.[332] With some reagents triple bonds[333] can add 1 or 2 moles, e.g.,[334]



$$RC\equiv CH \xrightarrow{R'_2AlH} RCH=CH-AlR'_2 \xrightarrow{R'_2AlH} RCH_2\underset{\underset{AlR'_2}{|}}{CH}-AlR'_2$$

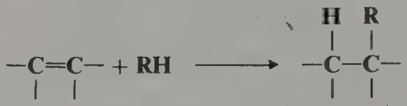
When 2 moles are added, electrophilic addition generally gives 1,1-dimetallic products (as with hydroboration), while free-radical addition usually gives the 1,2-dimetallic products.

G. Carbon on the Other Side

5-15 Addition of Alkanes and Alkenes
Hydro-alkyl-addition

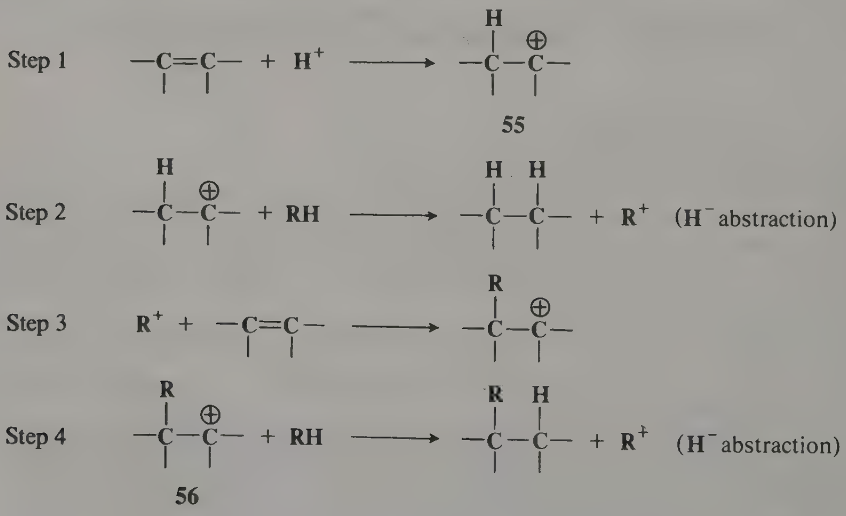


$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + RH \longrightarrow -\overset{H}{\underset{|}{\overset{|}{C}}}-\overset{R}{\underset{|}{\overset{|}{C}}}-$$

There are two important ways of adding alkanes to olefins—the thermal method and the acid-catalysis method.[335] Both give chiefly mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method the reactants are heated to high temperatures (about 500°C) at high pressures (150 to 300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.[336] The mechanism is undoubtedly of a free-radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:

$$\begin{array}{lrcl}
\text{Step 1} & CH_3CH_2CH_3 & \xrightarrow{\Delta} & CH_3\cdot + CH_3CH_2\cdot \\
\text{Step 2} & CH_3\cdot + CH_3CH_2CH_3 & \longrightarrow & CH_4 + CH_3\underset{\bullet}{C}HCH_3 \\
\text{Step 3} & CH_3\underset{\bullet}{C}HCH_3 + CH_2{=}CH_2 & \longrightarrow & (CH_3)_2CHCH_2CH_2\cdot \\
\text{Step 4} & (CH_3)_2CHCH_2CH_2\cdot + CH_3CH_2CH_3 & \longrightarrow & (CH_3)_2CHCH_2CH_3 + CH_3\underset{\bullet}{C}HCH_3
\end{array}$$

In the acid-catalysis method, a proton or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between −30 and 100°C. This is a Friedel–Crafts process with a carbocation mechanism (illustrated for a proton acid catalyst):



---

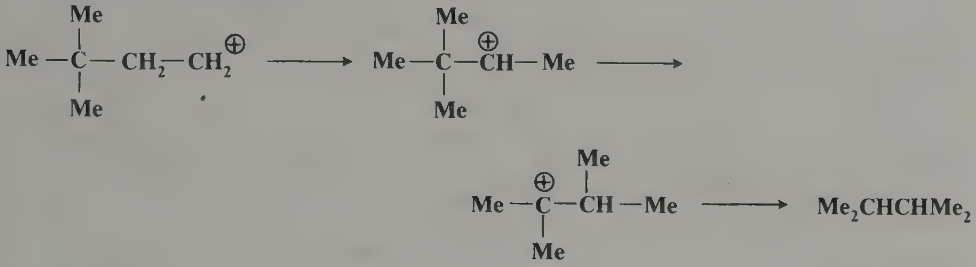
[336] Frey and Hepp, *Ind. Eng. Chem.* **28,** 1439 (1936).

56 often rearranges before it abstracts a hydride ion, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane:



$$\mathrm{Me{-}\overset{\displaystyle Me}{\underset{\displaystyle Me}{C}}{-}CH_2{-}\overset{\oplus}{C}H_2} \longrightarrow \mathrm{Me{-}\overset{\displaystyle Me}{\underset{\displaystyle Me}{C}}{-}\overset{\oplus}{C}H{-}Me} \longrightarrow \mathrm{Me{-}\overset{\oplus}{\underset{\displaystyle Me}{C}}{-}\overset{\displaystyle Me}{C}H{-}Me} \longrightarrow \mathrm{Me_2CHCHMe_2}$$

It is also possible for **55** (or **56**) instead of abstracting a hydride ion, to add to another mole of olefin, so that not only rearrangement products but also dimeric and polymeric products are frequent.

The addition of secondary or tertiary cations (generated from the corresponding alcohols, esters, or alkenes) to 1,1-dichloroethene gives carboxylic acids by hydrolysis of the intermediate ions (see **0-3**):[337]

$$\mathrm{R_3C^+ + CH_2{=}CCl_2 \longrightarrow R_3C{-}CH_2{-}\overset{\oplus}{C}Cl_2 \xrightarrow{H_2O} R_3CCH_2COOH}$$

The reaction may also be base-catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.[338] Carbanions most often used are those stabilized by one or more α-aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane:[339]

$$\mathrm{PhCH_3 \xrightarrow{Na} Ph\bar{C}H_2^{\ominus} + PhCH{=}CH_2 \longrightarrow Ph\overset{\ominus}{\bar{C}}H{-}CH_2CH_2Ph \xrightarrow{solvent} PhCH_2CH_2CH_2Ph}$$

Conjugated dienes give 1,4 addition.[340] This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids[341] (see also **0-98**):

$$\mathrm{CH_3COOK \xrightarrow{NaNH_2} \overset{\ominus}{\bar{C}}H_2COOK + CH_2{=}CH_2 \longrightarrow \overset{\ominus}{\bar{C}}H_2{-}CH_2CH_2COOK}$$

It is possible in the acid-catalyzed process for an olefin to add to an olefin so that the product is a dimer that contains one double bond, e.g., $\mathrm{CH_2{=}CH_2 + CH_2{=}CH_2 \rightarrow CH_2{=}CHCH_2CH_3}$. This reaction has also been carried out internally, e.g.,

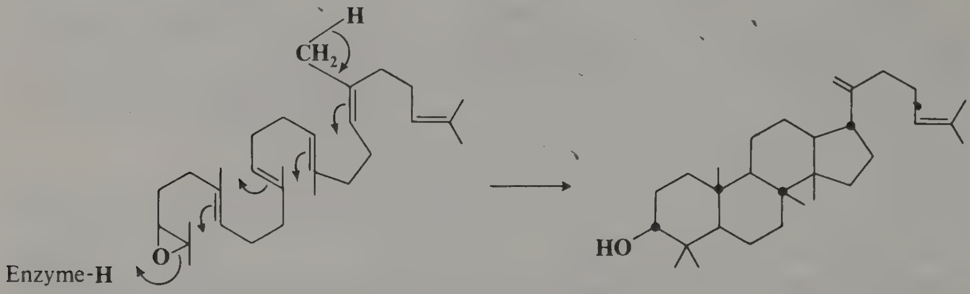
Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymic catalysis to dammaradienol.

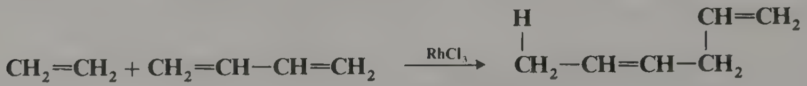


Squalene 2,3-oxide

Dammaradienol

The squalene → lanosterol biosynthesis (which is a key step in the biosynthesis of cholesterol) is similar.[342]

The addition of olefins to olefins can also be accomplished by bases[343] as well as by the use of catalyst systems[344] consisting of nickel complexes and alkylaluminum compounds (known as *Ziegler catalysts*)[345] and by catalysts derived from rhodium chloride.[346] These and similar catalysts also catalyze the 1,4-addition of olefins to dienes,[347] e.g.,



$$CH_2{=}CH_2 + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow{RhCl_3} \overset{\displaystyle H}{\overset{|}{C}}H_2{-}CH{=}CH{-}\overset{\displaystyle CH{=}CH_2}{\overset{|}{C}}H_2$$

In the presence of cuprous chloride and ammonium chloride, acetylene adds to another molecule of itself to give vinylacetylene.

$$HC{\equiv}CH + HC{\equiv}CH \xrightarrow[NH_4Cl]{CuCl} HC{\equiv}C{-}CH{=}CH_2$$

This type of alkyne dimerization is also catalyzed by certain nickel complexes, as well as other catalysts.[348]

Olefins and alkynes may also add to each other to give cyclic products (see **5-48** and **5-50**).

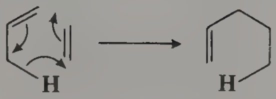
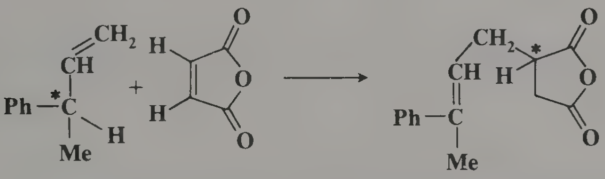
5-16 The Ene Synthesis
Hydro-allyl-addition

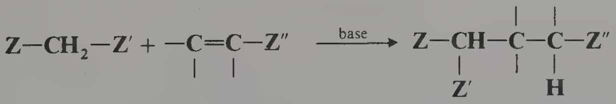


Olefins can add to double bonds in a reaction different from those discussed in **5-15,** which, however, is still formally the addition of RH to a double bond. This reaction is called the *ene synthesis*[349] and bears a certain similarity to the Diels–Alder reaction (**5-47**). For the reaction to proceed without a catalyst, one of the components must be a reactive dienophile (see **5-47** for a definition of this word) such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene such as propene. There has been much discussion of the mechanism of this reaction, and both concerted pericyclic (as shown above) and stepwise mechanisms have been suggested. The reaction between maleic anhydride and optically active $PhCHMeCH{=}CH_2$ gave an optically active product,[350] which is strong evidence for a concerted rather than a stepwise mechanism.[351] The reaction can be extended to less-reactive enophiles by the use of Lewis-acid catalysts, especially alkylaluminum halides.[352]



OS **IV,** 766; **V,** 459.

5-17 The Michael Reaction
Hydro-bis(ethoxycarbonyl)methyl-addition, etc.



$$Z{-}CH_2{-}Z' + {-}\underset{|}{C}{=}\underset{|}{C}{-}Z'' \xrightarrow{\text{base}} Z{-}\underset{\underset{Z'}{|}}{CH}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{\underset{H}{|}}{C}}{-}Z''$$

Compounds containing electron-withdrawing groups (Z is defined on p. 664) add, in the presence of bases, to olefins of the form C=C—Z (including quinones). This is called the *Michael reaction* and involves conjugate addition.[353] The base removes the acidic proton and then the mechanism is as outlined on p. 664. The reaction has been carried out with malonates, cyanoacetates, acetoacetates, other β-keto esters, and compounds of the form Z—CH_3, ZCH_2R, $ZCHR_2$, and $ZCHRZ'$, including esters, ketones, aldehydes, nitriles, nitro compounds,[354] and sulfones, as well as other compounds with relatively acidic hydrogens, such as indenes and fluorenes. These reagents do not add to ordinary double bonds, except in the presence of free-radical initiators (**5-21**). 1,2 addition (to the C═O or C≡N group) often competes and sometimes predominates (**6-42**). In particular, α,β-unsaturated *aldehydes* seldom give 1,4 addition.[355]

[351] For other evidence for a concerted mechanism, see Benn, Dwyer, and Chappell, *J. Chem. Soc., Perkin Trans. 2* 533 (1977).

[352] For a review, see Snider, *Acc. Chem. Res.* **13,** 426–432 (1980).

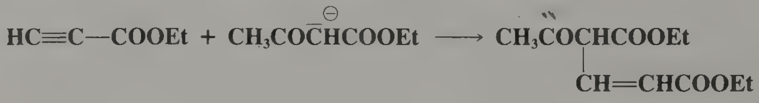
[353] For reviews, see Bergmann, Ginsburg, and Pappo, *Org. React.* **10,** 179–560 (1959); House, Ref. 128, pp. 595–623. The subject is also discussed at many places in Stowell, "Carbanions in Organic Synthesis," Wiley, New York, 1979.

Mannich bases (see **6-16**) and β-halo carbonyl compounds can also be used as substrates; these are converted to the C═C—Z compounds in situ by the base (**6-16, 7-14**).[356] Substrates of this kind are especially useful in cases where the C═C—Z compound is unstable. The reaction of C═C—Z compounds with enamines (**2-17**) can also be considered a Michael reaction. Michael reactions are reversible (**7-20**).

The ketene thioacetal monoxide $CH_2{=}C(SMe)SOMe$ (**57**) reacts with ZCH_2Z' compounds to give adducts that can be hydrolyzed to the substituted aldehydes $ZCHZ'CH_2CHO$.[357] **57** is thus a synthon for the —CH_2CHO group. This reaction has been performed with Z, Z′ = COR and COOR, as well as with simple esters $R'CH_2COOR$ and with enamines (see **2-17**).

The Michael reaction has been performed diastereoselectively and enantioselectively.[358]

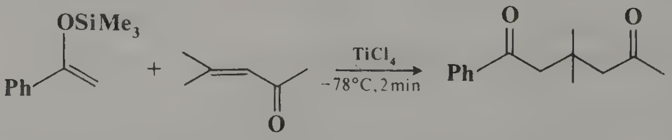
Michael reactions are sometimes applied to substrates of the type C≡C—Z, e.g.,



$$HC{\equiv}C{-}COOEt + CH_3CO\overset{\ominus}{C}HCOOEt \longrightarrow CH_3CO\underset{\displaystyle CH{=}CHCOOEt}{\underset{|}{C}}HCOOEt$$

Indeed, because of the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes, e.g., acetylene, to be substrates in this reaction.[359]

In a closely related reaction, silyl enol ethers add to α,β-unsaturated ketones and esters when catalyzed by $TiCl_4$, e.g.,[360]



Allylic silanes $R_2C{=}CHCH_2SiMe_3$ may be used instead of silyl enol ethers.[361]

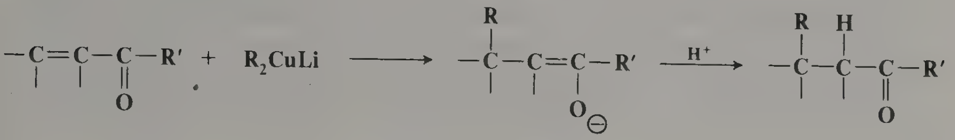
5-18 1,4 Addition of Organometallic Compounds to Activated Double Bonds

Hydro-alkyl-addition



58

Lithium dialkylcopper reagents (see **0-88**) adds to α,β-unsaturated aldehydes[362] and ketones (R′ = H, R, Ar) to give conjugate addition products[363] in a reaction closely related to the Michael reaction. α,β-Unsaturated esters are less reactive, and the corresponding acids do not react at all. R may be primary alkyl, vinyl, or aryl. Various functional groups such as OH and unconjugated C═O groups may be present in the substrate. A characteristic of the reaction is that only one of the R groups of R_2CuLi adds to the substrate; the other is wasted. This can be a limitation where the precursor (RLi or RCu, see p. 402) is expensive or available in limited amounts. The difficulty can be overcome by using one of the mixed reagents $R(R'C{\equiv}C)CuLi$,[364] R(O—*t*-Bu)CuLi,[365] or R(PhS)CuLi,[366] each of which transfers only the R group. These reagents are easily prepared by the reaction of RLi with $R'C{\equiv}CCu$ (R′ = *n*-Pr or *t*-Bu), *t*-BuOCu, or PhSCu, respectively. A further advantage of these mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents R(CN)CuLI[367] (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$[368] also selectively transfer the R group. The reagent $(H_2C{=}C[OMe])_2CuLi$ transfers the $H_2C{=}C(OMe)$ group, which can be hydrolyzed to CH_3—CO.[369] Another way to avoid waste is to use a reagent derived from equimolar amounts of RLi and CuI along with 2 to 3 moles of *n*-Bu_3P.[370] Conjugate addition to α,β-unsaturated and acetylenic acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $RCu \cdot BF_3$ (R = primary).[371] Some of these reagents have been shown to add diastereoselectively to chiral substrates.[371a]

There is generally little or no competition from 1,2 addition (to the C═O).However, when R is allyl, 1,4 addition is observed with some substrates and 1,2 addition with others.[372] R_2CuLi also add to α,β-unsaturated sulfones ($C{=}C{-}SO_2Ar$)[373] but not to simple α,β-unsaturated nitriles.[374]

[362] Chuit, Foulon, and Normant, *Tetrahedron* **36,** 2305 (1980); **37,** 1385 (1981). For a review, see Alexakis, Chuit, Commerçon-Bourgain, Foulon, Jabri, Mangeney, and Normant, *Pure Appl. Chem.* **56,** 91–98 (1984). A better reagent for the addition of a methyl group to an α,β-unsaturated aldehyde is $Me_5Cu_3Li_2$: Clive, Farina, and Beaulieu, *J. Org. Chem.* **47,** 2572 (1982).

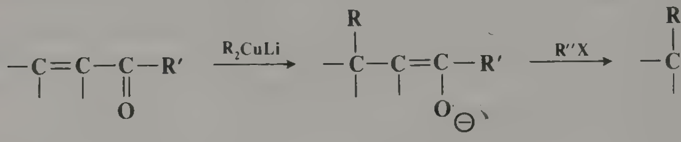
[373] Posner and Brunelle, *Tetrahedron Lett.* 935 (1973).

[374] House and Umen, Ref. 364.

Organocopper reagents RCu (as well as certain R_2CuLi) add to α,β-unsaturated and acetylenic sulfoxides C═C—SOR and C≡C—SOR.[375]

When the solvent is 1,2-dimethoxyethane, instead of hydrolyzing the enolate ion **58,** it is possible to alkylate it directly with an alkyl halide, where R″ is primary alkyl or allylic[376] (**0-97**). Thus, by

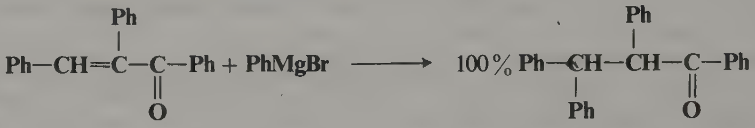


$$-\underset{|}{C}=\underset{|}{C}-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{R_2CuLi} -\overset{\overset{R}{|}}{\underset{|}{C}}-\underset{|}{C}=\underset{\underset{O^{\ominus}}{|}}{C}-R' \xrightarrow{R''X} -\overset{\overset{R}{|}}{\underset{|}{C}}-\overset{\overset{R''}{|}}{\underset{|}{C}}-\underset{\underset{O}{\|}}{C}-R'$$

58

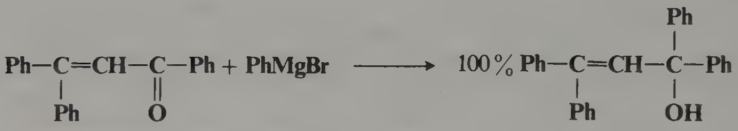
this method, both the α and β positions of a ketone are alkylated in one synthetic operation (see also **5-52**).

Grignard reagents also add to these substrates, but with these reagents, 1,2 addition may seriously compete:[377] the product is often controlled by steric factors. Thus **59** with phenylmagnesium bromide gives 100% 1,4 addition, while **60** gives 100% 1,2 addition:



$$Ph-CH=\overset{\overset{Ph}{|}}{C}-\underset{\underset{O}{\|}}{C}-Ph + PhMgBr \longrightarrow 100\%\ Ph-\underset{\underset{Ph}{|}}{CH}-\overset{\overset{Ph}{|}}{CH}-\underset{\underset{O}{\|}}{C}-Ph$$

59



$$Ph-\underset{\underset{Ph}{|}}{C}=CH-\underset{\underset{O}{\|}}{C}-Ph + PhMgBr \longrightarrow 100\%\ Ph-\underset{\underset{Ph}{|}}{C}=CH-\overset{\overset{Ph}{|}}{\underset{\underset{OH}{|}}{C}}-Ph$$

60

In general, substitution at the carbonyl group increases 1,4 addition, while substitution at the double bond increases 1,2 addition. In most cases both products are obtained, but α,β-unsaturated *aldehydes* nearly always give exclusive 1,2 addition when treated with Grignard reagents. However, the extent of 1,4 addition of Grignard reagents can be increased by the use of a copper ion catalyst, e.g., CuCl, $Cu(OAc)_2$.[378] It is likely that alkylcopper reagents, formed from RMgX and Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual attacking species in these cases.[363] Alkyllithiums, treated with compounds of the form $C{=}C{-}COCH_3$ and $C{=}C{-}COOC_2H_5$, gave only 1,2 addition,[379] but alkyllithiums can be made to give 1,4 addition with α,β-unsaturated ketones[380] and aldehydes[381] if the reactions are conducted in the presence of HMPT. Among alkyllithiums that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see **0-99**).[382]

1,4 Addition of alkyllithiums to α,β-unsaturated aldehydes can also be achieved by converting the aldehyde to a benzothiazole derivative (masking the aldehyde function),[383] from which the aldehyde group can be regenerated.

However, neither Grignard reagents nor lithium dialkylcopper reagents generally add to ordinary C═C double bonds. Grignard reagents in general add only to double bonds susceptible to nucleophilic attack, e.g., fluoroolefins and tetracyanoethylene.[384] However, active Grignard reagents (benzyl, allyl) also add to the double bonds[384a] of allylic amines,[385] and of allylic and homoallylic alcohols,[386] as well as to the triple bonds of propargyl alcohols and certain other alkynols.[387] It is likely that cyclic intermediates are involved in these cases, in which the magnesium coordinates with the hetero atom. Organolithium reagents (primary, secondary, and tertiary alkyl and in some cases aryl) also add to the double and triple bonds of allylic and propargylic alcohols[388] (in this case tetramethylethylenediamine is a catalyst) and to certain other olefins containing hetero groups such as OR, NR_2, or SR.[389] Allylic, benzylic, and tertiary Grignard reagents also add to 1-alkenes and strained internal alkenes, e.g., norbornene, if the reaction is carried out not in ether but in a hydrocarbon solvent such as pentane or in the alkene itself as solvent, heated, under pressure if necessary, to 60 to 130°C.[390] Yields are variable. *Intramolecular* addition of RMgX to completely unactivated double and triple bonds has been demonstrated,[391] e.g., refluxing of 6-chloro-1-heptene with Mg for 5 hr gave, after hydrolysis, an 88% yield of 1,2-dimethylcyclopentane.

An alkynyl group can be added to the double bond of an α,β-unsaturated ketone by use of the diethylalkynylalane reagents $Et_2AlC{\equiv}CR$.[392] In a similar manner, the alkenyl reagents $R_2AlCH{=}CR'$ transfer an alkenyl group.[393] Trialkylalanes R_3Al also add 1,4 to such ketones in the presence of nickel acetylacetonate.[394] Also used for 1,4 addition to these ketones are trialkylzinclithium reagents R_3ZnLi,[395] arylpalladium compounds,[395a] and arylmercury compounds with phase transfer catalysts.[396] Trialkylalanes R_3Al and dialkylzinc compounds R_2Zn add to triple bonds in the presence of a zirconium complex.[397]

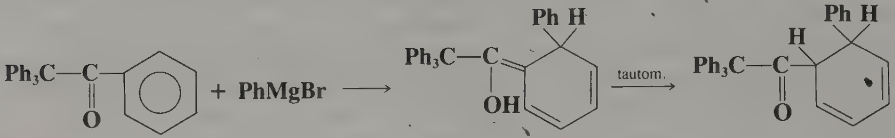
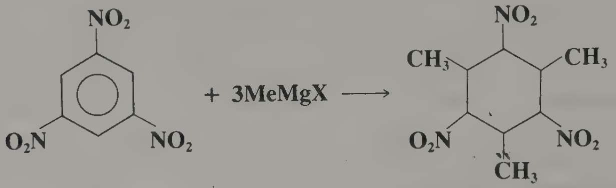
In certain cases, Grignard reagents add 1,4 to *aromatic* systems, e.g.,[398]

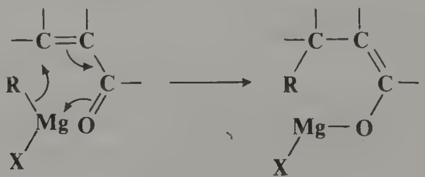


Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so that this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds:[399]



Both Grignard and R_2CuLi reagents[400] have also been added to triple-bond systems of the form C≡C—C═O.[401]

The mechanisms of most of these reactions are not well known. The 1,4 uncatalyzed Grignard reaction has been postulated to proceed by a cyclic mechanism



but there is evidence against it.[402] The R_2CuLi and copper-catalyzed Grignard additions may involve a free-radical mechanism of some type,[403] though the fact that retention of configuration at R has been demonstrated in several cases rules out a completely free R• radical.[404] The addition of R_3Al takes place by a free-radical mechanism.[394]

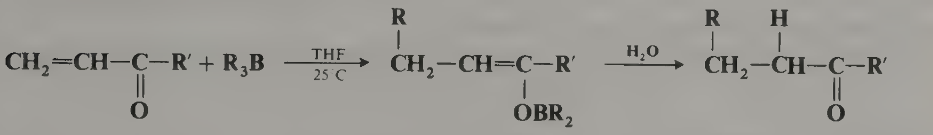
5-19 The Addition of Boranes to Activated Double Bonds

Hydro-alkyl-addition (overall transformation)



$$\mathrm{CH_2{=}CH{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R' + R_3B \xrightarrow[25^\circ C]{THF} \overset{\overset{\displaystyle R}{|}}{CH_2}{-}CH{=}\underset{\underset{\displaystyle OBR_2}{|}}{C}{-}R' \xrightarrow{H_2O} \overset{\overset{\displaystyle R}{|}}{CH_2}{-}\overset{\overset{\displaystyle H}{|}}{CH}{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}$$

$R' = H, Me$

Trialkylboranes rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain of their derivatives in THF at 25°C to give enol borinates, which can be hydrolyzed to aldehydes or ketones.[405] The water may be present from the beginning, so that the reaction can be run in one laboratory step. Since the boranes can be prepared from olefins (**5-13**), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group, such as crotonaldehyde $CH_3CH{=}CHCHO$ and 3-penten-2-one, fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or uv light.[406] As in the Michael reaction, the α,β-unsaturated compound can be generated in situ from the corresponding Mannich base (reaction **6-16**).[407] A disadvantage is that only one of the three R groups of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a B-alkyl borinate such as **61,**[408] which can be prepared as shown. **61** (R = *t*-butyl) can be made by treatment of **61** (R = OMe) with *t*-BuLi. The use of this reagent permits *t*-butyl groups to be added. B-1-Alkenyl-9-BBN compounds B-RCH=CR′-9-BBN (prepared by treatment of alkynes with 9-BBN) add to methyl vinyl ketones to give, after hydrolysis, γ,δ-unsaturated ketones,[409] though B-R-9-BBN, where R = a saturated group, are not useful here, because the R group of these reagents does not preferentially add to the substrate.[408] The corresponding B-1-alkynyl-9-BBN

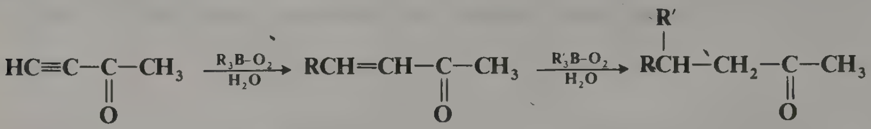
compounds also give the reaction.[410] Like the three substrates mentioned above, 3-butyn-2-one fails to react in the absence of air but undergoes the reaction when exposed to a slow stream of air:[411]



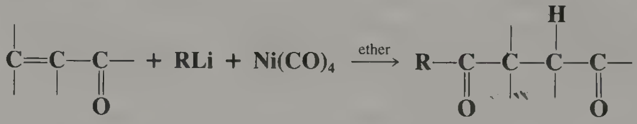
$$HC\equiv C-\underset{\underset{O}{\|}}{C}-CH_3 \xrightarrow[H_2O]{R_3B-O_2} RCH=CH-\underset{\underset{O}{\|}}{C}-CH_3 \xrightarrow[H_2O]{R'_3B-O_2} R\overset{\overset{R'}{|}}{C}H-CH_2-\underset{\underset{O}{\|}}{C}-CH_3$$

62

Since the product is an α,β-unsaturated ketone, it can be made to react with another BR_3, the same or different, to produce a wide variety of ketones **62.**

The fact that these reactions are catalyzed by free-radical initiators and inhibited by galvinoxyl[412] (a free-radical inhibitor) indicates that free-radical mechanisms are involved.

5-20 Acylation of Activated Double Bonds and of Triple Bonds
Hydro-acyl-addition

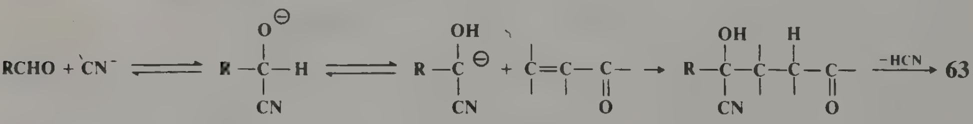


$$\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}-\underset{\underset{O}{\|}}{C}- + RLi + Ni(CO)_4 \xrightarrow{\text{ether}} R-\underset{\underset{O}{\|}}{C}-\overset{|}{\underset{|}{C}}-\overset{\overset{H}{|}}{\underset{|}{C}}-\underset{\underset{O}{\|}}{C}-$$

63

An acyl group can be introduced into the 4 position of an α,β-unsaturated ketone by treatment with an organolithium compound and nickel carbonyl.[413] The product is a 1,4-diketone. R may be aryl or primary alkyl. The reaction can also be applied to alkynes (which need not be activated), in which case 2 moles add and the product is also a 1,4-diketone, e.g., $R'C\equiv CH \rightarrow RCOCHR'CH_2COR$.[414]

Another method involves treatment with an aldehyde and cyanide ion (see **6-49**) in a polar aprotic solvent such as DMF or Me_2SO.[415]



$$RCHO + CN^- \rightleftharpoons R-\overset{\overset{O^{\ominus}}{|}}{\underset{\underset{CN}{|}}{C}}-H \rightleftharpoons R-\overset{\overset{OH}{|}}{\underset{\underset{CN}{|}}{C}}{}^{\ominus} + \overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}-\underset{\underset{O}{\|}}{C}- \rightarrow R-\overset{\overset{OH}{|}}{\underset{\underset{CN}{|}}{C}}-\overset{|}{\underset{|}{C}}-\overset{\overset{H}{|}}{\underset{|}{C}}-\underset{\underset{O}{\|}}{C}- \xrightarrow{-HCN} 63$$

64

This method has been applied to α,β-unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ-keto esters, and γ-keto nitriles, respectively (see also **6-55**). The ion **64** is a synthon for the unavailable $R\overset{\ominus}{\bar{C}}{=}O$ anion (see also p. 418); it is a masked $R\overset{\ominus}{\bar{C}}{=}O$ anion. Other masked carbanions that have been used in this reaction are the $EtS\overset{\ominus}{\bar{C}}RSOEt$ ion[416] (see p.

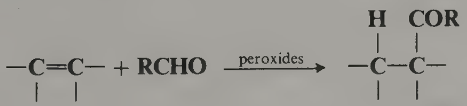
[415] For a review, see Stetter, *Angew. Chem. Int. Ed. Engl.* **15,** 639–647 (1976) [*Angew. Chem.* **88,** 695–704]. For a similar method involving thiazolium salts, see Stetter and Kuhlmann, *Chem. Ber.* **109,** 2890 (1976); Stetter and Mertens, *Liebigs Ann. Chem.* 1550 (1980).

[416] Herrmann, Richman, and Schlessinger, *Tetrahedron Lett.* 3271, 3275 (1973).

422), the $CH_2{=}\overset{\ominus}{\bar{C}}OEt$ ion,[417] $CH_2{=}C(OEt)Cu_2Li$,[418] $CH_2{=}CMe(SiMe_3)$,[418] and the $R\bar{C}^{\ominus}(OCHMeOEt)CN$ ion[419] (see p. 418). In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes (**0-99**) do not give 1,4 addition to these substrates (except in the presence of HMPT, see **5-18**) but add 1,2 to the C=O group instead (**6-42**).

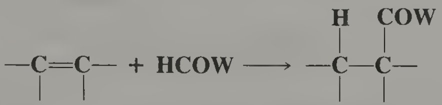
OS **59,** 53.

5-21 Addition of Alcohols, Amines, Esters, Aldehydes, etc.
Hydro-acyl-addition, etc.



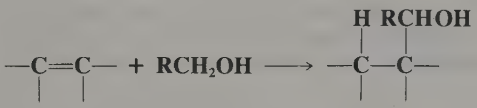
$$-\underset{|}{C}{=}\underset{|}{C}- + \mathbf{RCHO} \xrightarrow{\text{peroxides}} -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{COR}{|}}{C}}-$$

Aldehydes, formates, primary, and secondary alcohols, amines, ethers, alkyl halides, compounds of the type Z—CH_2—Z′, and a few other compounds add to double bonds in the presence of free-radical initiators.[420] This is formally the addition of RH to a double bond, but the "R" is not just any carbon but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as on p. 412). The addition of aldehydes is illustrated above. Formates and formamides[421] add similarly:



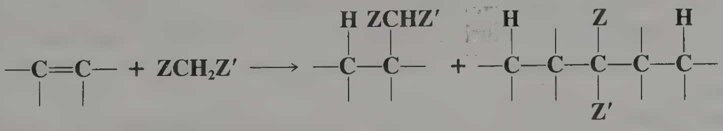
$$-\underset{|}{C}{=}\underset{|}{C}- + \mathbf{HCOW} \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{COW}{|}}{C}}- \qquad W = OR, NH_2$$

Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):



$$-\underset{|}{C}{=}\underset{|}{C}- + \mathbf{RCH_2OH} \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{RCHOH}{|}}{C}}-$$

ZCH_2Z' compounds react at the carbon bearing the active hydrogen:[422]



$$-\underset{|}{C}{=}\underset{|}{C}- + \mathbf{ZCH_2Z'} \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{ZCHZ'}{|}}{C}}- + -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{|}{C}}-\underset{\underset{Z'}{|}}{\overset{\overset{Z}{|}}{C}}-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{\overset{H}{|}}{C}}-$$

Similar additions have been successfully carried out with carboxylic acids, anhydrides,[423] cyclic ketones,[424] acyl halides, esters, nitriles, and other types of compounds.[425]

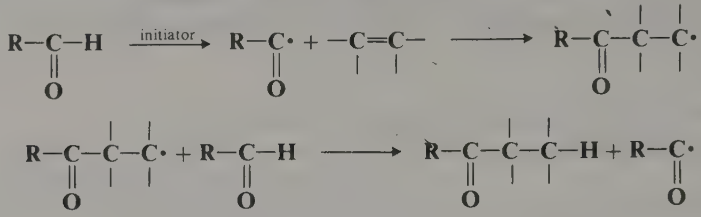
These reactions are not successful when the olefin contains electron-withdrawing groups such as halo or carbonyl groups. A free-radical initiator is required, usually peroxides or uv light. The mechanism is illustrated for aldehydes but is similar for the other compounds:



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}H} \xrightarrow{\text{initiator}} \mathrm{R{-}\underset{\underset{O}{\|}}{C}\cdot} + \mathrm{{-}\underset{|}{C}{=}\underset{|}{C}{-}} \longrightarrow \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\cdot}$$

$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\cdot} + \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}H} \longrightarrow \mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}H} + \mathrm{R{-}\underset{\underset{O}{\|}}{C}\cdot}$$

etc.

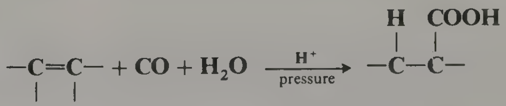
Polymers are often side products.

Similar reactions have been carried out on acetylene.[426]

OS **IV,** 430; **V,** 93; **55,** 57; **58,** 79.

5-22 Hydrocarboxylation

Hydro-carboxy-addition



$$\mathrm{{-}\underset{|}{C}{=}\underset{|}{C}{-}} + \mathrm{CO} + \mathrm{H_2O} \xrightarrow[\text{pressure}]{\mathrm{H^+}} \mathrm{{-}\overset{\overset{H}{|}}{C}{-}\overset{\overset{COOH}{|}}{C}{-}}$$

The acid-catalyzed hydrocarboxylation of olefins (the *Koch reaction*) can be performed in a number of ways.[427] In one method, the olefin is treated with carbon monoxide and water at 100 to 350°C and 500 to 1000 atm pressure with a mineral-acid catalyst. However, the reaction can also be performed under milder conditions. If the olefin is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0 to 50°C and 1 to 100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.[428] The formic acid procedure is called the *Koch–Haaf reaction* (the Koch–Haaf reaction can also be applied to alcohols, see **0-105**). Nearly all olefins can be hydrocarboxylated by one or more of these procedures. However, conjugated dienes are polymerized instead. If the olefin contains a functional group such as OH, NH_2, or $CONH_2$, the corresponding lactone (**0-24**), lactam (**0-56**), or cyclic imide may be the product.[429] Cyclic ketones can be produced from 1,5- and 1,6-dienes.

Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. This is more often applied to triple bonds to give α,β-unsaturated acids, in which cases the conditions are milder still. Acid catalysts are used along with the nickel carbonyl, but basic catalysts may also be employed.[430] Other metallic salts and complexes, e.g., bis(triphenylphosphine)palladium dichloride $(Ph_3P)_2PdCl_2$,[431] have also been used.

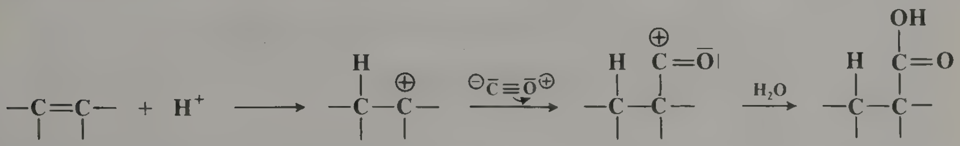
In another method, the palladium chloride complex of the olefin is treated with CO in ethanol at about 100°C.[432] The product in this case is the ethyl ester.

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism[433] involves initial attack by a proton, followed by attack of the resulting carbocation on carbon monoxide to give an acyl cation, which, with water, gives the product:



Therefore, Markovnikov's rule is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

For the nickel carbonyl reaction, the addition is syn for both alkenes and alkynes.[434] The following mechanism has been proposed:[434]

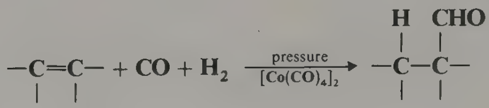
[434] Bird, Cookson, Hudec, and Williams, *J. Chem. Soc.* 410 (1963).

Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

In either the acid catalysis or the nickel carbonyl (or other metallic catalyst) method, if alcohols, mercaptans, amines, etc. are used instead of water, the product is the corresponding ester, thiol ester, or amide, instead of the carboxylic acid.

5-23 Hydroformylation
Hydro-formyl-addition



$$-\underset{|}{C}=\underset{|}{C}- + CO + H_2 \xrightarrow[{[Co(CO)_4]_2}]{\text{pressure}} -\underset{|}{\overset{\overset{H}{|}}{C}}-\underset{|}{\overset{\overset{CHO}{|}}{C}}-$$

Olefins can be hydroformylated[435] by treatment with carbon monoxide and hydrogen over a catalyst that is usually a cobalt carbonyl but may also be a rhodium complex[436] [e.g., hydridocarbonyltris(triphenylphosphine)rhodium] or another transition-metal compound. Commercially, this is called the *oxo process,* but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal olefins > straight-chain internal olefins > branched-chain olefins. Conjugated dienes give dialdehydes when rhodium catalysts are used[437] but saturated monoaldehydes (the second double bond is reduced) with cobalt carbonyls. Many functional groups, e.g., OH, CHO, COOR, CN, may be present in the molecule, though halogens usually interfere. Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.[438] Among the side reactions are aldol condensation (**6-40**), acetal formation, the Tishchenko reaction (**9-71**), and polymerization. Stereoselective syn addition has been reported.[439] Asymmetric hydroformylation has been accomplished with a chiral catalyst.[440]

When dicobalt octacarbonyl $[Co(CO)_4]_2$ is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt $HCo(CO)_3$.[441] Carbonylation $RCo(CO)_3 + CO \rightarrow RCo(CO)_4$ takes place, followed by a rearrangement and a reduction of the C—Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in **5-22.** The reducing agent in the reduction step is tetracarbonylhydrocobalt $HCo(CO)_4$,[442] or possibly under some conditions, H_2. Alcohols can be obtained by allowing the reduction to continue after all the carbon monoxide is used up. It has been shown[443] that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that $HCo(CO)_3$ is the reducing agent.

Res.* **14,** 259–266 (1981).

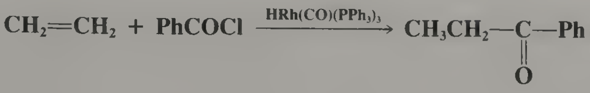
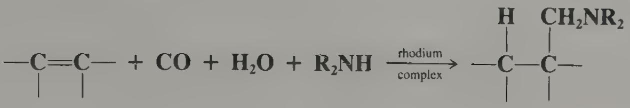
An indirect method for the hydroformylation of olefins involves formation of the trialkylborane (**5-13**) and treatment of this with carbon monoxide and a reducing agent (see **8-28**). *Hydroacylation* of alkenes has been accomplished, in variable yields, by treatment with an acyl halide and a rhodium complex catalyst, e.g.,[444]



$$CH_2{=}CH_2 + PhCOCl \xrightarrow{HRh(CO)(PPh_3)_3} CH_3CH_2{-}\underset{\underset{O}{\|}}{C}{-}Ph$$

OS **57**, 11.

5-24 Aminomethylation of Alkenes
Hydro-dialkylaminoalkyl-addition

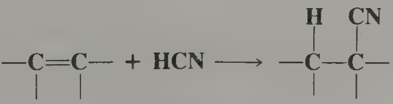


$$-\underset{|}{C}{=}\underset{|}{C}- + CO + H_2O + R_2NH \xrightarrow[\text{complex}]{\text{rhodium}} -\underset{|}{\overset{\overset{H}{|}}{C}}{-}\underset{|}{\overset{\overset{CH_2NR_2}{|}}{C}}-$$

65

Alkenes react with carbon monoxide, water, and a secondary amine to give the tertiary amines **65.** A catalyst is required; rhodium complexes give the highest yields.[445]

5-25 Addition of HCN
Hydro-cyano-addition



$$-\underset{|}{C}{=}\underset{|}{C}- + HCN \longrightarrow -\underset{|}{\overset{\overset{H}{|}}{C}}{-}\underset{|}{\overset{\overset{CN}{|}}{C}}-$$

Ordinary olefins do not react with HCN, but polyhalo olefins and olefins of the form C=C—Z add HCN to give nitriles.[446] The reaction is therefore a nucleophilic addition and is base-catalyzed.[447] When Z is COR or, more especially, CHO, 1,2 addition (**6-51**) is an important competing reaction and may be the only reaction. Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH_4Cl, and HCl or by Ni or Pd compounds.[448] One or two moles of HCN may be added to a triple bond, since the initial product is a Michael-type substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides, e.g., Et_2AlCN, or mixtures of HCN and trialkylalanes R_3Al are especially good reagents for conjugate addition of HCN[449] to α,β-unsaturated ketones and α,β-unsaturated acyl halides. HCN may be added to ordinary olefins in the presence of dicobalt octacarbonyl[450] or certain other transition-metal compounds.[451] *t*-Butyl isocyanide and $TiCl_4$ have been used to add HCN to C═C—Z olefins.[452]

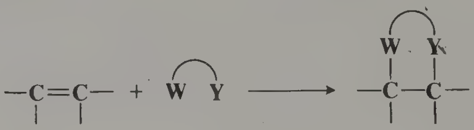
5-26 Addition of ArH

See **1-13** (Friedel–Crafts alkylation).

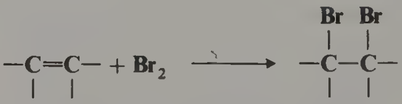
Reactions in Which Hydrogen Adds to Neither Side

Some of these reactions are *cycloadditions* (reactions **5-37, 5-38, 5-42, 5-44,** and **5-46** to **5-51**). In such cases addition to the multiple bond closes a ring:



A. Halogen on One or Both Sides

5-27 Halogenation of Double and Triple Bonds (Addition of Halogen, Halogen) **Dihalo-addition**



$$-\underset{|}{C}=\underset{|}{C}- + Br_2 \longrightarrow -\underset{|}{\overset{Br}{\overset{|}{C}}}-\underset{|}{\overset{Br}{\overset{|}{C}}}-$$

Most double bonds are easily halogenated with bromine, chlorine, or interhalogen compounds.[453] Iodination has also been accomplished, but the reaction is slower.[454] Under free-radical conditions, iodination proceeds more easily.[455] However, *vic*-diiodides are generally unstable and tend to revert to iodine and the olefin. The order of activity for some of the reagents is $BrCl > ICl > Br_2 > IBr > I_2$.[456] Mixed halogenations have also been achieved by other methods. Mixtures of Br_2 and Cl_2 have been used to give bromochlorination;[457] iodochlorination has been achieved with $CuCl_2$ and either I_2, HI, CdI_2, or other iodine donors;[458] iodofluorination[459] with mixtures of AgF and I_2;[460] and mixtures of N-bromo amides in anhydrous HF give bromofluorination.[461] Bromo-, iodo-, and chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2, I_2, or an N-chloro-, N-bromo-, or N-iodo amide in polyhydrogen fluoride–pyridine.[462] Under ordinary conditions fluorine itself is too reactive to give simple addition; it attacks other bonds and mixtures are obtained.[463] However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures ($-78°C$).[464] Addition of fluorine has also been accomplished with other reagents, e.g., CoF_3;[465] XeF_2;[466] and a mixture of PbO_2 and SF_4.[467]

The reaction with bromine is very rapid and is easily carried out at room temperature. Bromine is often used as a test, qualitative or quantitative, for unsaturation.[468] The vast majority of double bonds can be successfully brominated. Even when aldehyde, ketone, amine, etc., functions are present in the molecule, they do not interfere, since the reaction with double bonds is faster.

Several other reagents add Cl_2 to double bonds, among them NCl_3,[469] SO_2Cl_2,[470] PCl_5,[471] $SbCl_5$,[472] $MoCl_5$,[473] and iodobenzene dichloride $PhICl_2$.[474] A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide $C_5H_5NH^+ Br_3^-$.[475] Br_2 or Cl_2 can also be added with $CuBr_2$ or $CuCl_2$ in the presence of a compound such as acetonitrile, methanol, or triphenylphosphine.[476]

The mechanism is usually electrophilic (see p. 660), but when free-radical initiators (or uv light) are present, then addition may occur by a free-radical mechanism.[477] Once Br• or Cl• radicals are formed, however, substitution may compete (**4-1** and **4-2**). This is especially important when the olefin has allylic hydrogens. Under free-radical conditions (uv light) bromine or chlorine adds to the benzene ring to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see p. 113).[478]

Conjugated systems give both 1,2 and 1,4 addition.[478] Triple bonds add bromine, although generally more slowly than double bonds (see p. 671). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Two moles of bromine may be added to triple bonds to give tetrabromo products. There is evidence that the addition of the first mole of bromine to a triple bond may take place by a nucleophilic mechanism.[479] With allenes it is very easy to stop the reaction after only 1 mole has added, to give X—C—CX=C.[480] In most cases a second mole of halogen can be added only by forced treatment. Addition of halogen to ketenes gives α-halo acyl halides, but the yields are not good.

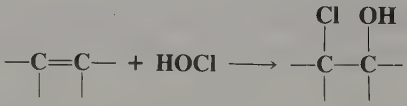
5-28 Addition of Hypohalous Acids and Hypohalites (Addition of Halogen, Oxygen)

Hydroxy-chloro-addition, etc.[481]



$$-\underset{|}{C}=\underset{|}{C}- + \text{HOCl} \longrightarrow -\underset{|}{\overset{\overset{\text{Cl}}{|}}{C}}-\underset{|}{\overset{\overset{\text{OH}}{|}}{C}}-$$

HOCl, HOBr, and HOI can be added to olefins to produce halohydrins.[482] HOBr and HOCl are often generated in situ by the reaction between water and Br_2 or Cl_2, respectively. HOI, generated from I_2 and H_2O, also adds to double bonds, if the reaction is carried out in tetramethylene sulfone–$CHCl_3$[483] or if an oxidizing agent such as HIO_3 is present.[484] HOF has also been added, but this reagent is difficult to prepare in a pure state and detonations occur.[485] HOBr can also be conveniently added by the use of a reagent consisting of an N-bromo amide [e.g., N-bromosuccinimide (NBS) or N-bromoacetamide] and a small amount of water in a solvent such as dimethyl sulfoxide or dioxane.[486] Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T ($TsNCl^- \ Na^+$)[487] in acetone–water.[487a]

The mechanism of HOX addition is electrophilic, with initial attack by the positive halogen end of the HOX dipole. Following Markovnikov's rule, the positive halogen goes to the side of the double bond that has more hydrogens. The resulting carbocation (or bromonium or iodonium ion) reacts with OH^- or H_2O to give the product. If the substrate is treated with Br_2 or Cl_2 (or another source of positive halogen such as NBS or BrN_3[488]) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly, $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OR$ or $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OCOR$, respectively (see also **5-36**). Even the weak nucleophile $CF_3SO_2O^-$ can participate in the second step: The addition of Cl_2 or Br_2 to olefins in the presence of this ion resulted in the formation of some β-haloalkyl triflates.[489] There is evidence that the mechanism with Cl_2 and H_2O is different from that with HOCl.[490] HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds —CX_2—CO—.

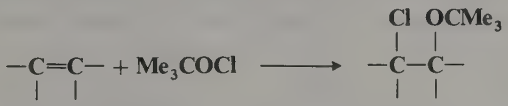
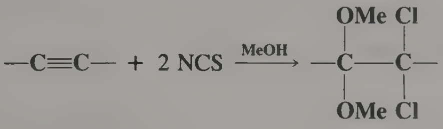
t-Butyl hypochlorite, hypobromite, and hypoiodite[491] add to double bonds to give *t*-butyl ethers, e.g.,



$$-\underset{|}{C}=\underset{|}{C}- + Me_3COCl \longrightarrow -\overset{\overset{Cl}{|}}{\underset{|}{C}}-\overset{\overset{OCMe_3}{|}}{\underset{|}{C}}-$$

This is a convenient method for the preparation of tertiary ethers. When Me_3COCl or Me_3COBr is added to olefins in the presence of excess ROH, the ether produced is $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OR$.[492] Vinyl ethers give β-halo acetals.[493] Two moles of "MeOCl" can be added to triple bonds by treatment with N-chlorosuccinimide in methanol.[494]



$$-C\equiv C- + 2\ NCS \xrightarrow{MeOH} -\overset{\overset{OMe}{|}}{\underset{\underset{OMe}{|}}{C}}-\overset{\overset{Cl}{|}}{\underset{\underset{Cl}{|}}{C}}-$$

These acetals can then be hydrolyzed to α,α-dichloro ketones. Chlorine acetate [solutions of which are prepared by treating Cl_2 with $Hg(OAc)_2$ in an appropriate solvent] adds to olefins to give acetoxy chlorides.[495] The latter are also produced by treatment of olefins with a mixture of $PdCl_2$ and $CuCl_2$ in acetic acid[496] or with chromyl chloride CrO_2Cl_2 in acetyl chloride.[497]

For a method of iodoacetyl addition, see **5-36.**

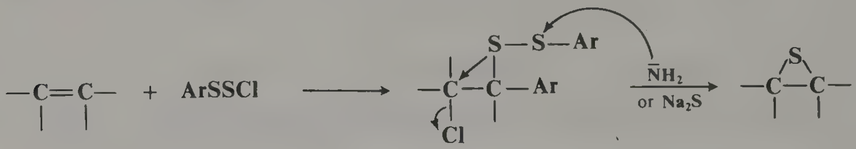
[498] When a general group (such as halo) is used, its priority is that of the lowest member of its group (see footnote 481). Thus the general name for this transformation is halo-alkylsulfonyl-addition, because "halo" has the same priority as "fluoro," its lowest member.

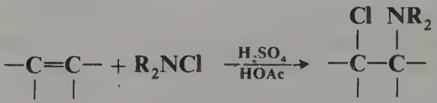
Sulfonyl halides add to double bonds, to give β-halo sulfones, in the presence of free-radical initiators. A particularly good catalyst is cuprous chloride.[499] Triple bonds behave similarly, to give β-halo-α,β-unsaturated sulfones.[500] In a similar reaction, sulfenyl chlorides, RSCl, give β-halo thioethers, $\mathrm{Cl{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}SR}$.[501] The latter may be free-radical or electrophilic additions, depending on conditions. Other sulfur compounds also add to double bonds by free-radical mechanisms.[502] β-Iodo thiocyanates can be prepared from alkenes by treatment with I_2 and KSCN.[503] Bromothiocyanation can be accomplished with Br_2 and thallium(I) thiocyanate.[504]

β-Halo disulfides, formed by addition of arenethiosulfenyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.[505]



The overall episufidation is a stereospecific syn addition.

5-30 Addition of Halogen and an Amino Group (Addition of Halogen, Nitrogen)
Dialkylamino-chloro-addition



$$\mathrm{-\underset{|}{C}{=}\underset{|}{C}- + R_2NCl \xrightarrow[HOAc]{H_2SO_4} -\overset{\overset{Cl}{|}}{\underset{|}{C}}-\overset{\overset{NR_2}{|}}{\underset{|}{C}}-}$$

The groups R_2N and Cl can be added directly to olefins, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-N-chloroamines and acids.[506] These are free-radical additions, with initial attack by the $R_2NH\cdot^+$ radical ion.[507] N-Halo amides RCONHX add RCONH and X to double bonds under the influence of uv light or chromous chloride.[508] For an indirect way of adding NH_2 and I to a double bond, see reaction **5-33.**

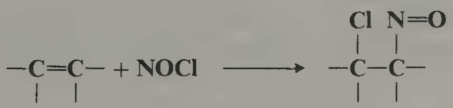
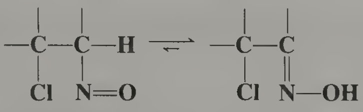
5-31 Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)

Nitroso-chloro-addition



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + \text{NOCl} \longrightarrow -\overset{\text{Cl}}{\underset{|}{\overset{|}{C}}}-\overset{\text{N=O}}{\underset{|}{\overset{|}{C}}}-$$

There are three possible products when NOCl is added to olefins.[509] The initial product is always the β-halo nitroso compound, but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime:



$$-\underset{\text{Cl}}{\underset{|}{\overset{|}{C}}}-\underset{\text{N=O}}{\underset{|}{\overset{|}{C}}}-\text{H} \rightleftharpoons -\underset{\text{Cl}}{\underset{|}{\overset{|}{C}}}-\underset{\text{N—OH}}{\underset{\|}{\overset{|}{C}}}$$

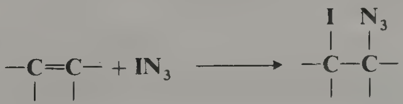
With some olefins, the initial β-halo nitroso compound is oxidized by the NOCl to a β-halo nitro compound.[510] Many functional groups can be present without interference, e.g., COOH, COOR, CN, OR. The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, although syn addition has been reported in some cases.[511] Markovnikov's rule is followed, the positive NO going to the carbon that has more hydrogens.

Nitryl chloride NO_2Cl also adds to olefins, to give β-halo nitro compounds, but this is a free-radical process. The NO_2 goes to the less-substituted carbon.[512] Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro olefins.[513] FNO_2 can be added to olefins[514] by treatment with HF in HNO_3[515] or by addition of the olefin to a solution of nitronium tetrafluoroborate NO_2^+ BF_4^- (see **1-2**) in 70% polyhydrogen fluoride–pyridine solution[516] (see also **5-27**).

OS **IV,** 711; **V,** 266, 863; **56,** 65.

5-32 Addition of XN_3 (Addition of Halogen, Nitrogen)

Azido-iodo-addition



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + IN_3 \longrightarrow -\overset{\text{I}}{\underset{|}{\overset{|}{C}}}-\overset{N_3}{\underset{|}{\overset{|}{C}}}-$$

The addition of iodine azide to double bonds gives β-iodo azides.[517] The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate (see p. 661).[518] The reaction has been performed on many double-bond compounds, including α,β-unsaturated ketones. Similar reactions can be performed with BrN_3 and ClN_3. 1,4 addition has been found with acylic conjugated dienes.[519] In the case of BrN_3 both electrophilic and free-radical mechanisms are important,[520] while with ClN_3 the additions are chiefly free-radical.[521] IN_3 also adds to triple bonds to give β-iodo-α,β-unsaturated azides.[522]

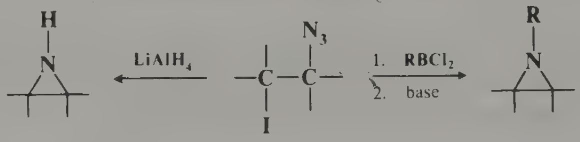
[517] For reviews, see Dehnicke, *Angew. Chem. Int. Ed. Engl.* **18,** 507–514 (1979) [*Angew. Chem.* **91,** 527–534]; Hassner, *Acc. Chem. Res.* **4,** 9–16 (1971); Biffin, Miller, and Paul, Ref. 185, pp. 136–147.

[518] See however Cambie, Hayward, Rutledge, Smith-Palmer, Swedlund, and Woodgate, *J. Chem. Soc., Perkin Trans. 1* 180 (1979).

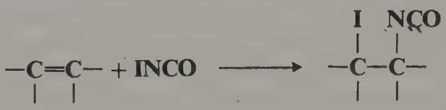
β-iodo azides can be reduced to aziridines with $LiAlH_4$[523] or converted to N-alkyl- or N-arylaziridines by treatment with an alkyl- or aryldichloroborane followed by a base.[524] In both cases



the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (reaction **0-45**) follows.

OS **57,** 83.

5-33 Addition of INCO (Addition of Halogen, Nitrogen)
Isocyanato-iodo-addition

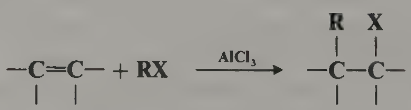


$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + \text{INCO} \longrightarrow -\overset{\text{I}}{\overset{|}{\underset{|}{C}}}-\overset{\text{NCO}}{\overset{|}{\underset{|}{C}}}-$$

In a reaction similar to **5-32,** iodine isocyanate adds to double bonds to give β-iodo isocyanates.[525] The addition is stereospecific and anti; the mechanism similar to that shown in **5-32.** The reaction has been applied to mono-, di-, and some trisubstituted olefins. The orientation generally follows Markovnikov's rule, the positive iodine adding to the less highly substituted side. α,β-Unsaturated carbonyl compounds do not react. Triple bonds give β-iodo-α,β-unsaturated isocyanates in low yields.[526] Allenes add 1 mole of INCO to give β-iodo-β,γ-unsaturated isocyanates.[527] Since an isocyanate group can be hydrolyzed to an amino group ($RNCO \rightarrow RNH_2$, **6-3**), the method is an indirect way of adding H_2N and I to double bonds.

OS **51,** 112.

5-34 Addition of Alkyl Halides (Addition of Halogen, Carbon)
Alkyl-halo-addition[498]



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + \text{RX} \xrightarrow{\text{AlCl}_3} -\overset{\text{R}}{\overset{|}{\underset{|}{C}}}-\overset{\text{X}}{\overset{|}{\underset{|}{C}}}-$$

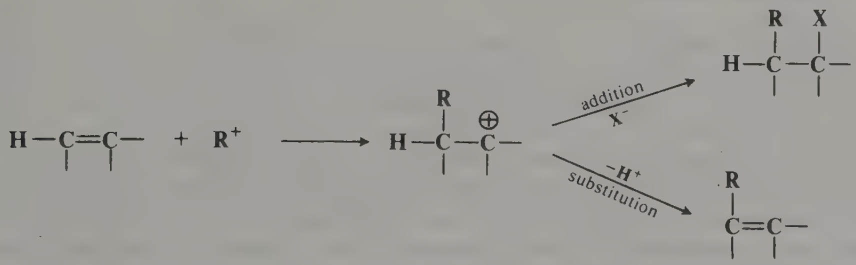
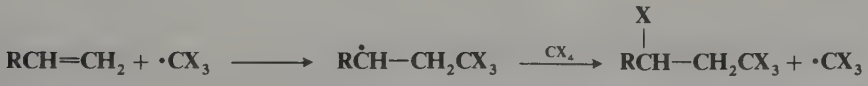
Alkyl halides can be added to olefins in the presence of a Friedel–Crafts catalyst, most often $AlCl_3$.[528] The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with **1-13**). Methyl and ethyl halides, which cannot rearrange, give no reaction at all. The attacking species is the carbocation formed from the alkyl halide and the catalyst (see **1-13**). The addition therefore follows Markovnikov's rule, with the cation going to the carbon with more hydrogens. Substitution is a side reaction, arising from loss of hydrogen from the carbocation formed when the original carbocation attacks the double bond:



Conjugated dienes can add 1,4.[529] Triple bonds also undergo the reaction, to give vinyl halides.[530]

CCl_4, $BrCCl_3$, ICF_3, and similar simple polyhalo alkanes add to olefins in good yield.[531] These are free-radical additions and require initiation by peroxides, metal halides (e.g., $FeCl_2$, CuCl),[532] dichlorotris(triphenylphosphine)ruthenium(II),[533] or uv light. The initial attack is by the carbon, and it goes to the carbon with more hydrogens, as in most free-radical attack:



$$\mathrm{RCH{=}CH_2 + \cdot CX_3 \longrightarrow R\dot{C}H{-}CH_2CX_3 \xrightarrow{CX_4} R\overset{X}{\overset{|}{C}}H{-}CH_2CX_3 + \cdot CX_3}$$

This type of polyhalo alkane adds to halogenated olefins in the presence of $AlCl_3$ by an electrophilic mechanism. This is called the *Prins reaction* (not to be confused with the other Prins reaction, **6-53**).[534]

ArX can be added across double bonds, in a free-radical process, by treatment of olefins with diazonium salts, though Meerwein arylation (substitution) (**4-17**) competes.[535] This addition may be either 1,2 or 1,4 with conjugated dienes.[536] Addition of ArX can also be accomplished by treatment with an arylmercury halide ArHgX in the presence of CuX_2, LiX, and a palladium compound catalyst, usually Li_2PdCl_4.[537] In this case also, substitution (**4-18**) is a side reaction. Yields of addition product are increased by increasing the concentration of CuX_2. Palladium compounds also catalyze the addition of allylic halides to alkynes.[538]

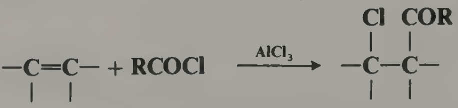
OS **II,** 312; **IV,** 727; **V,** 1076; **51,** 1.

5-35 Addition of Acyl Halides (Addition of Halogen, Carbon)
Acyl-halo-addition



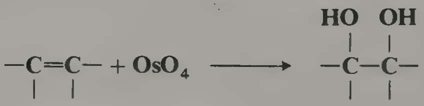
$$-\underset{|}{C}=\underset{|}{C}- + RCOCl \xrightarrow{AlCl_3} -\underset{|}{\overset{Cl}{\overset{|}{C}}}-\underset{|}{\overset{COR}{\overset{|}{C}}}-$$

Acyl halides have been added to many olefins, in the presence of Friedel–Crafts catalysts. The reaction has been applied to straight-chain, branched, and cyclic olefins, but to very few containing functional groups, except halogen.[539] The mechanism is similar to that of **5-34,** and, as in that case, substitution competes (**2-14**). Increasing temperature favors substitution,[540] and good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates. The reaction can be performed on triple-bond compounds, producing compounds of the form $RCO-\underset{|}{C}=\underset{|}{C}-Cl$.[541] A *formyl* group and a halogen can be added to triple bonds by treatment with N,N-disubstituted formamides and $POCl_3$ (Vilsmeier conditions, see **1-16**).[542]

OS **IV,** 186; **51,** 115.

B. Oxygen or Nitrogen on One or Both Sides

5-36 Hydroxylation (Addition of Oxygen, Oxygen)
Dihydroxy-addition



$$-\underset{|}{C}=\underset{|}{C}- + OsO_4 \longrightarrow -\underset{|}{\overset{HO}{\overset{|}{C}}}-\underset{|}{\overset{OH}{\overset{|}{C}}}-$$

There are many reagents that add two OH groups to a double bond.[543] OsO_4[544] and alkaline $KMnO_4$ give syn addition, from the less-hindered side of the double bond.[545] Osmium tetroxide adds rather slowly but almost quantitatively. The cyclic ester **66** is an intermediate and can be isolated, but is usually decomposed in solution, with sodium sulfite in ethanol or other reagents. Bases catalyze the reaction by coordinating with the ester. The chief drawback to this reaction is that OsO_4 is expensive and highly toxic, so that its use has been limited to small-scale preparations of scarce materials. However, the same result (syn addition) can be accomplished more economically by the use of H_2O_2, with OsO_4 present in catalytic amounts.[546] *t*-Butyl hydroperoxide in alkaline solution[547] and N-methylmorpholine-N-oxide[548] have been substituted for H_2O_2 in this procedure.

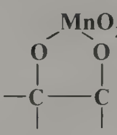
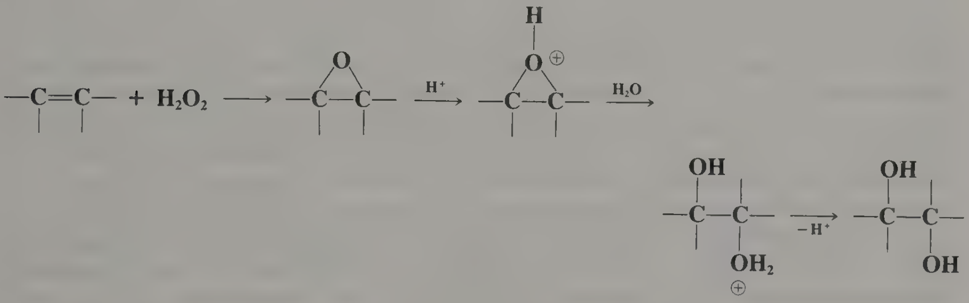
66



67

Potassium permanganate is a strong oxidizing agent and can oxidize the glycols[549] that are the products of this reaction (see **9-7** and **9-10**). In acid and neutral solution it always does so; hence it is not feasible to prepare glycols in this manner. Glycols can be prepared with alkaline permanganate, but the conditions must be mild. Even so, yields are seldom above 50%, though they can be improved with phase transfer catalysis[550] or increased stirring.[550a] As with OsO_4, it is likely that cyclic esters (**67**) are intermediates; species believed to be such intermediates have been detected spectrally.[551] This reaction is the basis of the *Baeyer test* for the presence of double bonds.

Anti hydroxylation can be achieved by treatment with H_2O_2 and formic acid. In this case, epoxidation (**5-37**) occurs first, followed by an SN2 reaction, which results in overall anti addition:



The same result can be achieved in one step with monopersuccinic acid.[552] Overall anti addition can also be achieved by the method of Prevost. In this method the olefin is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate (**68**). These can be isolated, and this represents a method of addition of IOCOPh. However, under the normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction, and it operates by the neighboring-group mechanism (p. 268), so that the groups are still anti:

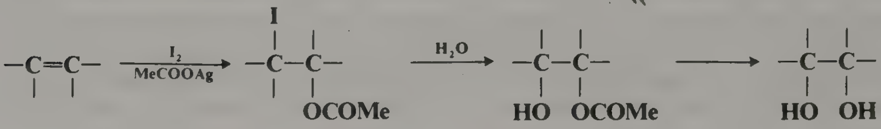
$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- \xrightarrow[\text{PhCOOAg}]{I_2} -\overset{I}{\underset{|}{C}}-\overset{|}{\underset{OCOPh}{C}}- \longrightarrow -\overset{PhCOO}{\underset{|}{C}}-\overset{|}{\underset{OCOPh}{C}}- \longrightarrow -\overset{OH}{\underset{|}{C}}-\overset{|}{\underset{OH}{C}}-$$

68

Hydrolysis of the ester does not change the configuration. Woodward's method is similar, but results in overall syn hydroxylation. The olefin is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water.[553] Here again, the initial product is a β-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal SN2 process, so that the monoacetate is syn.



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- \xrightarrow[\text{MeCOOAg}]{I_2} -\overset{I}{\underset{|}{C}}-\overset{|}{\underset{OCOMe}{C}}- \xrightarrow{H_2O} -\overset{|}{\underset{HO}{C}}-\overset{|}{\underset{OCOMe}{C}}- \longrightarrow -\overset{|}{\underset{HO}{C}}-\overset{|}{\underset{OH}{C}}-$$

Hydrolysis gives the glycol that is the product of overall syn addition. With cyclic trisubstituted olefins, both the Woodward and the Prevost methods may give allylic alcohols and ketones rather than the normal products.[554] Although the Woodward method results in overall syn addition, the product may be different from that with OsO_4 or $KMnO_4$, since the overall syn process is from the more-hindered side of the olefin.[555] Both the Prevost and the Woodward methods have also been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.[556] Addition of IOCOMe has also been accomplished with I_2 and peracetic acid[557] and with I_2 and potassium iodate in acetic acid.[558] The resulting β-iodo acetate can then be converted to the diol that is the product of syn addition by treatment with cupric acetate or potassium acetate. By a combination of the I_2-KIO_3 and $Cu(OAc)_2$ or KOAc methods, a double bond can be converted to the diol without the use of expensive silver acetate.[558]

Olefins can also be oxidized with metallic acetates such as lead tetraacetate[559] or thallium acetate[560] to give bisacetates of glycols.[561]

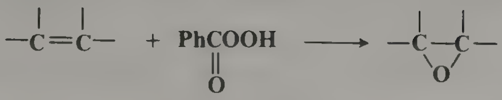
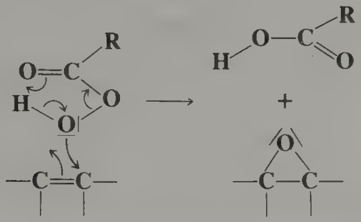
5-37 Epoxidation (Addition of Oxygen, Oxygen)



Olefins can be epoxidized with any of a number of peracids, of which *m*-chloroperbenzoic is the most often used. The reaction, called the *Prilezhaev reaction,* has wide utility.[562] Alkyl, aryl, hydroxyl, ester, and other groups may be present, though not amino groups, since these are affected by the reagent. Electron-donating groups increase the rate, and the reaction is particularly rapid with tetraalkyl olefins. Conditions are mild and yields are high. Other peracids, especially peracetic and perbenzoic, are also used; trifluoroperacetic acid[563] and 3,5-dinitroperoxybenzoic acid[564] are particularly reactive ones.

The following one-step mechanism[565] was proposed by Bartlett:[566]



Evidence for this mechanism is as follows:[567] (1) The reaction is second order. If ionization were the rate-determining step, it would be first order in peracid. (2) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited. (3) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.[568] (4) The addition is stereospecific, i.e., a trans olefin gives a trans epoxide and a cis olefin a cis epoxide.

Conjugated dienes can be epoxidized (1,2 addition), though the reaction is slower than for corresponding olefins, but α,β-unsaturated ketones do not generally give epoxides when treated with peracids.[569] However, α,β-unsaturated esters react normally, to give glycidic esters.[570] When a carbonyl group is in the molecule but not conjugated with the double bond, the Baeyer–Villiger reaction (**8-22**) may compete. Allenes are converted by peracids to allene oxides[571] (**69**) or spiro dioxides (**70**), which in certain cases can be isolated[572] but more often are unstable under the reaction conditions and react further to give other products.[573]

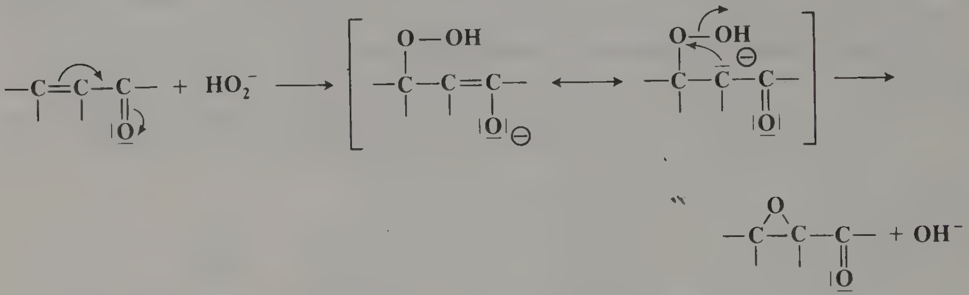
69 **70**

α,β-Unsaturated ketones (including quinones), aldehydes, and sulfones can be epoxidized with alkaline H_2O_2.[574] This is a nucleophilic addition by a Michael-type mechanism, involving attack by HO_2^-:[575]



Epoxides can also be prepared[576] by treating olefins with oxygen or with an alkyl peroxide,[577] catalyzed by a complex of V, Mo, Ti, or Co. The reaction with oxygen, which can also be carried out without a catalyst, is probably a free-radical process.[578] When the reaction is carried out with *t*-BuOOH, titanium tetraisopropoxide, and (+) or (−)-diethyl tartrate, allylic alcohols can be converted, by asymmetric induction, to optically active epoxides in better than 90% enantiomeric excess.[579]

It would be useful if triple bonds could be simply epoxidized to give oxirenes (**71**). However, oxirenes are not stable compounds.[580] Two of them have been trapped in solid argon matrices at very low temperatures, but they decayed on warming to 35 K.[581] Oxirenes probably form in the reaction[582] but react further before they can be isolated. Note that oxirenes bear the same relationship

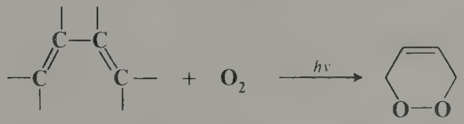
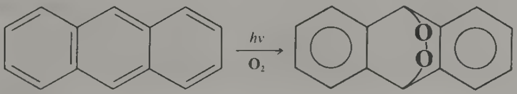
5-38 Photooxidation of Dienes (Addition of Oxygen, Oxygen)



Conjugated dienes react with oxygen under the influence of light to give internal peroxides.[585] The reaction has mostly been applied to cyclic dienes.[586] The scope extends to certain aromatic compounds,[587] e.g.,



In addition to those dienes and aromatic rings that can be photooxidized directly, there is a larger group that give the reaction in the presence of a photosensitizer such as eosin (see p. 211). Among these is α-terpinene, which is converted to ascaridole:

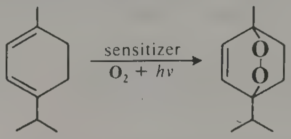
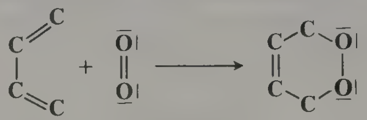
[587] For reviews, see, in Wasserman and Murray, "Singlet Oxygen," Academic Press, New York, 1979, the articles by Wasserman and Lipshutz, pp. 429–509, and Saito and Matsuura, pp. 511–574; Rigaudy, *Pure Appl. Chem.* **16,** 169–186 (1968).

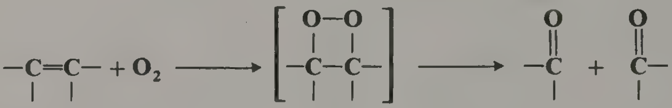


As in **4-8,** it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,[588] so the reaction is actually a Diels–Alder reaction (see **5-47**) with singlet oxygen as dienophile:[589]



Like **5-47,** this reaction is reversible.

We have previously discussed the reaction of singlet oxygen with double-bond compounds to give hydroperoxides (**4-8**), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate[590] (**73**), which usually cleaves to aldehydes or ketones[591] but has been isolated.[592]

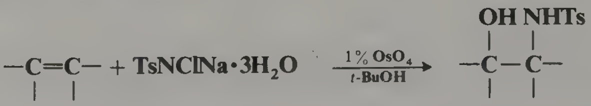


$$-\underset{|}{C}=\underset{|}{C}- + O_2 \longrightarrow \left[\begin{array}{c} O{-}O \\ |\quad\ | \\ -\underset{|}{C}-\underset{|}{C}- \end{array}\right] \longrightarrow -\underset{|}{\overset{\overset{O}{\|}}{C}} + \underset{|}{\overset{\overset{O}{\|}}{C}}-$$

73

5-39 Oxyamination (Addition of Oxygen, Nitrogen)

Tosylamino-hydroxy-addition



$$-\underset{|}{C}=\underset{|}{C}- + \text{TsNClNa}\cdot 3H_2O \xrightarrow[t\text{-BuOH}]{1\%\ OsO_4} -\underset{|}{\overset{\overset{OH}{|}}{C}}-\underset{|}{\overset{\overset{NHTs}{|}}{C}}-$$

N-Tosylated β-hydroxy alkylamines (which can be easily hydrolyzed to β-hydroxyamines[593]) can be prepared[594] by treatment of alkenes with the trihydrate of Chloramine-T.[487] In some cases yields can be improved by the use of phase-transfer catalysis.[595] In another procedure, certain β-hydroxy secondary alkylamines can be prepared by treatment of alkenes with the osmium compounds

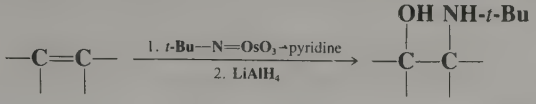
t-Bu—N=OsO$_3$, followed by reductive cleavage with LiAlH$_4$ of the initially formed osmic esters.[596] It is presumed that Ts—N=OsO$_3$ is an intermediate in the Chloramine-T reaction. Another oxyamination reaction involves treatment of a palladium complex of the olefin with a secondary or primary amine, followed by lead tetraacetate or another oxidant.[597]

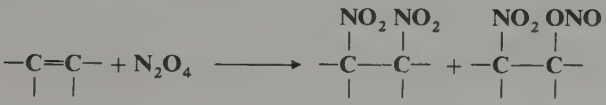


$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- \xrightarrow[2.\ \mathrm{LiAlH_4}]{1.\ t\text{-Bu}-\mathrm{N=OsO_3}\text{-pyridine}} -\overset{\mathrm{OH}}{\underset{|}{C}}-\overset{\mathrm{NH}\text{-}t\text{-Bu}}{\underset{|}{C}}-$$

OS **61,** 85, 93.

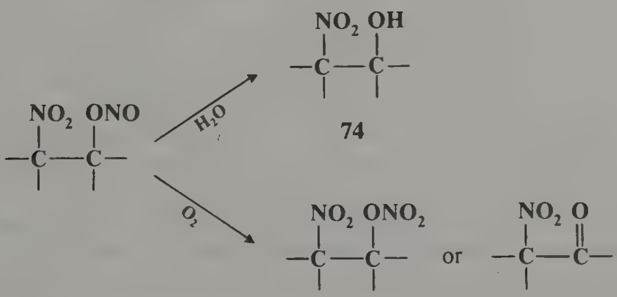
5-40 Addition of N_2O_4 and Related Reactions (Addition of Nitrogen, Nitrogen, or Nitrogen, Oxygen):

Dinitro-addition; Nitro-nitrosooxy-addition



$$-\overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}}- + N_2O_4 \longrightarrow -\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{NO_2}}{\underset{|}{C}}- + -\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{ONO}}{\underset{|}{C}}-$$

When olefins are treated with N_2O_4 in an ether, ester, or alkane[598] as solvent, *vic*-dinitro compounds and β-nitro alkyl nitrites are produced.[599] The reaction can be successfully performed with all kinds of olefins and acetylenes. Generally, both products are produced. The dinitro compound is usually stable, but the ester is quite reactive. Upon addition of water or alcohol it is hydrolyzed to a β-nitro alcohol. If oxygen is added, it is oxidized to a β-nitro alkyl nitrate or an α-nitro aldehyde or ketone.



$$-\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{ONO}}{\underset{|}{C}}- \xrightarrow{H_2O} -\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{OH}}{\underset{|}{C}}- \quad \mathbf{74}$$

$$-\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{ONO}}{\underset{|}{C}}- \xrightarrow{O_2} -\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{ONO_2}}{\underset{|}{C}}- \quad \text{or} \quad -\overset{\mathrm{NO_2}}{\underset{|}{C}}-\overset{\mathrm{O}}{\overset{\|}{C}}-$$

The nitrate is stable. Even without deliberate addition of oxygen, it is not uncommon to find some nitrate or ketone. It is therefore possible to prepare four types of compound in this reaction, not counting the nitrite.

[599] For reviews, see Ogata, in Trahanovsky, Ref. 562, pt. C, pp. 309–313; Larson, in Feuer, Ref. 354, pt. 1, pp. 316–323 (1969); Stacey and Harris, *Org. React.* **13,** 150–376 (1963), pp. 224–229, 361–367; Shechter, *Rec. Chem. Prog.* **25,** 55–76 (1964); Sosnovsky, Ref. 41, pp. 252–269; Noble, Borgardt, and Reed, *Chem. Rev.* **64,** 19–57 (1964), pp. 20–22.

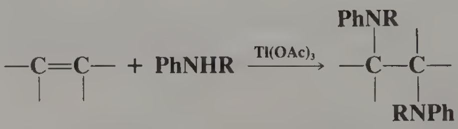
The mechanism is probably of the free-radical type,[600] with initial attack by NO_2 to give $-\dot{C}-C-NO_2$ as the intermediate for both products. In accord with this, the nitro group (in the nitrite derivatives) is found on the side with more hydrogens. When oxygen is completely absent, the product is a β-nitroso nitrate $O_2NOCR_2CR_2NO$, and it is likely that in this case N_2O_4 adds by a heterolytic mechanism.[601]

β-Nitro alcohols (**74**) can also be prepared indirectly, by addition of acetyl nitrate $AcONO_2$ to double bonds.[602] The resulting β-nitro acetate can be hydrolyzed to the alcohol. Side products of the addition of $AcONO_2$ are nitro olefins. The addition follows Markovnikov's rule, with the nitro group going to the carbon with more hydrogens.

β-Amino alcohols can be prepared by treatment of an olefin with a reagent prepared from HgO and HBF_4 along with aniline to give an aminomercurial compound $-\underset{\text{PhNH}}{\overset{|}{\underset{|}{C}}}-\underset{HgBF_4}{\overset{|}{\underset{|}{C}}}-$ (aminomercuration; see **5-8**) which is hydrolyzed to $-\underset{\text{PhNH}}{\overset{|}{\underset{|}{C}}}-\underset{OH}{\overset{|}{\underset{|}{C}}}-$.[603] The use of an alcohol instead of water gives the corresponding amino ether.

OS **50,** 84.

5-41 Diamination (Addition of Nitrogen, Nitrogen)
Di(alkylarylamino)-addition



$$-\overset{|}{C}=\overset{|}{C}- + \text{PhNHR} \xrightarrow{\text{Tl(OAc)}_3} -\underset{|}{\overset{\text{PhNR}}{\overset{|}{C}}}-\underset{\text{RNPh}}{\underset{|}{\overset{|}{C}}}-$$

Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.[604] The reaction is not successful for primary aliphatic amines. In another procedure, olefins can be diaminated by treatment with the osmium compounds R_2NOsO_2 and R_3NOsO (R = *t*-Bu),[605] analogous to the osmium compound mentioned at **5-39.** The palladium-promoted method of **5-39** has also been extended to diamination.[606] Alkenes can also be diaminated[607] indirectly by treatment of the aminomercurial compound mentioned in **5-40** with a primary or secondary aromatic amine.[608]

Two azide groups can be added to double bonds by treatment with sodium azide and hydrogen peroxide in the presence of ferrous ion:[609]

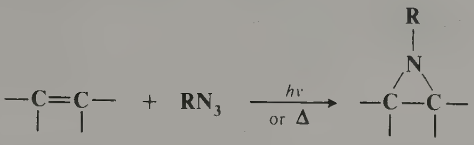
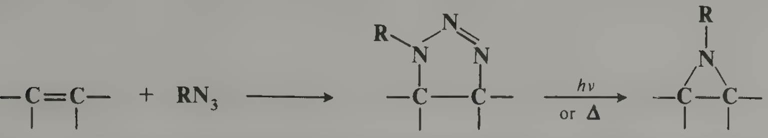
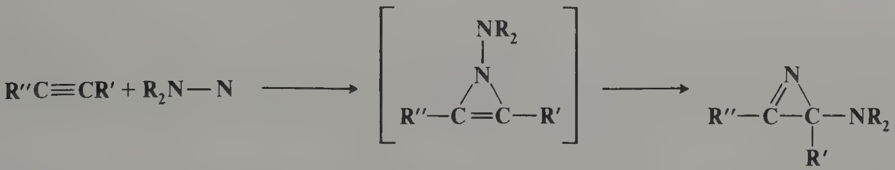
5-42 Formation of Aziridines (Addition of Nitrogen, Nitrogen)



Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and azide.[610] The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO_2, as well as other groups. The reaction can take place by at least two pathways. In one, the azide is converted to a nitrene (p. 176), which adds to the double bond in a manner analogous to that of carbene addition (reaction **5-49**). In the other pathway a 1,3 dipolar addition (reaction **5-46**) takes place to give a triazoline (which can be isolated), followed by extrusion of nitrogen (reaction **7-49**). Evidence for the nitrene pathway is most compelling for R = acyl groups.



As discussed on p. 176, singlet nitrenes add stereospecifically while triplet nitrenes do not. Diphenyl sulfimide Ph_2SNH converts Michael-type substrates to the corresponding aziridines.[611] Aminonitrenes R_2NN have been shown to add to triple bonds to give 1-azirines, which arise from rear-



rangement of the initially formed 2-azirines.[612] Like oxirenes (p. 737), 2-azirines are unstable, probably because of antiaromaticity.

Nitrenes can also add to aromatic rings to give ring-expansion products analogous to those mentioned in **5-49.**[613] Nitrenoids can also add to C=N bonds and C=O bonds to give diaziridines and oxaziranes, respectively.[614]

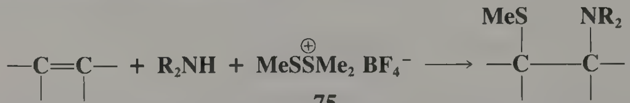
5-43 Azasulfenylation (Addition of Nitrogen, Sulfur)

Dialkylamino-alkylthio-addition

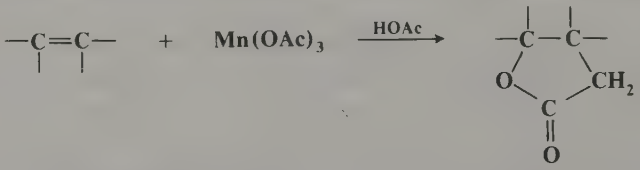


$$-\mathrm{C}{=}\mathrm{C}- + \mathrm{R_2NH} + \overset{\oplus}{\mathrm{MeSSMe_2}}\ \mathrm{BF_4^-} \longrightarrow -\overset{\mathrm{MeS}}{\mathrm{C}}-\overset{\mathrm{NR_2}}{\mathrm{C}}-$$

75

An amino group and a methylthio group can be added to a double bond by treatment with dimethyl(methylthio)sulfonium fluoroborate (**75**) and ammonia or an amine.[615] It is likely that **75** attacks as an electrophile and the amine as nucleophile. The reaction was extended to other nucleophiles:[616] N_3^-, NO_2^-, CN^-, OH^-, and OAc^- to give MeS—C—C—A, where A = N_3, NO_2, CN, OH, and OAc, respectively. The use of Me_2SO as nucleophile led (after addition of diisopropylethylamine) to β-keto sulfides MeS—C—C=O. All of these reactions give high yields.

5-44 The Conversion of Olefins to γ-Lactones (Addition of Oxygen, Carbon)



Olefins react with manganese(III) acetate to give γ-lactones.[617] The mechanism is probably free-radical, involving addition of $\cdot CH_2COOH$ to the double bond. Lactone formation has also been accomplished by treatment of olefins with α-bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,[618] and with lead tetraacetate.[619] Olefins can also be converted to γ-lactones by indirect routes.[620]

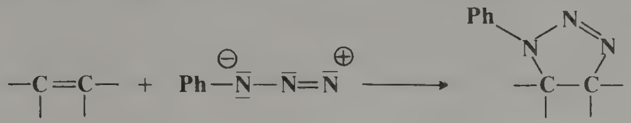
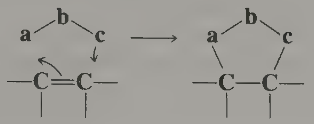
5-46 1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)



Azides add to double bonds to give triazolines. This is one example of a large group of reactions (2 + 3 cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds.[621] These are compounds that have a sequence of three atoms a—b—c, of which a has a sextet of electrons in the outer shell and c an octet with at least one unshared pair. The reaction can then be formulated as



Since compounds with six electrons in the outer shell of an atom are usually not stable, the a—b—c system is actually one canonical form of a resonance hybrid, for which at least one other form can be drawn, e.g., for azides

$$R-\overset{\ominus}{\underline{\overline{N}}}-\overline{N}=\overset{\oplus}{\overline{N}} \longleftrightarrow R-\overset{\ominus}{\underline{\overline{N}}}-\overset{\oplus}{N}\equiv\overline{N}$$

1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

$$-\overset{\oplus}{a}=\underline{b}-\overset{\ominus}{\underline{c}} \longleftrightarrow -a\equiv\overset{\oplus}{b}-\overset{\ominus}{\underline{c}}$$

If we limit ourselves to the first row of the periodic table, b can only be nitrogen, a can be carbon or nitrogen, and c can be carbon, oxygen, or nitrogen; hence there are six types. Among these are azides (a = b = c = N), illustrated above, and diazoalkanes ($R_2\overset{\ominus}{\overline{C}}-\overline{N}=\overset{\oplus}{\overline{N}}$).

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

$$-\overset{\oplus}{a}-\underline{b}-\overset{\ominus}{\underline{c}} \longleftrightarrow -a=\overset{\oplus}{b}-\overset{\ominus}{\underline{c}}$$

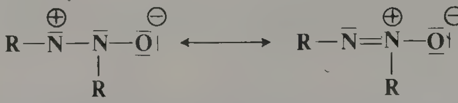
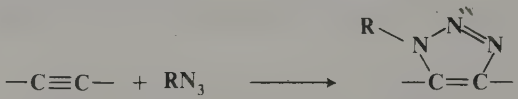
For reviews, see Bianchi, Gandolfi, and Grünanger, in Patai and Rappoport, Ref. 41, pp. 752–784; Bianchi, De Micheli, and Gandolfi, *Angew. Chem. Int. Ed. Engl.* **18,** 721–738 (1979) [*Angew. Chem.* **91,** 781–798]; in Patai, Ref. 1, pt. 1, pp. 369–532; Huisgen, in "Aromaticity," *Chem. Soc. Spec. Publ.* no. 21, 51–73 (1967), *Helv. Chim. Acta* **50,** 2421–2439 (1967), *Bull. Soc. Chim. Fr.* 3431 (1965), *Angew. Chem. Int. Ed. Engl.* **2,** 565–598, 633–645 (1963) [*Angew. Chem.* **75,** 604–637, 742–754], *Proc. Chem. Soc.* 357–369 (1961); Beltrame, in Bamford and Tipper, Ref. 1, vol. 9, pp. 117–131; Huisgen, Grashey, and Sauer, in Patai, Ref. 32, vol. 1, pp. 806–878; Black, Crozier, and Davis, *Synthesis* 205–221 (1975); Stuckwisch, *Synthesis* 469–483 (1973). For a review of intramolecular 1,3-dipolar additions, see Padwa, *Angew. Chem. Int. Ed. Engl.* **15,** 123–136 (1976) [*Angew. Chem.* **88,** 131–144]. See also Grigg, Gunaratne, and Kemp, *J. Chem. Soc., Perkin Trans. 1* 41 (1984).

Here b can be nitrogen or oxygen, and a and c can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, N—N—C is only another form of C—N—N. Examples are azoxy compounds:

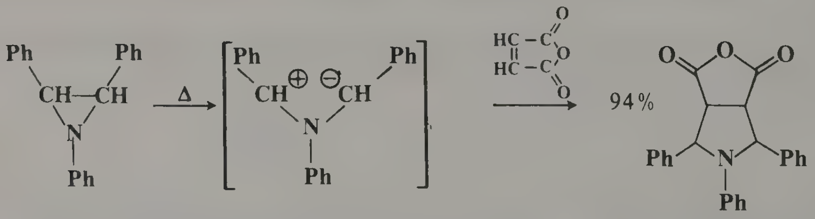


Of the 18 systems, some of which are unstable and must be generated in situ, the reaction has been accomplished for at least 15, though not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds). Not all olefins undergo 1,3-dipolar addition equally well. The reaction is most successful for those which are good dienophiles in the Diels–Alder reaction (**5-47**). The addition is stereoselective and syn, and the mechanism is probably a one-step synchronous process, as illustrated above.[622] As expected for this type of mechanism, the rates do not vary much with changes in solvent.[623] There are no simple rules covering orientation in 1,3-dipolar additions. Regioselectivities are complicated but have been explained by molecular-orbital treatments.[624]

Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.[625] For example, azides give triazoles:



The 1,3-dipolar reagent can in some cases be generated by the in situ opening of a suitable three-membered ring system. For example, aziridines can add to activated double bonds to give pyrrolidines, e.g.,[626]



Aziridines also add to C≡C triple bonds as well as to other unsaturated linkages, including C═O, C═N, and C≡N.[627] In some of these reactions it is a C—N bond of the aziridine that opens rather than the C—C bond.

The addition of the nitrile oxide **76** (generated in situ from the bromooxime $PhSO_2C(Br)$═N—OH) to alkenes, followed by reduction of the resulting adduct (**77**) with 2% sodium amalgam provides a method for adding CN and OH to a double bond.[628]

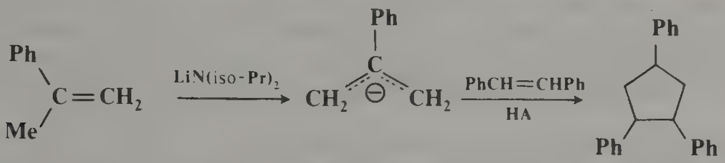
76 77

2 + 3 cycloadditions are also known in which the compound adding to the double or triple bond is not a 1,3-dipolar compound but an anion with a partial negative charge at *both* ends. Such reactions are called 1,3-*anionic cycloadditions*.[629] An important example is the case where the anion is an allylic carbanion and the product a cyclopentane. For example, α-methylstyrene adds to stilbene upon treatment with the strong base lithium diisopropylamide.[630]



In this case the reagent is an allylic anion,[631] but similar 2 + 3 cycloadditions involving allylic cations have also been reported.[632] Alkynes have been converted to cyclopentenes by treatment with allylic chlorides and zinc chloride.[633]

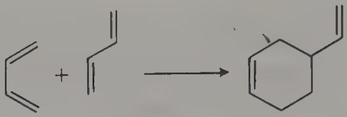
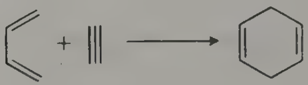
Chem. Int. Ed. Engl.* **5,** 211–230 (1966), **6,** 16–33 (1967) [*Angew. Chem.* **78,** 233–252, **79,** 76–94]. For a monograph on intramolecular Diels–Alder reactions, see Taber, "Intramolecular Diels–Alder and Alder Ene Reactions," Springer-Verlag, New York, 1984. For a review, see Fallis, *Can. J. Chem.* **62,** 183–234 (1984).

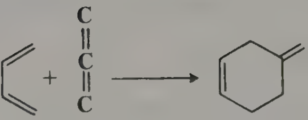
The reaction is easy and rapid and of very broad scope.[635a] Ethylene and simple olefins make poor dienophiles, although the reaction has been carried out with these compounds. Most dienophiles are of the form $-\underset{|}{C}=\underset{|}{C}-Z$ or $Z-\underset{|}{C}=\underset{|}{C}-Z'$, where Z and Z′ are CHO, COR, COOH, COOR, COCl, COAr, CN,[636] NO_2,[637] Ar, CH_2OH, CH_2Cl, CH_2NH_2, CH_2CN, CH_2COOH, halogen, or C=C.[638] In the latter case, the dienophile is itself a diene:



When two dienes react, mixtures are quite possible. Thus, butadiene and isoprene ($CH_2=CH-CMe=CH_2$) gave all nine possible Diels–Alder adducts, as well as eight-membered rings and trimers.[639] Particularly common dienophiles are maleic anhydride[640] and quinones.[641] Triple bond compounds ($-C\equiv C-Z$ or $Z-C\equiv C-Z'$) may be dienophiles[642]



as may allenes



Benzynes, although not isolable, act as dienophiles and can be trapped with dienes,[643] e.g.,

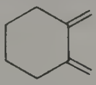
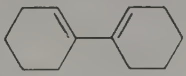
The low reactivity of ethylene can be overcome by using phenyl vinyl sulfone $PhSO_2CH{=}CH_2$ instead.[644] The $PhSO_2$ group can be easily removed with Na-Hg after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide $PhSOCH{=}CH_2$ can be used as a synthon for acetylene.[645] In this case PhSOH is lost from the sulfoxide product (**7-13**).

Besides carbon–carbon multiple bonds, other double- and triple-bond compounds can be dienophiles, giving rise to heterocyclic compounds. Among these are $N{\equiv}C{—}$, $—N{=}C—$, $—N{=}N—$, $O{=}N$, and $—C{=}O$ compounds[646] and, as we have seen (**5-38**), even molecular oxygen.

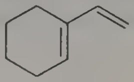
Dienes may be open-chain, inner-ring (e.g., **78**), outer-ring[647] (e.g., **79**), across rings (e.g., **80**), or inner-outer (e.g., **81**), except that they may not be frozen into a transoid conformation (see p. 748). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.[648]



79

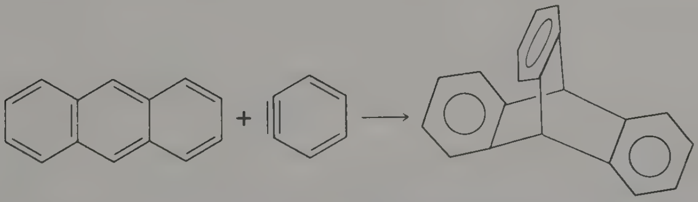


80



81

Aromatic compounds can also behave as dienes.[649] Benzene is very unreactive toward dienophiles; very few dienophiles (one of them is benzyne) have been reported to give Diels–Alder adducts with it.[650] Naphthalene and phenanthrene are also quite resistant, though naphthalene has given Diels–Alder addition at high pressures.[651] However, anthracene and other compounds with at least three linear benzene rings give Diels–Alder reactions readily. The interesting compound triptycene can be prepared by a Diels–Alder reaction between benzyne and anthracene:[652]



It is possible for a diene to have one double bond in an aromatic system and the other outside it, e.g.,

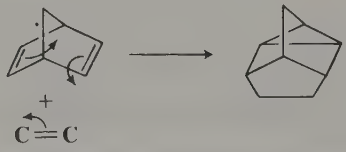
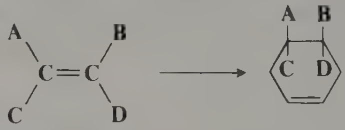
Even styrene has been shown to react in this manner.[653] Certain heterocyclic aromatic rings (among them furans) can also behave as dienes in the Diels–Alder reaction. Some hetero dienes that give the reaction are $-\mathrm{C{=}C{-}C{=}O}$, $\mathrm{O{=}C{-}C{=}O}$, and $\mathrm{N{=}C{-}C{=}N}$.[646] For both all-carbon and hetero systems, the "diene" may be a conjugated enyne. If the geometry of the molecule is suitable, the diene may even be nonconjugated, e.g.,[654]



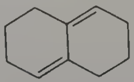
The stereochemistry of the Diels–Alder reaction can be considered from several aspects:[655]

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.[656] This means that groups that are cis in the olefin will be cis in the cyclohexene ring:



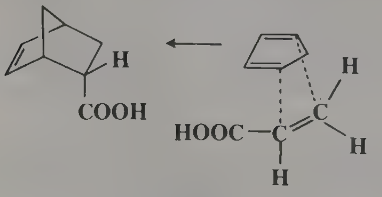
2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and syn. Thus, *trans,trans*-1,4-diphenylbutadiene gives *cis*-1,4-diphenylcyclohexene derivatives.

3. The diene must be in the cisoid conformation. If it is frozen into the transoid conformation, as in **82,** the reaction does not take place. The diene either must be frozen into the cisoid conformation or must be able to achieve it during the reaction.

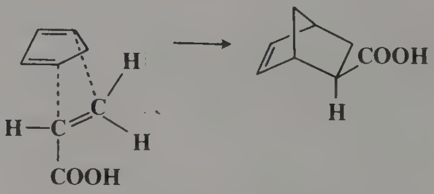


82

4. When the diene is cyclic, there are two possible ways in which addition can occur if the dienophile is not symmetrical. The larger side of the dienophile may be under the ring (*endo addition*), or it may be the smaller side (*exo addition*):



Endo addition



Exo addition

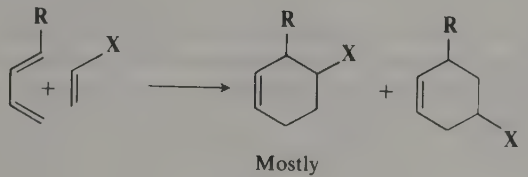
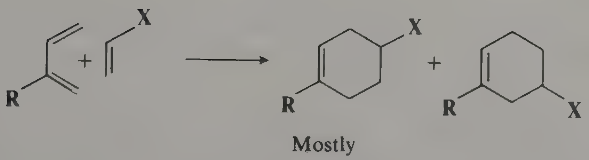
[655] For a review, see Martin and Hill, *Chem. Rev.* **61,** 537–562 (1961).

[656] For some exceptions, see Mark, *J. Org. Chem.* **39,** 3179, 3181 (1974).

Most of the time, the addition is predominantly endo; i.e., the more bulky side of the olefin is under the ring, and this is probably true for open-chain dienes also. However, exceptions are known, and in many cases mixtures of exo and endo addition products are found.[657]

When an unsymmetrical diene adds to an unsymmetrical dienophile, there are two possible products (not counting stereoisomers):





Although mixtures are often obtained, usually one predominates,[658] the one indicated above. This regioselectivity, in which the "ortho" or "para" product is favored over the "meta," has been explained by molecular-orbital considerations.[659]

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it. For the dienophile it is just the reverse: donating groups decrease the rate, and withdrawing groups increase it. Cyclic dienes, in which the cisoid conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the cisoid conformation by rotation.[660]

As should be apparent from the foregoing, many interesting compounds can be prepared by the Diels–Alder reaction, some of which we would be hard put to make in any other way. It has thus been exceedingly useful. Competing reactions are polymerization of the diene or dienophile, or both, and 1,2 cycloaddition (**5-48**). However, yields are usually quite high. No catalyst is needed, although it has been found that Lewis acids catalyze some Diels–Alder reactions,[661] usually those in which Z in the dienophile is a C═O or C═N group. A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above)[662] and the extent of endo addition.[663] The Diels–Alder reaction is usually reversible and has been used to protect double bonds.[664] A convenient substitute for butadiene in the Diels–Alder reaction is the compound 3-sulfolene since the latter is a solid which is easy to handle while the former is a gas.[665] Butadiene

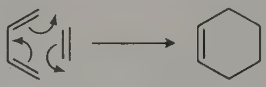
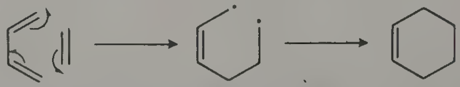
is generated in situ by a reverse Diels–Alder reaction (see **7-25**).

There are, broadly speaking, three possible mechanisms that have been considered for the Diels–Alder reaction.[666] In mechanism *a* there is a cyclic six-centered transition state and no intermediate.

Mechanism *a*



Mechanism *b*



The reaction is concerted and occurs in one step. In mechanism *b* one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened. A diradical formed in this manner must be a singlet; i.e., the two unpaired electrons must have opposite spins, by an argument similar to that outlined on p. 171. The third mechanism (*c*, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a diion. There have been many mechanistic investigations of the Diels–Alder reaction. The bulk of the evidence suggests that most Diels–Alder reactions take place by the one-step cyclic mechanism *a*,[666a] although it is possible that a diradical[667] or even a diion mechanism may be taking place in some cases. The main evidence in support of mechanism *a* is as follows: (1) The reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration. (2) In general, the rates of Diels–Alder reactions depend very little on the nature of the solvent. This would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (3) It was shown that, in the decomposition of **83**, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.[668] If bond *x* broke before bond *y*, there should surely be a secondary isotope effect. This result strongly indicates that the bond

[667] See, for example, Bartlett and Mallet, *J. Am. Chem. Soc.* **98,** 143 (1976); Jenner and Rimmelin, *Tetrahedron Lett.* **21,** 3039 (1980); Huybrechts, Poppelsdorf, Maesschalck, and van Mele, *Int. J. Chem. Kinet.* **16,** 93 (1984).

[668] Seltzer, *J. Am. Chem. Soc.* **85,** 1360 (1963), **87,** 1534 (1965); for other isotope effect evidence, see Taagepera and Thornton, *J. Am. Chem. Soc.* **94,** 1168 (1972).

breaking of x and y is simultaneous. This is the reverse of a Diels–Alder reaction, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds x and y. Subsequently, a similar experiment was carried out on the forward reaction[669] and the result was the same. There is also other evidence for mechanism *a*.[670] However, the fact that the mechanism is concerted does not necessarily mean that in the transition state both new σ bonds have been formed to the same extent. It could very well be that one bond has been formed to a greater degree than the other.[671]

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (p. 749) indicate that the diene is behaving as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, though the latter is normally the most reactive dienophile known. It is apparent, then, that this diene is the electrophile in its Diels–Alder reactions.[672]

We have emphasized that the Diels–Alder reaction generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of olefins to cyclobutanes (**5-48**) gives very poor results in most cases, except when photochemically induced. Fukui, Woodward, and Hoffmann have shown that these contrasting results can be explained by the *principle of conservation of orbital symmetry*,[673] which predicts that certain reactions are allowed and others forbidden. The orbital-symmetry rules (also called the Woodward–Hoffmann rules) apply *only to concerted reactions*, e.g., mechanism *a*, and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three of which are used more frequently than others.[674] Of these three we will discuss two: the frontier-orbital method and the Möbius–Hückel method. The third, called the correlation diagram method,[675] is less convenient to apply than the other two.

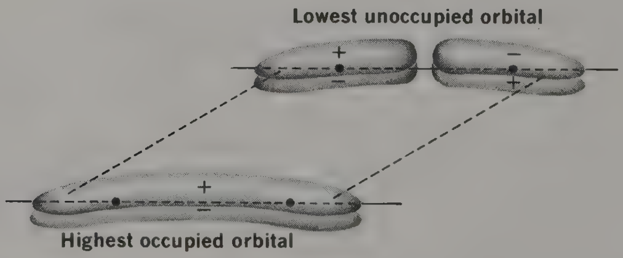
Figure 1 Schematic drawings of the π orbitals of an isolated C═C bond and a conjugated diene.

The Frontier-Orbital Method[676]

As applied to cycloaddition reactions the rule is that *reactions are allowed only when all overlaps between the highest-occupied molecular orbital* (HOMO) *of one reactant and the lowest-unoccupied molecular orbital* (LUMO) *of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe.* We may recall that monoolefins have two π molecular orbitals (p. 8) and that conjugated dienes have four (p. 28), as shown in Figure 1. A concerted cyclization of two monoolefins (a 2 + 2 reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe:



Lowest unoccupied orbital
+
−
Highest occupied orbital

On the other hand, the Diels–Alder reaction (a 4 + 2 reaction) is allowed, whether considered from either direction:

---

[676] Fukui and Fujimoto, *Bull. Chem. Soc. Jpn.* **40,** 2018 (1967), **42,** 3399 (1969); Fukui, *Fortschr. Chem. Forsch.* **15,** 1–85 (1970), *Acc. Chem. Res.* **4,** 57–64 (1971); Houk, *Acc. Chem. Res.* **8,** 361–369 (1975). See also Chu, *Tetrahedron* **34,** 645 (1978). For a monograph on frontier orbitals, see Fleming, Ref. 673. For reviews, see Fukui, *Angew. Chem. Int. Ed. Engl.* **21,** 801–809 (1982) [*Angew. Chem.* **94,** 852–861]; Houk, in Marchand and Lehr, "Pericyclic Reactions," vol. 2, pp. 181–271, Academic Press, New York, 1977.

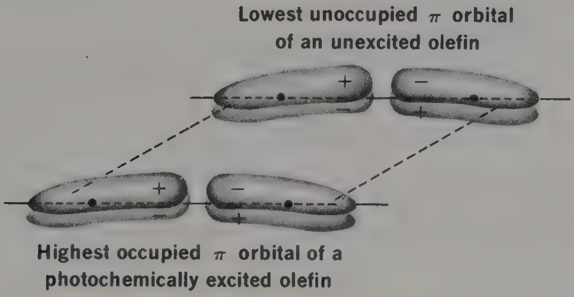
These considerations are reversed when the ring closures are photochemically induced since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the 2 + 2 reaction is now allowed:



Lowest unoccupied π orbital of an unexcited olefin
+
−
−
+
+
−
+
Highest occupied π orbital of a photochemically excited olefin

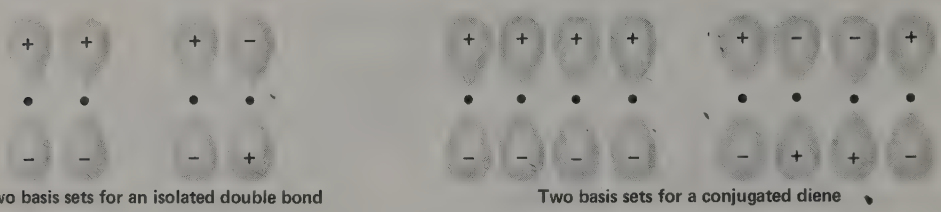
and the 4 + 2 reaction disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, Diels–Alder adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

The Möbius–Hückel Method[677]

In this method, the orbital symmetry rules are related to the Hückel aromaticity rule discussed in Chapter 2. Hückel's rule, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of $4n + 2$ electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle we are not concerned with ground states, but with transition states. In the present method we do not examine the molecular orbitals themselves, but rather the *p* orbitals before they overlap to form the molecular orbitals. Such a set of *p* orbitals is called a *basis set* (Figure 2). In investigating the possibility of a concerted reaction, we put the basis sets into the position they would occupy in the transition state. Figure 3 shows this for both the 2 + 2 and the 4 + 2 ring closures. What we look for are *sign inversions.* In Figure 3 we can see that

---

[677] Zimmerman, in Marchand and Lehr, Ref. 676, pp. 53–107; *Acc. Chem. Res.* **4,** 272–280 (1971); *J. Am. Chem. Soc.* **88,** 1564, 1566 (1966); Dewar, *Angew. Chem. Int. Ed. Engl.* **10,** 761–775 (1971) [*Angew. Chem.* **83,** 859–875]; Jefford and Burger, *Chimia,* **25,** 297–307 (1971); Herndon, *J. Chem. Educ.* **58,** 371–376 (1981).



Two basis sets for an isolated double bond
Two basis sets for a conjugated diene

Figure 2 Some basis sets.

there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or an even number* of sign inversions are called *Hückel systems.* Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Figure 4). Möbius systems do not enter into either of these reactions, but examples of such systems are shown on p. 1006 and 1027.

The rule may then be stated: *A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is 4n + 2. A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is 4n.* For photochemical reactions these rules are reversed. Since both the 4 + 2 and 2 + 2 cycloadditions are Hückel systems, the Möbius–Hückel method predicts that the 4 + 2 reaction, with 6 electrons, is thermally allowed, but the 2 + 2 reaction is not. On the other hand, the 2 + 2 reaction is allowed photochemically, while the 4 + 2 reaction is forbidden.

Note that both the 2 + 2 and 4 + 2 transition states are Hückel systems no matter what basis sets we chose. For example, Figure 5 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the frontier-orbital and Hückel–Möbius methods (and the correlation-diagram method as well) lead to the same conclusions: thermal 2 + 4 cycloadditions and photochemical 2 + 2 cycloadditions (and the reverse ring openings) are allowed, while photochemical 2 + 4 and thermal 2 + 2 ring closings (and openings) are forbidden. Application of the same procedures to other

ring closures shows that 4 + 4 and 6 + 2 ring closures and openings require photochemical induction while the 6 + 4 and 8 + 2 reactions can take place only thermally (see **5-51**). In general cycloaddition reactions allowed thermally are those with $4n + 2$ electrons, while those allowed photochemically have $4n$ electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, i.e., where two σ bonds are formed (or broken) at about the same time.[678] The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal Diels–Alder reaction (mechanism *a*) is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given Diels–Alder reaction proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal 2 + 2 cycloadditions in which the molecules assume a face-to-face geometry cannot[679] take place

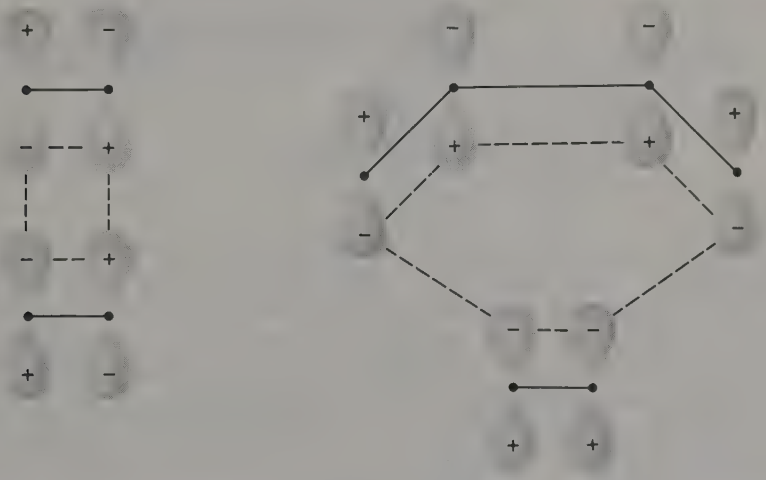

Figure 5 Transition states for 2 + 2 and 2 + 4 cyclizations involving other basis sets.

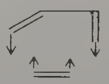
---

[678] For a discussion of concertedness in these reactions, see Lehr and Marchand, in Marchand and Lehr, Ref. 676, vol. 1, pp. 1–51.

[679] The possibility has been raised that some disallowed reactions may nevertheless proceed by concerted mechanisms: see Schmidt, *Helv. Chim. Acta* **54,** 862 (1971), *Tetrahedron Lett.* 581 (1972); Muszkat and Schmidt, *Helv. Chim. Acta* **54,** 1195 (1971); Baldwin, Andrist, and Pinschmidt, *Acc. Chem. Res.* **5,** 402–406 (1972); Berson, *Acc. Chem. Res.* **5,** 406–414 (1972); Baldwin, in Marchand and Lehr, Ref. 676, vol. 2, pp. 273–302.

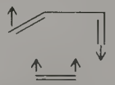
by a cyclic mechanism because their activation energies would be too high (however, see below). As we shall see (**5-48**), such reactions largely occur by two-step mechanisms. Similarly, 4 + 2 photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism[680] (mechanism *b*[681]).

In all of the above discussion we have assumed that a given molecule forms both the new σ bonds from the same face of the π system. This manner of bond formation, called *suprafacial,* is certainly most reasonable and almost always takes place. The subscript s is used to designate this geometry, and a normal Diels–Alder reaction would be called a $[_{\pi}4_s + {}_{\pi}2_s]$ cycloaddition (the subscript π indicates that π electrons are involved in the cycloaddition). However, we can conceive of another approach in which the newly forming bonds of the diene lie on *opposite* faces of the π system, i.e., they point in opposite directions.



Normal Diels-Alder reaction

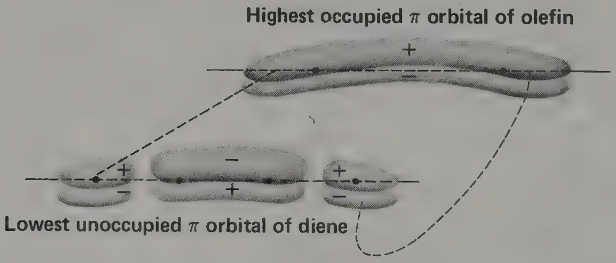
$[4_s + 2_s]$



Twisted Diels-Alder reaction

$[4_a + 2_s]$

This type of orientation of the newly formed bonds is called *antarafacial,* and the reaction would be a $[_{\pi}4_a + {}_{\pi}2_s]$ cycloaddition (a stands for antarafacial). We can easily show by the frontier-orbital method that this reaction (and consequently the reverse ring-opening reaction) are thermally forbidden and photochemically allowed. Thus in order for a $[_{\pi}4_a + {}_{\pi}2_s]$ reaction to proceed, overlap between the highest occupied π orbital of the olefin and the lowest unoccupied π orbital of the diene would have to occur as follows, with a + lobe overlapping a − lobe:



Highest occupied π orbital of olefin
+
−
−
+
+
−
+
−
Lowest unoccupied π orbital of diene

Since like signs are no longer overlapping, the thermal reaction is now forbidden. Similarly, thermal $[_{\pi}4_s + {}_{\pi}2_a]$ and $[_{\pi}2_a + {}_{\pi}2_a]$ cyclizations are forbidden, while thermal $[_{\pi}4_a + {}_{\pi}2_a]$ and $[_{\pi}2_s + {}_{\pi}2_a]$ cyclizations are allowed, and these considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a 2 + 4 cyclization,[682] but larger ring closures could take place by such a pathway, and 2 + 2 thermal cyclizations, where the $[_{\pi}2_s + {}_{\pi}2_s]$ pathway is forbidden, can also do so in certain cases (see **5-48**). We therefore see that whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.

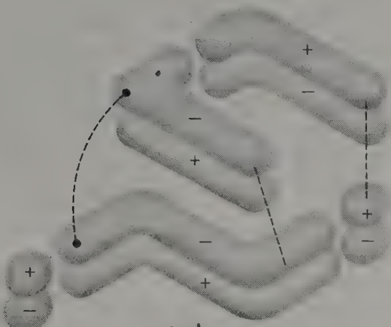
---

[680] It has been contended that 2 + 2 thermal and 2 + 4 photochemical cycloadditions occur by concerted mechanisms and the observed nonstereospecificity stems from completely concerted processes: Epiotis, *J. Am. Chem. Soc.* **95,** 1191, 1935, 1941 (1972).

[681] For example, see Sieber, Heimgartner, Hansen, and Schmid, *Helv. Chim. Acta* **55,** 3005 (1972). For discussions, see Bartlett, Helgeson, and Wersel, *Pure Appl. Chem.* **16,** 187–200 (1968); Seeley, *J. Am. Chem. Soc.* **94,** 4378 (1972); Kaupp, *Angew. Chem. Int. Ed. Engl.* **11,** 313, 718 (1972) [*Angew. Chem.* **84,** 259, 718].

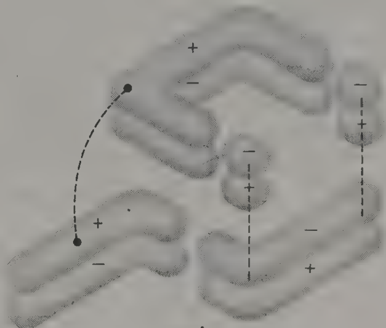
[682] A possible photochemical $[_{\pi}4_s + {}_{\pi}2_a]$ cycloaddition has been reported: Hart, Miyashi, Buchanan, and Sasson, *J. Am. Chem. Soc.* **96,** 4857 (1974).

Symmetry considerations have also been advanced to explain predominant endo addition.[683] In the case of 4 + 2 addition of butadiene to itself, the approach may be exo or endo:



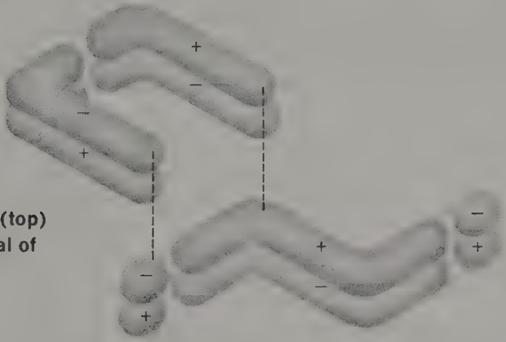
endo

Highest-occupied orbital of diene (top) overlaps lowest-unoccupied orbital of "olefin" (bottom)



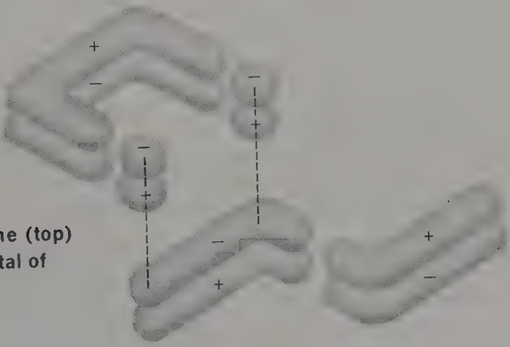
endo

Lowest-unoccupied orbital of diene (top) overlaps highest occupied orbital of "olefin" (bottom)



exo

Highest-occupied orbital of diene (top) overlaps lowest-unoccupied orbital of "olefin" (bottom)



exo

Lowest unoccupied orbital of diene (top) overlaps highest-occupied orbital of "olefin" (bottom)

---

[683] Hoffmann and Woodward, *J. Am. Chem. Soc.* **87**, 4388 (1965).

It can be seen that whether the highest-occupied molecular orbital of the diene overlaps with the lowest-unoccupied molecular orbital of the olefin or vice versa, the endo orientation is stabilized by additional secondary overlap of orbitals[684] of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that 6 + 4 cycloaddition is predicted by similar considerations to proceed with predominant exo orientation, and that is what is found.[685] However, this explanation does not account for endo orientation in cases where the dienophile does not possess additional π orbitals, and a number of alternative explanations have also been offered.[686]

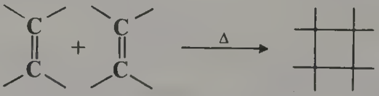
5-48 Dimerization of Olefins



The thermal reaction between two molecules of olefin to give cyclobutane derivatives (a 2 + 2 cycloaddition) can be carried out where the olefins are the same or different, but the reaction is not a general one for olefins.[687] Dimerization of like olefins occurs with the following compounds: $F_2C{=}CX_2$ (X = F or Cl) and certain other fluorinated alkenes (though not $F_2C{=}CH_2$), allenes (to give derivatives of **84**),[688] benzynes [to give biphenylene (**85**) derivatives], activated olefins (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.[689] Substituted ketenes dimerize to give cyclobutenone derivatives (**86**) as the major primary products, though ketene itself dimerizes in a different manner, to give an unsaturated β-lactone (**6-65**).[690]

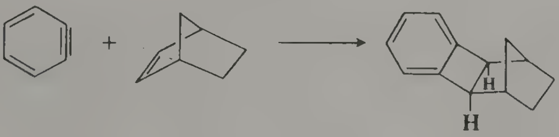
Different olefins combine as follows:

1. $F_2C{=}CX_2$ (X = F or Cl), especially $F_2C{=}CF_2$, form cyclobutanes with many olefins. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal Diels–Alder reactions.[691]

2. Allenes[692] and ketenes[693] react with activated olefins and alkynes. Ketenes give 1,2 addition, even with conjugated dienes.[694] Ketenes also add to unactivated olefins if sufficiently long reaction times are used.[695] A synthon for a ketene in this reaction is a ketenimmonium salt $R_2C{=}C{=}NR'_2{}^+\ ZnCl_3{}^-$.[696] The product is readily hydrolyzed (**6-2**) to the same cyclobutanone that would be obtained from the corresponding ketene. Allenes and ketenes also add to each other.[697]

3. Benzynes react with certain olefins,[698] e.g.,



4. Enamines[699] form four-membered rings with Michael-type olefins[700] and ketenes.[701] In both cases, only enamines from aldehydes give stable four-membered rings:

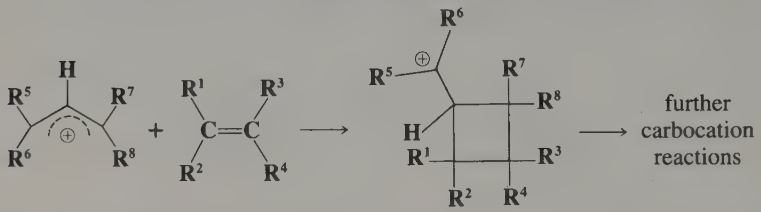
The reaction of enamines with ketenes can conveniently be carried out by generating the ketene in situ from an acyl halide and a tertiary amine. Ynamines react with ketenes to give the corresponding 3-dialkylaminocyclobutenones.[702]

5. Olefins with electron-withdrawing groups may form cyclobutanes with olefins containing electron-donating groups. The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with olefins of the form C=C—A, where A may be OR, SR (enol and thioenol ethers),[703] cyclopropyl,[704] or certain aryl groups.[705]

6. Certain allylic cations add to alkenes:[706]



R⁵ and R⁶ must be alkyl groups. If not, 3 + 2 cycloaddition takes place instead.

Solvents are not necessary for 2 + 2 cycloadditions. They are usually carried out at 100 to 225°C under pressure, although the reactions in group 5 occur under milder conditions.

The reaction is similar to the Diels–Alder (in action, not in scope), and if dienes are involved, the latter reaction may compete, though most olefins react with a diene either entirely by 1,2 or entirely by 1,4 addition. Three mechanisms can be proposed[707] analogous to those proposed for the Diels–Alder reaction. Mechanism *a* is a concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (**87**) and a diion (**88**) intermediate. As in **5-47,** a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, we would expect mechanism *c* to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. We would also expect mechanism *a* to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific, though if the second step of these processes takes place very rapidly, before **87** or **88** has a chance to rotate

Mechanism *a*

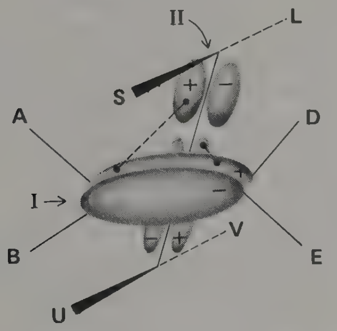
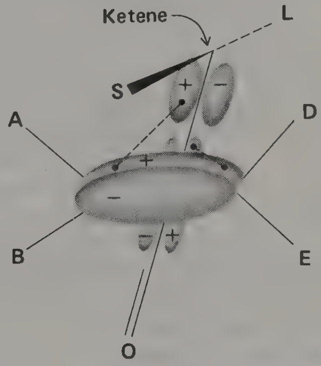
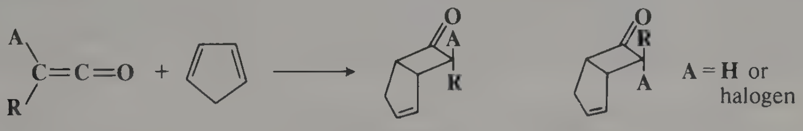
about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations such rapid ring closure might be more likely here than in a 4 + 2 cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[_{\pi}2_s + {}_{\pi}2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[_{\pi}2_s + {}_{\pi}2_a]$ mechanism is allowed (p. 756), and there is much evidence that ketenes and certain other linear molecules in which the steric hindrance to such an approach is minimal can and often do react by this mechanism.[707a] In a $[_{\pi}2_s + {}_{\pi}2_a]$ cycloaddition the molecules must approach each other in such a way that the + lobe of the HOMO of one molecule (I) overlaps with both + lobes of the LUMO of the other (II), even though these lobes are on opposite sides of the nodal plane of II.





The geometry of this approach requires that the groups S and U of molecule II project *into* the plane of molecule I. This has not been found to happen for ordinary alkenes,[708] but if molecule II is a ketene, the group marked U is not present and the $[_{\pi}2_s + {}_{\pi}2_a]$ reaction can take place. Among the evidence[709] for this mechanism is the following: (1) The reactions are stereospecific.[710] (2) The isomer that forms is the *more-hindered one*. Thus methylketene plus cyclopentadiene gave only the endo product (**89**, A = H, R = CH_3).[711] Even more remarkably, when haloalkyl ketenes



endo **89** exo **90**

[707a] There is evidence that a cyclopentyne (generated in situ) also adds to a double bond by an antarafacial process: Gilbert and Baze, *J. Am. Chem. Soc.* **106**, 1885 (1984).

Acta* **65**, 703 (1982).

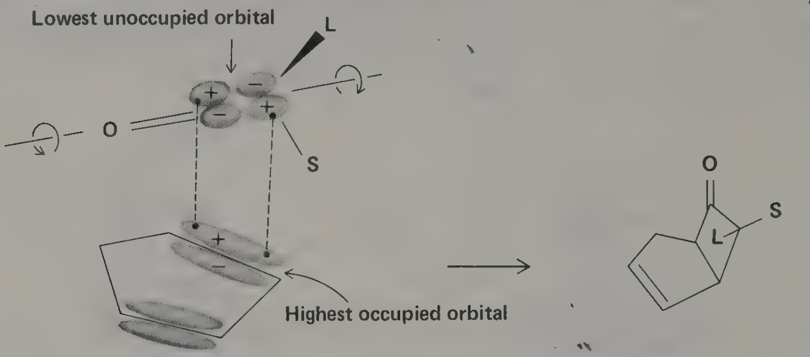
RXC=C=O were treated with cyclopentadiene, the endo–exo ratio of the product (**89**, **90**, A = halogen) actually *increased* substantially when R was changed from Me to iso-Pr to *t*-Bu![712] One would expect preferential formation of the exo products (**90**) from $[_{\pi}2_s + {_{\pi}2_s}]$ cycloadditions where the molecules approach each other face-to-face, but a $[_{\pi}2_s + {_{\pi}2_a}]$ process leads to endo products because the ketene molecule (which for steric reasons would approach with its smaller group directed toward the olefin) must twist as shown



(L = larger; S = smaller group) in order for the + lobes to interact and this swings the larger group into the endo position.[713] The experimental results in which the amount of endo isomer increases with the increasing size of the R group have been called *masochistic steric effects*, though, as we have seen, they are just what would be expected from a $[_{\pi}2_s + {_{\pi}2_a}]$ reaction. (3) There is only moderate polar solvent acceleration.[714] (4) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.[715] Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place by the $[_{\pi}2_s + {_{\pi}2_a}]$ mechanism,[716] but the evidence in these cases is more consistent with the diradical mechanism *b*.[717]

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes. These reactions are generally not stereospecific[718] and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C{=}CFCl$ gives **91**, not **92**. If one pair of electrons

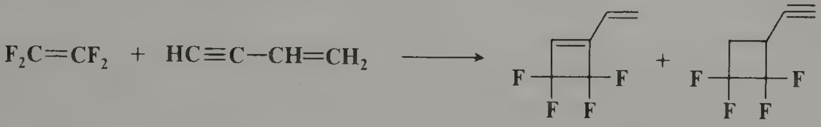
moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.[719]

The diion mechanism[720] *c* has been reported for at least some of the reactions[721] in categories 4 and 5,[722] as well as some ketene dimerizations.[723] For example, the rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether was strongly influenced by changes in solvent polarity.[724] Some of these reactions are nonstereospecific, but others are stereospecific.[725] As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given olefin reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the α positions of **87** or **88** help to stabilize a diradical, while donors such as oxygen and nitrogen favor a diion (they stabilize the positively charged end).[726] A table on p. 451 of reference 726 shows which mechanism is more likely for 2 + 2 cycloadditions of various pairs of olefins.

Thermal cleavage of cyclobutanes[727] to give two olefin molecules (*cycloreversion,*[728] the reverse of 2 + 2 cycloaddition) operates by the diradical mechanism, and the $[_{\sigma}2_s + {}_{\sigma}2_a]$ pathway has not been found[729] (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds, e.g.,



About equal amounts

The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see **5-50**)[730] or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (p. 53).[731]

Although thermal 2 + 2 cycloaddition reactions are essentially limited to the cases described above, many (though by no means all) double-bond compounds undergo such reactions *when photochemically excited* (either directly or by a photosensitizer—see p. 211), even if they are not in the above categories.[732] Simple alkenes absorb in the far uv (p. 206), which is difficult to reach experimentally, though this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes[733] (especially to strained compounds such as cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,[734] α,β-unsaturated ketones,[735] acids or acid derivatives, or quinones, since these compounds, because they are conjugated, absorb at longer wavelengths (p. 205). Both dimerizations and mixed additions are common, some examples being (see also the example on p. 216):

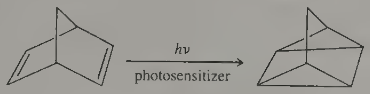
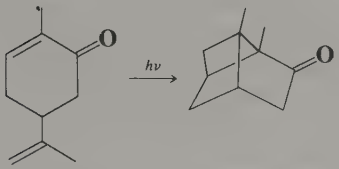
Photochemical 2 + 2 cycloadditions can also take place intramolecularly if a molecule has two double bonds that are properly oriented.[740] The cyclization of the quinone dimer shown above is one example. Other examples are



Quadricyclane

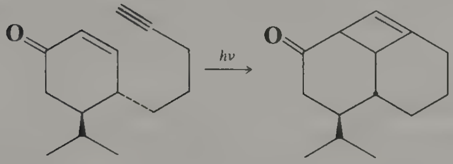
Ref. 741



Carvone

Carvonecamphor

Ref. 742



Ref. 743

It is obvious that many molecules can be constructed in this way that would be difficult to make by other procedures. However, attempted cyclizations of this kind are not always successful. In many cases polymeric or other side products are obtained instead of the desired product.

It is possible that some of these photochemical cycloadditions take place by a $[_{\pi}2_s + _{\pi}2_s]$ mechanism (which is of course allowed by orbital symmetry); when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.[744] The non-photosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,[745] making it likely that the $[_{\pi}2_s + _{\pi}2_s]$ mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place. Photosensitized $2\pi + 2\pi$ cycloadditions almost always involve the triplet state and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state (which is of course a singlet). Thus, in order to conserve spin,[746] the initially formed diradical must be a triplet; i.e., the two electrons must have the same spin. Consequently the second, or ring-closing, step of the mechanism cannot take place at once, because a new bond cannot form from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. We would therefore predict nonstereospecificity, and that is what is found.[747] At least some 2 + 2 photocycloadditions take place by way of exciplex intermediates[748] [an *exciplex*[749] is an excited EDA complex (p. 74) which is dissociated in the ground state; in this case one double bond is the donor and the other the acceptor].

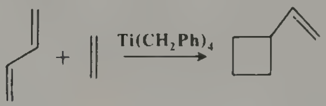
[743] Koft and Smith, *J. Am. Chem. Soc.* **106,** 2115 (1984).

[744] We have previously seen (p. 213) that reactions between two excited molecules are extremely rare.

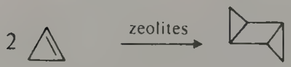
[745] Yamazaki and Cvetanović, Ref. 733; Yamazaki, Cvetanović, and Irwin, *J. Am. Chem. Soc.* **98,** 2198 (1976). For another likely example, see Lewis, Hoyle, and Johnson, *J. Am. Chem. Soc.* **97,** 3267 (1975).

[746] This is an example of the Wigner spin conservation rule (p. 211). Note that spin conservation is something entirely different from symmetry conservation.

It has been found that certain 2 + 2 cycloadditions which do not occur thermally can be made to take place without photochemical initiation by the use of certain catalysts, usually transition-metal compounds.[750] Examples are:



Ref. 751



Ref. 752

Among the catalysts used are Lewis acids[753] and phosphine–nickel complexes.[754] Certain of the reverse cyclobutane ring openings can also be catalytically induced (reaction **8-42**). The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the π or σ bonds of the substrate.[755] In such a case the reaction would of course be a concerted $2_s + 2_s$ process. However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon σ-bonded intermediates, at least in most cases.[756] For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by iridium complexes.[757]

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne[758] bearing electron-withdrawing groups.[759] These reactions are $_{\pi}2 + {}_{\sigma}2$ cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems such as bicyclo[1.1.0]butanes[760] and bicyclo[2.1.0]pentanes.

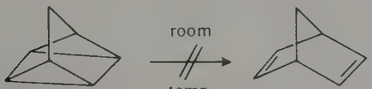
For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.[761] The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism. Photochemical[762] and metal-catalyzed[763] $_{\pi}2 + {}_{\sigma}2$ cycloadditions have also been reported.

In **5-47** we used the principle of conservation of orbital symmetry to explain why certain reactions take place readily and others do not. The orbital-symmetry principle can also explain why certain molecules are stable though highly strained. For example, quadricyclane and hexamethylprismane[764] are thermodynamically much less stable (because much more strained) than their corresponding isomeric dienes, norbornadiene and hexamethylbicyclo[2.2.0]hexadiene (**93**).[765] Yet the former two compounds can be kept indefinitely at room temperature, although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a $_{\sigma}2 + {}_{\sigma}2$ process) and, as we have seen, a thermal process of this sort is forbidden by the Woodward–Hoffmann rules. The process is allowed photochemically, and we are not surprised to find that both quadricyclane and hexamethylprismane can be photochemically converted to the respective dienes at room temperature or below.[766] It is also possible to conceive of simple bond rearrangements whereby hexamethylprismane is converted



Quadricyclane Norbornadiene

Ber.* **101,** 4083 (1968); Prinzbach, Sedelmeier, and Martin, *Angew. Chem. Int. Ed. Engl.* **16,** 103 (1977) [*Angew. Chem.* **89,** 111].

[763] See for example, Volger, Hogeveen, and Gaasbeek, *J. Am. Chem. Soc.* **91,** 218 (1969); Katz and Cerefice, *J. Am. Chem. Soc.* **91,** 2405, 6519 (1969).

[764] This compound can be prepared by photolysis of **93**, another example of an intramolecular photochemical 2 + 2 cycloaddition: Lemal and Lokensgard, *J. Am. Chem. Soc.* **88,** 5934 (1966); Schäfer, Criegee, Askani, and Grüner, *Angew. Chem. Int. Ed. Engl.* **6,** 78 (1967) [*Angew. Chem.* **79,** 54].

[765] For a review of this compound, see Schäfer and Hellmann, *Angew. Chem. Int. Ed. Engl.* **6,** 518–525 (1967) [*Angew. Chem.* **79,** 566–573].

[766] These conversions can also be carried out by the use of transition metal catalysts: Hogeveen and Volger, *Chem. Commun.* 1133 (1967), *J. Am. Chem. Soc.* **89,** 2486 (1967); Kaiser, Childs, and Maitlis, *J. Am. Chem. Soc.* **93,** 1270 (1971); Ref. 756; Landis, Gremaud, and Patrick, *Tetrahedron Lett.* **23,** 375 (1982).

to hexamethylbenzene, which of course is far more stable than either hexamethylprismane or **93.** It has been calculated that hexamethylbenzene is at least 90 kcal/mol more stable than hexamethylprismane. The fact that hexamethylprismane does not spontaneously undergo this reaction has prompted the observation[767] that the prismane has "the aspect of an angry tiger unable to break out of a paper cage." However, a correlation diagram for this reaction[767] discloses that it too is a symmetry-forbidden process. All three of these "forbidden" reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.[768]

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.[769] These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the Dewar formula.[770] On p. 24 it was mentioned that Dewar formulas are canonical forms (though not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.[771]

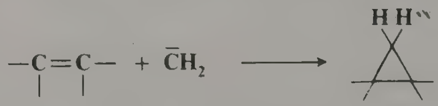
5-49 The Addition of Carbenes and Carbenoids to Double and Triple Bonds



Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives (2 + 1 cycloaddition).[772] Many derivatives of carbene, e.g., PhCH, ROCH,[773] MeOCCl,[773a] $Me_2C{=}C$, $C(CN)_2$, have been added to double bonds, but the reaction is most often performed with CH_2 itself, with halo and dihalocarbenes,[774] and with carbalkoxycarbenes[775] (generated from diazoacetic esters[776]). Alkylcarbenes HCR have been added to olefins,[777] but more often these rearrange to give olefins (p. 175). The carbene can be generated in any of the ways normally used (p. 173). However, most reactions in which a cyclopropane is formed by treatment of an olefin with a carbene "precursor" do not actually involve free carbene intermediates. In some cases, e.g., the Simmons–Smith procedure, p. 772, it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (p. 174) is actually involved.

[777] For example, see Frey, *J. Chem. Soc.* 2293 (1962).

Carbene itself is extremely reactive and gives many side reactions, especially insertion reactions (**2-18**), which greatly reduce yields.[778] When it is desired to add CH_2 for preparative purposes, free carbene is not used, but the Simmons–Smith procedure or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.[779] A few of the many ways[780] in which halocarbenes or carbenoids are generated for this reaction are the following,[781] most of which involve formal α elimination (the first two steps of the SN1cB mechanism, p. 314):

$$\mathbf{CH_2Cl_2 + RLi \longrightarrow CHCl}$$

$$\mathbf{N_2CHBr \xrightarrow{h\nu} CHBr}$$

$$\mathbf{CHCl_3 + OH^- \longrightarrow CCl_2}$$

$$\mathbf{PhHgCCl_2Br \xrightarrow{\Delta} CCl_2} \qquad \text{(Ref. 782)}$$

$$\mathbf{Me_3SnCF_3 + NaI \longrightarrow CF_2} \qquad \text{(Ref. 783)}$$

$$\mathbf{CHBr_2F + RLi \longrightarrow CFBr} \qquad \text{(Ref. 783)}$$

The reaction between $CHCl_3$ and OH^- is often carried out under phase transfer conditions.[784] It has been shown that the reaction between $PhCHCl_2$ and *t*-BuOK produces a carbenoid but when the reaction is run in the presence of a crown ether (p. 77), the free PhCCl is formed instead.[785] This is therefore a method for generating a free carbene.[786] Dihalocyclopropanes are very useful compounds[787] that can be reduced to cyclopropanes, treated with magnesium or sodium to give allenes (reaction **8-3**), or converted to a number of other products.

Olefins of all types can be converted to cyclopropane derivatives by this reaction (though difficulty may be encountered with sterically hindered ones).[788] Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.[789] Conjugated dienes give 1,2 addition:[790]

+ $\bar{C}H_2$

Addition of a second mole gives bicyclopropyl derivatives.[791] 1,4 addition is rare but has been reported for addition of $C(CN)_2$ to cyclooctatetraene.[792] Carbene adds to ketene to give cyclopropanone.[793]

Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation:[794]

A second mole gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.[795]

Triple-bond compounds[796] react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.[797] Cyclopropenones (p. 50) are obtained by hydrolysis of dihalocyclopropenes.[798] It has proved possible to add 2 moles of a carbene to an alkyne to give a bicyclobutane:[799]

Most carbenes are electrophiles, and, in accord with this, electron-donating substituents on the olefin increase the rate of the reaction, and electron-withdrawing groups decrease it,[800] though the range of relative rates is not very great.[801] As discussed on p. 171, carbenes in the singlet state (which is the most common state) react stereospecifically and syn,[802] probably by a one-step mechanism,[803] similar to mechanism *a* of **5-47** and **5-48:**

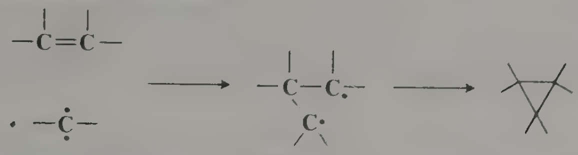
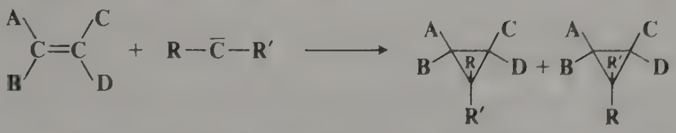
[803] For evidence that at least some singlet carbenes add by a two-step mechanism, see Giese, Lee, and Neumann, *Angew. Chem. Int. Ed. Engl.* **21,** 310 (1982) [*Angew. Chem.* **94,** 320].

Carbenes in the triplet state react nonstereospecifically,[804] probably by a diradical mechanism, similar to mechanism *b* of **5-47** and **5-48:**

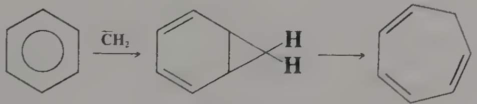


For carbenes or carbenoids of the type R—C—R′ there is another aspect of stereochemistry.[805] When these species are added to all but symmetrical olefins, two isomers are possible, even if the four groups originally on the double-bond carbons maintain their configurations:



Which isomer is predominantly formed depends on R, R′, and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R′ = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show anti stereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations. Optically active cyclopropanes can be enantioselectively prepared by the use of chiral catalysts.[806]

Carbenes are so reactive that they add to the "double bonds" of aromatic rings. The products are usually not stable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene:[807]



Norcaradiene

but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case[808] (it undergoes an electrocyclic rearrangement, p. 1003), though certain substituted norcaradienes, e.g., the product of addition of $C(CN)_2$ to benzene,[809] have been isolated.[810] With CH_2, insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of CH_2N_2 in the aromatic compound as solvent with CuCl or CuBr.[811] By this method better yields of cycloheptatrienes are obtained without insertion side products.[812] CHCl is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes,[813] e.g.,

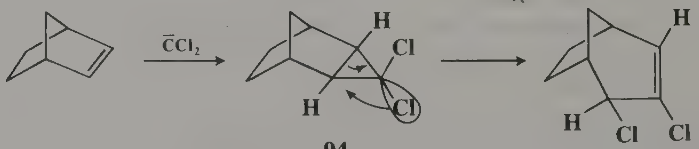
In such cases a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring expansion may occur even with nonaromatic compounds, when the driving force is supplied by relief of strain,[814] e.g.,



94

94 is so strained that it rearranges,[815] though it has been isolated.[816]

As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion side products.[817] This procedure involves treatment of the double-bond compound with CH_2I_2 and a Zn-Cu couple and leads to cyclopropane derivatives in good yields.[818] The Zn-Cu couple can be prepared in several ways,[819] of which heating Zn dust with CuCl in ether under nitrogen[820] is particularly convenient. The reaction has also been done with unactivated zinc and ultrasound.[821] The actual attacking species is an organozinc intermediate, probably $(ICH_2)_2Zn{\cdot}ZnI_2$. This intermediate is stable enough for solutions of it to be isolable.[822] These solutions give CH_2I_2 when treated with I_2 (**2-28**), and CH_3I when treated with

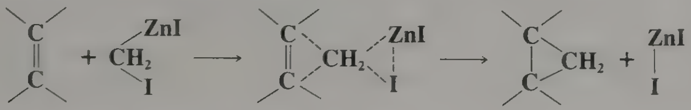
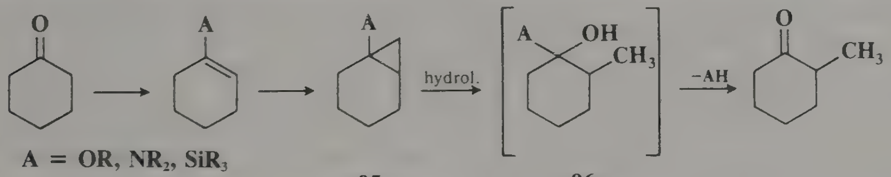
H_2O (**2-22**). The addition is stereospecifically syn, and a concerted mechanism is likely, perhaps[823]



With the Simmons–Smith procedure, as with free carbenes, conjugated dienes give 1,2 addition,[824] and allenes give methylenecyclopropanes or spiropentanes. An alternative way of carrying out the Simmons–Smith reaction is by treatment of the substrate with CH_2I_2 or another dihalomethane and Et_2Zn in ether. This method can be adapted to the introduction of RCH and ArCH by the use of $RCHI_2$ or $ArCHI_2$ instead of the dihalomethane.[825] Another method uses a *gem*-dihalide and copper.[826] In still another approach, the reagent $CpFe(CO)_2CH_2SMe_2^+\ BF_4^-$ (Cp = cyclopentadienyl) converts alkenes to cyclopropanes without the intervention of free CH_2.[827] This reaction has been extended to the transfer of CHMe by use of the reagent $CpFe(CO)_2CH(Me)SPh$.[828]

The Simmons–Smith reaction has been used as the basis of a method for the indirect α-methylation of a ketone.[829] The ketone (illustrated for cyclohexanone) is first converted to the enol ether, e.g., by **6-6,** or to the enamine (**6-14**) or silyl ether (**2-21**). Application of the Simmons–Smith reaction gives the norcarane derivative **95,** which is then cleaved (addition of water to a cyclopropane ring) to an intermediate **96,** which loses ROH, RNH_2, or R_3SiH, producing the methylated ketone. Cleavage of **95** is carried out by acid hydrolysis if A is OR, by basic hydrolysis if A is SiR_3,[830] and by neutral hydrolysis in aqueous methanol at 150 to 170°C if A is NR_2.



95

96

Double-bond compounds that undergo the Michael reaction (**5-17**) can be converted to cyclopropane derivatives with sulfur ylides.[831] Among the most common of these is dimethyloxosulfonium methylide (**97**),[832] which is widely used to transfer CH_2 to activated double bonds, but other sulfur ylides, e.g., **98** (A = acyl,[833] carbethoxy[834]), **99,**[835] and **100,**[836] which transfer CHA, CH—vinyl,

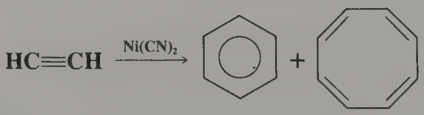
5-50 Trimerization and Tetramerization of Alkynes



When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.[841] It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes. This reaction has been used to prepare very crowded molecules. Diisopropylacetylene was trimerized over $Co_2(CO)_8$ and over $Hg[Co(CO)_4]_2$ to hexaisopropylbenzene, which was previously unknown.[842] The six isopropyl groups are not free to rotate but are lined up perpendicular to the plane of the benzene ring. Even more interesting was the *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF to give 1,2,3-tri-*t*-butyl-4,5,6-trifluorobenzene (**105**), the first time three adjacent *t*-butyl groups had been put onto a benzene ring.[843] The fact that this is a head-to-head joining makes the following sequence likely:

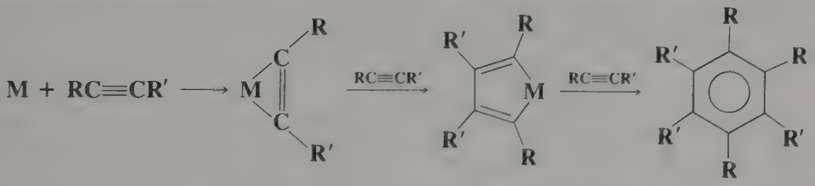
R = *t*-butyl **104** **105**

The fact that **104** (a bicyclo[2.2.0]hexadiene) was also isolated lends support to this scheme.

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene RC≡CH. The chief product is usually the 1,2,4-isomer, with lesser amounts of the 1,3,5-isomer also generally obtained, but little if any of the 1,2,3-isomer. Mechanisms of the catalyzed reactions are not well established, although coordination of the metal with the triple bond is believed to be involved.[844] However, it has been shown that at least some of these reactions proceed through three- and five-membered heterocyclic intermediates (**106** and **107**). Such intermediates (where M = Rh, Ir, or Ni) have been isolated and shown to give benzenes



106 **107**

when treated with alkynes.[845] Note that this pathway accounts for the predominant formation of the 1,2,4-isomer.

For addition of triple bonds to triple bonds, but not with ring formation, see **5-15.**

Conjugated dienes can be dimerized or trimerized at their 1,4 positions (formally, 4 + 4 and 4 + 4 + 4 cycloadditions) by treatment with certain complexes or other transition-metal compounds.[846] Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.[847] The relative amount of each product can be controlled by use of the proper catalyst. For example, $\mathrm{Ni{:}P(OC_6H_4\text{-}}o\mathrm{\text{-}Ph)_3}$ gives predominant dimerization, while $\mathrm{Ni(cyclooctadiene)_2}$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise mechanisms involving metal-olefin complexes.[848] Treatment of a mixture of ethylene and butadiene with the appropriate nickel compound gives 1,5-cyclodecadiene, formed from two molecules of the diene and one of the olefin[849] (a 4 + 4 + 2 cycloaddition). In a similar manner, cocyclization of butadiene and triple-bond compounds gives 1,4,7-cyclodecatrienes.[850]

As we have seen in reaction **5-47,** the Woodward–Hoffmann rules allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is $4n + 2$ and photochemically if the number is $4n$. Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight-membered or greater, concerted mechanisms, though allowed by orbital symmetry for the cases stated, become difficult to achieve because of the entropy factor (the two ends of one system must simultaneously encounter the two ends of the other), unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight-membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct 4 + 4 or 4 + 4 + 4 cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples are

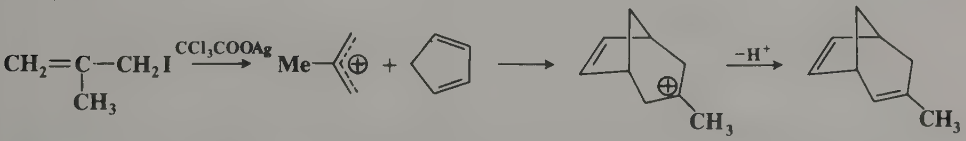
The suprafacial thermal addition of an allylic cation to a diene (a 4 + 3 cycloaddition) is allowed by the Woodward–Hoffmann rules (note that the highest-occupied molecular orbital of an allylic cation, p. 29, has the same symmetry as the highest-occupied orbital of a simple alkene, so that this reaction would be expected to follow the same rules as the Diels–Alder reaction). Such cycloadditions can be carried out[856] by treatment of a diene with an allylic halide in the presence of a suitable silver salt, e.g.,[857]



This reaction has even been carried out with benzene assuming the role of the diene.[858]

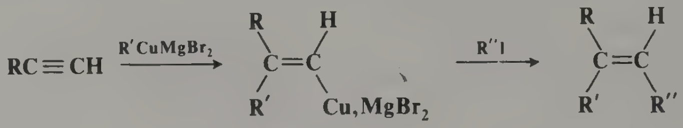
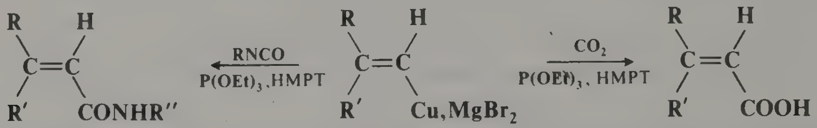
Two different alkyl groups can be added to a terminal alkyne[859] in one laboratory step by treatment with an alkylcopper–magnesium bromide reagent[860] and an alkyl iodide in ether–HMPT containing triethyl phosphite.[861] The groups add stereoselectively syn. The reaction, which has been applied to primary R′ and to primary, allylic, benzylic, vinylic, and α-alkoxyalkyl R″, involves initial addition of the alkylcopper reagent,[862] followed by a coupling reaction (**0-88**):

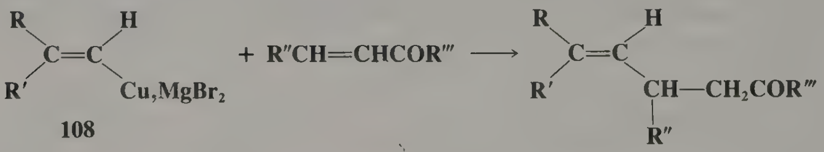


108

Acetylene itself (R = H) undergoes the reaction with R_2CuLi instead of the reagent mentioned above.[863] If the alkyl iodide is omitted, the vinylcopper intermediate **108** can be converted to a carboxylic acid by the addition of CO_2 (see **6-35**) or to an amide by the addition of an isocyanate



(see **6-37**), in either case in the presence of HMPT and a catalytic amount of triethyl phosphite.[864] The intermediate **108** can also be added to α,β-unsaturated ketones to give the Michael adducts:[865]



108

The reaction can also be performed on conjugated dienes, in which case the overall addition is 1,4.[866]

Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes R_3Al, with zirconium complexes as catalysts.[867]

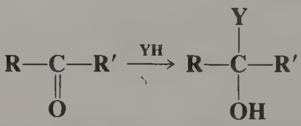
ADDITION TO CARBON–HETERO MULTIPLE BONDS

MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds and the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15.[1] Most of the questions that concerned us there either do not arise here or can be answered very simply. Since C=O, C=N, and C≡N bonds are strongly polar, with the carbon always the positive end (except for isonitriles, see p. 869), there is never any doubt about *orientation* of unsymmetrical addition to these bonds. Nucleophilic attacking species always go to the carbon and electrophilic ones to the oxygen or nitrogen. Additions to C=S bonds are much less common,[2] but in these cases the addition can be in the other direction. For example, thiobenzophenone $Ph_2C{=}S$, when treated with phenyllithium gives, after hydrolysis, benzhydryl phenyl sulfide Ph_2CHSPh.[3] The *stereochemistry* of addition is not generally a factor because it is not normally possible to determine whether the addition is syn or anti. In addition of YH to a ketone, e.g.,



$$R-\underset{\underset{\displaystyle O}{\|}}{C}-R' \xrightarrow{YH} R-\overset{\overset{\displaystyle Y}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}-R'$$

the product has a chiral carbon, but unless there is chirality in R or R′ or YH is optically active, the product must be a racemic mixture and there is no way to tell from its steric nature whether the addition of Y and H was syn or anti. The same holds true for C=N and C=S bonds, since in none of these cases can chirality be present at the hetero atom. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in *E* and *Z* forms (p. 110), but these reactions are not very important. Of course, if R or R′ *is* chiral, a racemic mixture will not always arise and the stereochemistry of addition can be studied in such cases. Cram's rule (p. 103) allows us to predict the direction of attack of Y in many cases.[4]

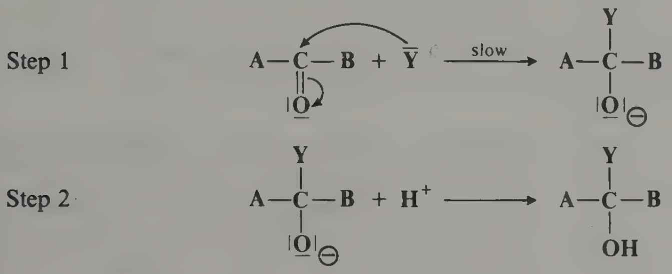
[4] For a discussion of such rules, see Eliel, "The Stereochemistry of Carbon Compounds," pp. 68–74, McGraw-Hill, New York, 1962. For reviews of the stereochemistry of addition to carbonyl compounds, see Bartlett, *Tetrahedron* **36,** 2–72 (1980), pp. 22–28; Ashby and Laemmle, *Chem. Rev.* **75,** 521–546 (1975); Goller, *J. Chem. Educ.* **51,** 182–185 (1974); Toromanoff, *Top. Stereochem.* **2,** 157–198 (1967); Kamernitskii and Akhrem, *Russ. Chem. Rev.* **30,** 43–61 (1961) [the last review can also be found in *Tetrahedron* **18,** 705–750 (1962)].

However, even in this type of study, the relative directions of attack of Y and H are not determined but only the direction of attack of Y with respect to the rest of the substrate molecule.

Not only are questions of orientation and stereochemistry not of great importance in the study of these mechanisms, but the picture is further simplified by the fact that free-radical additions to carbon–hetero double bonds are rare.[5] The principal question remaining is which attacks first, the nucleophile or electrophile. In most cases it is the nucleophile, and these reactions are regarded as *nucleophilic additions*, which can be represented thus (for the C=O bond, analogously for the others):

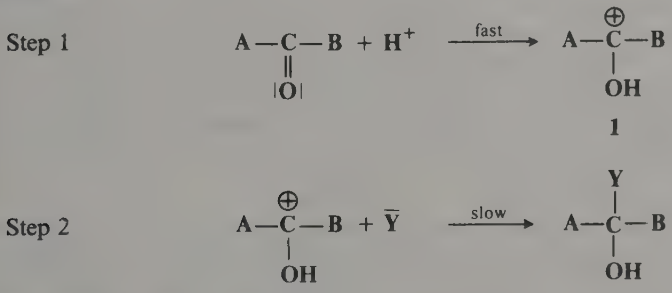


$$\text{Step 1}\qquad A-\underset{\underset{|\underline{O}|}{\|}}{C}-B + \overline{Y} \xrightarrow{\text{slow}} A-\overset{\overset{Y}{|}}{\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}}-B$$

$$\text{Step 2}\qquad A-\overset{\overset{Y}{|}}{\underset{\underset{|\underline{O}|^{\ominus}}{|}}{C}}-B + H^+ \longrightarrow A-\overset{\overset{Y}{|}}{\underset{\underset{OH}{|}}{C}}-B$$

The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter the electrophilic attacking atom is either hydrogen or carbon. It may be noted that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (p. 291), and it might be expected that substitution would compete with addition. However, this is seldom the case. When A and B are H, R, or Ar, the substrate is an aldehyde or ketone and these almost never undergo substitution, owing to the extremely poor nature of H, R, and Ar as leaving groups. For acids and their derivatives (B = OH, OR, NH_2, etc.) addition is seldom found, because these are much better leaving groups. It is thus the nature of A and B which determines whether a nucleophilic attack at a carbon–hetero multiple bond will lead to substitution or addition.

As is the case in the tetrahedral mechanism, it is also possible for the electrophilic species to attack first, in which case it goes to the hetero atom. This species is most often a proton and the mechanism is



$$\text{Step 1}\qquad A-\underset{\underset{|O|}{\|}}{C}-B + H^+ \xrightarrow{\text{fast}} A-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-B \quad \mathbf{1}$$

$$\text{Step 2}\qquad A-\overset{\oplus}{\underset{\underset{OH}{|}}{C}}-B + \overline{Y} \xrightarrow{\text{slow}} A-\overset{\overset{Y}{|}}{\underset{\underset{OH}{|}}{C}}-B$$

In each case the rate-determining step is usually the one involving nucleophilic attack. It may be observed that many of these reactions can be catalyzed by both acids and bases.[6] Bases catalyze the reaction by converting a reagent of the form YH to the more powerful nucleophile Y^- (see p. 305). Acids catalyze it by converting the substrate to an ion (e.g., **1**) in which the positive charge on the carbon is greatly increased, thus making it more attractive to nucleophilic attack. Similar catalysis can also be found with metallic ions, such as Ag^+, which act here as Lewis acids.[7] We have mentioned before (p. 146) that ions of type **1** are comparatively stable carbocations because the positive charge is spread by resonance.

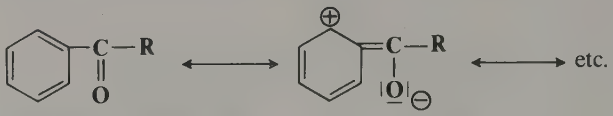
[6] For a discussion of acid and base catalysis in these reactions, see Jencks and Gilbert, *Pure Appl. Chem.* **49,** 1021–1027 (1977).

Reactivity factors in additions to carbon–hetero multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.[8] If A and/or B are electron-donating groups, rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule but is lost on going to the intermediate:

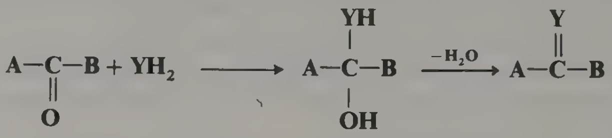


Double bonds in conjugation with the carbon–hetero multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4 addition (p. 664). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone[9] either do not undergo many of these reactions or require extreme conditions.

REACTIONS

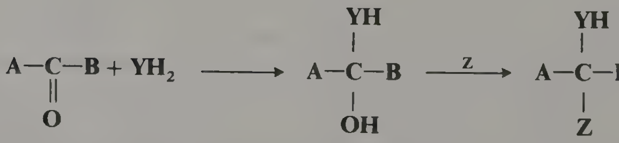
Many of the reactions in this chapter are simple additions to carbon–hetero multiple bonds, with the reaction ending as soon as the two groups have been added. But in many other cases subsequent reactions take place. We shall meet a number of such reactions, but most are of two types:

Type *A*



$$\mathrm{A-\underset{\underset{O}{\|}}{C}-B + YH_2 \longrightarrow A-\overset{\overset{YH}{|}}{\underset{\underset{OH}{|}}{C}}-B \xrightarrow{-H_2O} A-\overset{\overset{Y}{\|}}{C}-B}$$

Type *B*



$$\mathrm{A-\underset{\underset{O}{\|}}{C}-B + YH_2 \longrightarrow A-\overset{\overset{YH}{|}}{\underset{\underset{OH}{|}}{C}}-B \xrightarrow{Z} A-\overset{\overset{YH}{|}}{\underset{\underset{Z}{|}}{C}}-B}$$

In type *A*, the adduct loses water (or, in the case of addition to C═NH, ammonia, etc.), and the net result of the reaction is the substitution of C═Y for C═O (or C═NH, etc.). In type *B* there is a rapid substitution, and the OH (or NH_2, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is in most cases nucleophilic, since Y usually has an unshared pair and SN1 reactions occur very well on this type of compound (see p. 301), even when the leaving group is as poor as OH or NH_2. In this chapter we shall classify reactions according to what is initially adding to the carbon–hetero multiple bond, even if subsequent reactions take place so rapidly that it is not possible to isolate the initial adduct. It is true that this involves a certain danger, since we cannot always be sure just which reaction occurred first (e.g., **6-7** and **6-16**). In such cases we shall make the assumptions that seem most reasonable from the mechanistic data at hand.

[9] Liberman and Vasina, *J. Gen. Chem. USSR* **32,** 3179 (1962).

Most of the reactions considered in this chapter can be reversed. In many cases we shall consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another, e.g., **6-2** and **6-14.** For reactions that are reversible, the principle of microscopic reversibility (p. 189) applies.

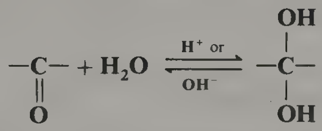
We shall discuss first reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the hetero atom and then reactions in which carbon adds to the hetero atom. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isonitriles, which are somewhat different in character, are treated at the end.

Reactions in Which Hydrogen or a Metallic Ion Adds to the Hetero Atom

A. Attack by OH (Addition of H_2O)

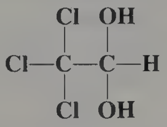
6-1 The Addition of Water to Aldehydes and Ketones. Formation of Hydrates

O-Hydro-C-hydroxy-addition

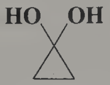


$$\underset{\underset{\displaystyle O}{\|}}{-C-} + H_2O \underset{OH^-}{\overset{H^+ \text{ or}}{\rightleftharpoons}} \underset{\underset{\displaystyle OH}{|}}{\overset{\overset{\displaystyle OH}{|}}{-C-}}$$

The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or a *gem*-diol.[10] These compounds are usually stable only in water solution and decompose on distillation; i.e., the equilibrium shifts back toward the carbonyl compound. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20°C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.[11] It has been found, by exchange with ^{18}O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.[12] Since methyl, a $+I$ group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral[13] is a stable crystalline substance. In order for it to revert to chloral, OH^- or H_2O must leave; this is made difficult by the electron-withdrawing character of the Cl_3C group. Some other[14] polychlorinated and polyfluorinated aldehydes and ketones[15] and α-keto aldehydes also form stable hydrates,



chloral hydrate



hydrate of cyclopropanone

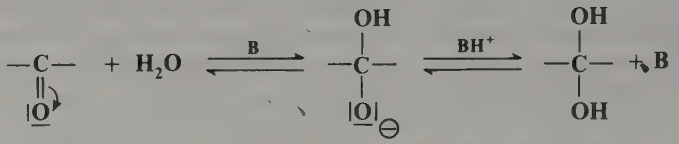
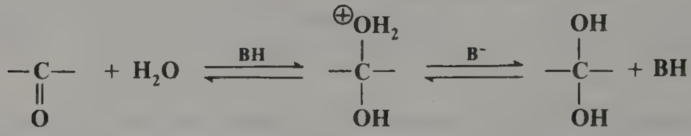
as do cyclopropanones.[16] In the last case[17] formation of the hydrate relieves some of the *I* strain (p. 240) of the parent ketone.

The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:[18]

Mechanism *a*



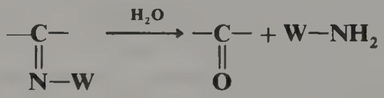
Mechanism *b*



In mechanism *a*, as the H_2O attacks, the base pulls off a proton, and the net result is addition of OH^-. This can happen because the base is already hydrogen-bonded to the H_2O molecule before the attack. In mechanism *b*, because HB is already hydrogen-bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way B and HB accelerate the reaction even beyond the extent that they form OH^- or H_3O^+ by reaction with water.

For the reaction between ketones and H_2O_2, see reaction **7-52.**

6-2 Hydrolysis of the Carbon–Nitrogen Double Bond
Oxo-de-alkylimino-bisubstitution, etc.



$$\underset{\text{N—W}}{\overset{}{\underset{\|}{\text{—C—}}}} \xrightarrow{H_2O} \underset{\text{O}}{\underset{\|}{\text{—C—}}} + W\text{—}NH_2$$

Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones. For imines (W = R or H) the hydrolysis is easy and can be carried out with water. When W = H, the imine is seldom stable enough for isolation, and hydrolysis usually occurs in situ, without isolation. The hydrolysis of Schiff bases (W = Ar) is more difficult and requires acid or basic catalysis. Oximes (W = OH), arylhydrazones (W = NHAr), and, most easily, semicarbazones (W = $NHCONH_2$) can also be hydrolyzed. Often a reactive aldehyde is added to combine with the liberated amine. Formaldehyde is generally used for this purpose, but levulinic acid is excellent for hydrolyzing oximes and arylhydrazones.[19]

A number of other reagents have been used to cleave C═N bonds, especially those not easily hydrolyzable with acidic or basic catalysts or which contain other functional groups which are attacked under these conditions. In particular, oximes have been converted to the corresponding aldehyde or ketone by treatment with, among other reagents, thallium(III) nitrate,[20] aqueous $TiCl_3$

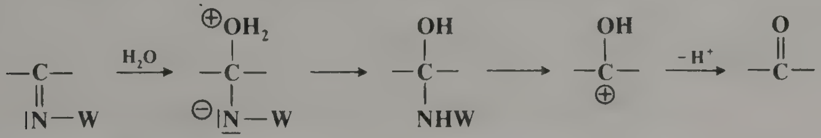
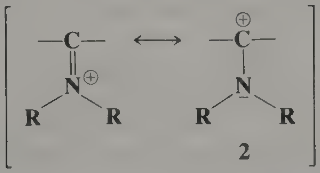
and acetic acid,[21] aqueous $NaHSO_3$,[22] iron pentacarbonyl and BF_3,[23] benzeneseleninic anhydride $(PhSeO)_2O$,[24] NOCl,[25] alkaline H_2O_2,[26] triethylammonium chlorochromate,[27] aluminum isopropoxide in isopropyl alcohol,[28] lead tetraacetate,[29] cerium(IV) ions,[30] and by treatment of the O-acetate of the oxime with chromium(II) acetate.[31] Tosylhydrazones can be hydrolyzed to the corresponding ketones with NaOCl,[32] thallium(III) acetate,[33] aqueous acetone and BF_3–etherate,[34] $CuSO_4{\cdot}5H_2O$,[35] sodium peroxide,[36] as well as with other reagents.[37] Among other reagents that have been used to cleave C═N bonds are nitrous acid (as well as nitrosonium salts such as $NO^+ \; BF_4^-$)[38] and ozone[39] (see **9-9**).

The hydrolysis of carbon–nitrogen double bonds involves initial addition of water and elimination of a nitrogen moiety:



It is thus an example of reaction type *A* (p. 782). The sequence shown is generalized.[40] In specific cases there are variations in the order of the steps, depending on acid or basic catalysis or other conditions.[41] Which step is rate-determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.[42] Iminium ions (**2**)[43] would be expected to undergo hydrolysis quite readily, since there is a contributing form with a positive charge on the carbon.



2

Indeed, they react with water at room temperature.[44] Acid-catalyzed hydrolysis of enamines (the last step of the Stork reaction, **2-17**) involves conversion to iminium ions:[45]

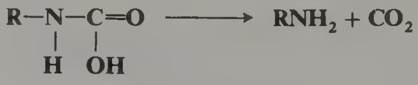
6-3 Hydrolysis of Isocyanates and Isothiocyanates

$$R{-}N{=}C{=}O + H_2O \xrightarrow{OH^- \text{ or } H^+} R{-}NH_2 + CO_2$$

A common method for the preparation of primary amines involves the hydrolysis of isocyanates or isothiocyanates.[46] The latter react more slowly and more vigorous conditions are required. The reaction is catalyzed by acids or bases. In this case simple addition of water to the carbon–nitrogen double bond would give an N-substituted carbamic acid (**3**). Such compounds are unstable and break down to carbon dioxide (or COS in the case of isothiocyanates) and the amine:



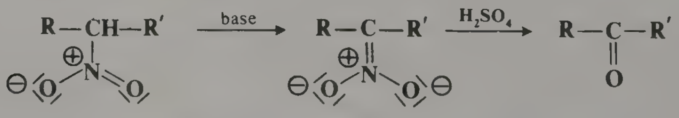
$$\underset{\text{H}}{\underset{|}{R{-}N}}{-}\underset{\text{OH}}{\underset{|}{C}}{=}O \longrightarrow RNH_2 + CO_2$$

3

In the absence of a basic catalyst, disubstituted ureas, RNHCONHR, can be obtained by a nucleophilic substitution of RNH_2 on the carbamic acid or by addition of RNH_2 to another mole of RNCO.[47]

OS **II,** 24; **IV,** 819; **V,** 273; **51,** 48.

6-4 Hydrolysis of Aliphatic Nitro Compounds
Oxo-de-hydro,nitro-bisubstitution



Primary or secondary aliphatic nitro compounds can be hydrolyzed, respectively, to aldehydes or ketones, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction.*[48] Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like **6-2,** this reaction involves hydrolysis of a C=N double bond. A possible mechanism is[49]

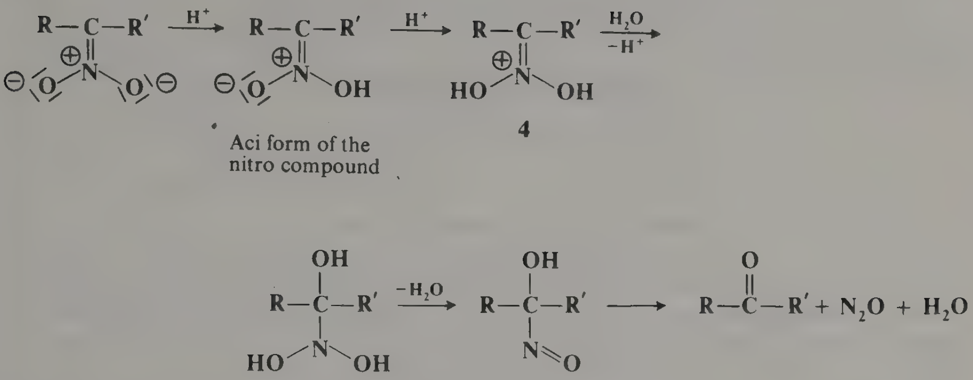
---

[45] Stamhuis and Maas, *J. Org. Chem.* **30,** 2156 (1965); Maas, Janssen, Stamhuis, and Wynberg, *J. Org. Chem.* **32,** 1111 (1967); Sollenberger and Martin, *J. Am. Chem. Soc.* **92,** 4261 (1970). For a review of enamine hydrolysis, see Stamhuis, in Cook, "Enamines," pp. 101–113, Marcel Dekker, New York, 1969.

[46] For a review of the mechanisms of reactions of isocyanates with various nucleophiles, see Satchell and Satchell, *Chem. Soc. Rev.* **4,** 231–250 (1975).

[47] Arnold, Nelson, and Verbang, *Chem. Rev.* **57,** 47 (1957).

[48] For a review, see Noland, *Chem. Rev.* **55,** 137–155 (1955).



Intermediates of type **4** have been isolated in some cases.[50]

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods. Among these are treatment of the nitro compound with aqueous $TiCl_3$,[51] activated dry silica gel,[52] 30% H_2O_2-K_2CO_3,[53] or a mixture of $NaNO_2$ and an alkyl nitrite,[54] and treatment of the conjugate base of the nitro compound with $KMnO_4$,[55] *t*-BuOOH and a catalyst,[56] ceric ammonium nitrate (CAN),[57] MoO_5-pyridine-HMPT,[58] or ozone.[59]

When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for preparing *them*. Both the Nef reaction and the hydroxamic acid process involve the aci form; the difference in products arises from higher acidity, e.g., a difference in sulfuric acid concentration from 2 *M* to 15.5 *M* changes the product from the aldehyde to the hydroxamic acid.[60] The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated aci form of the nitro compound is further protonated.

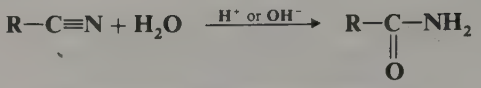
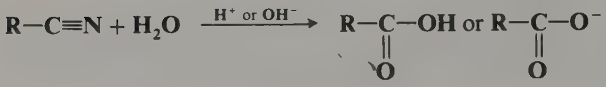
6-5 Hydrolysis of Nitriles



$$\mathrm{R{-}C{\equiv}N + H_2O \xrightarrow{H^+\ or\ OH^-} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}NH_2}$$

***NN*-Dihydro-*C*-oxo-biaddition**



$$\mathrm{R{-}C{\equiv}N + H_2O \xrightarrow{H^+\ or\ OH^-} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}OH\ or\ R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O^-}$$

Hydroxy,oxo-de-nitrilo-tersubstitution

Nitriles can be hydrolyzed to give either amides or carboxylic acids.[61] The amide is initially formed, but since amides are also hydrolyzed with acid or basic treatment, the carboxylic acid is the more common product. When the acid is desired, the reagent of choice is aqueous NaOH containing about 6 to 12% H_2O_2, though acid-catalyzed hydrolysis is also frequently carried out. However, there are a number of procedures for stopping at the amide stage,[62] among them the use of concentrated H_2SO_4; formic acid and HCl or HBr;[63] acetic acid and BF_3; H_2O_2 and OH^-;[64] and dry HCl followed by H_2O. The same result can also be obtained by use of water and certain metal ions or complexes;[65] MnO_2 in methylene chloride;[66] sodium superoxide NaO_2 in Me_2SO;[67] *t*-BuOH and solid KOH;[68] reduced copper;[69] KF-Al_2O_3;[70] or $TiCl_4$ and water.[71]

The hydrolysis of nitriles to carboxylic acids is one of the best methods for the preparation of these compounds. Nearly all nitriles give the reaction, with either acid or basic catalysts. The sequences

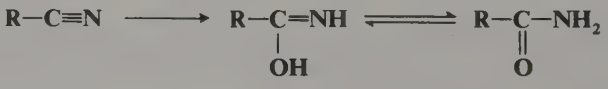
$$\mathrm{RX + NaCN \longrightarrow RCN \longrightarrow RCOOH} \tag{0-103}$$

$$\mathrm{RCHO + HCN \longrightarrow RCH(OH)CN \longrightarrow RCH(OH)COOH} \tag{6-49}$$

$$\mathrm{RCHO + NaCN + NH_4Cl \longrightarrow RCH(NH_2)CN \longrightarrow RCH(NH_2)COOH} \tag{6-50}$$

are very common. The last two sequences are often carried out without isolation of the cyanide intermediates.

The first addition product is **5**, which tautomerizes to the amide.



$$\mathrm{R{-}C{\equiv}N \longrightarrow \underset{\mathbf{5}}{R{-}\underset{\underset{\displaystyle OH}{|}}{C}{=}NH} \rightleftharpoons R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}NH_2}$$

Thiocyanates can be converted to thiocarbamates, in a similar reaction:[72] $R—S—C{\equiv}N + H_2O \xrightarrow{H^+} R—S—CO—NH_2$. Hydrolysis of cyanamides gives amines, produced by the breakdown of the unstable carbamic acid intermediates: $R_2NCN \rightarrow [R_2NCOOH] \rightarrow R_2NH$.

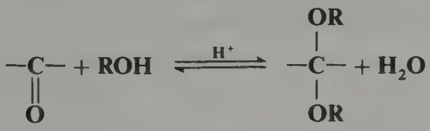
B. Attack by OR (Addition of ROH)

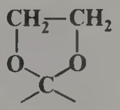
6-6 The Addition of Alcohols to Aldehydes and Ketones

O-Alkyl-*C*-alkoxy-addition



$$-\underset{\underset{O}{\|}}{C}- + ROH \underset{}{\overset{H^+}{\rightleftharpoons}} -\overset{\overset{OR}{|}}{\underset{\underset{OR}{|}}{C}}- + H_2O$$

Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.[73] This is a reversible reaction, and acetals and ketals can be hydrolyzed by treatment with acid (**0-7**). With small unbranched aldehydes the equilibrium lies to the right. If it is desired to prepare ketals, or acetals of larger molecules, the equilibrium must be shifted, usually by removal of water. This can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent such as Al_2O_3 or a molecular sieve.[74] The reaction in neither direction is catalyzed by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This makes this reaction a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope. Most aldehydes are easily converted to acetals. With ketones the process is more difficult, presumably for steric reasons, and the reaction often fails, though many ketals, especially from cyclic ketones, have been made in this manner. Many functional groups may be present without being affected. 1,2-Glycols and 1,3-glycols form cyclic acetals and ketals, e.g.,



and these are often used to protect aldehydes and ketones.[75]

The mechanism, which involves initial formation of a *hemiacetal,*[76] is the reverse of that given for acetal hydrolysis (**0-7**):

---

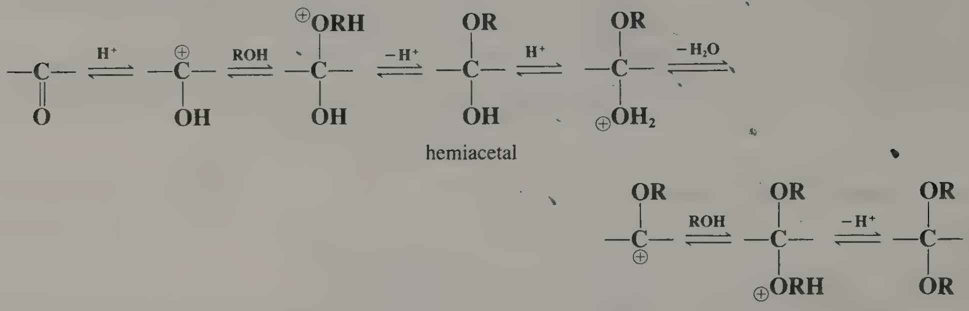
[72] Zil'berman and Lazaris, *J. Gen. Chem. USSR* **33,** 1012 (1963).

[73] For reviews, see Meskens, *Synthesis* 501–522 (1981); Sandler and Karo, "Organic Functional Group Preparations," vol. 3, pp. 4–17, 34–42, Academic Press, New York, 1972; Ogata and Kawasaki, Ref. 18, pp. 14–20; Schmitz and Eichhorn, in Patai, "The Chemistry of the Ether Linkage," pp. 309–351, Interscience, New York, 1967.

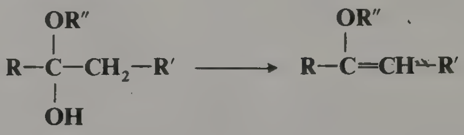
[74] For many examples of each of these methods, see Meskens, Ref. 73, pp. 502–505.

[75] For an improved procedure, see Chan, Brook, and Chaly, *Synthesis* 203 (1983).

[76] For a review of hemiacetals, see Hurd, *J. Chem. Educ.* **43,** 527–531 (1966).



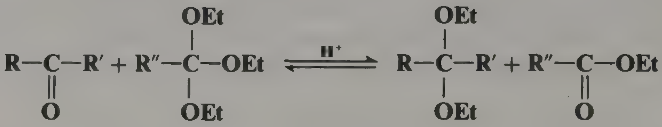
If the original aldehyde or ketone has an α-hydrogen, it is possible for water to split out in that way and enol ethers can be prepared in this manner:



$$R-\underset{OH}{\overset{OR''}{C}}-CH_2-R' \longrightarrow R-\overset{OR''}{C}=CH-R'$$

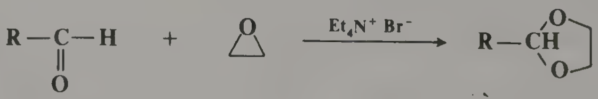
Hemiacetals themselves are no more stable than the corresponding hydrates (**6-1**). As with hydrates, hemiacetals of cyclopropanones[76a] and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, it is possible to get a transacetalation (see **0-19**). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,[77] in the presence of an acid catalyst (shown for an ortho ester):



$$R-\underset{O}{\underset{\|}{C}}-R' + R''-\underset{OEt}{\overset{OEt}{C}}-OEt \xrightleftharpoons{H^+} R-\underset{OEt}{\overset{OEt}{C}}-R' + R''-\underset{O}{\underset{\|}{C}}-OEt$$

This method is especially useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. In a variation of this method, aldehydes are converted to cyclic acetals by heating in an autoclave with an epoxide and a quaternary ammonium salt.[78]



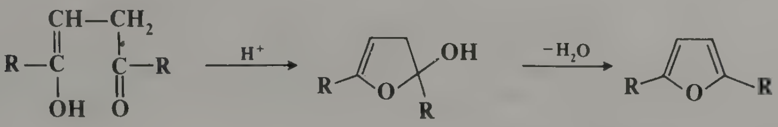
A feature of this method is that acid catalysts are not required. In another method, the substrate is treated with an alkoxysilane $ROSiMe_3$ in the presence of trimethylsilyl trifluoromethanesulfonate.[79]

[76a] For a review, see Salaun, *Chem. Rev.* **83**, 619–632 (1983).

[77] For a review with respect to ortho esters, see DeWolfe, "Carboxylic Ortho Ester Derivatives," pp. 154–164, Academic Press, New York, 1970.

[78] Nerdel, Buddrus, Scherowsky, Klamann, and Fligge, *Liebigs Ann. Chem.* **710**, 85 (1967).

1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds:

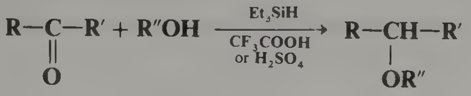


Similarly, 1,5-diketones give pyrans. Formic acid reacts with alcohols to give orthoformates.

OS **I,** 1, 298, 364, 381; **II,** 137; **III,** 123, 387, 502, 536, 644, 731, 800; **IV,** 21, 479, 679; **V,** 5, 292, 303, 450, 539; **56,** 44; **58,** 158; **59,** 10; **61,** 65. Also see OS **IV,** 558, 588; **V,** 25.

6-7 Reductive Alkylation of Alcohols

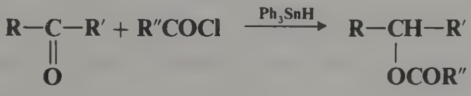
***C*-Hydro-*O*-alkyl-addition**



$$\underset{\displaystyle \overset{\|}{O}}{R{-}C{-}R'} + R''OH \xrightarrow[\text{CF}_3\text{COOH or H}_2\text{SO}_4]{\text{Et}_3\text{SiH}} \underset{\displaystyle \overset{|}{OR''}}{R{-}CH{-}R'}$$

Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid[80] or by hydrogenation in alcoholic acid in the presence of platinum oxide.[81] The process can formally be regarded as addition of ROH to give a hemiacetal RR′CHOR″, followed by reduction of the OH.

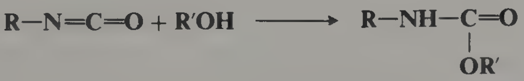
In this respect it is similar to **6-15.** In a similar reaction, ketones can be converted to carboxylic esters (reductive acylation of ketones) by treatment with an acyl chloride and triphenyltin hydride.[82]



$$\underset{\displaystyle \overset{\|}{O}}{R{-}C{-}R'} + R''COCl \xrightarrow{\text{Ph}_3\text{SnH}} \underset{\displaystyle \overset{|}{OCOR''}}{R{-}CH{-}R'}$$

6-8 The Addition of Alcohols to Isocyanates

***N*-Hydro-*C*-alkoxy-addition**



$$R{-}N{=}C{=}O + R'OH \longrightarrow R{-}NH{-}\underset{\displaystyle \overset{|}{OR'}}{C}{=}O$$

Carbamates (substituted urethans) are prepared when isocyanates are treated with alcohols.[46] This is an excellent reaction, of wide scope, and gives good yields. The carbamates are often used as derivatives of the alcohols. Cyanic acid HNCO gives unsubstituted carbamates. Addition of a second mole of HNCO gives *allophanates*, which make good derivatives for many alcohols.

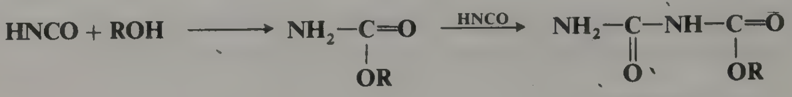
[80] Doyle, DeBruyn, and Kooistra, *J. Am. Chem. Soc.* **94,** 3659 (1972).

[81] Verzele, Acke, and Anteunis, *J. Chem. Soc.* 5598 (1963). For still another method, see Loim, Parnes, Vasil'eva, and Kursanov, *J. Org. Chem. USSR* **8,** 902 (1972).

[82] Kaplan, *J. Am. Chem. Soc.* **88,** 4970 (1966).



$$\mathrm{HNCO + ROH \longrightarrow NH_2{-}\underset{OR}{\underset{|}{C}}{=}O \xrightarrow{HNCO} NH_2{-}\underset{O}{\underset{\|}{C}}{-}NH{-}\underset{OR}{\underset{|}{C}}{=}O}$$

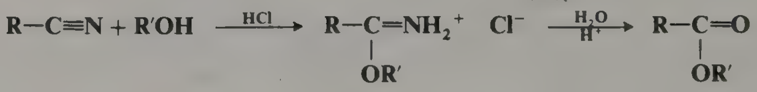
Allophanate

Polyurethans are made by combining compounds with two NCO groups with compounds containing two OH groups. Isothiocyanates similarly give thiocarbamates[83] RNHCSOR′, though they react slower than the corresponding isocyanates.

The details of the mechanism are poorly understood,[84] though the oxygen of the alcohol is certainly attacking the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.[85] The addition of ROH to isocyanates can also be catalyzed by organometallic compounds,[86] by light,[87] or, for tertiary ROH, by lithium alkoxides.[88]

OS **I,** 140; **V,** 162; **51,** 112; **56,** 40; **59,** 1, 132.

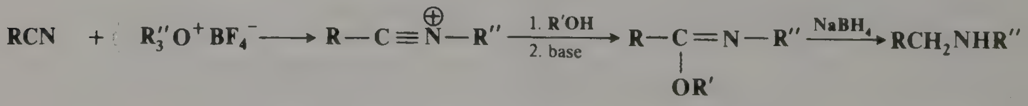
6-9 Alcoholysis of Nitriles
Alkoxy,oxo-de-nitrilo-tersubstitution



$$\mathrm{R{-}C{\equiv}N + R'OH \xrightarrow{HCl} R{-}\underset{OR'}{\underset{|}{C}}{=}NH_2^{+}\ \ Cl^{-} \xrightarrow[H^+]{H_2O} R{-}\underset{OR'}{\underset{|}{C}}{=}O}$$

The addition of dry HCl to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester (imino esters are also called imidates and imino ethers). This reaction is called the *Pinner synthesis*.[89] The salt can be converted to the free imino ester by treatment with a weak base such as sodium bicarbonate, or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aqueous HCl can be used and the need for adding gaseous HCl is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.[90]

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified with no diester or diacid present. Addition of alcohols to nitrilium salts (prepared by treatment of nitriles with $R_3O^+\ BF_4^-$, see **0-36**) gives N-alkylimino



$$\mathrm{RCN + R''_3O^{+}BF_4^{-} \longrightarrow R{-}C{\equiv}\overset{\oplus}{N}{-}R'' \xrightarrow[2.\ base]{1.\ R'OH} R{-}\underset{OR'}{\underset{|}{C}}{=}N{-}R'' \xrightarrow{NaBH_4} RCH_2NHR''}$$

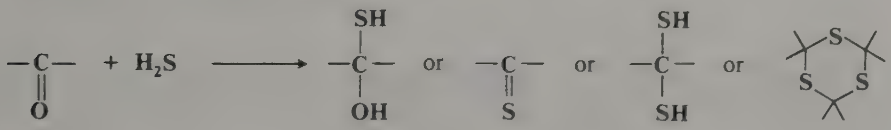
C. Sulfur Nucleophiles

6-11 The Addition of H_2S and Mercaptans to Carbonyl Compounds
***O*-Hydro-*C*-mercapto-addition**[95]



6 7 8 9

The addition of H_2S to an aldehyde or ketone can result in a variety of products.[96] The most usual product is the trithiane **9.**[97] α-Hydroxy thiols (**6**) can be prepared from polychloro and polyfluoro aldehydes and ketones.[98] Apparently **6** are stable only when prepared from these compounds, and not even for all of them. Thioketones[2] (**7**) can be prepared from certain ketones, such as diaryl ketones, by treatment with H_2S and an acid catalyst, usually HCl. They are often unstable and tend to trimerize (to **9**) or to react with air. Thioaldehydes are even less stable and simple ones[99] apparently have never been isolated, though *t*-BuCHS has been prepared in solution, where it exists for several hours at 20°C.[100] A high-yield synthesis of thioketones involves treatment of acyclic[101] ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide **10**.[102] **10** also converts the C=O groups of amides and carboxylic esters[102a] to C=S groups.[103] In a similar reaction, bis(tricyclohexyltin)-sulfide $(R_3Sn)_2S$ [R = cyclohexyl] and BCl_3 convert C=O groups of ketones, lactones and lactams to C=S groups.[104] Thioketones can also be prepared by treatment of ketones with P_4S_{10},[105] and from oximes or various types of hydrazone (overall conversion C=N— → C=S).[106]

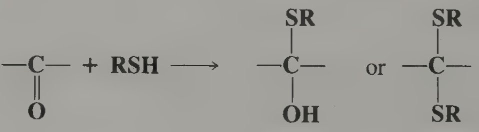
10

gem-Dithiols (**8**) are much more stable than the corresponding hydrates or α-hydroxy thiols.[107] They have been prepared by the treatment of ketones with H_2S under pressure[108] and under mild conditions with HCl as a catalyst.[109] *gem*-Dithiols can also be prepared by the treatment of imines with H_2S,[110] and this can be accomplished without isolation of the imine if the aldehyde or ketone is treated with H_2S in the presence of ammonia or an amine.[111] In some cases *gem*-dithiols can be converted to thioketones by elimination of H_2S.[112]

Mercaptans add to aldehydes and ketones[113] to give hemimercaptals and thioacetals.[114] Hemi-



$$-\underset{\underset{\displaystyle O}{\|}}{C}- + \mathrm{RSH} \longrightarrow -\overset{\overset{\displaystyle SR}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}- \quad \text{or} \quad -\overset{\overset{\displaystyle SR}{|}}{\underset{\underset{\displaystyle SR}{|}}{C}}-$$

hemimercaptal thioacetal

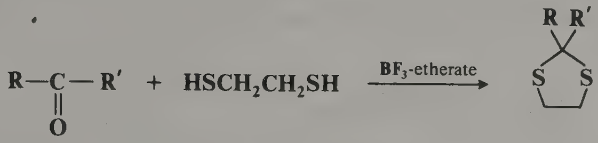
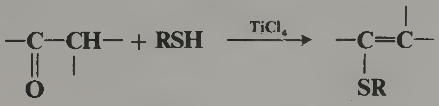
[114] When derived from aldehydes, these compounds are called *thioacetals* or *mercaptals*. When derived from ketones, they are often called *thioketals* or *mercaptoles*.

mercaptals are ordinarily unstable,[115] though they are more stable than the corresponding hemiacetals and can be isolated in certain cases.[116] Thioacetals, like acetals, are stable in the presence of bases, except that a strong base can remove the aldehyde proton, if there is one[117] (see **0-99**). A common method for the protection of ketones involves treatment with ethanedithiol to give a cyclic thioketal.[118] After subsequent reactions involving the R or R′ group, the protecting group can then be



removed by reaction **0-7.** Alternatively, the thioketal can be desulfurized with Raney nickel (**4-37**), giving the overall conversion C═O → CH_2. Thioacetals can also be prepared from aldehydes or ketones by treatment with mercaptans in the presence of $TiCl_4$,[119] with orthothioborates $(RS)_3B$,[120] with a disulfide RSSR (R = alkyl or aryl),[121] or with methylthiotrimethylsilane $MeSSiMe_3$.[122] If an aldehyde or ketone possesses an α-hydrogen, it can be converted to the corresponding enol thioether by treatment with a mercaptan in the presence of titanium tetrachloride:[123]



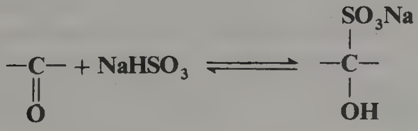
$$-\underset{\underset{O}{\|}}{C}-\underset{|}{CH}- + RSH \xrightarrow{TiCl_4} -\underset{\underset{SR}{|}}{C}=\overset{|}{C}-$$

Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine–borane, RCOR′ + R″SH $\xrightarrow{BH_3}$ RR′CHSR″,[124] in a reductive alkylation reaction, analogous to **6-7.**

OS **II,** 610; **IV,** 927; **56,** 8; **61,** 74. Also see OS **III,** 332; **IV,** 967; **V,** 780; **50,** 72.

6-12 Formation of Bisulfite Addition Products

***O*-Hydro-*C*-sulfonato-addition**



$$-\underset{\underset{O}{\|}}{C}- + NaHSO_3 \rightleftharpoons -\overset{\overset{SO_3Na}{|}}{\underset{\underset{OH}{|}}{C}}-$$

Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings), α-keto esters, and isocyanates, upon treatment with sodium bisulfite. Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base)[125] and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.[126]

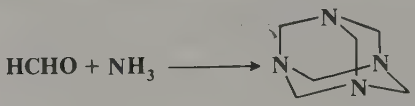
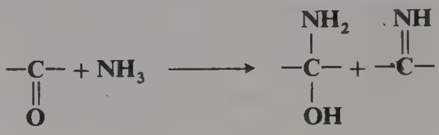
D. Attack by NH_2, NHR, or NR_2 (Addition of NH_3, RNH_2, R_2NH)

6-13 The Addition of Ammonia to Aldehydes and Ketones



11

The addition of ammonia to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be expected to be *hemiaminals* (also called "aldehyde ammonias") (**12**) and/or imines (**13**):



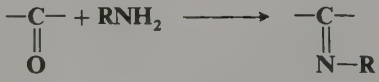
$$\underset{\underset{\mathrm{O}}{\|}}{-\mathrm{C}-} + NH_3 \longrightarrow \underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{NH_2}{|}}{-\mathrm{C}-}} + \overset{\overset{\mathrm{NH}}{\|}}{-\mathrm{C}-}$$

12 **13**

However, these compounds are generally unstable. Imines with a hydrogen on the nitrogen spontaneously polymerize.[127] Stable hemiaminals can be prepared from polychlorinated and polyfluorinated aldehydes and ketones. Aside from these, when stable compounds *are* prepared in this reaction, they are the result of combinations and condensations of one or more molecules of **12** and/or **13** with each other or with additional molecules of ammonia or carbonyl compound. The most important example of such a product is hexamethylenetetramine[128] (**11**), prepared from ammonia and formaldehyde.[129] Analogs of this compound have been prepared from aromatic aldehydes and ammonium carbonate.[130] Aromatic aldehydes give hydrobenzamides $ArCH(N{=}CHAr)_2$ derived from three molecules of aldehyde and two of ammonia.[131] Cyclic trimers of **13** can sometimes be isolated as crystalline compounds, but these are unstable in solution.[132]

OS **II,** 214, 219; **IV,** 451; **50,** 81; **52,** 135. Also see OS **III,** 471; **V,** 897.

6-14 The Addition of Amines to Aldehydes and Ketones
Alkylimino-de-oxo-bisubstitution



$$\underset{\underset{\mathrm{O}}{\|}}{-\mathrm{C}-} + RNH_2 \longrightarrow \underset{\underset{\mathrm{N-R}}{\|}}{-\mathrm{C}-}$$

---

[126] The reaction has also been used to protect an aldehyde group in the presence of a keto group: Chihara, Wakabayashi, and Taya, *Chem. Lett.* 1657 (1981).

[127] Methanimine $CH_2{=}NH$ is stable in solution for several hours at −95°C, but rapidly decomposes at −80°C: Braillon, Lasne, Ripoll, and Denis, *Nouveau J. Chem.* **6,** 121 (1982).

[128] For a review of this compound, see Blažević, Kolbah, Belin, Šunjić, and Kajfež, *Synthesis* 161–176 (1979).

[129] For a discussion of the mechanism, See Nielsen, Moore, Ogan, and Atkins, *J. Org. Chem.* **44,** 1678 (1979).

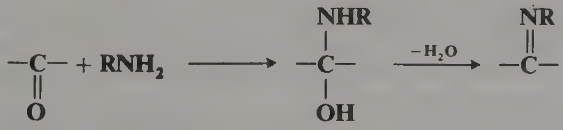
[131] Ogata, Kawasaki, and Okumura, *J. Org. Chem.* **29,** 1985 (1964); Crowell and McLeod, *J. Org. Chem.* **32,** 4030 (1967). See also Hasek, Elam, and Martin, *J. Org. Chem.* **26,** 1822 (1961).

[132] For example, see Nielsen, Atkins, DiPol, and Moore, *J. Org. Chem.* **39,** 1349 (1974).

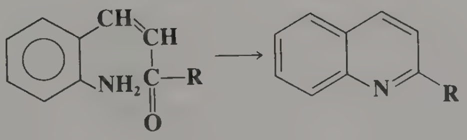
Primary, secondary, and tertiary amines can add to aldehydes[133] and ketones to give different kinds of products. Primary amines give imines.[134] In contrast to imines in which the nitrogen is attached to a hydrogen (**6-13**), these imines are stable enough for isolation. However, in some cases, especially with simple R groups, they rapidly decompose or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable. They are usually called *Schiff bases*, and this reaction is the best way to prepare them. The reaction is straightforward and proceeds in high yields. The initial N-substituted hemiaminals[134a] lose water to give the stable Schiff bases:



$$-\underset{\underset{\displaystyle O}{\|}}{C}- + RNH_2 \longrightarrow -\overset{\overset{\displaystyle NHR}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}- \xrightarrow{-H_2O} -\overset{\overset{\displaystyle NR}{\|}}{C}-$$

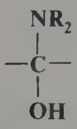
In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required. In addition, the equilibrium must often be shifted, usually by removal of the water, either azeotropically by distillation, or with a drying agent such as $TiCl_4$,[135] or with a molecular sieve.[136]

The reaction is often used to effect ring closure. The *Friedlander quinoline synthesis*[137] is an example:



Pyrylium ions react with ammonia or primary amines to give pyridinium ions[138] (see p. 313).

When secondary amines are added to aldehydes or ketones, the initially formed N,N-disubstituted hemiaminals (**14**) cannot lose water in the same way, and it is possible to isolate them.[139] However, they are generally unstable, and under the reaction conditions usually react further. If no α-hydrogen



$$-\overset{\overset{\displaystyle NR_2}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}-$$

For a review of the chemistry of imines, see Layer, *Chem. Rev.* **63,** 489–510 (1963).

[134a] Some of these have been observed spectrally; see Forlani, Marianucci, and Todesco, *J. Chem. Res.* (*Synop.*) 126 (1984).

[135] Weingarten, Chupp, and White, *J. Org. Chem.* **32,** 3246 (1967).

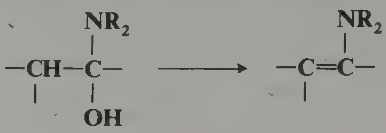
[136] Bonnett and Emerson, *J. Chem. Soc.* 4508 (1965); Roelofsen and van Bekkum, *Recl. Trav. Chim. Pays-Bas* **91,** 605 (1972).

[137] For a review, see Cheng and Yan, *Org. React.* **28,** 37–201 (1982).

[138] For a review, see Zvezdina, Zhadonva, and Dorofeenko, *Russ. Chem. Rev.* **51,** 469–484 (1982).

[139] For example, see Duhamel and Cantacuzène, *Bull. Soc. Chim. Fr.* 1843 (1962).

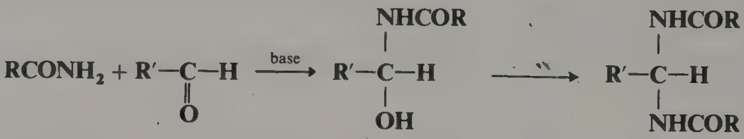
is present, **14** is converted to the more stable *aminal* (**15**).[139a] However, if an α-hydrogen is present, water (from **14**) or RNH_2 (from **15**) can be lost in that direction to give an enamine:[140]



$$-\underset{|}{CH}-\overset{NR_2}{\underset{OH}{C}}- \longrightarrow -\underset{|}{C}=\overset{NR_2}{C}-$$

This is the most common method for the preparation of enamines and usually takes place when an aldehyde or ketone containing an α-hydrogen is treated with a secondary amine. The water is usually removed azeotropically or with a drying agent,[141] but molecular sieves can also be used.[142] Secondary amine perchlorates react with aldehydes and ketones to give iminium salts (**2**, p. 785).[143] Tertiary amines can only give salts (**16**).

Amides can add to aldehydes in the presence of bases (so the nucleophile is actually $RCONH^-$) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides:[144]



$$RCONH_2 + R'-\underset{O}{\underset{\|}{C}}-H \xrightarrow{\text{base}} R'-\overset{NHCOR}{\underset{OH}{C}}-H \longrightarrow R'-\overset{NHCOR}{\underset{NHCOR}{C}}-H$$

If the R′ group contains an α-hydrogen, water may split out.

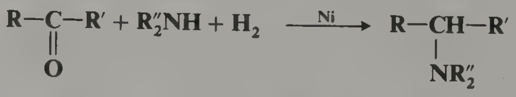
6-15 Reductive Alkylation of Ammonia or Amines
Hydro,dialkylamino-de-oxo-bisubstitution



$$R-\underset{O}{\underset{\|}{C}}-R' + R''_2NH + H_2 \xrightarrow{\text{Ni}} R-\underset{NR''_2}{\underset{|}{CH}}-R'$$

When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen and a hydrogenation catalyst (heterogeneous or homogeneous[145]), *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.[146] The reaction can formally be regarded as occurring in the following manner (shown for a primary amine), which probably *does* correspond to the actual sequence of steps:[147]

[139a] For a review of aminals, see Duhamel, in Patai, "The Chemistry of Functional Groups, Supplement F," pt. 2, pp. 849–907, Wiley, New York, 1982.

[140] For reviews of the preparation of enamines, see Pitacco and Valentin, in Patai, Ref. 139a, pt. 1, pp. 623–714; in Cook, Ref. 45, the articles by Haynes, pp. 55–100, and Kuehne, 315–341; Szmuszkovicz, *Adv. Org. Chem.* **4,** 1–113 (1963), pp. 9–12; Sandler and Karo, Ref. 73, vol. 2, pp. 86–94 (1971).

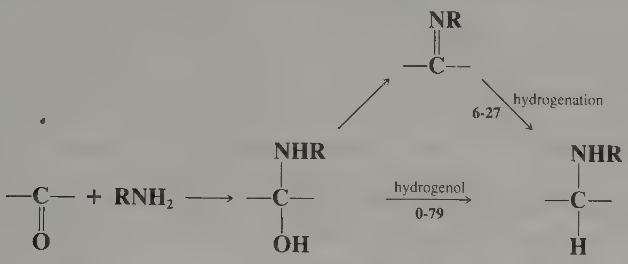
[143] Leonard and Paukstelis, *J. Org. Chem.* **28,** 3021 (1963).

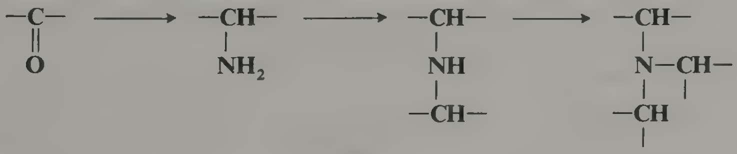
[144] For reviews, see Challis and Challis, in Zabicky, Ref. 62, pp. 754–759; Zaugg and Martin, *Org. React.* **14,** 52–269 (1965), pp 91–95, 104–112. For a discussion, see Gilbert, *Synthesis* 30 (1972).

[145] Markó and Bakos, *J. Organomet. Chem.* **81,** 411 (1974).



For ammonia and primary amines there are two possible pathways, but when secondary amines are involved, only the hydrogenolysis pathway is possible. Other reducing agents can be used instead of hydrogen and a catalyst, among them zinc and HCl, sodium cyanoborohydride $NaBH_3CN$,[148] sodium borohydride,[149] iron pentacarbonyl and alcoholic KOH,[150] selenophenol PhSeH,[151] and formic acid. When the last is used, the process is called the *Wallach reaction*. In the particular case where primary or secondary amines are reductively methylated with *formaldehyde* and formic acid, the method is called the *Eschweiler–Clarke procedure*. It is possible to use ammonium (or amine) salts of formic acid, or formamides, as a substitute for the Wallach conditions. This method is called the *Leuckart reaction*,[152] and in this case the products obtained are often the N-formyl derivatives of the amines instead of the free amines. Primary and secondary aromatic amines can be N-ethylated (e.g., ArNHR → ArNREt) by treatment with $NaBH_4$ in acetic acid.[153]

When the reagent is ammonia, it is possible for the initial product to react again and for this product to react again, so that secondary and tertiary amines are usually obtained as side products:



Similarly, primary amines give tertiary as well as secondary amines. In order to minimize this, the aldehyde or ketone is treated with an excess of ammonia or primary amine (unless of course the higher amine is desired).

Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent. Smaller aldehydes are usually too reactive to permit isolation of the primary amine. Secondary amines have been prepared by both possible procedures: 2 moles of ammonia and 1 mole of aldehyde or ketone, and 1 mole of primary amine and 1 mole of carbonyl compound, the latter method being better for all but aromatic aldehydes. Tertiary amines can be prepared in three ways, but the method is seldom carried out with 3 moles of ammonia and 1 mole of carbonyl compound. Much more often they are prepared from primary or secondary amines.[154] The most common method for this purpose is the Eschweiler–Clarke procedure, i.e., treatment of the primary or secondary amine with formaldehyde and formic acid. Amines of the form $RNMe_2$ and R_2NMe are prepared in this manner.[155] Another method for accomplishing the conversions $RNH_2 \rightarrow RNMe_2$ and $R_2NH \rightarrow R_2NMe$ is to treat the amine with aqueous formaldehyde and $NaBH_4$[156] or $NaBH_3CN$.[157]

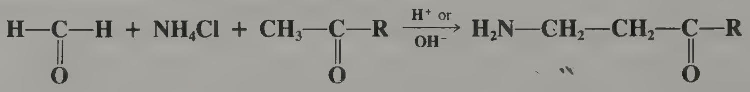
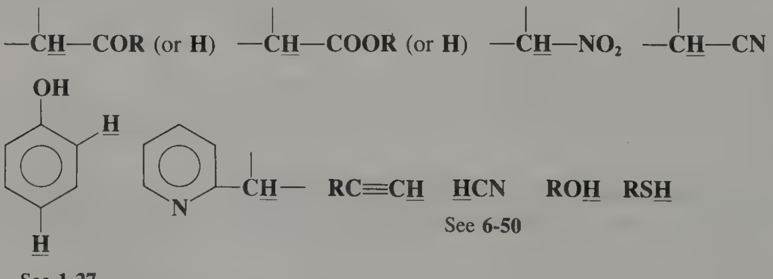
6-16 The Mannich Reaction

Acyl,amino-de-oxo-bisubstitution, etc.



$$H-\underset{\underset{O}{\|}}{C}-H + NH_4Cl + CH_3-\underset{\underset{O}{\|}}{C}-R \xrightarrow[OH^-]{H^+ \text{ or}} H_2N-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-R$$

In the *Mannich reaction,* formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.[158] This can formally be considered as an addition of ammonia to give H_2NCH_2OH, followed by a nucleophilic substitution. Instead of ammonia, the reaction can be carried out with salts of primary or secondary amines,[159] or with amides,[160] in which cases the product is substituted on the nitrogen with R, R_2, and RCO, respectively. Arylamines do not normally give the reaction. In any case, the product is referred to as a *Mannich base.* Many active hydrogen compounds give the reaction. Among these are the following types, with the active hydrogen underlined:



$$-\overset{|}{C}\underline{H}-COR \text{ (or H)} \quad -\overset{|}{C}\underline{H}-COOR \text{ (or H)} \quad -\overset{|}{C}\underline{H}-NO_2 \quad -\overset{|}{C}\underline{H}-CN$$

$$RC\equiv C\underline{H} \quad \underline{H}CN \quad RO\underline{H} \quad RS\underline{H}$$

[158] For reviews, see Tramontini, *Synthesis* 703–775 (1973); House, "Modern Synthetic Reactions," 2d ed. pp. 654–660, W. A. Benjamin, New York, 1972. For a review of Mannich reactions in which the active-hydrogen component is a nitro compound, see Baer and Urbas, in Feuer, "The Chemistry of the Nitro and Nitroso Groups," pp. 117–130, Interscience, New York, 1970.

[159] For a review where the amine component is an amino acid, see Agababyan, Gevorgyan, and Mndzhoyan, *Russ. Chem. Rev.* **51,** 387–396 (1982).

[160] Hellmann, *Angew. Chem.* **69,** 463 (1957), *Newer Methods Prep. Org. Chem.* **2,** 277–302 (1963).

The Mannich base can react further in three ways. If it is a primary or secondary amine, then it may condense with one or two additional molecules of aldehyde and active compound, e.g.,

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow[CH_3COR]{HCHO} HN(CH_2CH_2COR)_2 \xrightarrow[CH_3COR]{HCHO} N(CH_2CH_2COR)_3}$$

If the active hydrogen compound has two or three active hydrogens, the Mannich base may condense with one or two additional molecules of aldehyde and ammonia or amine, e.g.,

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_2CHCOR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_3CCOR}$$

Another further reaction consists of condensation of the Mannich base with excess formaldehyde:

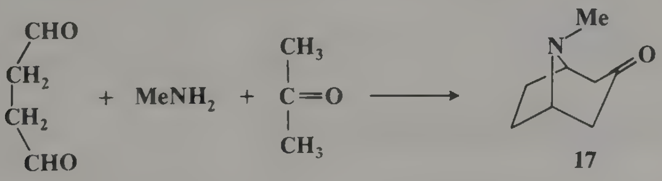
$$\mathrm{H_2NCH_2CH_2COR + HCHO \longrightarrow H_2C{=}NCH_2CH_2COR}$$

Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times they are side products.

When the Mannich base contains an amino group β to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to α,β-unsaturated aldehydes, ketones, esters, etc.:

$$\mathrm{H_2NCH_2CH_2COR \xrightarrow{\Delta} H_2C{=}CHCOR}$$

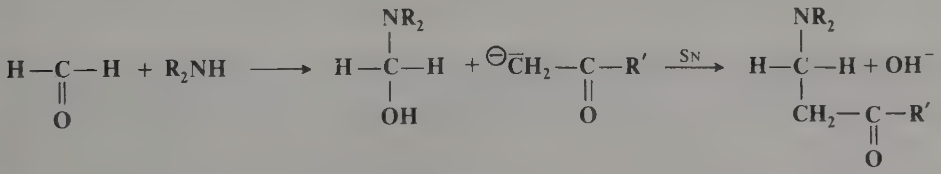
The Mannich reaction is an important biosynthetic route to natural products, mainly alkaloids, and some of these routes have been duplicated in the laboratory. A classic example is the synthesis of tropinone (**17**) by Robinson in 1917. Robinson synthesized tropinone by a Mannich reaction involving succindialdehyde, methylamine, and acetone:[161]



17

Studies of the reaction kinetics have led to the following proposals for the mechanism of the Mannich reaction.[162]

The base-catalyzed reaction



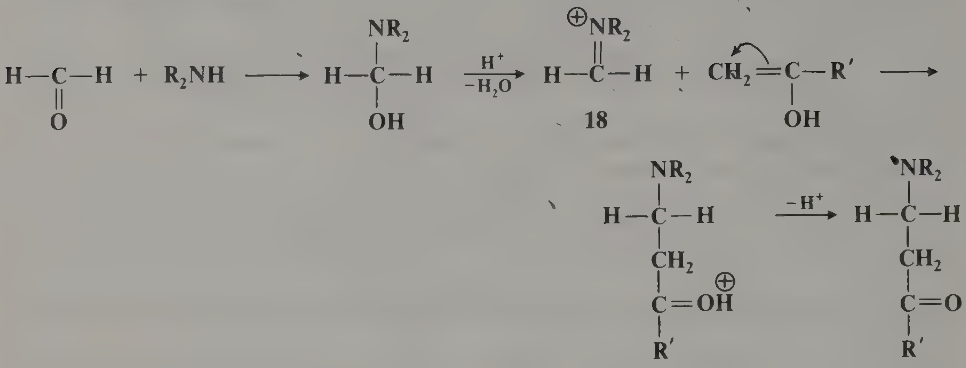
$$\mathrm{H{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H} + \mathrm{R_2NH} \longrightarrow \mathrm{H{-}\overset{\overset{\displaystyle NR_2}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}{-}H} + {}^{\ominus}\overline{\mathrm{C}}\mathrm{H_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} \xrightarrow{\mathrm{S_N}} \mathrm{H{-}\overset{\overset{\displaystyle NR_2}{|}}{\underset{\underset{\displaystyle CH_2{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'}{|}}{C}}{-}H} + \mathrm{OH^-}$$

---

[161] Robinson, *J. Chem. Soc.* **111,** 762 (1917).

[162] Cummings and Shelton, *J. Org. Chem.* **25,** 419 (1960).

The acid-catalyzed reaction



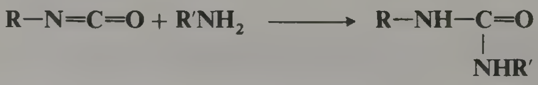
According to this mechanism, it is the free amine, not the salt that reacts, even in acid solution; and the active-hydrogen compound (in the acid-catalyzed process) reacts as the enol when that is possible. This latter step is similar to what happens in reaction **2-4.** There is kinetic evidence for the intermediacy of the iminium ion (**18**).[163]

When it is desired to use an unsymmetrical ketone as the active-hydrogen component, it is possible to get two products. Regioselectivity has been obtained by treatment of the ketone with preformed iminium ions:[164] the use of $Me_2\overset{\oplus}{N}{=}CH_2\quad CF_3COO^-$ in CF_3COOH gives substitution at the more highly substituted position, while with iso-$Pr_2\overset{\oplus}{N}{=}CH_2\quad ClO_4^-$ the reaction takes place at the less highly substituted position.[165] The preformed iminium compound dimethyl(methylene)ammonium iodide $CH_2{=}NMe_2^+\ I^-$, called *Eschenmoser's salt,*[166] has also been used in Mannich reactions.[167]

Regioselective synthesis of Mannich bases can also be carried out in an indirect manner (see **6-36**). Also see **6-50** and **1-27.**

OS **III,** 305; **IV,** 281, 515, 816; **57,** 95, 102; **59,** 153.

6-17 The Addition of Amines to Isocyanates
N-Hydro-*C*-alkylamino-addition



$$R{-}N{=}C{=}O + R'NH_2 \longrightarrow R{-}NH{-}\underset{\displaystyle NHR'}{\underset{|}{C}}{=}O$$

Ammonia and primary and secondary amines can be added to isocyanates to give substituted ureas.[46] Isothiocyanates give thioureas. This is an excellent method for the preparation of ureas and thioureas, and these compounds are often used as derivatives for primary and secondary amines. Cyanic acid

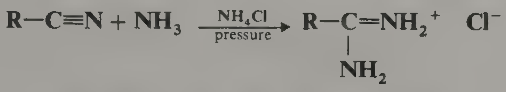
[167] See Holy, Fowler, Burnett, and Lorenz, *Tetrahedron* **35,** 613 (1979); Bryson, Bonitz, Reichel, and Dardis, *J. Org. Chem.* **45,** 524 (1980), and references cited in these papers.

HNCO also gives the reaction; usually its salts, e.g., NaNCO, are used. Wöhler's famous synthesis of urea involved the addition of ammonia to a salt of cyanic acid.[168]

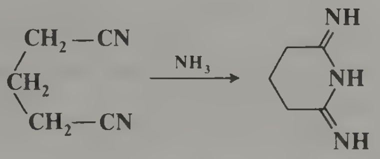
OS **II,** 79; **III,** 76, 617, 735; **IV,** 49, 180, 213, 515, 700; **V,** 555, 801, 802, 967; **51,** 121; **56,** 95.

6-18 The Addition of Ammonia or Amines to Nitriles
***N*-Hydro-*C*-amino-addition**



$$R{-}C{\equiv}N + NH_3 \xrightarrow[\text{pressure}]{NH_4Cl} R{-}\underset{\displaystyle NH_2}{\underset{|}{C}}{=}NH_2^{+} \quad Cl^-$$

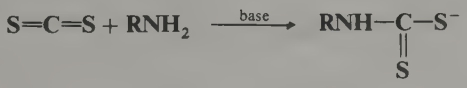
Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.[169] Many amidines have been made in this way. Dinitriles of suitable chain length can give imidines:[170]



Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; e.g., Cl_3CCN gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.[171] However, aniline can be added to benzonitrile with $AlCl_3$ as catalyst. The addition of ammonia to cyanamide NH_2CN gives guanidine $(NH_2)_2C{=}NH$.

OS **I,** 302 [but also see OS **V,** 589]; **IV,** 245, 247, 515, 566, 769. See also OS **V,** 39.

6-19 The Addition of Amines to Carbon Disulfide and Carbon Dioxide
***S*-Metallo-*C*-alkylamino-addition**



$$S{=}C{=}S + RNH_2 \xrightarrow{\text{base}} RNH{-}\underset{\displaystyle S}{\underset{\|}{C}}{-}S^-$$

Salts of dithiocarbamic acid can be prepared by the addition of primary amines to carbon disulfide.[171a] This reaction is similar to **6-10.** H_2S can be eliminated from the product, directly or indirectly, to give isothiocyanates RNCS. Isothiocyanates can be obtained directly by the reaction of primary amines and CS_2 in pyridine in the presence of dicyclohexylcarbodiimide.[172] In the presence of diphenyl phosphite and pyridine, primary amines add to CO_2 and to CS_2 to give, respectively, symmetrically substituted ureas and thioureas:[173]

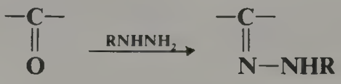
E. Other Nitrogen Nucleophiles

6-20 The Addition of Hydrazine Derivatives to Carbonyl Compounds
Hydrazono-de-oxo-bisubstitution

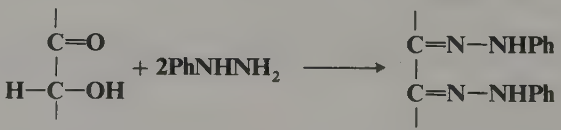


$$\mathrm{{-}\underset{\underset{\displaystyle O}{\|}}{C}{-} \xrightarrow{RNHNH_2} {-}\underset{\underset{\displaystyle N{-}NHR}{\|}}{C}{-}}$$

The product of condensation of a hydrazine and an aldehyde or ketone is called a *hydrazone*. Hydrazine itself gives hydrazones only with aryl ketones. With other aldehydes and ketones, either no useful product can be isolated, or the remaining NH_2 group condenses with a second mole of carbonyl compound to give an *azine*. This type of product is especially important for aromatic aldehydes:

$$\mathrm{ArCH{=}N{-}NH_2 + ArCHO \longrightarrow \underset{\text{An azine}}{ArCH{=}N{-}N{=}CHAr}}$$

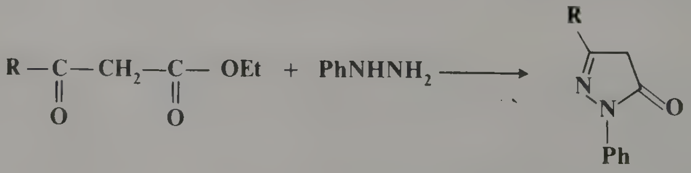
However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.[174] Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl, are used much more often and give the corresponding hydrazones with most aldehydes and ketones.[175] Since these are usually solids, they make excellent derivatives and are commonly employed for this purpose. α-Hydroxy aldehydes and ketones and α-dicarbonyl compounds give *osazones*, in which two adjacent carbons have carbon–nitrogen double bonds:



$$\begin{array}{c} | \\ \mathrm{C{=}O} \\ | \\ \mathrm{H{-}C{-}OH} \\ | \end{array} + \mathrm{2PhNHNH_2} \longrightarrow \begin{array}{l} | \\ \mathrm{C{=}N{-}NHPh} \\ | \\ \mathrm{C{=}N{-}NHPh} \\ | \end{array}$$

An osazone

Osazones are particularly important in carbohydrate chemistry. In contrast to this behavior, β-diketones and β-keto esters give *pyrazoles* and *pyrazolones*, respectively (illustrated for β-keto esters):



---

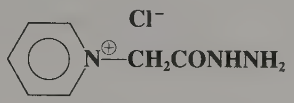
[173] Yamazaki, Higashi, and Iguchi, *Tetrahedron Lett.* 1191 (1974). For another method for the conversion of amines and CO_2 to ureas, see Ogura, Takeda, Tokue, and Kobayashi, *Synthesis* 394 (1978).

[174] For example, see Day and Whiting, *Org. Synth.* **50,** 3.

[175] For a review of arylhydrazones, see Buckingham, *Q. Rev., Chem. Soc.* **23,** 37–56 (1969).

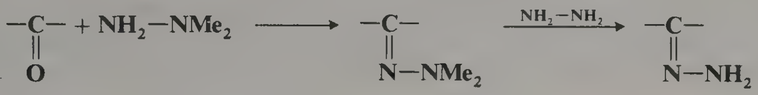
Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide $NH_2NHCONH_2$, in which case the hydrazone is called a semicarbazone, and *Girard's reagents T and P,* in which case the hydrazone is water-soluble because of the ionic group. Girard's reagents are often used for purification of carbonyl compounds.

$Cl^- \; Me_3NCH_2CONHNH_2$



Girard's reagent T Girard's reagent P

Simple N-unsubstituted hydrazones can be obtained by an exchange reaction. The N,N-dimethylhydrazone is prepared first and then treated with hydrazine:[176]

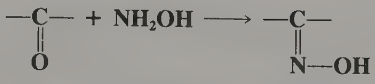


$$\underset{\text{O}}{\overset{\|}{-\text{C}-}} + \text{NH}_2\text{—NMe}_2 \longrightarrow \underset{\text{N—NMe}_2}{\overset{\|}{-\text{C}-}} \xrightarrow{\text{NH}_2\text{—NH}_2} \underset{\text{N—NH}_2}{\overset{\|}{-\text{C}-}}$$

No azines are formed under these conditions.

OS **II,** 395; **III,** 96, 351; **IV,** 351, 377, 536, 884; **V,** 27, 258, 747, 929; **50,** 3, 102; **52,** 122; **55,** 52, 73; **57,** 69; **59,** 42; **61,** 141. Also see OS **III,** 708; **50,** 6.

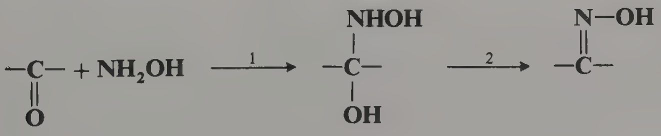
6-21 The Formation of Oximes
Hydroxyimino-de-oxo-bisubstitution



$$\underset{\text{O}}{\overset{\|}{-\text{C}-}} + \text{NH}_2\text{OH} \longrightarrow \underset{\text{N—OH}}{\overset{\|}{-\text{C}-}}$$

In a reaction very much like **6-20,** oximes can be prepared by the addition of hydroxylamine to aldehydes or ketones.[177] Derivatives of hydroxylamine, e.g., H_2NOSO_3H and $HON(SO_3Na)_2$, have also been used. For hindered ketones, such as hexamethylacetone, high pressures, e.g., 10,000 atm, may be necessary.[178] Another procedure, successful for hindered ketones, is to allow the ketone to stand with hydroxylamine and a strongly basic catalyst for 1 to 6 months. High yields of oximes are achieved in this way.[179]

It has been shown[180] that the rate of formation of oximes is at a maximum at a pH which depends on the substrate but is usually about 4, and that the rate decreases as the pH is either raised or lowered from this point. We have previously seen (p. 292) that bell-shaped curves like this are often caused by changes in the rate-determining step. In this case, at low pH values step 2 is rapid



$$\underset{\text{O}}{\overset{\|}{-\text{C}-}} + \text{NH}_2\text{OH} \xrightarrow{1} \underset{\text{OH}}{\overset{\text{NHOH}}{-\text{C}-}} \xrightarrow{2} \overset{\text{N—OH}}{\overset{\|}{-\text{C}-}}$$

[180] Jencks, *J. Am. Chem. Soc.* **81,** 475 (1959), *Prog. Phys. Org. Chem.* **2,** 63–128 (1964).

(because it is acid-catalyzed), and step 1 is slow (and rate-determining), because under these acidic conditions most of the NH_2OH molecules have been converted to the conjugate NH_3OH^+ ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free NH_2OH molecules increases and consequently so does the reaction rate, until the maximum rate is reached at about pH = 4. As the rising pH has been causing an increase in the rate of step 1, it has also been causing a *decrease* in the rate of the acid-catalyzed step 2, although this latter process has not affected the overall rate since step 2 was still faster than step 1. However, when the pH goes above about 4, step 2 becomes rate-determining, and although the rate of step 1 is still increasing (as it will until essentially all the NH_2OH is unprotonated), it is now step 2 that determines the rate, and this step is slowed by the decrease in acid concentration. Thus the overall rate decreases as the pH rises beyond about 4. It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.[181] There is evidence that when the nucleophile is 2-methylthiosemicarbazide, there is a second change in the rate-determining step: above pH about 10 *basic* catalysis of step 2 has increased the rate of this step to the point where step 1 is again rate-determining.[182] Still a third change in the rate-determining step has been found at about pH = 1, showing that at least in some cases step 1 actually consists of two steps: formation of a zwitterion, e.g., $HO\overset{\oplus}{N}H_2{-}\overset{|}{\underset{|}{C}}{-}O^{\ominus}$ in the case shown above, and conversion of this to **19.**[183] The intermediate **19** has been detected by nmr in the reaction between NH_2OH and acetaldehyde.[184]

In another type of process, oximes can be obtained by passing a mixture of ketone vapor, NH_3, and O_2 over a silica-gel catalyst.[185] Ketones can also be converted to oximes by treatment with other oximes, in a transoximation reaction.[186]

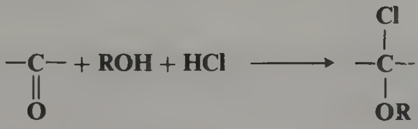
6-24 The Formation of α-Halo Ethers

Alkoxy,halo-de-oxo-bisubstitution



$$\underset{\underset{\displaystyle \text{O}}{\|}}{-\text{C}-} + \text{ROH} + \text{HCl} \longrightarrow -\overset{\overset{\displaystyle \text{Cl}}{|}}{\underset{\underset{\displaystyle \text{OR}}{|}}{\text{C}}}-$$

α-Halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and HX. The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. Aromatic aldehydes and ketones react poorly.[198]

The addition of HX to an aldehyde or ketone gives α-halo alcohols, which are usually unstable, although exceptions are known, especially with perfluoro and perchloro species.[199] Unstable α-halo alcohols may be quite stable in the dimeric form $2XCR_2OH \rightarrow XCR_2OCR_2X$.

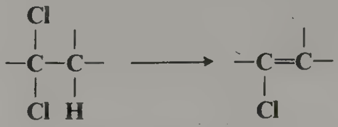
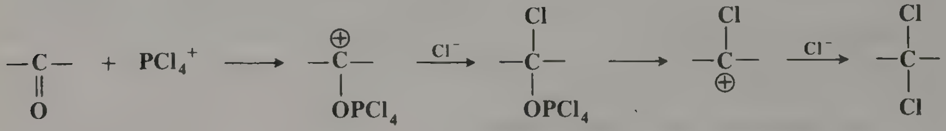
Aliphatic aldehydes and ketones can be converted to *gem*-dichlorides by treatment with PCl_5. The reaction fails for perhalo ketones.[200] If the aldehyde or ketone has an α-hydrogen, elimination of HCl may follow and a vinyl chloride is a frequent side product:[201]



$$-\underset{Cl}{\overset{Cl}{\underset{|}{\overset{|}{C}}}}-\underset{H}{\underset{|}{\overset{|}{C}}}- \longrightarrow -\underset{Cl}{\underset{|}{C}}=\overset{|}{C}-$$

or even the main product.[202] PBr_5 does not give good yields of *gem*-dibromides, but BBr_3 does, at least with aromatic aldehydes.[203]

The mechanism of *gem*-dichloride formation involves initial attack of PCl_4^+ (which is present in solid PCl_5) at the oxygen, followed by addition of Cl^- to the carbon:[204]



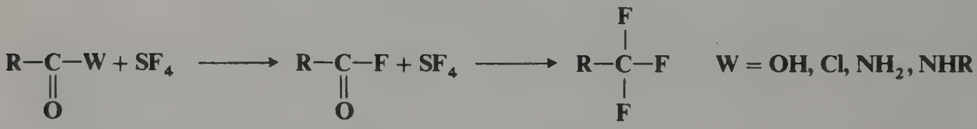
$$-\underset{O}{\underset{\|}{C}}- + PCl_4^+ \longrightarrow -\underset{OPCl_4}{\underset{|}{\overset{\oplus}{C}}}- \xrightarrow{Cl^-} -\underset{OPCl_4}{\underset{|}{\overset{Cl}{\overset{|}{C}}}}- \longrightarrow -\underset{\oplus}{\overset{Cl}{\overset{|}{C}}}- \xrightarrow{Cl^-} -\underset{Cl}{\underset{|}{\overset{Cl}{\overset{|}{C}}}}-$$

20

This chloride ion may come from PCl_6^- (which is also present in solid PCl_5). There follows a two-step SN1 process. Alternatively, **20** can be converted to the product without going through the chlorocarbocation, by an SNi process.

This reaction has sometimes been performed on esters, though these compounds very seldom undergo any addition to the C=O bond. An example is the conversion of $F_3CCOOPh$ to F_3CCCl_2OPh.[205] However, formates commonly give the reaction. PCl_5 converts hydrazides $RCONHNH_2$ to di- or trichlorides $RCHCl_2$ or $RCCl_3$.[206] R may be alkyl or aryl.

Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride SF_4,[207] including quinones, which give 1,1,4,4-tetrafluorocyclohexadiene derivatives. Carboxylic acids, acyl chlorides, and amides react with SF_4 to give 1,1,1-trifluorides. In these cases the first product is the acyl fluoride, which then undergoes the *gem*-difluorination reaction:



$$R-\underset{O}{\underset{\|}{C}}-W + SF_4 \longrightarrow R-\underset{O}{\underset{\|}{C}}-F + SF_4 \longrightarrow R-\underset{F}{\underset{|}{\overset{F}{\overset{|}{C}}}}-F \qquad W = OH, Cl, NH_2, NHR$$

The acyl fluroide can be isolated. Esters also give trifluorides, though more vigorous conditions are required, but in this case the carbonyl group of the ester is attacked first, and RCF_2OR' can be isolated from $RCOOR'$ and then converted to the trifluoride. Anhydrides can react in either manner, and both types of intermediate are isolable under the right conditions. SF_4 even converts carbon dioxide to CF_4. A disadvantage of reactions with SF_4 is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride SeF_4 gives similar reactions, but atmospheric pressure and ordinary glassware can be used.[208] Other reagents that have been used to convert aldehydes and ketones to *gem*-difluorides are phenylsulfur trifluoride $PhSF_3$,[209] carbonyl fluoride COF_2,[210] molybdenum hexafluoride MoF_6,[211] and the commercially available diethylaminosulfur trifluoride (DAST) Et_2NSF_3.[212] Gaseous ClF and HF has been used to convert carboxylic esters to RCF_2OR'.[213]

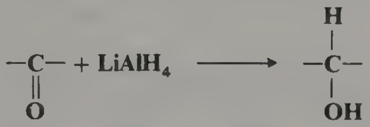
G. Attack by Hydrogen

6-26 Reduction of Aldehydes and Ketones to Alcohols

***C,O*-Dihydro-addition**



$$-\underset{\underset{O}{\|}}{C}- + LiAlH_4 \longrightarrow -\overset{\overset{H}{|}}{\underset{\underset{OH}{|}}{C}}-$$

Aldehydes can be reduced to primary alcohols, and ketones to secondary alcohols, by a number of reducing agents, of which lithium aluminum hydride and other metallic hydrides are the most commonly used.[214] These reagents have two main advantages over many other reducing agents: they do not reduce carbon–carbon double (or triple) bonds, and they generally contain a lot of hydrogen in a small amount of reagent—with $LiAlH_4$, all four hydrogens are usable for reduction. The reaction is broad and general. $LiAlH_4$ easily reduces aliphatic, aromatic, alicyclic, and heterocyclic aldehydes, containing double or triple bonds and/or nonreducible groups such as NR_3, OH, OR, F, etc. If the molecule contains a group reducible by $LiAlH_4$ (e.g., NO_2, CN, COOR), then it is also reduced.[215] $LiAlH_4$ reacts readily with water and alcohols, so that these compounds must be excluded. Common solvents are ether and THF. $NaBH_4$ has a similar scope but is more selective and so may be used with NO_2, Cl, COOR, CN, etc. in the molecule. Another advantage of $NaBH_4$ is that it can be used in water or alcoholic solvents and so reduces compounds such as sugars that are not soluble in ethers. The double bonds that are generally not affected by metallic hydrides may be isolated or conjugated, but double bonds that are conjugated with the C=O group may or may not be reduced, depending on the substrate, reagent, and reaction conditions. For example, it has proved possible to reduce only the C=O bonds of α,β-unsaturated ketones with AlH_3 and with diisobutylaluminum hydride (p. 694). Also, both $LiAlH_4$[216] and $NaBH_4$[217] predominantly reduce only the C=O bonds of C=C—C=O systems in most cases, though substantial amounts of fully saturated alcohols have been found in some cases[216] (p. 694). The scope of these reagents with ketones is similar to that with aldehydes. $LiAlH_4$ reduces even sterically hindered ketones.

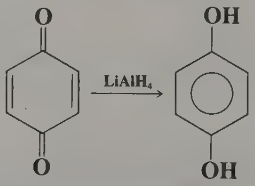
[217] Chaikin and Brown, *J. Am. Chem. Soc.* **71,** 122 (1949).

When a functional group is selectively attacked in the presence of a different functional group, the reaction is said to be *chemoselective*. A number of reagents have been found to reduce aldehydes much faster than ketones. Among these[218] are $NaBH_4$ in isopropyl alcohol,[219] sodium triacetoxyborohydride,[220] lithium tris[(3-ethyl-3-pentyl)oxy]aluminum hydride $Li(Et_3CO)_3AlH$,[221] 9-BBN-pyridine,[222] and tributyltin hydride.[223] On the other hand, ketones can be chemoselectively reduced in the presence of aldehydes with $NaBH_4$ in aqueous EtOH at −15°C in the presence of cerium trichloride $CeCl_3$.[224] The reagent lithium N-dihydropyridylaluminum hydride reduces diaryl ketones much better than it does dialkyl or alkyl aryl ketones.[225] Most other hydrides reduce diaryl ketones more slowly than other types of ketones. It is obvious that reagents can often be found to reduce one kind of carbonyl function in the presence of another. For a discussion of selectivity in reduction reactions, see p. 1093. Quinones are reduced to hydroquinones by $LiAlH_4$, $SnCl_2$-HCl, or sodium hydrosulfite $Na_2S_2O_4$, as well as by other reducing agents.



The reagent lithium tri-*sec*-butylborohydride $LiBH(sec\text{-}Bu)_3$, prepared by treatment of tri-*sec*-butylborane with lithium trimethoxyaluminum hydride $LiAlH(OMe)_3$, reduces cyclic and bicyclic ketones in a highly stereoselective manner, giving the less stable isomer.[226] For example, 2-methylcyclohexanone gave *cis*-2-methylcyclohexanol with an isomeric purity greater than 99%. The more usual reagents, e.g., $LiAlH_4$, $NaBH_4$, reduce relatively unhindered cyclic ketones either with little or no stereoselectivity or give predominant formation of the more stable isomer.[227] The less stable axial alcohol is also predominantly formed when cyclohexanones are reduced with (among other reagents) AlH_3 in ether at −70°C,[228] with triethyl phosphite and iridium tetrachloride in aqueous isopropyl alcohol,[229] with potassium triisopropoxyborohydride,[230] or with lithium dimesitylborohydride bis(dimethoxyethane).[231] Cyclohexanones that have a large degree of steric hindrance near the carbonyl group usually give predominant formation of the axial alcohol, even with $LiAlH_4$ and $NaBH_4$. The commercially available chiral reducing agent B-(3-pinanyl)-9-borabicyclo[3.3.1]nonane reduces deuterated aldehydes with almost complete optical purity.[232] The same reagent also reduces prochiral ketones (RCOR′), though optical purities are lower[233] unless high pressures are used.[233a]

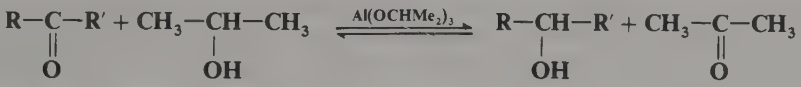
[230] Brown, Krishnamurthy, and Kim, *J. Chem. Soc., Chem. Commun.* 391 (1973).

Among other reagents that reduce aldehydes and ketones to alcohols are the following:

1. *Hydrogen and a catalyst.*[234] The most common catalysts are platinum and ruthenium, but homogeneous catalysts have also been used.[235] Before the discovery of the metal hydrides this was one of the most common ways of effecting this reduction, but it suffers from the fact that C═C, C≡C, C═N, and C≡N bonds are more susceptible to attack than C═O bonds.

2. *Sodium in ethanol.*[236] This is called the *Bouveault–Blanc procedure* and was more popular for the reduction of esters (**9-43**) than of aldehydes or ketones before the discovery of $LiAlH_4$.

3. *Isopropyl alcohol and aluminum isopropoxide.* This is called the *Meerwein–Ponndorf–Verley reduction.*[237] It is reversible, and the reverse reaction is known as the *Oppenauer oxidation* (see **9-3**):



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R' + CH_3{-}\underset{\underset{\displaystyle OH}{|}}{CH}{-}CH_3 \xrightleftharpoons{Al(OCHMe_2)_3} R{-}\underset{\underset{\displaystyle OH}{|}}{CH}{-}R' + CH_3{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}CH_3}$$

The equilibrium is shifted by removal of the acetone by distillation. The reaction takes place under very mild conditions and is highly specific for aldehydes and ketones, so that C═C bonds (including those conjugated with the C═O bonds) and many other functional groups can be present without themselves being reduced.[238] This includes acetals, so that one of two carbonyl groups in a molecule may be specifically reduced if the other is first converted to an acetal. β-Keto esters, β-diketones, and other ketones and aldehydes with a relatively high enol content do not give this reaction. In a variation of this reaction, aldehydes are selectively reduced by isopropyl alcohol or diisopropylcarbinol on dehydrated alumina.[239]

4. Borane BH_3 and substituted boranes[240] reduce aldehydes and ketones in a manner similar to their addition to C═C bonds (**5-13**).[241] That is, the boron adds to the oxygen and the hydrogen to the carbon:[242]

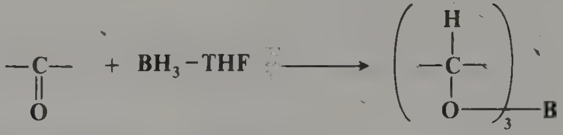
[241] For a review, see Cragg, "Organoboranes in Organic Synthesis," pp. 324–335, Marcel Dekker, New York, 1973.



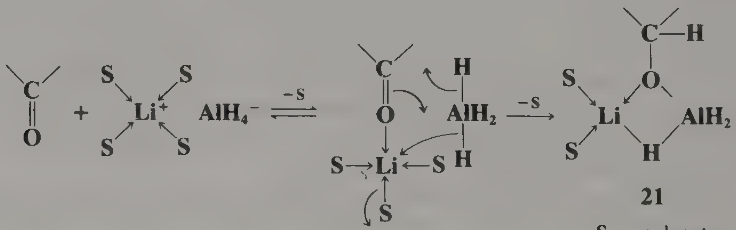
The borate is then hydrolyzed to the alcohol. 9-BBN[243] (p. 427) and BH_3-Me_2S[244] reduce only the C=O group of conjugated aldehydes and ketones. It has been reported that pyridine–borane in CF_3COOH reduces aldehydes to symmetrical ethers: $2RCHO \rightarrow RCH_2OCH_2R$.[245]

5. *Diimide* (N_2H_2, see p. 698) reduces aromatic aldehydes[246] and ketones, but aliphatic carbonyl compounds react very poorly.[247]

6. A single carbonyl group of an α-diketone can be reduced (to give an α-hydroxy ketone) by heating with zinc powder in aqueous dimethylformamide.[248] This has also been accomplished with aqueous VCl_2.[249]

7. In the Cannizzaro reaction (**9-70**) aldehydes without an α-hydrogen are reduced to alcohols.

With most reagents there is an initial attack on the carbon of the carbonyl group by H^- or some carrier of it, though with BH_3[250] the initial attack is on the oxygen. Detailed mechanisms are not known in most cases.[227] With metallic hydrides of aluminum or boron, the attacking species is the AlH_4^- (or BH_4^-) ion, which, in effect, transfers H^- to the carbon. The following mechanism has been proposed for $LiAlH_4$:[251]



21

S = solvent molecules

Evidence that the cation plays an essential role, at least in some cases, is that when the Li^+ was effectively removed from $LiAlH_4$ (by the addition of a crown ether), the reaction did not take place.[252] The complex **21** must now be hydrolyzed to the alcohol. For $NaBH_4$ the Na^+ does not seem to participate in the transition state, but kinetic evidence shows that an OR group from the solvent does participate and remains attached to the boron:[253]

Free H^- cannot be the attacking entity in most reductions with boron or aluminum hydrides because the reactions are frequently sensitive to the size of the MH_4^- [or $MR_mH_n^-$ or $M(OR)_mH_n^-$, etc.].

There has been much controversy about whether the initial complex in the $LiAlH_4$ reduction (**21**, which can be written as $H—C—OAlH_3^-$, **22**) can reduce another carbonyl to give $(H—C—O)_2AlH_2^-$, and so on. It has been shown[254] that this is probably not the case but that, more likely, **22** disproportionates to $(H—C—O)_4Al^-$ and AlH_4^-, which is the only attacking species. However, disproportion does not take place in the $NaBH_4$ reaction.[255]

22 is essentially $LiAlH_4$ with one of the hydrogens replaced by an alkoxy group, i.e., $LiAlH_3OR$. The fact that **22** and other alkoxy derivatives of $LiAlH_4$ are less reactive than $LiAlH_4$ itself has led to the use of such compounds as reducing agents that are less reactive and more selective than $LiAlH_4$.[256] We have already met some of these, e.g., LiAlH(O-*t*-Bu)$_3$ (reactions **0-84** to **0-86;** see also Table 5, Chapter 19, p. 1095). As an example of selectivity in this reaction it may be mentioned that LiAlH(O-*t*-Bu)$_3$ has been used to reduce only the keto group in a molecule containing both keto and ester groups.[257] However, the use of such reagents is sometimes complicated by the disproportionation mentioned above, which may cause $LiAlH_4$ to be the active species, even if the reagent is an alkoxy derivative. Another highly selective reagent (reducing aldehydes and ketones, but not other functional groups), which does not disproportionate, is potassium triisopropoxyborohydride.[230] The use of tin hydrides, such as Ph_2SnH_2, gives alcohols from aldehydes or ketones directly; i.e., both hydrogens come from the hydride, and no hydrolysis is needed.[258]

The Meerwein–Ponndorf–Verley reaction usually[259] involves a cyclic transition state:[260]

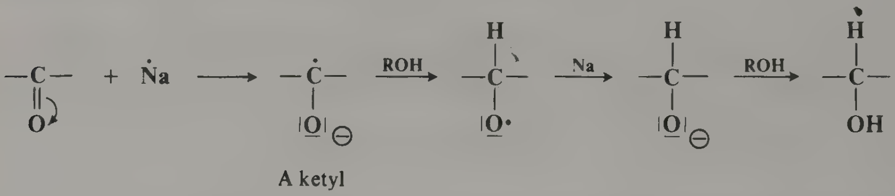
[258] Kuivila and Beumel, *J. Am. Chem. Soc.* **83,** 1246 (1961). For a review of reductions with organotin hydrides, see Kuivila, *Synthesis* 499–509 (1970).

[259] It has been shown that in some cases reduction with metal alkoxides, including aluminum isopropoxide, involves free-radical intermediates (SET mechanism): Ashby, Goel, and Argyropoulos, *Tetrahedron Lett.* **23,** 2273 (1982).

[260] See for example, Shiner and Whittaker, *J. Am. Chem. Soc.* **85,** 2337 (1963); Warnhoff, Reynolds-Warnhoff, and Wong, *J. Am. Chem. Soc.* **102,** 5956 (1980).

but in some cases 2 moles of aluminum alkoxide are involved—one attacking the carbon and the other the oxygen, a conclusion that stems from the finding that in these cases the reaction was 1.5 order in alkoxide.[261] Although, for simplicity, we have shown the alkoxide as a monomer, it actually exists as trimers and tetramers, and it is these that react.[262]

The mechanism[263] of the reaction with sodium in ethanol is similar to that of the Birch reduction (**5-11**) and involves a ketyl intermediate, which can be isolated.[264]



The mechanism of catalytic hydrogenation of aldehydes and ketones is probably similar to that of reaction **5-10,** though not much is known about it.[265]

For other reduction reactions of aldehydes and ketones, see reactions **9-38** and **9-63.** Also see reaction **9-70.**

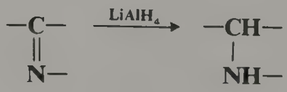
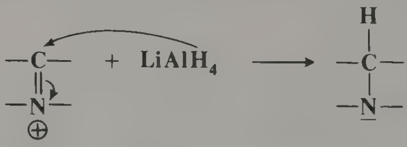
6-27 Reduction of the Carbon–Nitrogen Double Bond

C,N-Dihydro-addition



$$\begin{matrix} -\text{C}- \\ \| \\ \text{N}- \end{matrix} \xrightarrow{\text{LiAlH}_4} \begin{matrix} -\text{CH}- \\ | \\ \text{NH}- \end{matrix}$$

Imines, Schiff bases, hydrazones, and other C═N compounds can be reduced with $LiAlH_4$, $NaBH_4$, Na–EtOH, hydrogen and a catalyst, as well as with other reducing agents.[266] Iminium salts are also reduced by $LiAlH_4$, though here there is no "addition" to the nitrogen:[267]



Isocyanates have been catalytically hydrogenated to N-substituted formamides: RNCO → R—NH—CHO.[268]

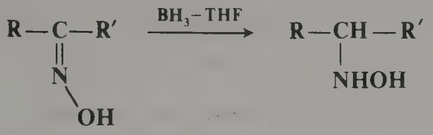
[266] For a review, see Harada, in Patai, "The Chemistry of the Carbon–Nitrogen Double Bond," Ref 40, pp. 276–293. For a review with respect to catalytic hydrogenation, see Rylander, Ref. 146, pp. 123–138.

[267] For a review of nucleophilic additions to iminium salts, see Paukstelis, in Cook, Ref. 45, pp. 169–209.

[268] Howell, Synth. Commun. **13,** 635 (1983).

Oximes are generally reduced to amines (**9-52**), but simple addition of H_2 to give hydroxylamines can be accomplished with borane at 25°C[269] or with sodium cyanoborohydride.[148]



$$\underset{\underset{\text{OH}}{\overset{\|}{\text{N}}}}{\text{R—C—R}'} \xrightarrow{\text{BH}_3\text{-THF}} \underset{\text{NHOH}}{\text{R—CH—R}'}$$

OS **III,** 328, 827; **51,** 24. Also see OS **IV,** 283.

6-28 The Reduction of Nitriles to Amines
***CC,NN*-Tetrahydro-biaddition**

$$\text{R—C}\equiv\text{N} + \text{LiAlH}_4 \longrightarrow \text{R—CH}_2\text{—NH}_2$$

Nitriles can be reduced to primary amines with many reducing agents,[270] including $LiAlH_4$, BH_3-Me_2S,[271] NaOEt, and hydrogen and a catalyst.[272] $NaBH_4$ does not generally reduce nitriles but does so in alcoholic solvents when a $CoCl_2$ catalyst is added[273] or in the presence of Raney nickel.[274] The reaction is of wide scope and has been applied to many nitriles. When catalytic hydrogenation is used, secondary amines $(RCH_2)_2NH$ are often side products. These can be avoided by adding a compound such as acetic anhydride, which removes the primary amine as soon as it is formed,[275] or by the use of excess ammonia to drive the equilibria backward.[276]

It is not possible to stop with the addition of only 1 mole of hydrogen, i.e., to convert the nitrile to an imine, except where the imine is subsequently hydrolyzed (reaction **6-29**).

N-Alkylnitrilium ions are reduced to secondary amines by $NaBH_4$.[277]

$$\text{RCN} \xrightarrow{\text{R}'_3\text{O}^+\ \ \text{BF}_4^-} \text{R—C}\equiv\overset{\oplus}{\text{N}}\text{—R}' \xrightarrow[\text{diglyme}]{\text{NaBH}_4} \text{RCH}_2\text{—NH—R}'$$

Since nitrilium salts can be prepared by treatment of nitriles with trialkyloxonium salts (see **6-9**), this is a method for the conversion of nitriles to secondary amines. In contrast, triethylsilane reduces nitrilium ions to imines: $\text{R—C}\equiv\overset{\oplus}{\text{N}}\text{—R}' \rightarrow \text{R—CH=N—R}'$.[278] The imines can be hydrolyzed to aldehydes RCHO, making this an indirect method for the conversion of nitriles to aldehydes.

OS **III,** 229, 358, 720; **53,** 21.

6-29 The Reduction of Nitriles to Aldehydes
Hydro,oxy-de-nitrilo-tersubstitution

$$\text{R—C}\equiv\text{N} \xrightarrow[\text{2. hydrolysis}]{\text{1. HCl, SnCl}_2} \text{R—CH=O}$$

[278] Fry, *J. Chem. Soc., Chem. Commun.* 45 (1974).

There are two principal methods for the reduction of nitriles to aldehydes.[279] In one of these, known as the *Stephen reduction,* the nitrile is treated with HCl to form

$$\mathrm{RCCl{=}NH_2^+\ Cl^-}$$

23

This is reduced with anhydrous $SnCl_2$ to RCH=NH, which precipitates as a complex with $SnCl_4$ and is then hydrolyzed (**6-2**) to the aldehyde. The Stephen reduction is most successful when R is aromatic, but it can be done for aliphatic R up to about six carbons.[280] It is also possible to prepare **23** in a different way, by treating ArCONHPh with PCl_5. The **23** obtained in this way can then be converted to the aldehyde. This is known as the *Sonn–Müller method.*

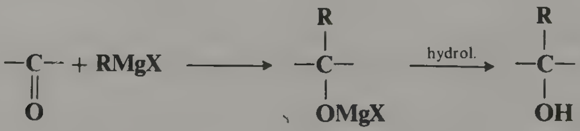
The other way of reducing nitriles to aldehydes involves using a metal hydride reducing agent to add 1 mole of hydrogen and hydrolysis, in situ, of the resulting imine (which is undoubtedly coordinated to the metal). This has been carried out with $LiAlH_4$, $LiAlH(OEt)_3$,[281] $AlH(CH_2CHMe_2)_2$,[282] and $NaAlH_4$.[283] The metal hydride method is useful for aliphatic and aromatic nitriles. Reduction to the aldehyde has also been accomplished[284] by treatment of the nitrile with sodium hypophosphate and Raney nickel in aqueous acetic acid–pyridine of formic acid,[285] and with zinc and a Cob(I)alamin catalyst in aqueous acetic acid.[286] Another method for the conversion of nitriles to aldehydes (by way of the nitrilium ion) was mentioned at **6-28.**

OS **III,** 626, 818; **51,** 20.

H. Carbon Attack by Organometallic Compounds

6-30 The Addition of Organometallic Compounds to Aldehydes and Ketones

***O*-Hydro-*C*-alkyl-addition**



$$\underset{\substack{\| \\ \mathrm{O}}}{-\mathrm{C}-} + \mathrm{RMgX} \longrightarrow \overset{\substack{\mathrm{R} \\ |}}{\underset{\substack{| \\ \mathrm{OMgX}}}{-\mathrm{C}-}} \xrightarrow{\text{hydrol.}} \overset{\substack{\mathrm{R} \\ |}}{\underset{\substack{| \\ \mathrm{OH}}}{-\mathrm{C}-}}$$

The addition of Grignard reagents to aldehydes and ketones is known as the *Grignard reaction.*[287] Formaldehyde gives primary alcohols; other aldehydes give secondary alcohols; and ketones give tertiary alcohols. The reaction is of very broad scope, and hundreds of alcohols have been prepared in this manner. R may be alkyl or aryl. In many cases the hydrolysis step is carried out with dilute HCl or H_2SO_4, but this cannot be done for tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (reaction **7-1**). In such cases

[286] Fischli, *Helv. Chim. Acta* **61,** 2560 (1978).

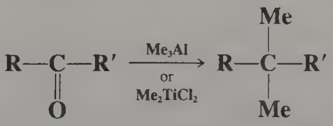
[287] For reviews of the addition of organometallic compounds to carbonyl groups, see Eicher, in Patai, "The Chemistry of the Carbonyl Group," Ref. 40, pp. 621–693; Kharasch and Reinmuth, "Grignard Reactions of Nonmetallic Substances," pp. 138–528, Prentice-Hall, Englewood Cliffs, N.J., 1954.

(and often for other alcohols as well) an aqueous solution of ammonium chloride is used instead of a strong acid. Other organometallic compounds may also be used, but in general only of active metals; e.g., alkylmercurys do not react. In practice, the only organometallic compounds used to any extent, besides Grignard reagents, are alkyl- and aryllithiums, though alkylzinc reagents were used in the past.[288] For the addition of acetylenic groups, sodium may be the metal used: RC≡CNa (**6-42**); while vinylalanes (prepared as in **5-14**) are the reagents of choice for the addition of vinyl groups.[289] Allyltrialkyltin compounds (in the presence of BF_3-etherate) have been used for the addition of allyl groups.[290]

The reaction with alkyl- and aryllithium reagents has also been carried out without preliminary formation of RLi: a mixture of RX and the carbonyl compound was added to a suspension of lithium pieces in THF.[291] Yields were generally satisfactory. The magnesium analog of this process is called the *Barbier reaction*.[292] Lithium dimethylcopper Me_2CuLi reacts with aldehydes[293] and with certain ketones[294] to give the expected alcohols.

Chiral secondary alcohols with high optical yields have been obtained by addition to aldehydes or alkyllithium and Grignard reagents in the presence of chiral amino alcohols as ligands.[295] These are enantioselective syntheses. Diastereoselective syntheses have been carried out with crotylmetallic reagents ($CH_3CH{=}CH{-}CH_2M$).[296]

Trimethylaluminum[297] and dimethyltitanium dichloride[298] exhaustively methylate ketones to give *gem*-dimethyl compounds (see also **0-91**):



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} \xrightarrow[\mathrm{Me_2TiCl_2}]{\mathrm{Me_3Al}\ \text{or}} \mathrm{R{-}\overset{\overset{\displaystyle Me}{|}}{\underset{\underset{\displaystyle Me}{|}}{C}}{-}R'}$$

α,β-Unsaturated aldehydes or ketones can give 1,4 addition as well as normal 1,2 addition (see p. 714). In general, alkyllithiums give less 1,4 addition than the corresponding Grignard reagents.[299] Quinones add Grignard reagents on one or both sides or give 1,4 addition. In a compound containing both an aldehydic and a ketonic carbonyl group it is possible to add RMgX chemoselectively to the aldehydic function without significantly disturbing the ketonic group.[300] On the other hand, chemoselective addition to a ketonic group can be carried out if the aldehyde is protected with a titanium tetrakis(dialkylamide).[301]

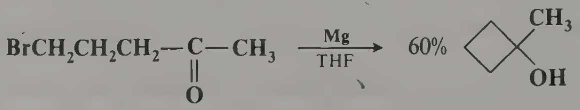
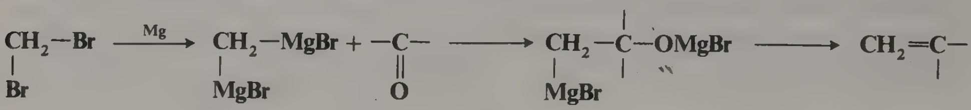
[299] An example was given on p. 714. Another can be found in Wessely, Budzikiewicz, and Janda, *Monatsh. Chem.* **92,** 621 (1961).

In some cases the Grignard reaction can be performed intramolecularly. For example, treatment of 5-bromo-2-pentanone with magnesium and a small amount of mercuric chloride in tetrahydrofuran



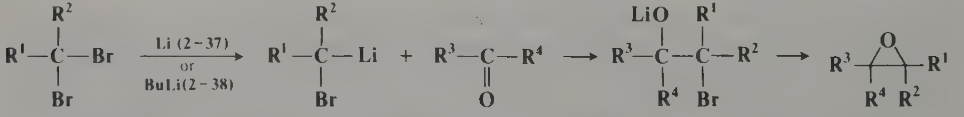
produced 1-methyl-1-cyclobutanol in 60% yield.[302] Other four- and five-membered ring compounds were also prepared by this procedure. Similar closing of five- and six-membered rings was achieved by treatment of a δ- or ε-halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenylporphine.[303]

The *gem*-disubstituted magnesium compounds formed from CH_2Br_2 or CH_2I_2 (reaction **2-37**) react with aldehydes or ketones to give olefins in moderate-to-good yields.[304] The reaction could



$$\underset{\displaystyle Br}{\overset{}{CH_2}}\!-\!Br \xrightarrow{Mg} \underset{\displaystyle MgBr}{CH_2}\!-\!MgBr + -\underset{\displaystyle O}{\overset{}{\underset{\|}{C}}}- \longrightarrow \underset{\displaystyle MgBr}{CH_2}\!-\!\overset{|}{\underset{|}{C}}\!-\!OMgBr \longrightarrow CH_2\!=\!\underset{|}{C}-$$

not be extended to other *gem*-dihalides. Similar reactions with *gem*-dimetallic compounds prepared with metals other than magnesium have also produced olefins, though sometimes with low yields.[305] However, exceptions are the α,α-dimetallic derivatives of phenyl sulfones $PhSO_2CM_2R$ (M = Li or Mg), which react with aldehydes or ketones R′COR″ to give good yields of the α,β-unsaturated sulfones $PhSO_2CR{=}CR'R''$,[306] which can be reduced with aluminum amalgam (see **0-96**) or with $LiAlH_4$-$CuCl_2$ to give the olefins $CHR{=}CR'R''$.[307] These reactions are closely related to the Wittig reaction (**6-47**) and, like it, provide a means of achieving the conversion $R_2C{=}O \rightarrow R_2C{=}R_2'$. On the other hand, *gem*-dihalides treated with a carbonyl compound and Li or BuLi give epoxides[308]



(see also **6-63**). In another use of *gem*-dihalo compounds, methylene halides add the CHX_2 group to aldehydes or ketones when treated with lithium dicyclohexylamide at low temperatures.[309]

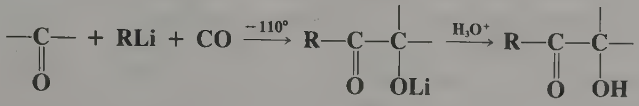
$$CH_2X_2 + \underset{\underset{\displaystyle O}{\|}}{-C-} \xrightarrow[\text{2. } H_2O]{\text{1. } LiN(C_6H_{11})_2,\ -78^\circ C} -\overset{|}{\underset{\underset{\displaystyle OH}{|}}{C}}-CHX_2 \qquad X = Cl, Br, I$$

It is possible to add an acyl group to a ketone to give (after hydrolysis) an α-hydroxy ketone. This is done by adding RLi and CO to the ketone at −110°C:[310]

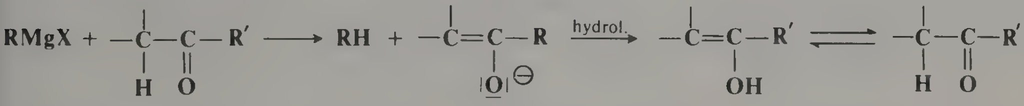


$$\underset{\underset{\displaystyle O}{\|}}{-C-} + RLi + CO \xrightarrow{-110^\circ} R-\underset{\underset{\displaystyle O}{\|}}{C}-\overset{|}{\underset{\underset{\displaystyle OLi}{|}}{C}}- \xrightarrow{H_3O^+} R-\underset{\underset{\displaystyle O}{\|}}{C}-\overset{|}{\underset{\underset{\displaystyle OH}{|}}{C}}-$$

When the same reaction is carried out with carboxylic esters R′COOR″, α-diketones RCOCOR′ are obtained.[310]

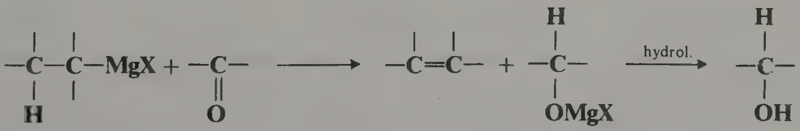
Although most aldehydes and ketones react very nicely with most Grignard reagents, there are several types of side reaction that occur mostly with hindered ketones and with bulky Grignard reagents. The two most important of these are *enolization* and *reduction*. The former requires that the aldehyde or ketone have an α-hydrogen, and the latter requires that the Grignard reagent have a β-hydrogen:

Enolization



$$RMgX + -\overset{|}{\underset{\underset{\displaystyle H}{|}}{C}}-\underset{\underset{\displaystyle O}{\|}}{C}-R' \longrightarrow RH + -\overset{|}{C}=\underset{\underset{\displaystyle \overline{\underline{O}}^{\ominus}}{|}}{C}-R \xrightarrow{\text{hydrol.}} -\overset{|}{C}=\underset{\underset{\displaystyle OH}{|}}{C}-R' \rightleftharpoons -\overset{|}{\underset{\underset{\displaystyle H}{|}}{C}}-\underset{\underset{\displaystyle O}{\|}}{C}-R'$$

Reduction



$$-\overset{|}{\underset{\underset{\displaystyle H}{|}}{C}}-\overset{|}{\underset{|}{C}}-MgX + \underset{\underset{\displaystyle O}{\|}}{-C-} \longrightarrow -\overset{|}{C}=\overset{|}{C}- + -\overset{\overset{\displaystyle H}{|}}{\underset{\underset{\displaystyle OMgX}{|}}{C}}- \xrightarrow{\text{hydrol.}} -\overset{\overset{\displaystyle H}{|}}{\underset{\underset{\displaystyle OH}{|}}{C}}-$$

Enolization is an acid–base reaction (**2-22**) in which a proton is transferred from the α-carbon to the Grignard reagent. The carbonyl compound is converted to its enolate ion form, which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol form, e.g., β-keto esters, etc. In reduction, the carbonyl compound is reduced to an alcohol (**6-26**) by the Grignard reagent, which itself undergoes elimination to give an olefin. Two other side reactions are condensation (between enolate ion and excess ketone) and Wurtz-type coupling (**0-93**). Such highly hindered tertiary alcohols as triisopropylcarbinol, tri-*t*-butylcarbinol, and diisopropylneopentylcarbinol cannot be prepared (or can be prepared only in extremely low yields) by the addition of Grignard reagents to ketones, because reduction and/or enolization become prominent.[311] However, these carbinols can be prepared by the use of alkyllithiums at −80°C,[312] under which conditions enolization and reduction are much less important.[313] Other methods of increasing the degree of addition at the expense of reduction consist of complexing the Grignard reagent with $LiClO_4$ or $Bu_4N^+ Br^-$,[314] or using benzene or toluene instead of ether as solvent.[315]

Another way to avoid complications is to add $(RO)_3TiCl$, $(RO)_3ZrCl$, or $(R_2N)_3TiX$ to the Grignard or lithium reagent. This produces organotitanium or organozirconium compounds that are much more selective than Grignard or organolithium reagents.[316] An important advantage of these reagents is that they do not react with NO_2 or CN functions that may be present in the substrate, as Grignard and organolithium reagents do.

There has been much controversy regarding the mechanism of addition of Grignard reagents to aldehydes and ketones.[317] The reaction is difficult to study because of the variable nature of the species present in the Grignard solution (p. 159) and because the presence of small amounts of impurities in the magnesium seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.[318] Furthermore, the mechanism seems to be quite complicated, since both RMgX and R_2Mg can react with the ketone, since both of these species as well as Mg_2X form complexes (Chapter 3) with the ketone.[319] and since the products initially formed can then react further (as described below). A detailed mechanism for the reaction between methylmagnesium bromide and 2-methylbenzophenone has been proposed by Ashby and co-workers,[320] based on the discovery that this reaction proceeds by two paths—one first order in MeMgBr and the other first order in Me_2Mg.[321] The initial stages of this mechanism, which starts with the three complexes formed from MeMgBr, Me_2Mg, and $MgBr_2$, are[322]

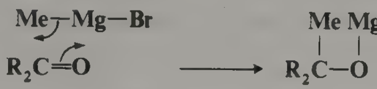
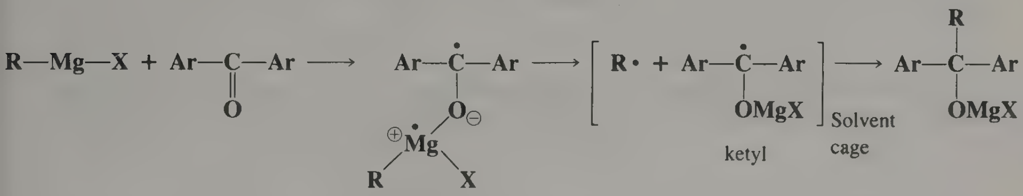
[322] The coefficient 2 in front of the MeMgBr refers only to the Schlenk equilibrium, presented horizontally, and not to the reactions between MeMgBr and the ketone, presented vertically.

When excess Grignard reagent is present, the steps shown are essentially all that are required to describe the mechanism, but when the ketone-to-Grignard ratio is about 1 : 1, or when excess ketone is present, **24** and **25** react further—with each other and with additional molecules of RMgX and of ketone to give dimeric and trimeric species. Although the formation of these species complicates the mechanistic picture, they present no synthetic problem, since the hydrolysis step at the end of the reaction converts them all to the same alcohol, in this case R_2MeCOH. The exact nature of the step by which MeMgBr or Me_2Mg reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:[323]



In the case of RLi, addition of a cryptand (p. 78) that binds Li^+ inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.[324]

The mechanism just outlined is not the only one. There is evidence that, in some cases, at least a part of the reaction may go through a ketyl (p. 169) intermediate:[325]



This pathway is called the *single-electron-transfer* (SET) *pathway*.[326] The SET pathway is more likely for conjugated (including aromatic) aldehydes and ketones and is favored by the presence of small amounts of transition metals[327] (which are often found as impurities in the magnesium). Among the evidence[328] for the SET mechanism are esr spectra[329] and the obtention of  $\underset{OH}{Ar_2C}—\underset{OH}{CAr_2}$ side products (from dimerization of the ketyl).[330]

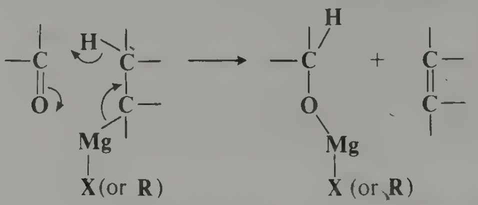
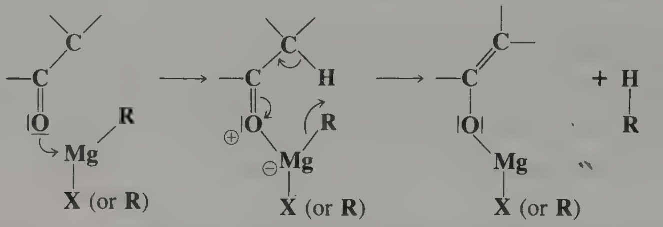
There is general agreement that the mechanism leading to reduction[331] is usually as follows:



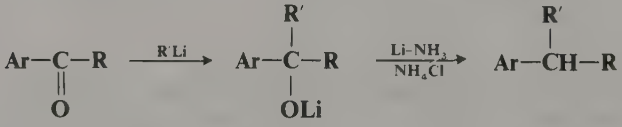
reduction

However, it has been shown that reduction can also take place by an SET mechanism.[332] There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium:[333]



enolization

Aromatic aldehydes and ketones can be alkylated and reduced in one reaction vessel by treatment with an alkyl- or aryllithium, followed by lithium and ammonia and then by ammonium chloride.[334]



$$\mathrm{Ar{-}C({=}O){-}R} \xrightarrow{\mathrm{R'Li}} \mathrm{Ar{-}CR'(OLi){-}R} \xrightarrow[\mathrm{NH_4Cl}]{\mathrm{Li{-}NH_3}} \mathrm{Ar{-}CHR'{-}R}$$

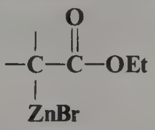
[333] Pinkus and Servoss, *J. Chem. Soc., Perkin Trans.* 2 1600 (1979); Pinkus and Sabesan, *J. Chem. Soc., Perkin Trans.* 2 273 (1981).

[334] Hall and Lipsky, *J. Org. Chem.* **38,** 1735 (1973); Lipsky and Hall, *Org. Synth.* **55,** 7; McEnroe, Sha, and Hall, *J. Org. Chem.* **41,** 3456 (1976).

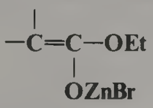
The *Reformatsky reaction* is very similar to **6-30.**[335] An aldehyde or ketone is treated with zinc and a halide; the halide is nearly always an α-halo ester or a vinylog of an α-halo ester (e.g., RCHBrCH═CHCOOEt), though α-halo nitriles,[336] α-halo N,N-disubstituted amides, and the zinc salts of α-halo carboxylic acids[337] have also been used. With the last reagent the product is a β-hydroxy acid. The reaction has also been carried out with tin[338] or activated indium[339] instead of zinc, and with a Zn-Cu couple.[340] The aldehyde or ketone may be aliphatic, aromatic, or heterocyclic or contain various functional groups. The reaction can be run in less time with higher yields if done in the presence of ultrasound.[341]

Formally, the reaction can be regarded as if it were analogous to the Grignard reaction (**6-30**), with **26** as an intermediate analogous to RMgX. There *is* an intermediate derived from zinc and



$-\overset{|}{\underset{\underset{\text{ZnBr}}{|}}{C}}-\overset{\overset{\text{O}}{\|}}{C}-\text{OEt}$

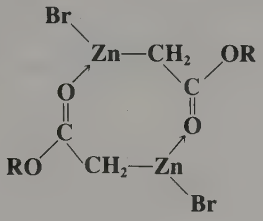
26



$-\overset{|}{C}{=}\underset{\underset{\text{OZnBr}}{|}}{C}-\text{OEt}$

27

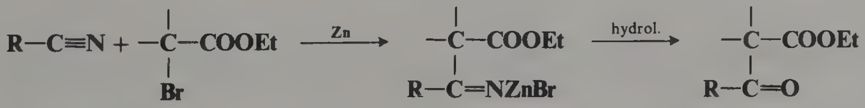
the ester, and there has been much controversy as to whether it has the structure **26** or the enolate structure **27.**[342] However, x-ray crystallography of the solid intermediate prepared from $t\text{-BuOCOCH}_2\text{Br}$ and Zn showed it to be dimeric with the structure **28,**[343] so it has characteristics of both **26** and **27.**



R = *t*-Bu

28

Usually, after hydrolysis, the alcohol is the product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an olefin. Since Grignard reagents cannot be formed from α-halo esters, the method is quite useful, although there are competing reactions and yields are sometimes low. A similar reaction (called the *Blaise reaction*) has been carried out on nitriles:[344]



$$\text{R}-\text{C}{\equiv}\text{N} + -\overset{|}{\underset{\underset{\text{Br}}{|}}{C}}-\text{COOEt} \xrightarrow{\text{Zn}} -\overset{|}{\underset{\underset{\text{R}-\text{C}=\text{NZnBr}}{|}}{C}}-\text{COOEt} \xrightarrow{\text{hydrol.}} -\overset{|}{\underset{\underset{\text{R}-\text{C}=\text{O}}{|}}{C}}-\text{COOEt}$$

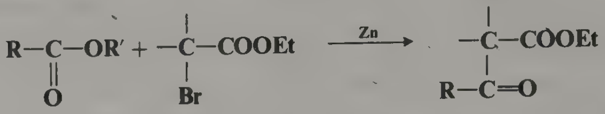
[343] Dekker, Boersma, and van der Kerk, *J. Chem. Soc., Chem. Commun.* 553 (1983).

[344] See Cason, Rinehart, and Thornton, *J. Org. Chem.* **18,** 1594 (1953); Bellassoued and Gaudemar, *J. Organomet. Chem.* **81,** 139 (1974); Hannick and Kishi, *J. Org. Chem.* **48,** 3833 (1983).

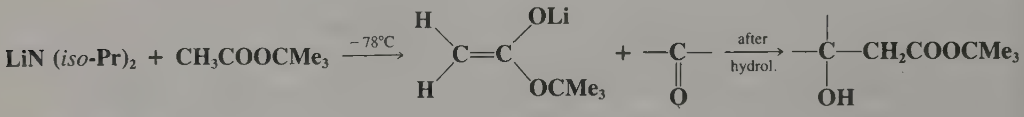
Esters have also been used as substrates, but then, as might be expected (p. 781), the result is substitution and not addition:



$$\text{R}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{OR}' + -\overset{|}{\underset{\underset{\text{Br}}{|}}{\text{C}}}-\text{COOEt} \xrightarrow{\text{Zn}} -\overset{|}{\underset{\underset{\text{R}-\text{C}=\text{O}}{|}}{\text{C}}}-\text{COOEt}$$

The product in this case is the same as with the corresponding nitrile, though the pathways are different.

Addition of *t*-butyl acetate to lithium diisopropylamide in hexane at −78°C gives the lithium salt of *t*-butyl acetate[345] (**2-20**) as a stable white solid. The nmr and ir spectra of this salt in benzene show it to have the enolate structure **29**, similar to the structure **27** given above.



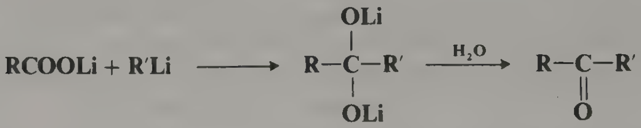
29

Reaction of **29** with a ketone provides a simple rapid alternative to the Reformatsky reaction as a means of preparing β-hydroxy *t*-butyl esters. A similar reaction involves treatment of a ketone with a silyl ketene acetal $R_2C{=}C(OSiMe_3)OR'$ in the presence of $TiCl_4$.[346]

OS **III,** 408; **IV,** 120, 444.

6-32 The Conversion of Carboxylic Acid Salts to Ketones with Organometallic Compounds

Alkyl-de-oxido-substitution



$$\text{RCOOLi} + \text{R}'\text{Li} \longrightarrow \text{R}-\overset{\overset{\text{OLi}}{|}}{\underset{\underset{\text{OLi}}{|}}{\text{C}}}-\text{R}' \xrightarrow{\text{H}_2\text{O}} \text{R}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{R}'$$

Good yields of ketones can often be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent, followed by hydrolysis.[347] The reaction can be run in two ways: the acid can be treated with 2 moles of R′Li, or the lithium carboxylate can be independently prepared and treated with 1 mole of R′Li. R′ may be aryl or primary, secondary, or tertiary alkyl. MeLi and PhLi have been employed most often. R may be alkyl or aryl, though lithium acetate generally gives low yields. Tertiary alcohols are side products.

A reaction between ArCOOLi and RLi is one step in a conversion of an aromatic aldehyde to an alkyl aryl ketone. The aldehyde is converted to the corresponding cyclic acetal, which is treated with excess RLi.[348]

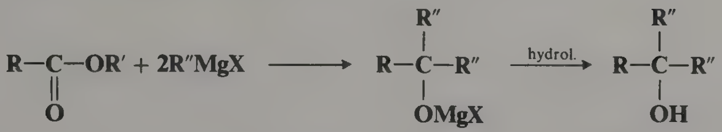
OS **V**, 775.

6-33 The Addition of Grignard Reagents to Acid Derivatives

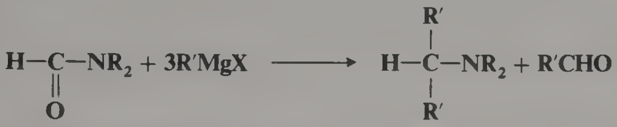


$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}OR' + 2R''MgX \longrightarrow R{-}\underset{\underset{OMgX}{|}}{\overset{\overset{R''}{|}}{C}}{-}R'' \xrightarrow{\text{hydrol.}} R{-}\underset{\underset{OH}{|}}{\overset{\overset{R''}{|}}{C}}{-}R''}$$

When esters are treated with Grignard reagents, there is usually concomitant addition to the carbonyl (**6-30**) and substitution of R″ for OR′ (**0-106**), so that tertiary alcohols are formed in which two R groups are the same. Formates give secondary alcohols and carbonates give tertiary alcohols in which all three R groups are the same: $(EtO)_2C{=}O + RMgX \rightarrow R_3COMgX$. Acyl halides and anhydrides behave similarly, though these substrates are employed less often.[349] There are many side reactions possible, especially when the acid derivative or the Grignard reagent is branched: enolizations, reductions (not for esters, but for halides), condensations, and cleavages, but the most important is simple substitution (**0-106**), which in some cases can be made to predominate. Trimethylaluminum, which exhaustively methylates ketones (**6-30**), also exhaustively methylates carboxylic acids to give *t*-butyl compounds[350] (see also **0-91**):

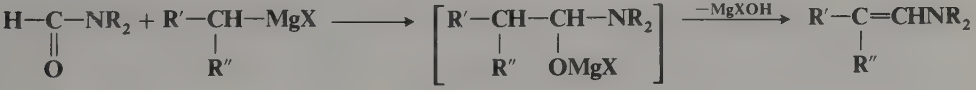
$$\mathrm{RCOOH + excess\ Me_3Al \xrightarrow{120^\circ C} RCOOAlMe_2 \xrightarrow{Me_3Al} RCMe_3}$$

Disubstituted formamides can give addition of 2 moles of Grignard reagent.



$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}NR_2 + 3R'MgX \longrightarrow H{-}\underset{\underset{R'}{|}}{\overset{\overset{R'}{|}}{C}}{-}NR_2 + R'CHO}$$

The products of this reaction (called the *Bouveault reaction*) are an aldehyde and a tertiary amine.[351] The use of an amide other than a formamide can give a ketone instead of an aldehyde, but yields are generally low. It has proven possible to add two different R groups by sequential addition of two Grignard reagents.[352] Alternatively, if R′ contains an α-hydrogen, the product may be an enamine, and enamines have been synthesized in good yields by this method.[353]



$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}NR_2 + R'{-}\underset{\underset{R''}{|}}{CH}{-}MgX \longrightarrow \left[R'{-}\underset{\underset{R''}{|}}{CH}{-}\underset{\underset{OMgX}{|}}{CH}{-}NR_2\right] \xrightarrow{-MgXOH} R'{-}\underset{\underset{R''}{|}}{C}{=}CHNR_2}$$

OS **I,** 226; **II,** 179, 602; **III,** 237, 831, 839; **IV,** 601; **52,** 19; **55,** 39.

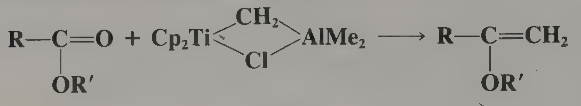
6-34 Conversion of Carboxylic Esters to Enol Ethers

Methylene-de-oxo-bisubstitution



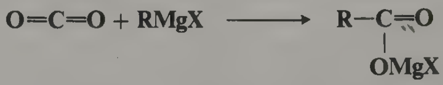
30

Cp = cyclopentadienide

Carboxylic esters and lactones can be converted in good yields to the corresponding enol ethers by treatment with the titanium cyclopentadienide complex **30** in toluene–THF containing a small amount of pyridine.[354] **30** is prepared from dicyclopentadienyltitaniumdichloride and trimethylaluminum. There are several methods for the conversion C=O to $C{=}CH_2$ when the substrate is an aldehyde or ketone (see **6-40** to **6-44, 6-47**), but very few ways to make the same conversion for a carboxylic ester. The enol ether can be hydrolyzed to a ketone (**0-7**), so this is also an indirect method for making the conversion RCOOR′ → $RCOCH_3$ (see also **0-107**).

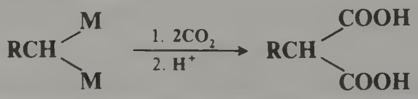
6-35 The Addition of Organometallic Compounds to CO_2

C-Alkyl-*O*-halomagnesio-addition



$$O{=}C{=}O + RMgX \longrightarrow \begin{array}{l} R{-}C{=}O \\ \quad\ | \\ \quad OMgX \end{array}$$

Grignard reagents add to one C=O bond of CO_2 exactly as they do to an aldehyde or a ketone.[355] Here, of course, the product is the salt of a carboxylic acid. The reaction is usually performed by adding the Grignard reagent to dry ice. Many carboxylic acids have been prepared in this manner, and, along with the sequence **0-103–6-5** and reaction **8-9,** this constitutes an important way of increasing a carbon chain by one unit. Since labeled CO_2 is commercially available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also been used (RLi, RNa, RCaX, etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO_2 to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also **6-43**). Addition of CO_2 to *gem*-dimetallic compounds gives replacement of both metal atoms, the product being a malonic acid.[356]



$$RCH\begin{array}{l} M \\ M \end{array} \xrightarrow[2.\ H^+]{1.\ 2CO_2} RCH\begin{array}{l} COOH \\ COOH \end{array}$$

α,β-Unsaturated acids can be prepared by carbonation of an ate complex of a vinylalane.[357]

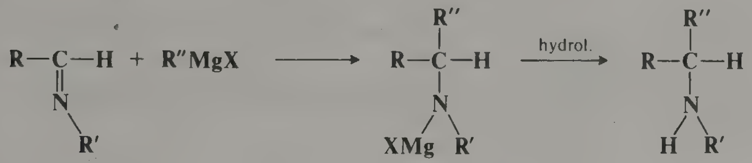
[357] Zweifel and Steele, *J. Am. Chem. Soc.* **89,** 2754, 5085 (1967).

Vinylalanes can be prepared by addition of a dialkylalane to a triple bond (**5-14**).

OS **I,** 361, 524; **II,** 425; **III,** 413, 553, 555; **V,** 890, 1043; **59,** 85.

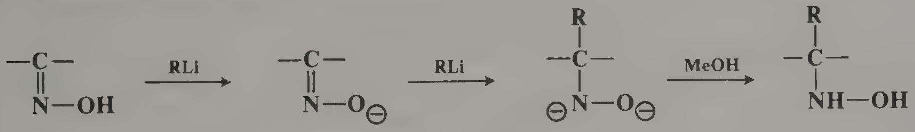
6-36 The Addition of Organometallic Compounds to C═N compounds

***N*-Hydro-*C*-alkyl-addition**[358]



$$\mathrm{R{-}\underset{\substack{\| \\ N \\ \diagdown \\ R'}}{C}{-}H} + \mathrm{R''MgX} \longrightarrow \mathrm{R{-}\overset{\substack{R'' \\ |}}{\underset{\substack{| \\ N \\ / \ \backslash \\ XMg \ \ R'}}{C}}{-}H} \xrightarrow{\text{hydrol.}} \mathrm{R{-}\overset{\substack{R'' \\ |}}{\underset{\substack{| \\ N \\ / \ \backslash \\ H \ \ R'}}{C}}{-}H}$$

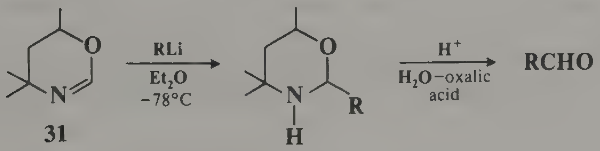
Aldimines can be converted to secondary amines by treatment with Grignard reagents.[359] Ketimines generally give reduction instead of addition. However, organolithium compounds give the normal addition product with both aldimines and ketimines.[360] Many other C═N systems (phenylhydrazones, oxime ethers, etc.) give normal addition when treated with Grignard reagents; others give reduction; others (oximes) give an active hydrogen to the Grignard reagent; still others give miscellaneous reactions. Oximes can be converted to hydroxylamines by treatment with 2 moles of an alkyllithium reagent, followed by methanol.[361]



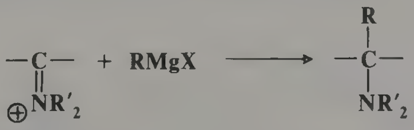
$$\mathrm{{-}\underset{\substack{\| \\ N{-}OH}}{C}{-}} \xrightarrow{\text{RLi}} \mathrm{{-}\underset{\substack{\| \\ N{-}O^{\ominus}}}{C}{-}} \xrightarrow{\text{RLi}} \mathrm{{-}\overset{\substack{R \\ |}}{\underset{\substack{| \\ {}^{\ominus}N{-}O^{\ominus}}}{C}}{-}} \xrightarrow{\text{MeOH}} \mathrm{{-}\overset{\substack{R \\ |}}{\underset{\substack{| \\ NH{-}OH}}{C}}{-}}$$

The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of $\mathrm{ClCH{=}NMe_2^+\ Cl^-}$ to give oximes: $\mathrm{RCH{=}N(O)OLi + R'MgX \rightarrow RR'C{=}NOH}$.[361a]

Alkyllithium compounds add to the C═N bond of the dihydro-1,3-oxazine **31**.[362] Since the products can be hydrolyzed to aldehydes, this is a method for the conversion of RLi to RCHO (see also **2-31**).



Iminium salts[267] give tertiary amines directly, with just R adding:



$$\mathrm{{-}\underset{\substack{\| \\ {}^{\oplus}NR'_2}}{C}{-}} + \mathrm{RMgX} \longrightarrow \mathrm{{-}\overset{\substack{R \\ |}}{\underset{\substack{| \\ NR'_2}}{C}}{-}}$$

---

[358] This name also applies to reaction **6-37**.

[359] For reviews of the addition of organometallic reagents to C═N bonds, see Harada, in Patai, "The Chemistry of the Carbon–Nitrogen Double Bond," Ref. 40, pp. 266–272; Kharasch and Reinmuth, Ref. 287, pp. 1204–1227.

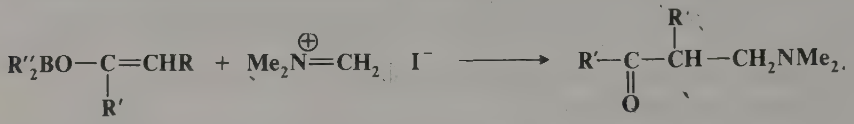
[360] Huet, *Bull. Soc. Chim. Fr.* 952, 960, 967, 973 (1964).

[361] Richey, McLane, and Phillips, *Tetrahedron Lett.* 233 (1976).

[361a] Fujisawa, Kurita, and Sato, *Chem. Lett.* 1537 (1983).

[362] Meyers and Adickes, *Tetrahedron Lett.* 5151 (1969).

Enol borinates react with iminium ions to give β-dialkylamino ketones (Mannich bases):[363]



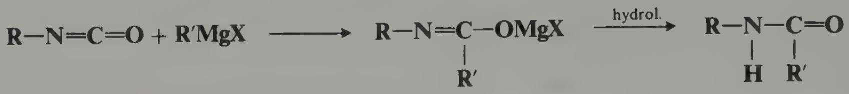
$$\mathrm{R''_2BO{-}\underset{\displaystyle R'}{\underset{|}{C}}{=}CHR} + \mathrm{Me_2\overset{\oplus}{N}{=}CH_2\ \ I^-} \longrightarrow \mathrm{R'{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}\overset{\displaystyle R}{\overset{|}{C}}H{-}CH_2NMe_2}.$$

This reaction provides a means of constructing a Mannich base from a given ketone in a regioselective manner, since either enol borinate can be prepared at will. The enol borinates (which need not be isolated) are prepared as in **0-101.**

For the addition of alkyllithium compounds to the C=N bond of ketenimines, see **2-17.**

OS **IV,** 605; **54,** 42. Also see OS **III,** 329.

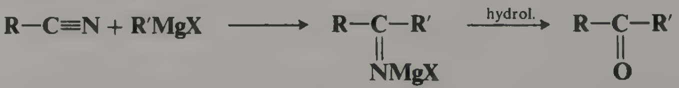
6-37 The Addition of Grignard Reagents to Isocyanates



$$\mathrm{R{-}N{=}C{=}O + R'MgX} \longrightarrow \mathrm{R{-}N{=}\underset{\displaystyle R'}{\underset{|}{C}}{-}OMgX} \xrightarrow{\text{hydrol.}} \mathrm{R{-}\underset{\displaystyle H}{\underset{|}{N}}{-}\underset{\displaystyle R'}{\underset{|}{C}}{=}O}$$

The addition of Grignard reagents to isocyanates gives, after hydrolysis, N-substituted amides. The reaction is written above as involving addition to C=O, but the ion is a resonance hybrid and the addition might just as well have been shown as occurring on the C=N. In any event, hydrolysis gives the amide. This is a very good reaction and may be used to prepare derivatives of alkyl and aryl halides. The reaction has also been performed with alkyllithium compounds.[364] Isothiocyanates give N-substituted thioamides.

6-38 The Addition of Grignard Reagents to Nitriles
Alkyl,oxo-de-nitrilo-tersubstitution (Overall transformation)



$$\mathrm{R{-}C{\equiv}N + R'MgX} \longrightarrow \mathrm{R{-}\underset{\displaystyle NMgX}{\underset{\|}{C}}{-}R'} \xrightarrow{\text{hydrol.}} \mathrm{R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R'}$$

Ketones can be prepared by addition of Grignard reagents to nitriles and subsequent hydrolysis. Many ketones have been made in this manner, though when both R groups are alkyl, yields are not high.[365] Better yields are obtained when benzene containing one equivalent of ether is used as the solvent, rather than ether alone.[366] The ketimine salt does not in general react with Grignard reagents; hence tertiary alcohols or tertiary alkyl amines are not often side products.[367] By careful hydrolysis of the salt it is sometimes possible to isolate ketimines $\mathrm{R{-}\underset{\displaystyle NH}{\underset{\|}{C}}{-}R'}$.[368] The addition of Grignard reagents to the C≡N group is normally slower than to the C=O group, and CN-containing aldehydes add the Grignard reagent without disturbing the CN group.[369] In a similar reaction, triethylaluminum[370] reacts with nitriles (in a 2:1 ratio) to give, after hydrolysis, ethyl ketones.[371]

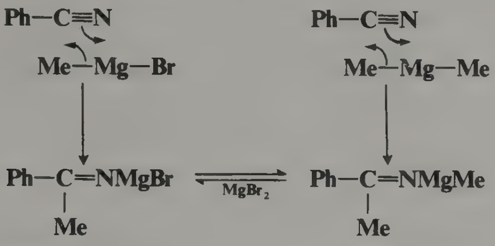
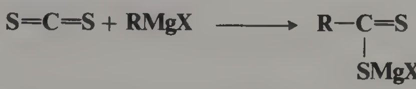
The following mechanism has been proposed for the reaction of the methyl Grignard reagent with benzonitrile:[372]



OS **III,** 26, 562; **V,** 520.

6-39 The Addition of Grignard Reagents to CS_2

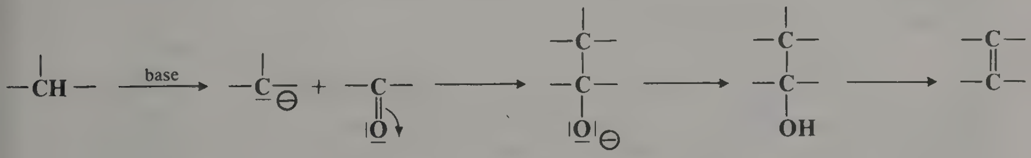
***C*-Alkyl-*S*-halomagnesio-addition**



$$S{=}C{=}S + RMgX \longrightarrow \underset{\substack{|\\ SMgX}}{R{-}C{=}S}$$

This reaction is analogous to **6-33.**[373] See also **6-43.**

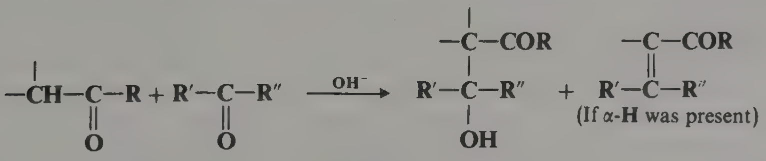
I. Carbon Attack by Active Hydrogen Compounds. Reactions **6-40** through **6-48** are base-catalyzed condensations (although some of them are also catalyzed by acids).[374] In **6-40** through **6-47,** a base removes a C—H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an α-hydrogen is present and on whether the new double bond would be in conjugation with double bonds already present:



The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 1 illustrates the differences. Reaction **6-48** is an analogous reaction involving addition to C≡N.

6-40 The Aldol Condensation

***O*-Hydro-*C*-(α-acylalkyl)-addition; α-Acylalkylidene-de-oxo-bisubstitution**



$$-\overset{|}{C}H-\underset{\substack{\|\\ O}}{C}-R + R'-\underset{\substack{\|\\ O}}{C}-R'' \xrightarrow{OH^-} R'-\overset{\substack{|\\ -C-COR\\ |}}{\underset{\substack{|\\ OH}}{C}}-R'' + R'-\overset{\substack{-C-COR\\ \|}}{C}-R'' \quad \text{(If α-H was present)}$$

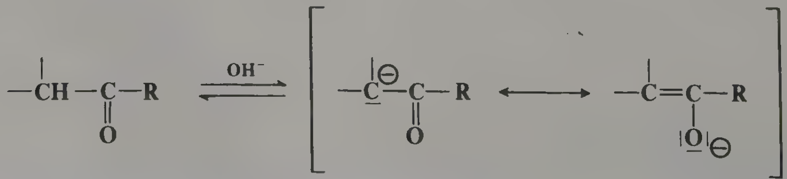
TABLE 1 Base-catalyzed condensations showing the active-hydrogen components and the carbonyl components

Reaction	Active-hydrogen component	Carbonyl component	Subsequent reactions
6-40 Aldol condensation	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone $-\underset{\vert}{C}H-COR$	Aldehyde, ketone	Dehydration may follow
6-41	Ester $-\overset{\vert}{C}H-COOR$	Aldehyde, ketone (usually without α-hydrogens)	Dehydration may follow
6-42 Knoevenagel reaction	$Z-CH_2-Z'$, $Z-CHR-Z'$, and similar molecules	Aldehyde, ketone (usually without α-hydrogens)	Dehydration usually follows
6-43	$-\overset{\vert}{C}H-Z \quad Z = COR, COOR, NO_2$	CO_2, CS_2	
6-44 Perkin reaction	Anhydride $-\overset{\vert}{C}H-COOCOR$	Aromatic aldehyde	Dehydration usually follows
6-45 Darzen's reaction	α-Halo ester $X\overset{\vert}{C}H-COOR$	Aldehyde, ketone	Epoxidation (SN reaction) follows
6-46 Tollens' reaction	Aldehyde $-\overset{\vert}{C}H-CHO$ Ketone $-\overset{\vert}{C}H-COR$	Formaldehyde	Crossed Cannizzaro reaction follows
6-47 Wittig reaction	Phosphorus ylide $Ph_3\overset{\oplus}{P}-\overset{\vert}{\underline{C}}^{\ominus}$	Aldehyde, ketone	"Dehydration" always follows
6-48 Thorpe reaction	Nitrile $-\overset{\vert}{C}H-CN$	Nitrile	

In the *aldol condensation* the α-carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.[375] The base most often used is OH^-, though stronger bases, e.g., aluminum *t*-butoxide, are sometimes employed. Hydroxide ion is not a strong enough base to convert substantially all of an aldehyde or ketone molecule to the corresponding enolate ion, i.e., the equilibrium

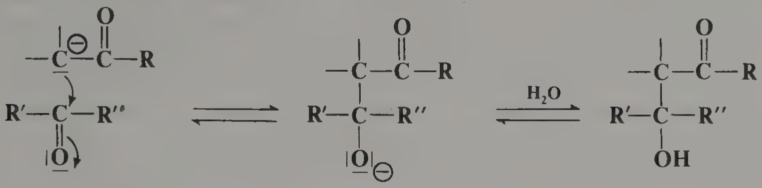


$$-\overset{|}{C}H-\underset{\overset{\|}{O}}{C}-R \xrightleftharpoons{OH^-} \left[-\overset{|}{\underline{C}}^{\ominus}-\underset{\overset{\|}{O}}{C}-R \longleftrightarrow -\overset{|}{C}=\underset{\overset{|}{\underline{O}}|^{\ominus}}{C}-R \right]$$

---

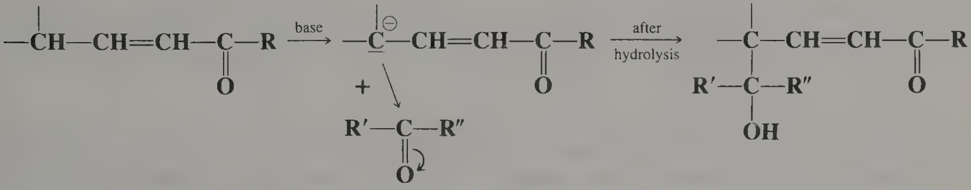
[375] For reviews, see Hajos, in Augustine, "Carbon–Carbon Bond Formation," vol. 1, pp. 1–84, Marcel Dekker, New York, 1979; Nielsen and Houlihan, *Org. React.* **16,** 1–438 (1968).

lies well to the left, for both aldehydes and ketones. Nevertheless, enough enolate ion is present for the reaction to proceed:



The product is a β-hydroxy aldehyde (called an *aldol*) or ketone, which in some cases is dehydrated during the course of the reaction. Even if the dehydration is not spontaneous, it can usually be done easily, since the new double bond will be in conjugation with the C=O bond; so that this is a method of preparing α,β-unsaturated aldehydes and ketones as well as β-hydroxy aldehydes and ketones. The entire reaction is an equilibrium (including the dehydration step), and α,β-unsaturated and β-hydroxy aldehydes and ketones can be cleaved by treatment with OH^-. There is evidence that an SET mechanism (see **6-30**) can intervene when the substrate is an aromatic ketone.[376]

The reverse reaction is known as the *retrograde aldol reaction*. Under the principle of vinylology, the active hydrogen may be one in the γ position of an α,β-unsaturated carbonyl compound:



The scope of the aldol condensation may be discussed under five headings:

1. *Condensation between two molecules of the same aldehyde.* This equilibrium lies far to the right,[377] and the reaction is quite feasible. Many aldehydes have been converted to aldols and/or their dehydration products in this manner. The most effective catalysts are basic ion-exchange resins. Of course, the aldehyde must be one with an α-hydrogen.

2. *Condensation between two molecules of the same ketone.* In this case the equilibrium lies well to the left, and the reaction is feasible only if the equilibrium can be shifted. This can often be done by allowing the reaction to proceed in a Soxhlet extractor (for example, see OS **I**, 199). In this method the ketone is refluxed in such a way that the condensate drips into a separate chamber, in which the base is present. In this chamber the reaction proceeds to the small extent permitted by the unfavorable equilibrium. When the chamber is full, the mixture of the ketone and its dimer is siphoned back into the original flask, out of contact with the base. Since the boiling point of the dimer is higher than that of the ketone, only the ketone is volatilized back to the chamber containing the base, where a little more of it is converted to dimer, and the process is repeated until a reasonable yield of dimer is obtained. Two molecules of the same ketone can also be condensed without a Soxhlet extractor, by use of the reagent barium pernitride Ba_3N_4[378] and by treatment with basic Al_2O_3.[379] Unsymmetrical ketones condense on the side that has more hydrogens.

---

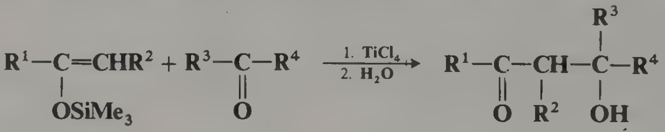
[379] Muzart, *Synthesis* 60 (1982).

(An exception is butanone, which reacts at the CH_2 group with acid catalysts, though with basic catalysts, it too reacts at the CH_3 group.)

3. *Condensation between two different aldehydes.* In the most general case, this will produce a mixture of four products (eight, if the olefins are counted). However, if one aldehyde does not have an α-hydrogen, only two aldols are possible, and in many cases the crossed product is the main one. The crossed aldol condensation is often called the *Claisen–Schmidt reaction.*

4. *Condensation between two different ketones.* This is seldom attempted (except with the use of preformed enolates, see below), but similar considerations apply. Enolizable ketones, such as β-diketones, can be condensed with aromatic aldehydes and ketones with KH as base.[380]

5. *Condensation between an aldehyde and a ketone.* This is usually feasible, especially when the aldehyde has no α-hydrogen, since there is no competition from ketone condensing with itself. This is also called the *Claisen–Schmidt reaction.* Even when the aldehyde has an α-hydrogen, it is the α-carbon of the ketone that adds to the carbonyl of the aldehyde, not the other way around. The reaction can be made regioselective by preparing an enol derivative of the ketone separately[381] and then adding this to the aldehyde (or ketone), which assures that the coupling takes place on the desired side of an unsymmetrical ketone. One way of doing this is to add a lithium enolate (prepared by **2-20**) in the presence of $ZnCl_2$;[382] in this case the aldol product is stabilized by chelation of its two oxygen atoms with the zinc ion.[383] Another pre-formed reagent is the silyl enol ether of the ketone. This can be condensed with an aldehyde or ketone with various catalysts,[384] including $TiCl_4$.[385] This reaction can also be run with the aldehyde or ketone in the form of its acetal $R^3R^4C(OR')_2$, in which case the product is the ether $RCOCHR^2CR^3R^4OR'$ instead of **32.**[386] Enol acetates and enol ethers also give this product when treated with acetals and $TiCl_4$ or a similar catalyst.[387] Another type of pre-formed enol derivative that reacts with aldehydes and ketones are enol borinates $R'CH{=}CR''{-}OBR_2$.[388]



$$R^1-\underset{\underset{OSiMe_3}{|}}{C}=CHR^2 + R^3-\underset{\underset{O}{\|}}{C}-R^4 \xrightarrow[2.\ H_2O]{1.\ TiCl_4} R^1-\underset{\underset{O}{\|}}{C}-\underset{\underset{R^2}{|}}{CH}-\overset{\overset{R^3}{|}}{\underset{\underset{OH}{|}}{C}}-R^4$$

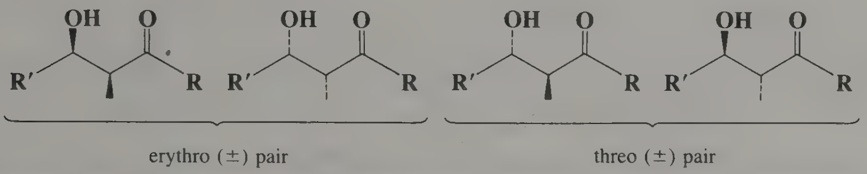
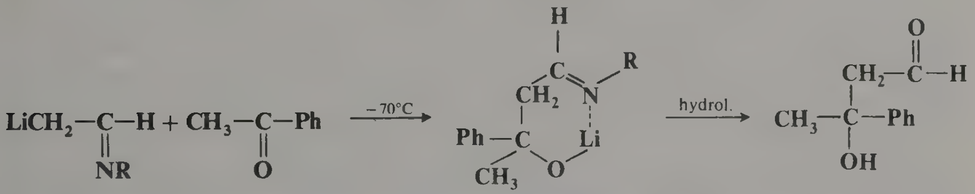
The reactions with pre-formed enol derivatives provide a way to control the stereoselectivity of the aldol condensation. In recent years much progress has been made in this area.[389] The reaction creates two new chiral centers, and, in the most general case, there are four stereoisomers of the aldol product, which can be represented as



In general, the *Z* enol derivatives give the erythro pair, while the *E* derivatives give the threo pair. Among the pre-formed enol derivatives used in this way have been enolates of magnesium, lithium,[390] zirconium,[391] and tin,[392] silyl enol ethers,[393] and enol borinates.[394] These reactions can also be made enantioselective (in which case only one of the four isomers predominates) by using chiral enol derivatives,[395] chiral aldehydes or ketones,[396] or both.[397]

It is possible to make the α-carbon of the aldehyde add to the carbonyl carbon of the ketone, by using an imine instead of an aldehyde, and $LiN(iso\text{-}Pr)_2$ as the base:[398]



This is known as the *directed aldol reaction*. Similar reactions have been performed with α-lithiated dimethylhydrazones of aldehydes or ketones.[399] A way to make the α carbon of acetaldehyde add to the C=O of a ketone (or another aldehyde) is to use the enolate LiCH=CHOEt.[400]

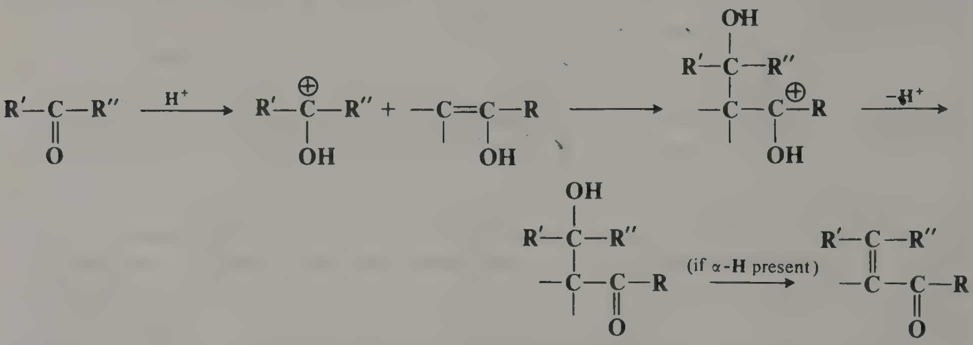
The aldol condensation can also be performed with acid catalysts, in which case dehydration usually follows. Here there is initial protonation of the carbonyl group, which attacks the α-carbon of the *enol* form of the other molecule:



With respect to the enol, this mechanism is similar to that of α halogenation (**2-4**).

A side reaction that is sometimes troublesome is further condensation, since the product of an aldol condensation is still an aldehyde or ketone.

Aldol condensations are often used to close five- and six-membered rings. Because of the favorable entropy (p. 185), such ring closures generally take place with ease, even where a ketone condenses with a ketone. An important example is the *Robinson annulation reaction,*[401] which has often been used in the synthesis of steroids and terpenes. In this reaction a cyclic ketone is converted to another cyclic ketone, with one additional six-membered ring containing a double bond. The substrate is treated with methyl vinyl ketone (or a simple derivative of methyl vinyl ketone) and a base.[402] The enolate ion of the substrate adds to the methyl vinyl ketone in a Michael reaction (**5-17**) to give a diketone that undergoes or is made to undergo an internal aldol condensation and subsequent dehydration to give the product. Because methyl vinyl ketone has a tendency to polymerize, precursors are often used instead, i.e., compounds that will give methyl vinyl ketone when treated with a base. One common example, $MeCOCH_2CH_2NEt_2Me^+ I^-$ (see **7-8**), is easily prepared by quaternization of $MeCOCH_2CH_2NEt_2$, which itself is prepared by a Mannich reaction (**6-16**) involving acetone, formaldehyde, and dimethylamine. The Robinson annulation reaction has also been carried out with 3-butyn-2-one, in which case the new ring of the product contains two double bonds.[403] α-Silylated vinyl ketones $RCOC(SiMe_3){=}CH_2$ have also been used successfully in annulation reactions.[404] The $SiMe_3$ group is easily removed. 1,5-Diketones prepared in other ways are also frequently cyclized by internal aldol condensations.

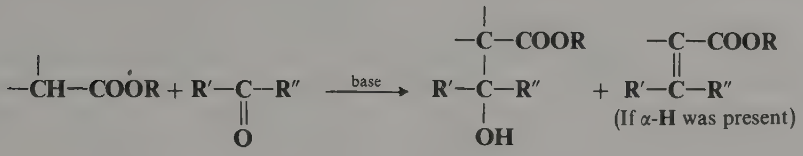
6-41 Condensations between Esters and Aldehydes or Ketones

O-Hydro-*C*-(α-alkoxycarbonylalkyl)-addition; α-Alkoxycarbonylalkylidene-de-oxo-bisubstitution



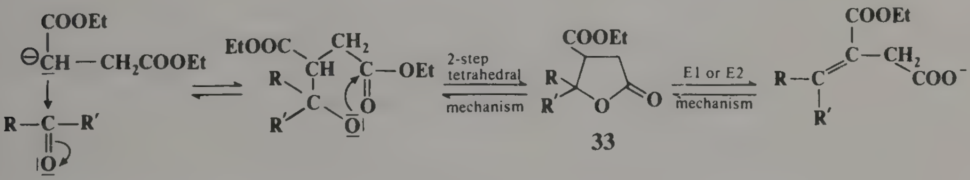
$$-\overset{|}{C}H-COOR + R'-\underset{\underset{O}{\|}}{C}-R'' \xrightarrow{\text{base}} R'-\overset{\overset{|}{-C-COOR}}{\underset{\underset{OH}{|}}{\overset{|}{C}}}-R'' + R'-\overset{-C-COOR}{\overset{\|}{C}}-R''$$

(If α-H was present)

In the presence of a strong base, the α-carbon of an ester can condense with the carbonyl carbon of an aldehyde or ketone to give a β-hydroxy ester, which may or may not be dehydrated to the α,β-unsaturated ester. This reaction is sometimes called the Claisen condensation,[405] an unfortunate usage since that name is more firmly connected to **0-111.** It is also possible for the α-carbon of an aldehyde or ketone to add to the carbonyl carbon of an ester, but this is a different reaction (**0-112**) involving nucleophilic substitution and not addition to a C=O bond. It can, however, be a side reaction if the aldehyde or ketone has an α-hydrogen.

Besides ordinary esters (containing an α-hydrogen), the reaction can also be carried out with lactones and, as in **6-40,** with the γ position of α,β-unsaturated esters (vinylology).

For most esters, a much stronger base is needed than for aldol condensations; $(i\text{-}Pr)_2NLi$, Ph_3CNa and $LiNH_2$[406] are among those employed. However, one type of ester reacts more easily, and such strong bases are not needed: diethyl succinate and its derivatives condense with aldehydes and ketones in the presence of bases such as NaOEt, NaH, or $KOCMe_3$. This reaction is called the *Stobbe condensation.*[407] One of the ester groups (sometimes both) is hydrolyzed in the course of the reaction. The following mechanism accounts for (1) the fact that succinic esters react so much better than others; (2) one ester group is always cleaved; and (3) the alcohol is not the product but the olefin. In addition, intermediate lactones **33** have been isolated from the mixture:[408]



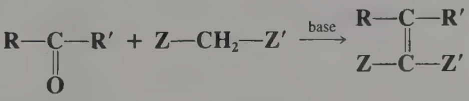
33

The Stobbe condensation has been extended to di-*t*-butyl esters of glutaric acid.[409]

OS **I,** 252; **III,** 132; **V,** 80, 564. Also see OS **IV,** 278, 478; **V,** 251.

6-42 The Knoevenagel Condensation

Bis(ethoxycarbonyl)methylene-de-oxo-bisubstitution, etc.



$$R-\underset{\underset{O}{\|}}{C}-R' + Z-CH_2-Z' \xrightarrow{\text{base}} \begin{matrix} R-C-R' \\ \| \\ Z-C-Z' \end{matrix}$$

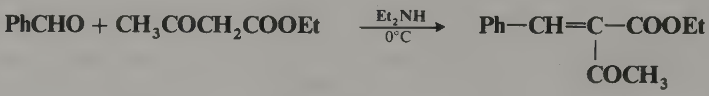
The condensation of aldehydes or ketones, usually not containing an α-hydrogen, with compounds of the form Z—CH$_2$—Z′ or Z—CHR—Z′ is usually called the *Knoevenagel reaction*,[410] although some limit the use of this name to only some of the active-hydrogen compounds that give the reaction. Z and Z′ may be CHO, COR, COOH, COOR, CN, NO$_2$,[411] SOR, SO$_2$R, SO$_2$OR, or similar groups. When Z = COOH, decarboxylation of the product often takes place in situ. If a strong enough base is used, the reaction can be performed on compounds possessing only a single Z, e.g., CH$_3$Z or RCH$_2$Z. Other active hydrogen compounds can also be employed, among them CHCl$_3$, 2-methylpyridines, terminal acetylenes, cyclopentadienes, etc.; in fact any compound that contains a C—H bond the hydrogen of which can be removed by a base. The following examples illustrate the wide scope of the reaction:



$$\mathrm{PhCHO + CH_3COCH_2COOEt \xrightarrow[0^\circ C]{Et_2NH} Ph{-}CH{=}\underset{\displaystyle COCH_3}{\underset{|}{C}}{-}COOEt}$$

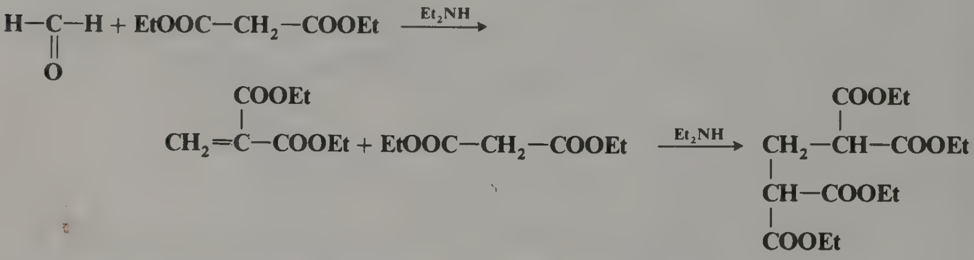
We see from these examples that many of the carbon nucleophiles we encountered in Chapter 10 are also nucleophiles toward aldehydes and ketones (compare reactions **0-96** through **0-100** and **0-102**). As we have seen in Chapter 10, the initial products in many of these cases, e.g., **34** through **37**, can be converted by relatively simple procedures (hydrolysis, reduction, decarboxylation, etc.) to various other products. In the reaction with terminal acetylenes,[423] sodium acetylides are the most common reagents (when they are used, the reaction is often called the *Nef reaction*), but lithium,[424] magnesium, and other metallic acetylides have also been used. A particularly convenient reagent is lithium acetylide–ethylenediamine complex,[425] a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of a base, so that the acetylide is generated in situ. This procedure is called the *Favorskii reaction*, not to be confused with the Favorskii rearrangement (**8-8**).[426] 1,4-Diols can be prepared by the treatment of aldehydes with dimetalloacetylenes $MC{\equiv}CM$.[427]

With most of these reagents the alcohol is not isolated (only the olefin) if the alcohol has a hydrogen in the proper position. However, in some cases it is the alcohol that is the major product. When the reactant is of the form ZCH_2Z', aldehydes react much better than ketones and few successful reactions with ketones have been reported. However, it is possible to get good yields of olefin from the condensation of ethyl malonate $CH_2(COOEt)_2$ with ketones, as well as with aldehydes, if the reaction is run with $TiCl_4$ and pyridine in tetrahydrofuran.[428] In reactions with ZCH_2Z', the catalyst is most often a secondary amine (piperidine is the most common), though many other catalysts have been used. When the catalyst is pyridine (to which piperidine may or may not be added) the reaction is known as the *Doebner modification* of the Knoevenagel reaction. Alkoxides are also common catalysts. In some cases it is possible to get a second molecule of active compound to add to the initial product, in a Michael reaction, e.g.,



$$\mathrm{H{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}H + EtOOC{-}CH_2{-}COOEt \xrightarrow{Et_2NH}}$$

$$\mathrm{CH_2{=}\overset{\overset{\displaystyle COOEt}{|}}{C}{-}COOEt + EtOOC{-}CH_2{-}COOEt \xrightarrow{Et_2NH} \begin{array}{l} CH_2{-}\overset{\overset{\displaystyle COOEt}{|}}{CH}{-}COOEt \\ | \\ CH{-}COOEt \\ | \\ COOEt \end{array}}$$

As with **6-40**, these reactions have sometimes been performed with acid catalysts.[429]

Imines can be employed instead of aldehydes or ketones; the products are the same—an amine is lost instead of water.[430]

A number of special applications of the Knoevenagel reaction follow:

1. The dilithio derivative of N-methanesulfinyl-*p*-toluidine[431] (**38**) adds to aldehydes and ketones to give, after hydrolysis, the hydroxysulfinamides **39**, which, upon heating, undergo stereospecifically syn eliminations to give olefins.[432] The reaction is thus a method for achieving the conversion $RR'CO \rightarrow RR'C{=}CH_2$ and represents an alternative to the Wittig reaction.[433]

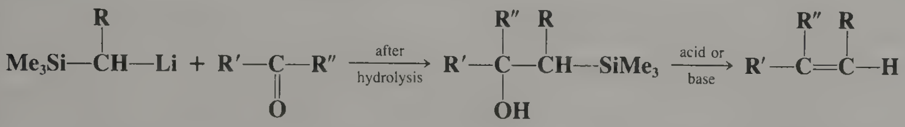
$$\mathrm{R-}\overset{\mathrm{R'}}{\underset{\mathrm{OH}}{\mathrm{C}}}\mathrm{-CH_2SONHAr} \xrightarrow{\Delta} \mathrm{R-}\underset{\mathrm{R'}}{\mathrm{C}}\mathrm{{=}CH_2 + SO_2 + ArNH_2} \qquad \mathrm{Ar} = p\text{-tolyl}$$

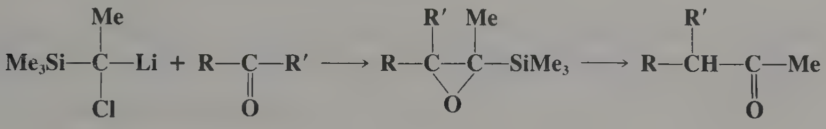
39

2. Another alternative to the Wittig reaction is the *Peterson olefination reaction.*[434] In this method, the lithio (or sometimes magnesio) derivative of a trialkylsilane[435] adds to an aldehyde or



$$\mathrm{Me_3Si-}\overset{\mathrm{R}}{\mathrm{C}}\mathrm{H-Li} + \mathrm{R'-}\underset{\mathrm{O}}{\overset{}{\underset{\|}{\mathrm{C}}}}\mathrm{-R''} \xrightarrow[\text{hydrolysis}]{\text{after}} \mathrm{R'-}\overset{\mathrm{R''}}{\underset{\mathrm{OH}}{\mathrm{C}}}\mathrm{-}\overset{\mathrm{R}}{\mathrm{C}}\mathrm{H-SiMe_3} \xrightarrow[\text{base}]{\text{acid or}} \mathrm{R'-}\overset{\mathrm{R''}}{\mathrm{C}}\mathrm{{=}}\overset{\mathrm{R}}{\mathrm{C}}\mathrm{-H}$$

ketone to give a β-hydroxysilane, which spontaneously eliminates water, or can be made to do so by treatment with acid or base, to produce an olefin. R can also be a COOR group, in which case the product is an α,β-unsaturated ester,[436] or an SO_2Ph group, in which case the product is a vinyl sulfone.[437] When aldehydes or ketones are treated with reagents of the form **40,** the product is an epoxy silane (**6-63**), which can be hydrolyzed to a methyl ketone.[438] For aldehydes, this is a method for converting RCHO to a methyl ketone RCH_2COMe.



$$\mathrm{Me_3Si-}\overset{\mathrm{Me}}{\underset{\mathrm{Cl}}{\mathrm{C}}}\mathrm{-Li} + \mathrm{R-}\underset{\mathrm{O}}{\underset{\|}{\mathrm{C}}}\mathrm{-R'} \longrightarrow \mathrm{R-}\overset{\mathrm{R'}}{\mathrm{C}}\overset{}{\underset{\mathrm{O}}{\diagdown\!\diagup}}\overset{\mathrm{Me}}{\mathrm{C}}\mathrm{-SiMe_3} \longrightarrow \mathrm{R-}\overset{\mathrm{R'}}{\mathrm{C}}\mathrm{H-}\underset{\mathrm{O}}{\underset{\|}{\mathrm{C}}}\mathrm{-Me}$$

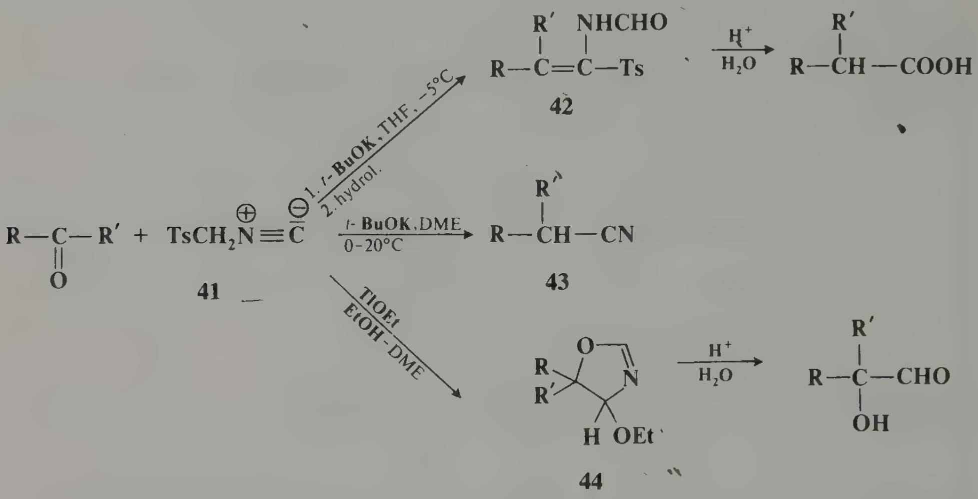
3. The reaction of ketones with tosylmethylisocyanide (**41**) gives different products,[439] depending on the reaction conditions. When the reaction is run with potassium *t*-butoxide in THF at −5°C,



one obtains (after hydrolysis) the normal Knoevenagel product **42,** except that the isonitrile group has been hydrated (**6-67**).[440] With the same base but with 1,2-dimethoxyethane (DME) as solvent the product is the nitrile **43.**[441] When the ketone is treated with **41** and thallium(I) ethoxide in a 4:1 mixture of absolute ethanol and DME at room temperature, the product is a 4-ethoxy-2-oxazoline **44.**[442] Since **43** can be hydrolyzed[443] to a carboxylic acid[440] and **44** to an α-hydroxy aldehyde,[442] this versatile reaction provides a means for achieving the conversion of RCOR′ to RCHR′COOH, RCHR′CN, or RCR′(OH)CHO. The conversions to RCHR′COOH[444] and to RCHR′CN[445] have also been carried out with certain aldehydes (R′ = H).

4. Aldehydes and ketones RCOR′ react with α-methoxyvinyllithium $CH_2=C(Li)OMe$ to give hydroxy enol ethers $RR'C(OH)C(OMe)=CH_2$, which are easily hydrolyzed to acyloins $RR'C(OH)COMe$.[446] In this reaction, the $CH_2=C(Li)OMe$ is a synthon for the unavailable $CH_3—C=O$ ion. The reagent also reacts with esters RCOOR′ to give $RC(OH)(COMe=CH_2)_2$. A synthon for the $Ph—\overset{\ominus}{\bar{C}}=O$ ion is $Ph\overset{\ominus}{\bar{C}}(CN)OSiMe_3$, which adds to aldehydes and ketones RCOR′ to give, after hydrolysis, the α-hydroxy ketones RR′C(OH)COPh.[447]

5. A procedure for converting an aldehyde or ketone RR′CO to the homologous aldehyde

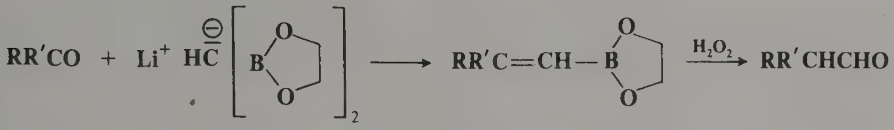
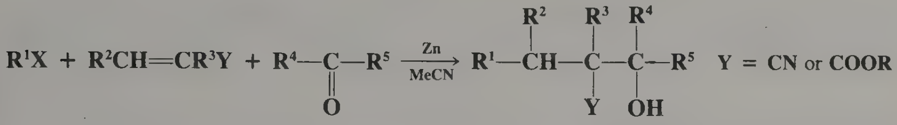
RR′CHCHO consists of treating the substrate with lithium bis(ethylenedioxyboryl)methide, followed by oxidation with aqueous H_2O_2:[448]



6. An α-CN or α-COOR unit can be added to aldehydes and ketones by treatment in one laboratory step with a primary or secondary halide R^1X, an activated olefin $R^2CH{=}CR^3Y$ (Y = CN or COOR) and zinc powder in MeCN.[449]



$$R^1X + R^2CH{=}CR^3Y + R^4{-}\underset{\underset{O}{\|}}{C}{-}R^5 \xrightarrow[MeCN]{Zn} R^1{-}\overset{\overset{R^2}{|}}{CH}{-}\overset{\overset{R^3}{|}}{\underset{\underset{Y}{|}}{C}}{-}\overset{\overset{R^4}{|}}{\underset{\underset{OH}{|}}{C}}{-}R^5 \quad Y = \text{CN or COOR}$$

7. The lithium salt of an active hydrogen compound adds to the lithium salt of the tosylhydrazone of an aldehyde to give product **45.** If X = CN, SPh, or SO_2R, **45** spontaneously loses N_2 and LiX to give the alkene **46.** The entire process is done in one reaction vessel: The active hydrogen compound is mixed with the tosylhydrazone and the mixture is treated with $(i\text{-}Pr)_2NLi$ to form both salts at once.[450] This process is still another alternative to the Wittig reaction for forming double bonds.

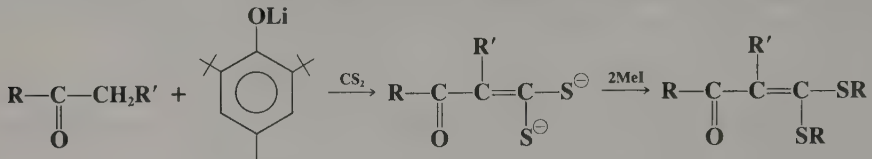
Ketones of the form $RCOCH_3$ and $RCOCH_2R'$ can be carboxylated indirectly by treatment with magnesium methyl carbonate **47.**[451] Because formation of the chelate **48** provides the driving force of the reaction, carboxylation cannot be achieved at a disubstituted α-position. The reaction has also been performed on CH_3NO_2 and compounds of the form RCH_2NO_2[452] and on certain lactones.[453] Direct carboxylation has been reported in a number of instances. Various ketones, esters, and other active hydrogen compounds have been carboxylated in the α position with the aid of phenolate bases ArONa, though yields are generally low.[454] Ketones have been carboxylated in the α position to give β-keto acids.[455] The base here was lithium 4-methyl-2,6-di-*t*-butylphenoxide (**49**). This base has also been used in the addition of ketones to CS_2 to give dianions (**50**), which are easily alkylated

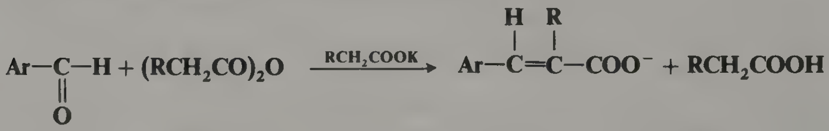


49 **50** **51**

to α-dithiomethylene ketones **51.**[456] Compounds of the form ZCH_2Z' also react with bases and CS_2 to give dianions analogous to **50.**[457]

6-44 The Perkin Reaction

α-Carboxyalkylidene-de-oxo-bisubstitution



$$\mathrm{Ar{-}\underset{O}{\overset{\|}{C}}{-}H + (RCH_2CO)_2O \xrightarrow{RCH_2COOK} Ar{-}\overset{H}{\overset{|}{C}}{=}\overset{R}{\overset{|}{C}}{-}COO^- + RCH_2COOH}$$

The condensation of aromatic aldehydes with anhydrides is called the *Perkin reaction.*[458] When the anhydride has two α-hydrogens (as shown), dehydration always occurs; the β-hydroxy acid salt is never isolated. In some cases, anhydrides of the form $(R_2CHCO)_2O$ have been used, and then the hydroxy compound is the product since dehydration cannot take place. The base in the Perkin reaction is nearly always the sodium or potassium salt of the acid corresponding to the anhydride. Besides aromatic aldehydes, their vinylogs ArCH=CHCHO also give the reaction. Otherwise, the reaction is not suitable for aliphatic aldehydes.[459] There is a possible side reaction: decarboxylation of the initial β-hydroxy acid salt instead of simple dehydration. Sometimes this is the main reaction:

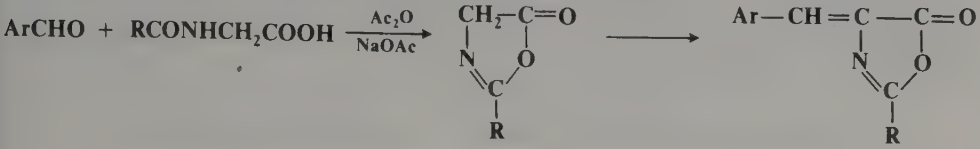
[459] Crawford and Little, *J. Chem. Soc.* 722 (1959).

An important variation of the Perkin reaction is the *Erlenmeyer azlactone synthesis.*[460] In this reaction aromatic aldehydes are condensed with N-acyl derivatives of glycine in the presence of acetic anhydride and sodium acetate. The product is an azlactone:



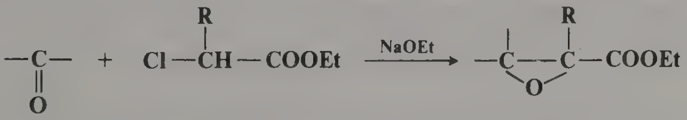
52

An azlactone

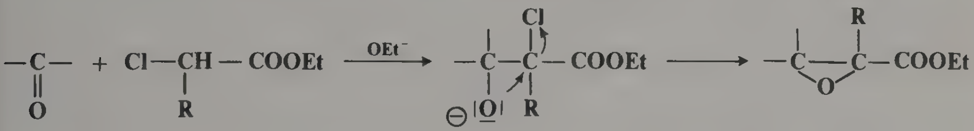
The intermediate **52** is formed first and then condenses with the aldehyde. When **52** was prepared independently, it reacted with aromatic aldehydes to give azlactones.[461] The Erlenmeyer reaction can be extended to aliphatic aldehydes by the use of THF as solvent and replacement of NaOAc by $Pb(OAc)_2$.[462]

OS **I,** 398; **II,** 1, 55, 61, 229, 489; **III,** 426. Also see OS **II,** 333, 519.

6-45 Darzen's Glycidic Ester Condensation



Aldehydes and ketones condense with α-halo esters in the presence of bases to give α,β-epoxy esters, called *glycidic esters.* This is called *Darzen's condensation.*[463] The reaction consists of an initial Knoevenagel-type condensation (**6-42**), followed by an internal SN2 reaction (**0-15**):[464]



Although the intermediate halo alkoxide is generally not isolated, it has been done, not only with α-fluoro esters (since fluorine is such a poor leaving group in nucleophilic substitutions) but also with α-chloro esters.[465] This is only one of several types of evidence that rule out a carbene intermediate.[466] Sodium ethoxide is often used as the base, although other bases, including sodium amide, are sometimes used. Aromatic aldehydes and ketones give good yields, but aliphatic aldehydes react poorly. However, the reaction can be made to give good yields (~80%) with simple aliphatic aldehydes as well as with aromatic aldehydes and ketones by treatment of the α-halo ester with the base lithium bis(trimethylsilyl)amide $LiN(SiMe_3)_2$ in tetrahydrofuran at −78°C (to form the conjugate base of the ester) and addition of the aldehyde or ketone to this solution.[467] If a preformed dianion of an α-halo carboxylic acid $\mathrm{Cl{-}\overset{\ominus}{C}R{-}COO^{\ominus}}$ is used instead, α,β-epoxy acids are produced directly.[468] The Darzen's reaction has also been carried out on α-halo ketones, α-halo nitriles,[469] α-halo sulfones,[470] α-halo N,N-disubstituted amides,[471] and even on allylic[472] and benzylic halides. Phase transfer catalysis has been used.[473] Aldehydes react with a dialkyltelluronium iodide to give α,β-unsaturated epoxides:[474]

---

[460] For reviews, see Ref. 459; Carter, *Org. React.* **3,** 198–239 (1946); Baltazzi, *Q. Rev., Chem. Soc.* **9,** 150–173 (1955).

[461] Crawford and Little, *J. Chem. Soc.* 729 (1959).

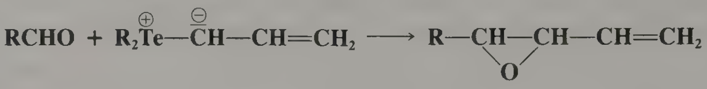
[462] Baltazzi and Robinson, *Chem. Ind.* (*London*) 191 (1954).

[463] For a review, see Berti, *Top. Stereochem.* **7,** 93–251 (1973), pp. 210–218.

[464] For discussions of the mechanism of the reaction, and especially of the stereochemistry, see Roux-Schmitt, Seyden-Penne, and Wolfe, *Tetrahedron* **28,** 4965 (1972); Bansal and Sethi, *Bull. Chem. Soc. Jpn.* **53,** 1197 (1980).

[465] Ballester and Pérez-Blanco, *J. Org. Chem.* **23,** 652 (1958); Martynov and Titov, *J. Gen. Chem. USSR* **30,** 4072 (1960), **32,** 716 (1962), **33,** 1350 (1963), **34,** 2139 (1964); Elkik and Francesch, *Bull. Soc. Chim. Fr.* 1277, 1281 (1973).

[466] Another, based on the stereochemistry of the products, is described by Zimmerman and Ahramjian, *J. Am. Chem. Soc.* **82,** 5459 (1960).

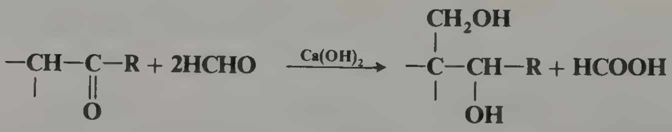


The mechanism is similar.

Glycidic esters can easily be converted to aldehydes (**2-39**). The reaction has been extended to the formation of analogous aziridines by treatment of an imine with an α-halo ester or an α-halo N,N-disubstituted amide and *t*-BuOK in the solvent 1,2-dimethoxyethane.[475] However, yields were not high. Acid-catalyzed Darzen's reactions have also been reported.[476] See also **6-63.**

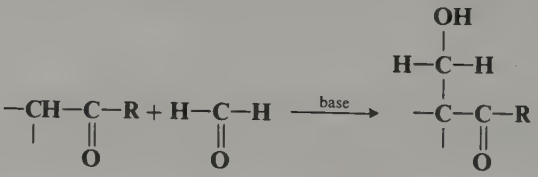
OS **III,** 727; **IV,** 459, 649.

6-46 Tollens' Reaction
***O*-Hydro-*C*-(β-hydroxyalkyl)-addition**



$$\mathrm{-\underset{|}{C}H-\underset{\overset{\|}{O}}{C}-R + 2HCHO \xrightarrow{Ca(OH)_2} -\underset{|}{\overset{\overset{CH_2OH}{|}}{C}}-\underset{\overset{|}{OH}}{C}H-R + HCOOH}$$

In *Tollens' reaction* an aldehyde or ketone containing an α-hydrogen is treated with formaldehyde in the presence of $\mathrm{Ca(OH)_2}$ or a similar base. The first step is a mixed aldol condensation (**6-40**), in which the α-carbon of the aldehyde or ketone adds to the carbonyl carbon of formaldehyde:



$$\mathrm{-\underset{|}{C}H-\underset{\overset{\|}{O}}{C}-R + H-\underset{\overset{\|}{O}}{C}-H \xrightarrow{base} -\underset{|}{\overset{\overset{\overset{\overset{OH}{|}}{H-C-H}}{|}}{C}}-\underset{\overset{\|}{O}}{C}-R}$$

The reaction can be stopped at this point, but more often a second mole of formaldehyde is permitted to reduce the newly formed aldol to a 1,3-glycol, in a crossed Cannizzaro reaction (**9-70**). If the aldehyde or ketone has several α-hydrogens, they can all be replaced. An important use of the reaction is to prepare pentaerythritol from acetaldehyde:

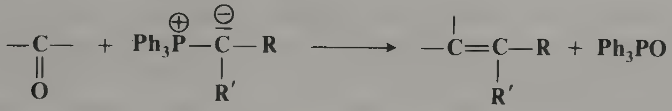
$$\text{CH}_3\text{CHO} + 4\text{HCHO} \longrightarrow \text{C(CH}_2\text{OH)}_4 + \text{HCOOH}$$

When aliphatic nitro compounds are used instead of aldehydes or ketones, no reduction occurs, and the reaction is essentially a Knoevenagel reaction, though it is usually also called a Tollens' reaction:

$$\text{CH}_3\text{NO}_2 + \text{HCHO} \xrightarrow{\text{OH}^-} \text{HOCH}_2\text{CH}_2\text{NO}_2$$

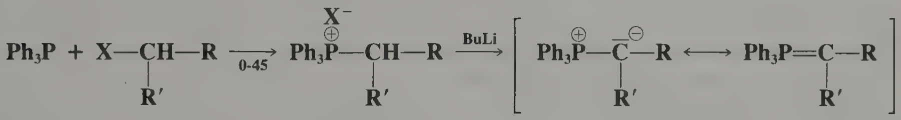
OS **I,** 425; **IV,** 907; **V,** 833.

6-47 The Wittig Reaction
Alkylidene-de-oxo-bisubstitution



$$\underset{\text{O}}{\overset{}{\underset{\|}{-\text{C}-}}} + \text{Ph}_3\overset{\oplus}{\text{P}}-\underset{\text{R}'}{\underset{|}{\overset{\ominus}{\bar{\text{C}}}}}-\text{R} \longrightarrow -\overset{|}{\text{C}}=\underset{\text{R}'}{\underset{|}{\text{C}}}-\text{R} + \text{Ph}_3\text{PO}$$

In the *Wittig reaction* an aldehyde or ketone is treated with a *phosphorus ylide* (also called a *phosphorane*) to give an olefin.[477] Phosphorus ylides, which are hybrids of two canonical forms, are usually prepared by treatment of a phosphonium salt with a base, and phosphonium salts are usually prepared from the phosphine and an alkyl halide (**0-45**):



$$\text{Ph}_3\text{P} + \text{X}-\underset{\text{R}'}{\underset{|}{\text{CH}}}-\text{R} \xrightarrow[\text{0-45}]{} \text{Ph}_3\overset{\overset{\text{X}^-}{\oplus}}{\text{P}}-\underset{\text{R}'}{\underset{|}{\text{CH}}}-\text{R} \xrightarrow{\text{BuLi}} \left[\text{Ph}_3\overset{\oplus}{\text{P}}-\underset{\text{R}'}{\underset{|}{\overset{\ominus}{\bar{\text{C}}}}}-\text{R} \longleftrightarrow \text{Ph}_3\text{P}=\underset{\text{R}'}{\underset{|}{\text{C}}}-\text{R}\right]$$

Phosphonium salt

Ylide

The overall sequence of three steps may be called the Wittig reaction, or only the final step.[478] Phosphonium salts are also prepared by addition of phosphines to Michael olefins (like **5-8**) and in other ways. The phosphonium salts are most often converted to the ylides by treatment with a strong base such as butyllithium, sodium amide,[479] sodium hydride, or a sodium alkoxide, though weaker bases may be used if the salt is acidic enough. For $(\text{Ph}_3\text{P}^+)_2\text{CH}_2$, sodium carbonate is a strong enough base.[480] When the base used does not contain lithium, the ylide is said to be prepared under "salt-free" conditions.[481] The conversion of phosphonium salts to ylides is apparently a simple acid–base reaction (**2-19**), but, at least with alkyllithiums, it must be more complicated than that, since, in addition to a simple proton abstraction, exchange of groups can occur. Thus, $Ph_3\overset{\oplus}{P}CH_3\ Br^-$ with methyllithium gave 26% *benzene*.[482] It is likely that an intermediate Ph_3PMe_2 was formed, which lost either methane or benzene to give an ylide.

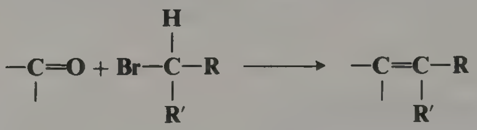
[478] When phosphonium *fluorides* are used, no base is necessary, as these react directly with the substrate to give the olefin· Schiemenz, Becker, and Stöckigt, *Chem. Ber.* **103,** 2077 (1970).

[479] For a convenient method of doing this that results in high yields, see Schlosser and Schaub, *Chimia* **36,** 396 (1982).

[480] Ramirez, Pilot, Desai, Smith, Hansen, and McKelvie, *J. Am. Chem. Soc.* **89,** 6273 (1967).

In the overall Wittig reaction, an olefin is formed from the aldehyde or ketone and an alkyl halide in which the halogen-bearing carbon contains at least one hydrogen:

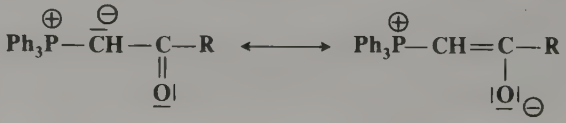


$$-\underset{|}{C}=O + Br-\underset{\underset{R'}{|}}{\overset{\overset{H}{|}}{C}}-R \longrightarrow -\underset{|}{C}=\underset{\underset{R'}{|}}{C}-R$$

This result is similar to that obtained in the Reformatsky reaction (**6-31**), but this is more general since no ester or other group is required to be α to the halogen. Another important advantage of the Wittig reaction is that the *position* of the new double bond is always certain, in contrast to the result in the Reformatsky reaction and in most of the base-catalyzed condensations (**6-40** to **6-46**). Examples of this are given below.

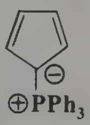
The reaction is very general. The aldehyde or ketone may be aliphatic, alicyclic, or aromatic (including diaryl ketones); it may contain double or triple bonds; it may contain various functional groups, such as OH, OR, NR_2, aromatic nitro or halo, acetal, or even ester groups.[483] Double or triple bonds *conjugated* with the carbonyl also do not interfere, the attack being at the C=O carbon. In some cases enolization of the aldehyde or ketone is a side reaction that decreases the yield. This can be avoided by repeated addition of stoichiometric amounts of water and the ylide.[484]

The phosphorus ylide may also contain double or triple bonds and certain functional groups. Simple ylides (R, R′ = hydrogen or alkyl) are highly reactive, reacting with oxygen, water, hydrohalic acids, and alcohols, as well as carbonyl compounds and esters, so that the reaction must be run under conditions where these materials are absent. When an electron-withdrawing group, e.g., COR, CN, COOR, CHO, is present in the α position, the ylides are much more stable. The stability is increased because the charge on the carbon is spread by resonance:



$$Ph_3\overset{\oplus}{P}-\overset{\ominus}{C}H-\underset{\underset{O}{\|}}{C}-R \longleftrightarrow Ph_3\overset{\oplus}{P}-CH=\underset{\underset{O^{\ominus}}{|}}{C}-R$$

These ylides react readily with aldehydes, but slowly or not at all with ketones. In extreme cases, e.g., compound **53**, the ylide does not react with ketones *or* aldehydes. Besides these groups, the



53

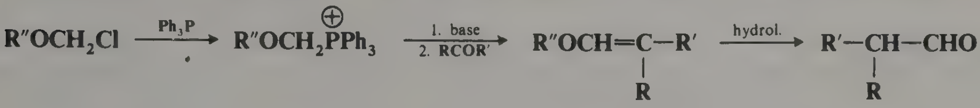
[481] Bestmann, *Angew. Chem. Int. Ed. Engl.* **4,** p. 586 (1965) [*Angew. Chem.* **77,** p. 612].

[482] Seyferth, Hughes, and Heeren, *J. Am. Chem. Soc.* **87,** 2847, 3467 (1965).

[483] Although phosphorus ylides also react with esters, that reaction is too slow to interfere: Greenwald, Chaykovsky, and Corey, *J. Org. Chem.* **28,** 1128 (1963).

[484] Adlercreutz and Magnusson, *Acta Chem. Scand., Ser. B* **34,** 647 (1980).

ylide may contain one or two α-halogens[485] or an α-OR or α-OAr group. In the latter case the product is an enol ether, which can be hydrolyzed (**0-7**) to an aldehyde,[486] so that this reaction is

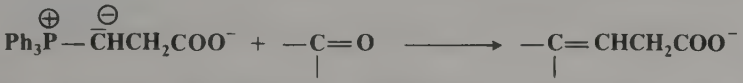


$$R''OCH_2Cl \xrightarrow{Ph_3P} R''OCH_2\overset{\oplus}{P}Ph_3 \xrightarrow[2.\ RCOR']{1.\ base} R''OCH{=}\underset{\displaystyle R}{\underset{|}{C}}{-}R' \xrightarrow{hydrol.} R'{-}\underset{\displaystyle R}{\underset{|}{CH}}{-}CHO$$

a means of achieving the conversion RCOR′ → RR′CHCHO. However, the ylide may not contain an α-nitro group. If the phosphonium salt contains a potential leaving group, such as Br or OMe, in the β position, treatment with a base gives elimination, instead of the ylide:

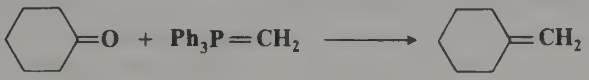
$$Ph_3\overset{\oplus}{P}CH_2CH_2Br \xrightarrow{base} Ph_3\overset{\oplus}{P}CH{=}CH_2$$

However, a β-COO⁻ group may be present, and the product is a β,γ-unsaturated acid:[487]

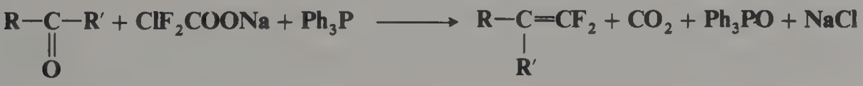


$$Ph_3\overset{\oplus}{P}{-}\overset{\ominus}{\bar{C}}HCH_2COO^- + {-}\underset{|}{C}{=}O \longrightarrow {-}\underset{|}{C}{=}CHCH_2COO^-$$

This is the only convenient way to make these compounds, since elimination by any other route gives the thermodynamically more stable α,β-unsaturated isomers. This is an illustration of the utility of the Wittig method for the specific location of a double bond. Another illustration is the conversion of cyclohexanones to olefins containing exocyclic double bonds, e.g.,[488]



This is the only general method for the synthesis of these compounds. Still another example is the easy formation of anti-Bredt bicycloalkenones[489] (see p. 138). As indicated above, α,α′-dihalophosphoranes can be used to prepare 1,1-dihaloalkenes. Another way to prepare such compounds is to treat the carbonyl compound with a mixture of CBr_4 (or CCl_4) and triphenylphosphine, either with or without the addition of zinc dust (which allows less Ph_3P to be used).[490] Aldehydes and ketones can be converted to 1,1-difluoroalkenes by treatment with a salt of chlorodifluoroacetic acid in the presence of triphenylphosphine:[491]



$$R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}R' + ClF_2COONa + Ph_3P \longrightarrow R{-}\underset{\displaystyle R'}{\underset{|}{C}}{=}CF_2 + CO_2 + Ph_3PO + NaCl$$

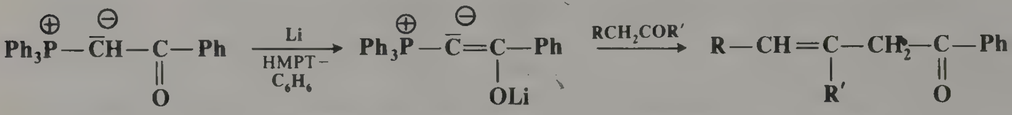
[491] Fuqua, Duncan, and Silverstein, *J. Org. Chem.* **30,** 1027, 2543 (1965).

The Wittig reaction has been carried out with polymer-supported ylides[492] (see p. 373).

When the phosphorane **54** is treated with lithium in HMPT–benzene, a second proton is removed to give the enolate ylide **55.** This ylide reacts with ketones of the form RCH$_2$COR′ to give the

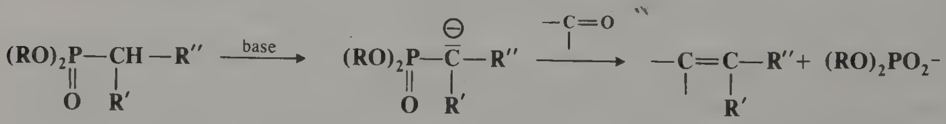


$$\overset{\oplus}{Ph_3P}-\overset{\ominus}{\overline{C}H}-\underset{\underset{O}{\|}}{C}-Ph \xrightarrow[\text{HMPT}-C_6H_6]{Li} \overset{\oplus}{Ph_3P}-\overset{\ominus}{\overline{C}}=\underset{\underset{OLi}{|}}{C}-Ph \xrightarrow{RCH_2COR'} R-CH=\underset{\underset{R'}{|}}{C}-CH_2-\underset{\underset{O}{\|}}{C}-Ph$$

54 **55** **56**

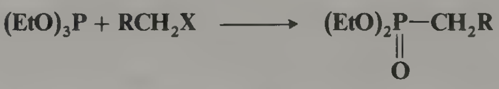
nonconjugated β,γ-unsaturated ketones **56.**[493] As mentioned above, ylides of the type **54** are too unreactive to react with the ketones themselves, but if **54** did react directly with RCH$_2$COR′, the normal Wittig product would be the α,β-unsaturated ketone RCH$_2$CR′=CHCOPh.

Ylides are usually prepared from triphenylphosphine, but other triarylphosphines,[494] trialkylphosphines,[495] and triphenylarsine have also been used. The Wittig reaction has also been carried out with other types of ylides, the most important being prepared from phosphonates:[496]



$$(RO)_2\underset{\underset{O}{\|}}{P}-\underset{\underset{R'}{|}}{CH}-R'' \xrightarrow{\text{base}} (RO)_2\underset{\underset{O}{\|}}{P}-\overset{\ominus}{\underset{\underset{R'}{|}}{\overline{C}}}-R'' \xrightarrow{\underset{|}{-C=O}} -\underset{|}{C}=\underset{\underset{R'}{|}}{C}-R'' + (RO)_2PO_2^-$$

This method, sometimes called the *Horner–Emmons* or *Wadsworth–Emmons reaction,*[497] has several advantages over the use of phosphoranes. These ylides are more reactive than the corresponding phosphoranes, and when R′ is an electron-withdrawing group, these compounds often react with ketones that are inert to phosphoranes. In addition, the phosphorus product is a phosphate ester and hence soluble in water, unlike Ph$_3$PO, which makes it easy to separate it from the olefin product. Phosphonates are also cheaper than phosphonium salts and can easily be prepared by the *Arbuzov reaction:*[498]



$$(EtO)_3P + RCH_2X \longrightarrow (EtO)_2\underset{\underset{O}{\|}}{P}-CH_2R$$

Ylides formed from $Ar_2\underset{\underset{O}{\|}}{P}CHRR'$, phosphonic acid bisamides (R$_2''$N)$_2$POCHRR′,[499] and alkyl phosphonothionates (MeO)$_2$PSCHRR′[500] share some of these advantages. Phosphonates Ph$_2$POCH$_2$NR$^1_2$ react with aldehydes or ketones R^{2}COR^3 to give good yields of enamines R^{2}R^{3}C=CHNR$^1_2$.[501]

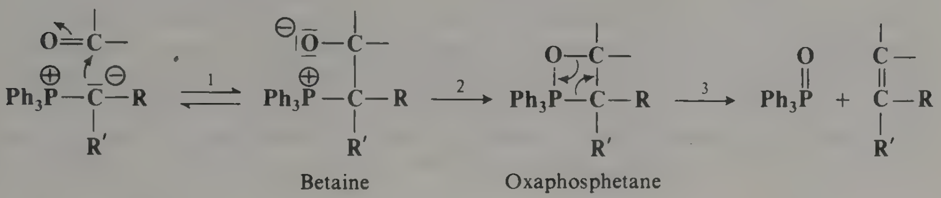
The mechanism[502] of the key step[503] of the Wittig reaction consists of at least two, and perhaps three steps:



Step 1 may or may not be an equilibrium reaction. Steps 2 and 3 constitute an elimination of Ph_3PO (see **7-23**) and may be simultaneous.[504] Either step 1 or steps 2–3 may be rate-determining. Step 1 has been shown to be reversible for stable ylides (those containing COR, CN, etc. groups) by the preparation in another way of the betaine and the demonstration that the ylide can be prepared from it.[505] With unstable ylides it has been suggested[506] that steps 1 and 2 may be simultaneous[507] (so that the betaine is not an intermediate). Evidence for this is that ^{31}P nmr spectra taken of the reaction mixture at low temperatures are compatible with an oxaphosphetane structure that persists for some time but not with a tetracoordinated phosphorus species. Since a betaine, an ylide, and a phosphine oxide all have tetracoordinated phosphorus, these species could not be causing the spectra, leading to the conclusion that an oxaphosphetane intermediate is present in the solution.[508] Under these conditions, steps 1 and 2 are obviously fast and step 3 rate-determining. According to any of these mechanisms, an optically active phosphonium salt $RR'R''\overset{\oplus}{P}CHR_2$ should retain its configuration all the way through the reaction, and it should be preserved in the phosphine oxide $RR'R''PO$. This has been shown to be the case.[509]

When ylides of the form $Ph_3P{=}CHR$ undergo the Wittig reaction in protic solvents, a different mechanism may compete with the one shown above, depending on the structure of the reactants and the reaction conditions. This mechanism involves protonation of the betaine and cleavage of the resulting β-hydroxy phosphonium salt.[510]

In reactions in which there is a betaine intermediate, we may examine the question of when step 1 is faster than steps 2–3 and vice versa. We have already seen that the ylide is increased in stability (and decreased in reactivity) by the presence of electron-withdrawing groups on the carbon. Another factor is the presence of electron-donating groups on the phosphorus. These groups stabilize the ylide canonical form (of the resonance hybrid) at the expense of the C=P form by decreasing the positive charge on the phosphorus. This increases the reactivity of the ylide and explains, for example, why trialkyl phosphorus ylides are more reactive than the triaryl variety. On the other hand, once the betaine is formed, these factors work in precisely the opposite direction. Electron-withdrawing groups on the carbon increase the reactivity of the betaine because they stabilize (by conjugation) the newly forming double bond; and electron-donating substituents on the phosphorus decrease the reactivity of the betaine since they decrease the positive charge on the phosphorus and make it less attractive to the negative oxygen. We see from all this that with ylides containing electron-donating groups on the phosphorus, the first step will be faster than the subsequent ones. In some cases, indeed, it has proved possible to isolate the betaine, an example being **57**.[511] However,

---

[502] It has been contended that another mechanism, involving single electron transfer, may be taking place in some cases, at least as a competing pathway: Olah and Krishnamurthy, *J. Am. Chem. Soc.* **104,** 3987 (1982).

[503] It has been proposed that step 3 consists of two steps: cleavage of the C—P bond to give a different type of betaine, followed by cleavage of the C—O bond: Bestmann, *Pure Appl. Chem.* **52,** 771–788 (1980).

[504] For a review of the mechanism, see Cockerill and Harrison, Ref. 181, pp. 232–240.

[505] Speziale and Bissing, *J. Am. Chem. Soc.* **85,** 3878 (1963). However, this interpretation has been challenged: see Nesmayanov, Binshtok, and Reutov, *Doklad. Chem.* **210,** 499 (1973).

[506] Vedejs and Snoble, *J. Am. Chem. Soc.* **95,** 5778 (1973); Vedejs, Meier, and Snoble, *J. Am. Chem. Soc.* **103,** 2823 (1981).

[507] Such a mechanism has been suggested for stable ylides as well: Nesmeyanov, Binshtok, and Reutov, Ref. 505.

[508] In certain cases, oxaphosphetanes have been isolated: Birum and Matthews, *Chem. Commun.* 137 (1967); Mazhar-Ul-Haque, Caughlan, Ramirez, Pilot, and Smith, *J. Am. Chem. Soc.* **93,** 5229 (1971). See also Schlosser, Piskala, Tarchini, and Tuong, *Chimia* **29,** 341 (1975); Reitz, Mutter, and Maryanoff, *J. Am. Chem. Soc.* **106,** 1873 (1984).

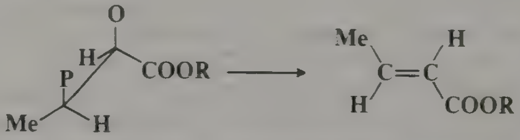
$$Ar_3\overset{\oplus}{P}-CH_2-\underset{O^{\ominus}}{\underset{|}{CH}}Ph \qquad Ar = p\text{-}MeOC_6H_4$$

57

if there are electron-withdrawing groups on the carbon, the first step will be slower than the subsequent ones and it should be much more difficult to isolate the betaine. Up to now, no such betaine has been isolated.

These considerations make possible at least some conclusions about the stereochemistry of the reaction.[512] If the betaine has two chiral carbons, there are two diastereomeric *dl* pairs. In cases where betaine formation is reversible, the thermodynamically more stable diastereomer will be predominantly formed before elimination (a syn process, in this case) occurs, and this diastereomer will normally give the trans olefin:



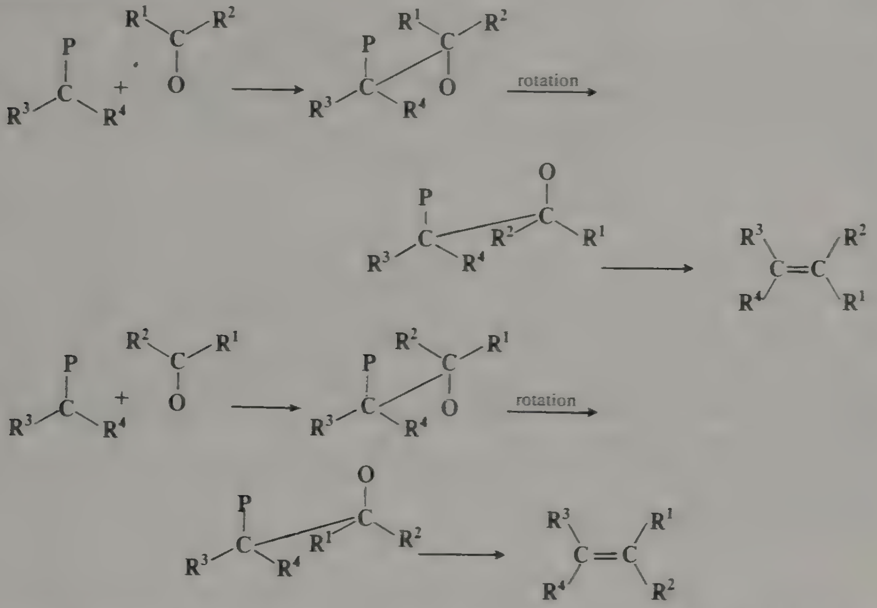
Indeed, it is generally found that ylides containing stabilizing groups or formed from trialkylphosphines give trans olefins.[513] However, ylides formed from triarylphosphines and not containing stabilizing groups often give cis or a mixture of cis and trans olefins.[513] One explanation for this[506] is based on the suggestion, mentioned earlier, that in these cases steps 1 and 2 of the mechanism are simultaneous. If this is so, the reaction of the ylide with the carbonyl compound is a 2 + 2 cycloaddition, which in order to be concerted must adopt the $[_{\pi}2_s + _{\pi}2_a]$ pathway. As we have seen earlier (p. 762), this pathway leads to the formation of the more sterically crowded product, in this case the cis olefin. It is also possible to explain the formation of cis olefins and cis–trans mixtures, even in reactions in which there is a betaine intermediate, if we assume that in cases where such products are formed, step 1 is irreversible. In such cases, which diastereomer forms is determined by the way the ylide and carbonyl compound line up. Once the betaine is formed, the stereochemistry of the olefin is determined by the fact that elimination is syn. The two possibilities can be shown:

---

[511] Wittig, Weigmann, and Schlosser, *Chem. Ber.* **94**, 676 (1961). See also Schlosser, Tuong, and Tarchini, *Chimia*, **31**, 219 (1977); Schlosser and Tuong, *Angew. Chem. Int. Ed. Engl.* **18**, 633 (1979) [*Angew. Chem.* **91**, 675]; Allen, *J. Chem. Res., Synop.* 384 (1980).

[512] For reviews of the stereochemistry of the Wittig reaction, see Gosney and Rowley, in Cadogan, Ref. 477, pp. 17–153; Reucroft and Sammes, *Q. Rev., Chem. Soc.* **25**, 135–169 (1971), pp. 137–148, 169; Schlosser, *Top. Stereochem.* **5**, 1–30 (1970). Also see Bergelson and Shemyakin, *Tetrahedron* **19**, 149 (1963); House, Jones, and Frank, *J. Org. Chem.* **29**, 3327 (1964); Wadsworth, Schupp, Seus, and Ford, *J. Org. Chem.* **30**, 680 (1965); Schlosser, Müller, and Christmann, *Angew. Chem. Int. Ed. Engl.* **5**, 667 (1966) [*Angew. Chem. Soc., Perkin Trans. 1* 243 (1984).

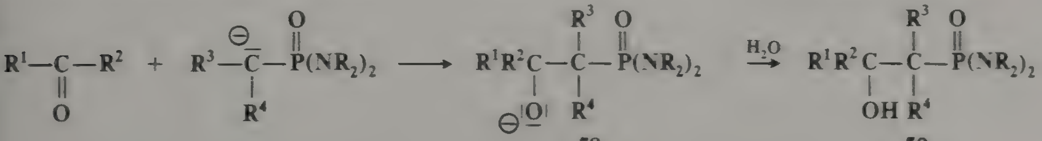
[513] See, for example, Ketcham, Jambotkar, and Martinelli, *J. Org. Chem.* **27**, 4666 (1962); House and Rasmusson, *J. Org. Chem.* **26**, 4278 (1961); Bestmann and Kratzer, Ref. 495; Yanovskaya and Kucherov, *Bull. Acad. Sci. USSR, Div. Chem. Sci.* 1252 (1964).



The natural preference seems to be for the ylide and carbonyl compound to line up in such a way as to give the cis isomers ultimately, probably because the three aryl groups on the phosphorus cause steric hindrance.[514] It is also possible that cis isomers are not formed by the betaine pathway at all, but only by the $[_{\pi}2_s + {}_{\pi}2_a]$ route.

The cis–trans ratio of the product can often be changed by a change in solvent or by the addition of salts. It has been found possible to control the reaction so that either the cis or the trans olefin is the main product.

Another way of controlling the stereochemistry of the product is by use of the aforementioned phosphonic acid bisamides. In this case the betaine (**58**) does not undergo spontaneous elimination



58 **59**

$$R^1-\underset{\underset{\displaystyle O}{\|}}{C}-R^2 + R^3-\underset{\underset{\displaystyle R^4}{|}}{\overset{\ominus}{\bar{C}}}-\overset{\overset{\displaystyle O}{\|}}{P}(NR_2)_2 \longrightarrow R^1R^2\underset{\underset{\displaystyle \ominus|\underline{\bar{O}}|}{|}}{C}-\overset{\displaystyle R^3}{\underset{\underset{\displaystyle R^4}{|}}{\overset{|}{C}}}-\overset{\overset{\displaystyle O}{\|}}{P}(NR_2)_2 \xrightarrow{H_2O} R^1R^2\underset{\underset{\displaystyle OH}{|}}{C}-\overset{\displaystyle R^3}{\underset{\underset{\displaystyle R^4}{|}}{\overset{|}{C}}}-\overset{\overset{\displaystyle O}{\|}}{P}(NR_2)_2$$

but when treated with water gives the β-hydroxyphosphonic acid bisamides **59**, which can be crystallized and then cleaved to $R^1R^2C{=}CR^3R^4$ by refluxing in benzene or toluene in the presence of silica gel.[499] **59** are generally formed as mixtures of diastereomers, and these mixtures can be separated by recrystallization. Cleavage of the two diastereomers gives the two isomeric olefins.

In reactions where the betaine intermediate is present in the solution, it is possible to extend the chain further if a hydrogen is present α to the phosphorus. For example, reaction of ethylidenetriphenylphosphorane with heptanal at −78°C gave the betaine **60**, which with butyllithium gave the ylide **61**. Treatment of this with an aldehyde R′CHO gave the intermediate **62**, which

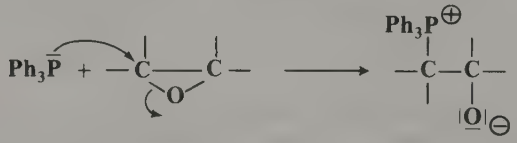
60 **61** **62** **63**

R = n-C_6H_{13}

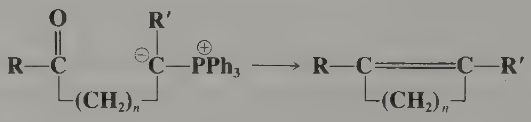
after workup gave **63**.[515] This reaction gives the unsaturated alcohols **63** stereoselectively. **61** also reacts with other electrophiles. For example, treatment of **61** with N-chlorosuccinimide or $PhICl_2$ gives the vinyl chloride RCH═CMeCl stereoselectively: NCS giving the cis and $PhICl_2$ the trans isomer.[516] The use of Br_2 and $FClO_3$ gives the corresponding bromides and fluorides, respectively.[517] Reactions of **61** with electrophiles have been called *scoopy* reactions (α-substitution plus carbonyl olefination via β-oxido phosphorus ylides).[518]

The betaine can be formed in a completely different manner, by nucleophilic substitution by a phosphine on an epoxide (**0-51**):



The betaine formed in this way, of course, can then be converted to the olefin.

The Wittig reaction has been carried out intramolecularly, to prepare rings containing from 5 to 16 carbons,[519] both by single ring closure



and double ring closure.[520]

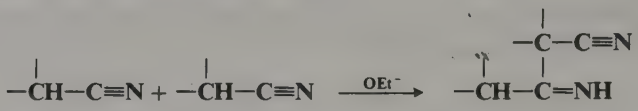
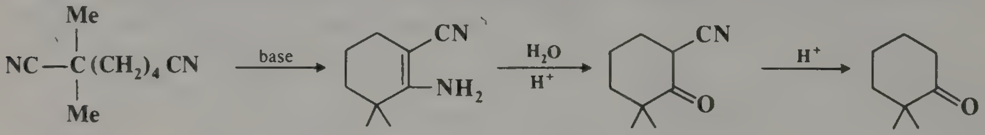
6-48 The Thorpe Reaction
***N*-Hydro-*C*-(α-cyanoalkyl)-addition**



$$-\overset{|}{C}H-C\equiv N + -\overset{|}{C}H-C\equiv N \xrightarrow{OEt^-} -\overset{|}{C}H-\overset{\overset{|}{-C-C\equiv N}}{\overset{|}{C}}=NH$$

In the *Thorpe reaction,* the α-carbon of one nitrile molecule is added to the CN carbon of another, so that this reaction is analogous to the aldol condensation (**6-40**). The C=NH bond is, of course, hydrolyzable (**6-2**), so that β-keto nitriles can be prepared in this manner. The Thorpe reaction can be done internally, in which case it is called the *Thorpe–Ziegler reaction.*[527] This is a useful method for closing large rings. Yields are high for five- to eight-membered rings, fall off to about zero for rings of nine to thirteen members, but are high again for fourteen-membered and larger rings, if high-dilution techniques are employed. The product in the Thorpe–Ziegler reaction is not the imine, but the tautomeric enamine, e.g., **66;** if desired this can be hydrolyzed to an α-cyano ketone (**6-2**), which can in turn be hydrolyzed and decarboxylated (**6-5, 2-39**). Other active compounds can also be added to nitriles.[528]

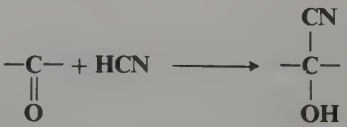


66

OS **53,** 98.

J. Other Carbon Nucleophiles

6-49 The Formation of Cyanohydrins
***O*-Hydro-*C*-cyano-addition**

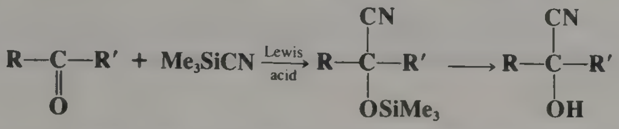


$$-\underset{\underset{O}{\|}}{C}- + HCN \longrightarrow -\overset{\overset{CN}{|}}{\underset{\underset{OH}{|}}{C}}-$$

[527] For a monograph, see Taylor and McKillop, "The Chemistry of Cyclic Enaminonitriles and *ortho*-Amino Nitriles," Interscience, New York, 1970. For a review, see Schaefer and Bloomfield, *Org. React.* **15,** 1–203 (1967).

[528] See for example, Josey, *J. Org. Chem.* **29,** 707 (1964); Barluenga, Fustero, Rubio, and Gotor, *Synthesis* 780 (1977); Hiyama and Kobayashi, *Tetrahedron Lett.* **23,** 1597 (1982).

The addition of HCN to aldehydes or ketones produces cyanohydrins.[529] This is an equilibrium reaction. For aldehydes and aliphatic ketones the equilibrium lies to the right; therefore the reaction is quite feasible, except with sterically hindered ketones such as diisopropyl ketone. However, ketones ArCOR give poor yields, and the reaction cannot be carried out with ArCOAr since the equilibrium is too far to the left. With aromatic aldehydes the benzoin condensation (**6-55**) competes. With α,β-unsaturated aldehydes and ketones, 1,4 addition competes (reaction **5-25**). Ketones of low reactivity, such as ArCOR, can be converted to cyanohydrins by treatment with diethylaluminum cyanide Et_2AlCN (see OS **52,** 96) or, indirectly, with cyanotrimethylsilane Me_3SiCN in the presence of a Lewis acid,[530] followed by hydrolysis of the resulting O-trimethylsilyl cyanohydrin.[531]



$$\mathrm{R{-}\underset{\underset{O}{\|}}{C}{-}R'} + \mathrm{Me_3SiCN} \xrightarrow[\text{acid}]{\text{Lewis}} \mathrm{R{-}\overset{\overset{CN}{|}}{\underset{\underset{OSiMe_3}{|}}{C}}{-}R'} \longrightarrow \mathrm{R{-}\overset{\overset{CN}{|}}{\underset{\underset{OH}{|}}{C}}{-}R'}$$

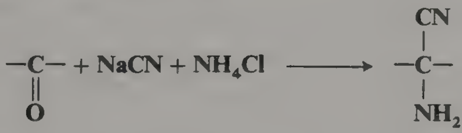
Frequently it is the bisulfite addition product that is treated with CN^-, in which case the reaction is actually nucleophilic substitution. This method is especially useful for aromatic aldehydes, since it avoids competition from the benzoin condensation. If desired, it is possible to hydrolyze the cyanohydrin in situ to the corresponding α-hydroxy acid. This reaction is important in the *Kiliani–Fischer* method of extending the carbon chain of a sugar.

The addition is nucleophilic and the actual nucleophile is CN^-, so that the reaction rate is increased by the addition of base.[532] This was demonstrated by Lapworth in 1903, and consequently this was one of the first organic mechanisms to be known.[533]

OS **I,** 336; **II,** 7, 29, 387; **III,** 436; **IV,** 58, 506; **52,** 96; **60,** 14, 126. For the reverse reaction, see OS **III,** 101.

6-50 The Strecker Synthesis

Cyano,amino-de-oxo-bisubstitution



$$\mathrm{{-}\underset{\underset{O}{\|}}{C}{-}} + \mathrm{NaCN} + \mathrm{NH_4Cl} \longrightarrow \mathrm{{-}\overset{\overset{CN}{|}}{\underset{\underset{NH_2}{|}}{C}}{-}}$$

α-Amino nitriles can be prepared in one step by the treatment of an aldehyde or ketone with NaCN and NH_4Cl. This is called the *Strecker synthesis;* it is a special case of the Mannich reaction (**6-16**). Since the CN is easily hydrolyzed to the acid, this is a convenient method for the preparation of α-amino acids. The reaction has also been carried out with NH_3 + HCN and with NH_4CN. Salts of primary and secondary amines can be used instead of NH_4^+ to obtain N-substituted and N,N-disubstituted α-amino nitriles. When *formaldehyde* is treated with NaCN and the salt of an amine, the reaction is known as *cyanomethylation* of the amine. Unlike reaction **6-49,** the Strecker synthesis is useful for aromatic as well as aliphatic ketones.

There are two possible pathways for the reaction. The cyanohydrin may be produced first and a nucleophilic substitution (**0-48**) may then follow, or ammonia (or the amine) may add first to give an imine (**6-13**), to which NaCN adds (**6-51**).[534]

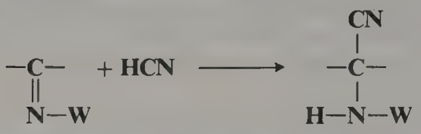
6-51 The Addition of HCN to C═N and C≡N Bonds

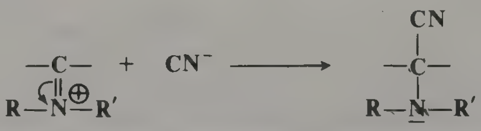
***N*-Hydro-*C*-cyano-addition**



$$-\underset{\underset{\text{N}-\text{W}}{\|}}{\text{C}}- \; + \text{HCN} \longrightarrow -\overset{\overset{\text{CN}}{|}}{\underset{\underset{\text{H}-\text{N}-\text{W}}{|}}{\text{C}}}-$$

W = H, R, Ar, OH, NHAr, etc.

HCN adds to imines, Schiff bases, hydrazones, oximes, and similar compounds. CN^- can be added to iminium ions:[267]

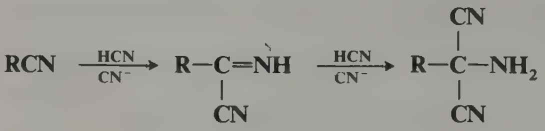


$$-\underset{\underset{\text{R}-\overset{\oplus}{\text{N}}-\text{R}'}{\|}}{\text{C}}- \; + \; \text{CN}^- \longrightarrow -\overset{\overset{\text{CN}}{|}}{\underset{\underset{\text{R}-\underline{\text{N}}-\text{R}'}{|}}{\text{C}}}-$$

The addition of KCN to triisopropylbenzenesulfonyl hydrazones **67** provides an indirect method for achieving the conversion RR′CO → RR′CHCN.[535] The reaction is successful for hydrazones of aliphatic aldehydes and ketones.

$$\underset{\textbf{67}}{\text{RR}'\text{C}{=}\text{NNHSO}_2\text{Ar}} + \text{KCN} \xrightarrow{\text{MeOH}} \text{RR}'\text{CHCN} \qquad \text{Ar} = 2,4,6\text{-(i-Pr)}_3\text{C}_6\text{H}_2$$

HCN can also be added to the C≡N bond to give iminonitriles or α-aminomalononitriles.[536]



$$\text{RCN} \xrightarrow[\text{CN}^-]{\text{HCN}} \text{R}-\underset{\underset{\text{CN}}{|}}{\text{C}}{=}\text{NH} \xrightarrow[\text{CN}^-]{\text{HCN}} \text{R}-\overset{\overset{\text{CN}}{|}}{\underset{\underset{\text{CN}}{|}}{\text{C}}}-\text{NH}_2$$

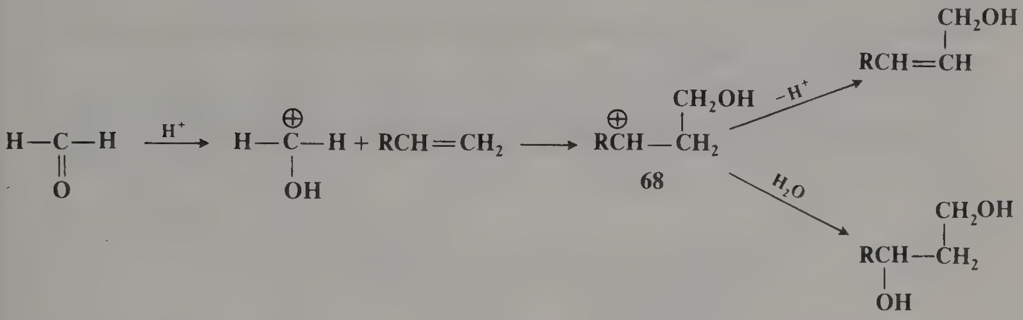
Chem.* **37,** 3746 (1972); Walia, Bannore, Walia, and Guillot, *Chem. Lett.* 1005 (1974). For evidence for both pathways, see Taillades and Commeyras, *Tetrahedron* **30,** 2493 (1974).

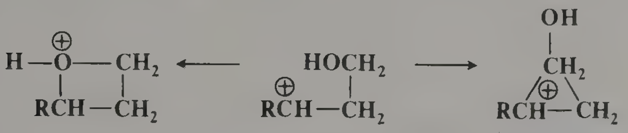
[535] Jiricny, Orere, and Reese, *J. Chem. Soc., Perkin Trans. 1* 1487 (1980). For other methods of achieving this conversion, see Ziegler and Wender, *J. Org. Chem.* **42,** 2001 (1977); Cacchi, Caglioti, and Paolucci, *Synthesis* 120 (1975).

[536] For an example, see Ferris and Sanchez, *Org. Synth.* **V,** 344.

The addition of an olefin to formaldehyde in the presence of an acid[537] catalyst is called the *Prins reaction.*[538] Three main products are possible; which one predominates depends on the olefin and the conditions. When the product is the 1,3-diol or the dioxane,[539] the reaction involves addition to the C=C as well as to the C=O. The mechanism is one of electrophilic attack on both double bonds. The acid first protonates the C=O, and the resulting carbocation attacks the C=C:



68 may undergo loss of H^+ to give the olefin or may add water to give the diol.[540] It has been proposed that **68** is stabilized by neighboring-group attraction, with either the oxygen[541] or a carbon[542] stabilizing the charge (**69** and **70**, respectively). This stabilization is postulated to explain the fact that with 2-butenes[543] and with cyclohexenes the addition is anti. A backside attack of H_2O on the three- or four-membered ring would account for it. Other products are obtained too, which can be explained on the basis of **69** or **70.**[541,542] Additional evidence for the intermediacy of **69** is the finding that oxetanes (**71**) subjected to the reaction conditions (which would protonate **71** to give **69**) give essentially the same product ratios as the corresponding alkenes.[544] An argument against the intermediacy of **69** and **70** is that not all alkenes show the anti stereoselectivity mentioned above. Indeed, the stereochemical results are often quite complex, with syn, anti, and nonster-



69 **68** **70**

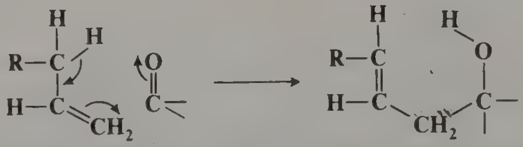
[544] Meresz, Leung, and Denes, *Tetrahedron Lett.* 2797 (1972).

eoselective addition reported, depending on the nature of the reactants and the reaction conditions.[545] Since addition to the C=C bond is electrophilic, the reactivity of the olefin increases with alkyl substitution and Markovnikov's rule is followed. The dioxane product may arise from a reaction between the 1,3-diol and formaldehyde[546] (**6-6**) or between **68** and formaldehyde, or even between the olefin and a formaldehyde dimer $HOCH_2OCH_2^+$.[547]

Lewis acids such as $SnCl_4$ also catalyze the reaction, in which case the species that adds to the olefins is $H_2\overset{\oplus}{C}—O—\overset{\oplus}{S}nCl_4$.[548] The reaction can also be catalyzed by peroxides, in which case the mechanism is probably a free-radical one.

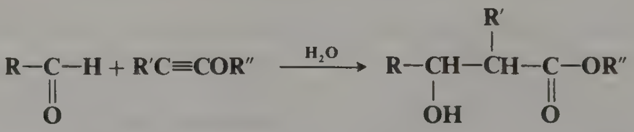
The reaction has been performed with other aldehydes and even with ketones; without a catalyst, but with heat.[549] The aldehydes and ketones here are active ones, such as chloral and acetoacetic ester. The product in these cases is a β-hydroxy olefin, and a cyclic mechanism has been postulated:[550]



This reaction is reversible and suitable β-hydroxy olefins can be cleaved by heat (**7-46**). There is evidence that the cleavage reaction occurs by a cyclic mechanism (p. 935), and, by the principle of microscopic reversibility, the addition mechanism should be cyclic too.[551] Note that this reaction is an oxygen analog of the ene synthesis (**5-16**). This reaction can also be done with unactivated aldehydes (aliphatic and aromatic), if Lewis-acid catalysts such as dimethylaluminum chloride Me_2AlCl[552] or ethylaluminum dichloride[553] are used.[554]

OS **IV,** 786.

6-54 The Addition of Triple-Bond Compounds
***O*-Hydro-*C*-(α-alkoxycarbonylalkyl)-addition**



$$R-\underset{\underset{O}{\|}}{C}-H + R'C{\equiv}COR'' \xrightarrow{H_2O} R-\underset{\underset{OH}{|}}{CH}-\overset{\overset{R'}{|}}{CH}-\underset{\underset{O}{\|}}{C}-OR''$$

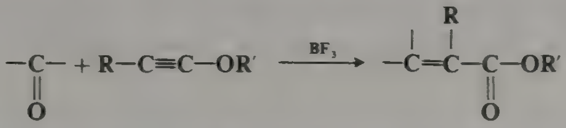
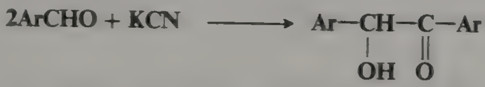
Aldehydes and water can be added to alkynyl ethers to give β-hydroxy esters.[555] The reaction is applicable to aldehydes only, but the yields rapidly diminish with chain length.[556] Formaldehyde is most commonly used. If the alkynyl ether is treated with a carbonyl compound in the absence of water but in the presence of BF_3, an α,β-unsaturated ester is produced:[557]



$$-\underset{\underset{O}{\|}}{C}- + R-C{\equiv}C-OR' \xrightarrow{BF_3} -\overset{|}{C}{=}\overset{\overset{R}{|}}{C}-\underset{\underset{O}{\|}}{C}-OR'$$

This reaction is much more general, and the carbonyl compound may be an aldehyde, ketone, ester, or amide.

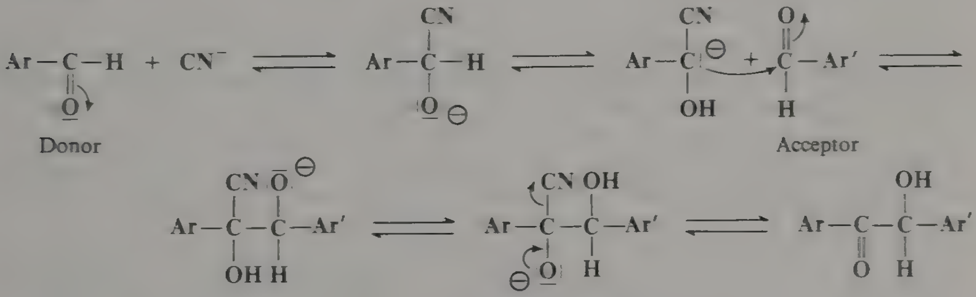
6-55 The Benzoin Condensation



$$2ArCHO + KCN \longrightarrow Ar-\underset{\underset{OH}{|}}{CH}-\underset{\underset{O}{\|}}{C}-Ar$$

When certain aldehydes are treated with cyanide ion, *benzoins* are produced in a reaction called the *benzoin condensation*. The condensation may be regarded as involving the addition of one molecule of aldehyde to the C=O group of another. The reaction can be accomplished only for aromatic aldehydes, though not for all of them,[558] and for glyoxals RCOCHO. The two molecules of aldehyde obviously perform different functions. The one that no longer has a C—H bond in the product is called the *donor*, because it has "donated" its hydrogen to the oxygen of the other molecule, the *acceptor*. Some aldehydes can perform only one of these functions and hence cannot be self-condensed, though they can often be condensed with a different aldehyde. For example, *p*-dimethylaminobenzaldehyde is not an acceptor but only a donor. Thus it cannot condense with itself, but it can condense with benzaldehyde, which can perform both functions, but is a better acceptor than it is a donor.

The following is the accepted mechanism [559] which was originally proposed by Lapworth in 1903:[560]



---

[558] For a review, see Ide and Buck, *Org. React.* **4**, 269–304 (1948).

[559] For a discussion, see Kuebrich, Schowen, Wang, and Lupes, *J. Am. Chem. Soc.* **93**, 1214 (1971).

[560] Lapworth, *J. Chem. Soc.* **83**, 995 (1903), **85**, 1206 (1904).

The reaction is reversible. The key step, the loss of the aldehydic proton, can take place because the acidity of this C—H bond is increased by the electron-withdrawing power of the CN group. Thus, CN^- is a highly specific catalyst for this reaction, because, almost uniquely, it can perform three functions: (1) It acts as a nucleophile; (2) its electron-withdrawing ability permits loss of the aldehydic proton; and (3) having done this, it then acts as a leaving group. Certain thiazolium salts can also catalyze the reaction.[561] In this case aliphatic aldehydes can also be used[562] (the products are called *acyloins*), and mixtures of aliphatic and aromatic aldehydes give mixed α-hydroxy ketones.[563]

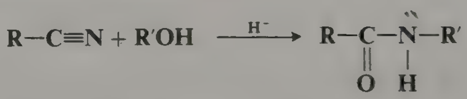
OS **I,** 94.

Reactions in Which Carbon Adds to the Hetero Atom

A. Oxygen Adding to the Carbon

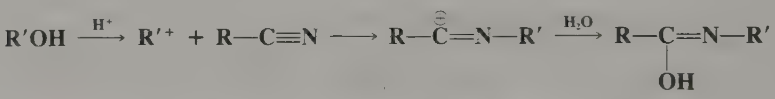
6-56 The Ritter Reaction

***N*-Hydro,*N*-alkyl-*C*-oxo-biaddition**



$$R{-}C{\equiv}N + R'OH \xrightarrow{H^+} R{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{H}{|}}{N}{-}R'$$

Alcohols can be added to nitriles in an entirely different manner from that of **6-9**. In this reaction, the alcohol is converted by a strong acid to a carbocation, which adds to the negative nitrogen, water adding to the carbon:



$$R'OH \xrightarrow{H^+} R'^+ + R{-}C{\equiv}N \longrightarrow R{-}\overset{\oplus}{C}{=}N{-}R' \xrightarrow{H_2O} R{-}\underset{\underset{OH}{|}}{C}{=}N{-}R'$$

The immediate product tautomerizes to the N-alkyl amide. Only alcohols that give rise to fairly stable carbocations react (secondary, tertiary, benzylic, etc.); primary alcohols do not give the reaction. The carbocation need not be generated from an alcohol but may come from protonation of an olefin or from other sources. In any case, the reaction is called the *Ritter reaction.*[564] HCN also gives the reaction, the product being a formamide. Since the amides (especially the formamides) are easily hydrolyzable to amines, the Ritter reaction provides a method for achieving the conversions $R'OH \rightarrow R'NH_2$ (see **0-48**) and alkene → $R'NH_2$ (see **5-8**) in those cases where R′ can form a relatively stable carbocation. The reaction is especially useful for the preparation of tertiary alkyl amines because there are few alternate ways of preparing these compounds. The reaction can be extended to alcohols that do not give stable carbocations (e.g., 1-decanol) by treating the alcohol with $Ph_2CCl^+\ SbCl_6^-$ or a similar salt in the nitrile as solvent.[565]

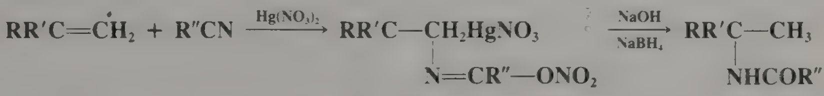
React.* **17,** 213–325 (1969); Beckwith, in Zabicky, Ref. 62, pp. 125–130; Johnson and Madroñero, *Adv. Heterocycl. Chem.* **6,** 95–146 (1966); Zil'berman, *Russ. Chem. Rev.* **29,** 331–344 (1960), pp. 334–337.

[565] Barton, Magnus, Garbarino, and Young, *J. Chem. Soc., Perkin Trans 1* 2101 (1974). See also Top and Jaouen, *J. Org. Chem.* **46,** 78 (1981).

Olefins of the form RCH=CHR′ and RR′C=CH_2 add to nitriles in the presence of mercuric nitrate to give, after treatment with $NaBH_4$, the same amides that would be obtained by the Ritter reaction.[566] This method has the advantage of avoiding strong acids.



$$RR'C{=}CH_2 + R''CN \xrightarrow{Hg(NO_3)_2} RR'\underset{\displaystyle N{=}CR''{-}ONO_2}{\underset{|}{C}}{-}CH_2HgNO_3 \xrightarrow[NaBH_4]{NaOH} RR'\underset{\displaystyle NHCOR''}{\underset{|}{C}}{-}CH_3$$

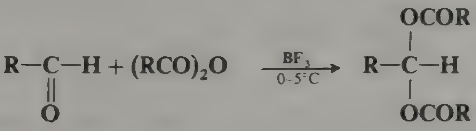
Two other methods use alkyl halides rather than alcohols: RCN + R′X → RCONHR′. In one of these, primary, secondary, and tertiary halides (X = any of the four halogens) are treated with nitrosonium hexafluorophosphate $NOPF_6$ in the nitrile as solvent.[567] Carbocations (produced by $RX + NO^+ \rightarrow R^+ + NOX$) are intermediates in at least some of these cases. In the other method, primary and secondary bromides and iodides react with nitriles in the presence of pulverized KOH and *t*-BuOH.[568]

The Ritter reaction can be applied to cyanamides RNHCN to give ureas RNHCONHR′.[569]

OS **V**, 73, 471.

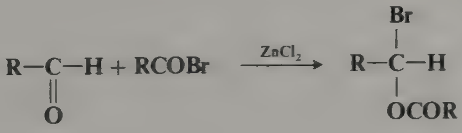
6-57 Acylation of Aldehydes and Ketones

***O*-Acyl-*C*-acyloxy-addition**



$$R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}H + (RCO)_2O \xrightarrow[0\text{–}5^\circ C]{BF_3} R{-}\overset{\displaystyle OCOR}{\underset{\displaystyle OCOR}{\overset{|}{\underset{|}{C}}}}{-}H$$

Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of BF_3, other Lewis acids,[570] proton acids,[571] or PCl_3.[572] The reaction cannot normally be applied to ketones, though an exception has been reported when the reagent is trichloroacetic anhydride, which gives acylals with ketones without a catalyst.[573] In a similar reaction, aldehydes and some ketones add the elements of an acyl bromide when treated with the acyl bromide and $ZnCl_2$:[574]



$$R{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}H + RCOBr \xrightarrow{ZnCl_2} R{-}\overset{\displaystyle Br}{\underset{\displaystyle OCOR}{\overset{|}{\underset{|}{C}}}}{-}H$$

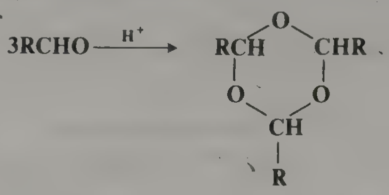
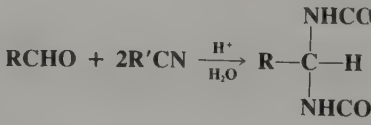
6-58 The Addition of Aldehydes to Aldehydes



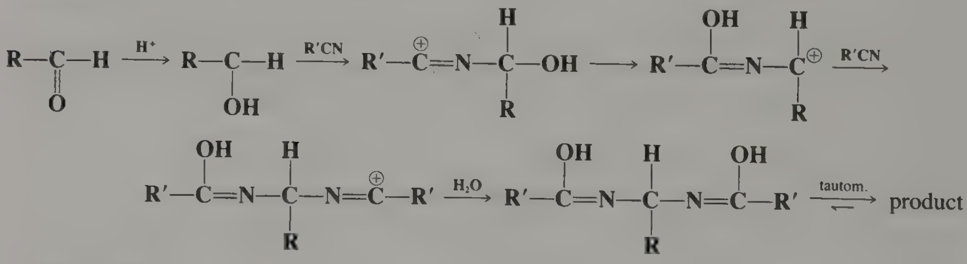
When catalyzed by acids, low-molecular-weight aldehydes add to each other to give cyclic acetals, the most common product being the trimer.[575] The cyclic trimer of formaldehyde is called *trioxane*, and that of acetaldehyde is known as *paraldehyde*. Under certain conditions, it is possible to get tetramers[576] or dimers. Aldehydes can also polymerize to linear polymers, but here a small amount of water is required to form hemiacetal groups at the ends of the chains. The linear polymer formed from formaldehyde is called *paraformaldehyde*. Since trimers and polymers of aldehydes are acetals, they are stable to bases but can be hydrolyzed by acids. Because formaldehyde and acetaldehyde have low boiling points, it is often convenient to use them in the form of their trimers or polymers.

6-59 The Addition of Aldehydes to Nitriles
Bis(acylamino)-de-oxo-bisubstitution



$$\mathrm{RCHO} + 2\mathrm{R'CN} \xrightarrow[\mathrm{H_2O}]{\mathrm{H^+}} \mathrm{R{-}\underset{\underset{\textstyle NHCOR'}{|}}{\overset{\overset{\textstyle NHCOR'}{|}}{C}}{-}H}$$

In the presence of acids, 2 moles of a nitrile add to 1 mole of aldehyde to give *amidals*.[577] The reaction is applicable only to aldehydes that do not contain an α-hydrogen. Apparently the mechanism is



$$\mathrm{R{-}\underset{\underset{\textstyle O}{\|}}{C}{-}H} \xrightarrow{\mathrm{H^+}} \mathrm{R{-}\underset{\underset{\textstyle OH}{|}}{C}{-}H} \xrightarrow{\mathrm{R'CN}} \mathrm{R'{-}\overset{\oplus}{C}{=}N{-}\underset{\underset{\textstyle R}{|}}{\overset{\overset{\textstyle H}{|}}{C}}{-}OH} \longrightarrow \mathrm{R'{-}\overset{\overset{\textstyle OH}{|}}{C}{=}N{-}\underset{\underset{\textstyle R}{|}}{\overset{\overset{\textstyle H}{|}}{C}}{}^{\oplus}} \xrightarrow{\mathrm{R'CN}}$$

$$\mathrm{R'{-}\overset{\overset{\textstyle OH}{|}}{C}{=}N{-}\underset{\underset{\textstyle R}{|}}{\overset{\overset{\textstyle H}{|}}{C}}{-}N{=}\overset{\oplus}{C}{-}R'} \xrightarrow{\mathrm{H_2O}} \mathrm{R'{-}\overset{\overset{\textstyle OH}{|}}{C}{=}N{-}\underset{\underset{\textstyle R}{|}}{\overset{\overset{\textstyle H}{|}}{C}}{-}N{=}\overset{\overset{\textstyle OH}{|}}{C}{-}R'} \xrightleftharpoons{\text{tautom.}} \text{product}$$

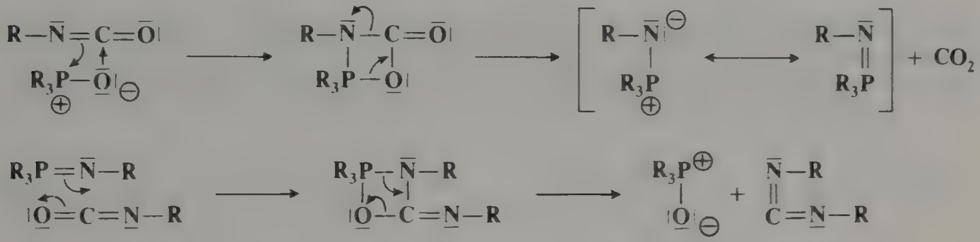
[576] Barón, *Nature* **192**, 258 (1961); Barón, Manderola, and Westerkamp, *Can. J. Chem.* **41**, 1893 (1963).

[577] For a review, see Zil'berman, Ref. 564, pp. 333–334.

The treatment of isocyanates with 3-methyl-1-ethyl-3-phospholene-1-oxide (**72**) is a useful method for the synthesis of carbodiimides[578] in good yields.[579] The mechanism does not simply involve the addition of one molecule of isocyanate to another, since the kinetics are first order in isocyanate and first order in catalyst. The following mechanism has been proposed (the catalyst is here represented as $R_3\overset{\oplus}{P}—\overset{\ominus}{O}$):[580]



The first two steps together are rate-determining. According to this mechanism, one molecule of isocyanate undergoes addition to C═O and the other, addition to C═N. Evidence is that ^{18}O labeling experiments have shown that each molecule of CO_2 produced contains one oxygen atom derived from the ioscyanate and one from the phospholene oxide,[581] which is precisely what is predicted by this mechanism. Certain other catalysts are also effective.[582]

OS **V**, 501.

6-61 The Conversion of Acid Salts to Nitriles
Nitrilo-de-oxido,oxo-tersubstitution

$$RCOO^- + BrCN \xrightarrow{250\text{-}300°C} RCN + CO_2$$

Salts of aliphatic or aromatic acids can be converted to the corresponding nitriles by heating with BrCN or ClCN. Despite appearances, this is not a substitution reaction. When $R^{14}COO^-$ was used, the label appeared in the nitrile, not in the CO_2,[583] and optical activity in R was retained.[584] The acyl isocyanate RCON═C═O could be isolated from the reaction mixture; hence the following mechanism was proposed:[583]

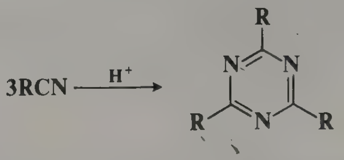
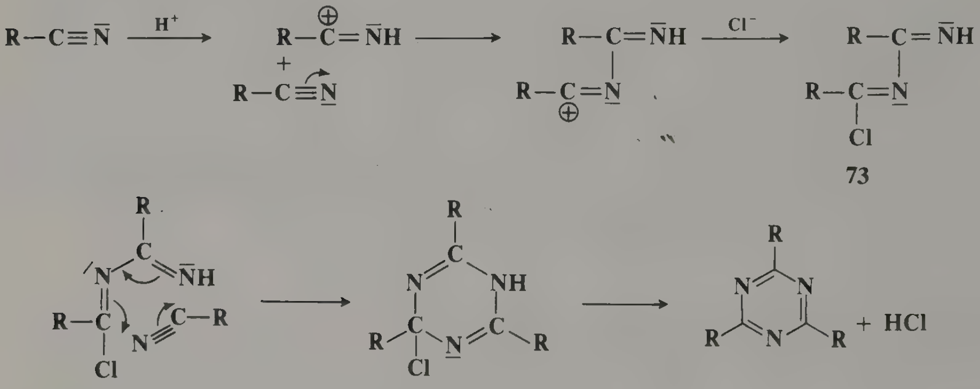
6-62 The Trimerization of Nitriles



Nitriles can be trimerized with various acids, bases, or other catalysts.[585] HCl is most often used, and then the reaction is similar to reaction **6-58.** However, most nitriles with an α-hydrogen do not give the reaction. Mixed triazines can be obtained from mixtures of nitriles.[586] The mechanism with HCl may be as follows:



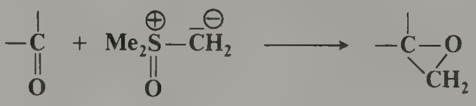
73

Intermediates of the type **73** have been isolated.

OS **III,** 71.

C. Carbon Adding to the Carbon. The reactions in this group (6-63 to 6-66) are cycloadditions.

6-63 The Formation of Epoxides from Aldehydes and Ketones



74

Aldehydes and ketones can be converted to epoxides[587] in good yields with the sulfur ylides dimethyloxosulfonium methylide (**74**) and dimethylsulfonium methylide (**75**).[588] For most purposes,

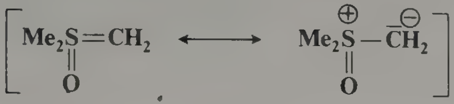
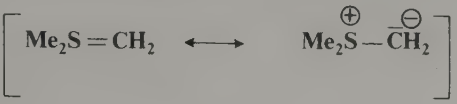
[587] For reviews, see Block, "Reactions of Organosulfur Compounds," pp. 101–105, Academic Press, New York, 1978; Berti, *Top. Stereochem.* **7,** 93–251 (1973), pp. 218–232.

[588] For reviews, see House, Ref. 158, pp. 709–733; Durst, *Adv. Org. Chem.* **6,** 285–388 (1969), pp. 321–330; Johnson, Ref. 477, pp. 328–351. For a monograph on sulfur ylides, see Trost and Melvin, "Sulfur Ylides," Academic Press, New York, 1975.

74 is the reagent of choice, because **75** is much less stable and ordinarily must be used as soon as

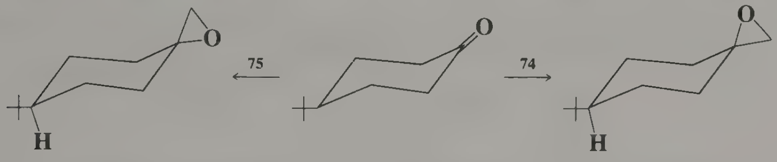


74



75

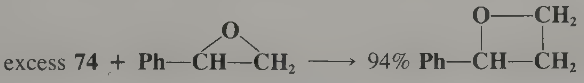
it is formed, while **74** can be stored several days at room temperature. However, when diastereomeric epoxides can be formed, **75** usually attacks from the more hindered and **74** from the less-hindered side. Thus, 4-*t*-butylcyclohexanone, treated with **74** gave exclusively **77** while **75** gave mostly **76.**[589] Another difference in behavior between **74** and **75** is that with α,β-unsaturated ketones, **74** gives only cyclopropanes (reaction **5-49**), while **75** gives oxirane formation. Other sulfur ylides have been used in an analogous manner, to transfer CHR or CR_2. Among these are $Me_2S{=}CHCOO^-$,[590] $Me_2S{=}CHPh$,[591] $Me_2S{=}CH$—vinyl,[592] and **100** on p. 774,[593] which transfer $CHCOO^-$, CHPh, CH—vinyl, and CPh_2, respectively. Nitrogen-containing sulfur ylides, such as **101** on p. 774 and $Ph(Me_2N)SO{=}CH_2$, as well as carbanions like **103** on p. 774 and trimethylsulfonium iodide $Me_3S^+\ I^-$ (with a phase-transfer catalyst)[594] have also been used.[595] High yields have been achieved by the use of sulfonium ylides anchored to insoluble polymers under phase transfer conditions.[596]



76 **77**

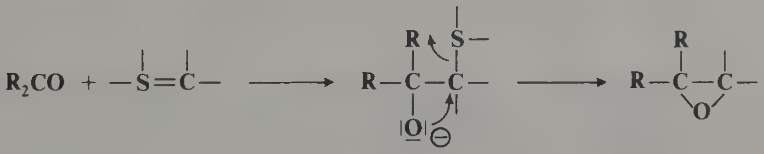
New bond is axial New bond is equatorial

74 reacts with epoxides to give oxetanes,[596a] e.g.,



$$\text{excess } \mathbf{74} + \text{Ph—}\overset{\text{O}}{\text{CH—CH}_2} \longrightarrow 94\%\ \text{Ph—}\overset{\text{O——CH}_2}{\text{CH—CH}_2}$$

The generally accepted mechanism for the reaction between sulfur ylides and aldehydes or ketones is



$$R_2CO + -\overset{|}{S}{=}\overset{|}{C}- \longrightarrow R-\underset{\underset{|\overline{O}|^{\ominus}}{|}}{\overset{R}{C}}-\overset{-S-}{C}- \longrightarrow R-\overset{R}{C}-C-$$

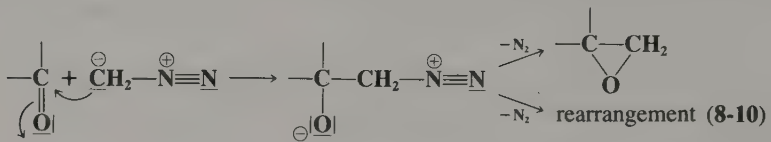
which is similar to that of the reaction of sulfur ylides with C=C double bonds (**5-49**).[597] The stereochemical difference in the behavior of **74** and **75** has been attributed to formation of the betaine **78** being reversible for **74** but not for the less stable **75**, so that the more-hindered product is the result of kinetic control and the less-hindered of thermodynamic control.[598]

Phosphorus ylides do not give this reaction, but give **6-47** instead.

Aldehydes and ketones can also be converted to epoxides by treatment with a diazoalkane,[599] most commonly diazomethane, but an important side reaction is the formation of an aldehyde or ketone with one more carbon than the starting compound (reaction **8-10**). The reaction can be carried out with many aldehydes, ketones, and quinones. A mechanism that accounts for both products is

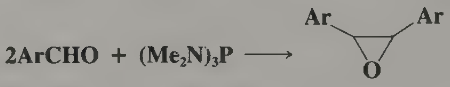


79

Compound **79** or nitrogen-containing derivatives of it have sometimes been isolated.

Dihalocarbenes and carbenoids, which readily add to C=C bonds (**5-49**), do not generally add to the C=O bonds of ordinary aldehydes and ketones, though addition of CCl_2 to certain cyclic ketones has been accomplished with $CHCl_3$ and OH^- under phase transfer conditions.[600]

Symmetrical epoxides can be prepared by treatment of aromatic aldehydes with hexamethylphosphorus triamide.[601]

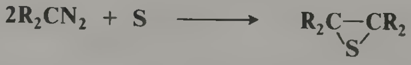


It is likely that the betaine $(Me_2N)_2\overset{+}{P}CHRO^-$ is formed first and then attacks a second molecule of the aldehyde.

See also **6-45**.

OS **V**, 358, 755.

6-64 The Formation of Episulfides and Episulfones[602]



Diazoalkanes, treated with sulfur, give episulfides.[603] It is likely that $R_2C=S$ is an intermediate, which is attacked by another molecule of diazoalkane, in a process similar to that shown in **6-63**. Thioketones *do* react with diazoalkanes to give episulfides.[604] Thioketones have also been converted to episulfides with sulfur ylides.[589] Several methods exist for converting ordinary aldehydes and ketones to episulfides with one more carbon, for example by treating them with a metallated 2-(alkylthio)-2-oxazoline (**80**).[605]

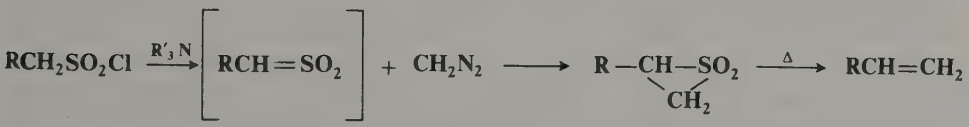
80

Alkanesulfonyl chlorides, when treated with diazomethane in the presence of a base (usually a tertiary amine), give episulfones (**82**).[606] The base removes HCl from the sulfonyl halide to produce

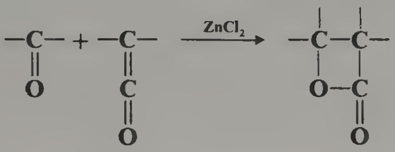


81 **82**

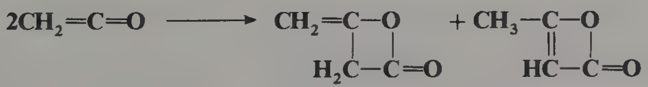
the highly reactive sulfene (**81**) (**7-15**), which then adds CH_2. The episulfone can then be heated to give off SO_2 (**7-25**), making the entire process a method for achieving the conversion $RCH_2SO_2Cl \rightarrow RCH{=}CH_2$.[607]

OS **V**, 231, 877.

6-65 The Formation of β-Lactones and Oxetanes



Aldehydes, ketones, and quinones react with ketenes to give β-lactones, diphenylketene being used most often.[608] The reaction is catalyzed by Lewis acids, and without them most ketenes do not give adducts because the adducts decompose at the high temperatures necessary when no catalyst is used. When ketene was added to chloral Cl_3CCHO in the presence of the chiral catalyst (+)-quinidine, the (S)-β-lactone was produced in 98% enantiomeric excess.[609] Ketene adds to another molecule of itself:



This dimerization is so rapid that ketene does not form β-lactones with aldehydes or ketones, except at low temperatures. Other ketenes dimerize more slowly. In these cases the major dimerization product is not the β-lactone, but a cyclobutenone (see p. 758). However, the proportion of ketene that dimerizes to β-lactone can be increased by the addition of catalysts such as triethylamine or triethyl phosphite $(EtO)_3P$.[610] 1,1-Dialkoxyalkenes (ketene acetals) $R_2C{=}C(OR')_2$ add to aldehydes and ketones in the presence of $ZnCl_2$ to give the corresponding oxetanes.[611] Oxetanes have also been prepared from ketones by treatment with the ion $MeSO({=}NTs)CH_2^-$.[612]

[609] Wynberg and Staring, *J. Am. Chem. Soc.* **104,** 166 (1982).

Ordinary aldehydes and ketones can add to olefins, under the influence of uv light, to give oxetanes. This reaction, called the *Paterno–Büchi reaction*,[613] is similar to the photochemical dimerization of olefins discussed at **5-48.** In general, the mechanism consists of the addition of an excited state of the carbonyl compound to the ground state of the olefin, in many cases through the intermediacy of an exciplex[614] (p. 776). Both singlet (S_1)[615] and n,π^* triplet[616] states have been shown to add to olefins to give oxetanes. A diradical intermediate  $\dot{O}{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\dot{C}}{-}$ has been detected spectrally.[617] Yields in the Paterno–Büchi reaction are variable, ranging from very low to fairly high (80 to 90%). There are several side reactions. When the reaction proceeds through a triplet state, it can in general be successful only when the alkene possesses a triplet energy comparable to, or higher than, the carbonyl compound; otherwise energy transfer from the excited carbonyl group to the ground-state alkene can take place (triplet–triplet photosensitization, see p. 212). In most cases quinones react normally with alkenes, giving oxetane products, but other α,β-unsaturated ketones usually give preferential cyclobutane formation (**5-48**). Aldehydes and ketones also add photochemically to allenes to give the corresponding alkylideneoxetanes and dioxaspiro compounds:[618]

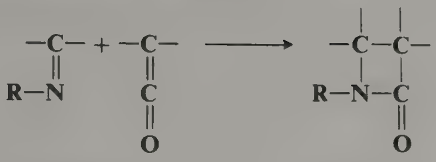
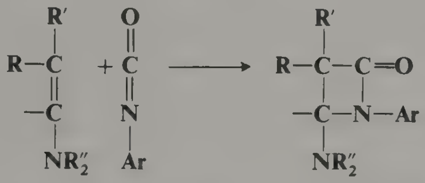
6-66 The Formation of β-Lactams



Ketenes add to imines to give β-lactams.[619] The reaction is generally carried out with ketenes of the form $R_2C=C=O$. It has not been successfully applied to $RCH=C=O$, except when these are generated in situ by decomposition of a diazo ketone (the Wolff rearrangement, **8-9**) in the presence of the enamine. It has been done with ketene, but the more usual course with this reagent is an addition to the enamine tautomer of the substrate. Thioketenes $R_2C=C=S$ give β-thiolactams.[620] Like the similar cycloaddition of ketenes to olefins (**5-48**), most of these reactions probably take place by the diionic mechanism *c* (p. 760).[621] β-Lactams have also been prepared in the opposite manner: by the addition of enamines to isocyanates:[622]



The reactive compound chlorosulfonyl isocyanate[623] $ClSO_2NCO$ forms β-lactams even with unactivated alkenes,[624] as well as with allenes,[625] conjugated dienes,[626] and cyclopropenes.[627]

OS **V,** 673.

Addition to Isonitriles[628]

Addition to $R-\overset{\oplus}{N}\equiv\overset{\ominus}{C}$ is not simply a matter of a species with an electron pair adding to one atom and a species without a pair adding to the other, as is addition to the other types of double and triple bonds in this chapter and Chapter 15. In these additions the electrophile and the nucleophile *both add to the carbon.* No species adds to the nitrogen, which, however, loses its positive charge by obtaining as an unshared pair one of the triple-bond pairs of electrons:

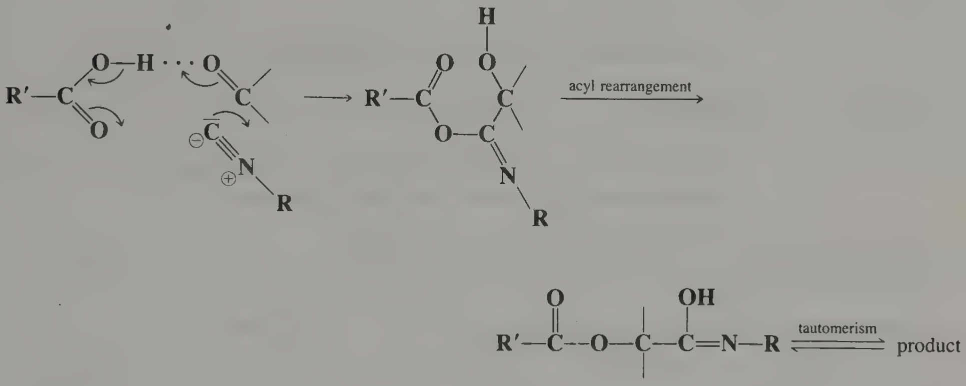
[630] For reviews, see Ugi, *Angew, Chem. Int. Ed. Engl.* **21,** 810–819 (1982), **1,** 8–21 (1962) [*Angew Chem.* **94,** 826–836, **74,** 9–22], *Newer Methods Prep. Org. Chem.* **4,** 1–36 (1968); Marquarding, Gokel, Hoffmann, and Ugi, Ref. 628, pp. 133–143; Gokel, Lüdke, and Ugi, Ref. 628, pp. 145–199, 252–254.

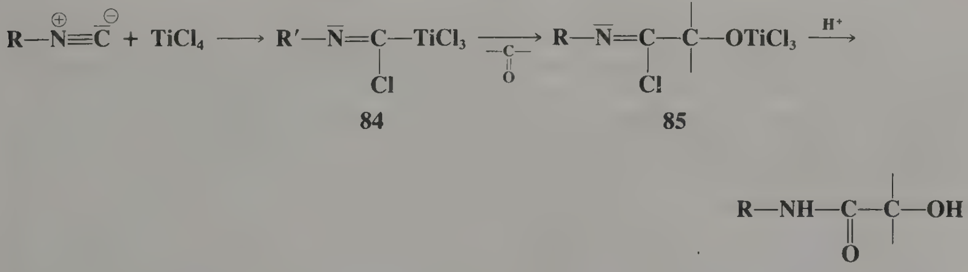
When an isonitrile is treated with a carboxylic acid and an aldehyde or ketone, an α-acyloxy amide is prepared. This is called the *Passerini reaction.* The following mechanism has been postulated:



If ammonia or an amine is also added to the mixture (in which case the reaction is known as the *Ugi reaction,* or the *Ugi four-component condensation,* abbreviated 4 CC), the product is the corresponding bisamide $R'—\underset{\underset{O}{\|}}{C}—NH—\overset{|}{\underset{|}{C}}—\underset{\underset{O}{\|}}{C}—NH—R$ (from NH_3) or $R'—\underset{\underset{O}{\|}}{C}—NR''—\overset{|}{\underset{|}{C}}—\underset{\underset{O}{\|}}{C}—NH—R$ (from a primary amine $R''NH_2$). This product probably arises from a reaction between the carboxylic acid, the isonitrile, and the *imine* formed from the aldehyde or ketone and ammonia or the primary amine. The use of an N-protected amino acid or peptide as the carboxylic acid component and/or the use of an isonitrile containing a C-protected carboxyl group allows the reaction to be used for peptide synthesis.[631]

The Ugi reaction can also be carried out with an isonitrile, an aldehyde or ketone, and ammonia or an amine, but with some other YH substituting for the carboxylic acid, e.g., H_2O, HN_3, HNCO.

In a variation of the Passerini reaction, isonitriles are treated with $TiCl_4$ to give adducts **84** which add to aldehydes or ketones to give **85,** which are hydrolyzed to α-hydroxy amides.[632]



$$R—\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}} + TiCl_4 \longrightarrow \underset{\textbf{84}}{R'—\bar{N}=\underset{\underset{Cl}{|}}{C}—TiCl_3} \xrightarrow[\underset{O}{\|}]{—C—} \underset{\textbf{85}}{R—\bar{N}=\underset{\underset{Cl}{|}}{C}—\overset{|}{\underset{|}{C}}—OTiCl_3} \xrightarrow{H^+} R—NH—\underset{\underset{O}{\|}}{C}—\overset{|}{\underset{|}{C}}—OH$$

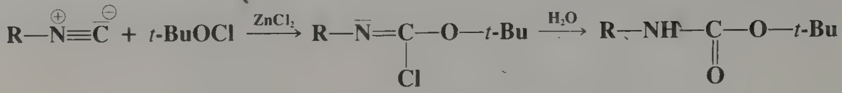
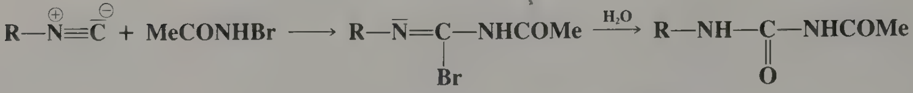
6-70 The Addition of O- and N-Halides to Isonitriles



$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}} + t\text{-BuOCl} \xrightarrow{ZnCl_2} R-\bar{N}=\underset{\displaystyle Cl}{\underset{|}{C}}-O-t\text{-Bu} \xrightarrow{H_2O} R-NH-\underset{\displaystyle O}{\underset{\|}{C}}-O-t\text{-Bu}$$

1/*N*-Hydro-2/*C*-butoxy,2/*C*-oxo-biaddition



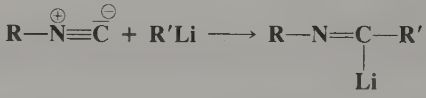
$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}} + MeCONHBr \longrightarrow R-\bar{N}=\underset{\displaystyle Br}{\underset{|}{C}}-NHCOMe \xrightarrow{H_2O} R-NH-\underset{\displaystyle O}{\underset{\|}{C}}-NHCOMe$$

1/*N*-Hydro-2/*C*-acylamino,2/C-oxo-biaddition

Alkyl hypochlorites and N-halo amides add to isonitriles to give, after hydrolysis, carbamates and N-acylureas (ureides), respectively.[633]

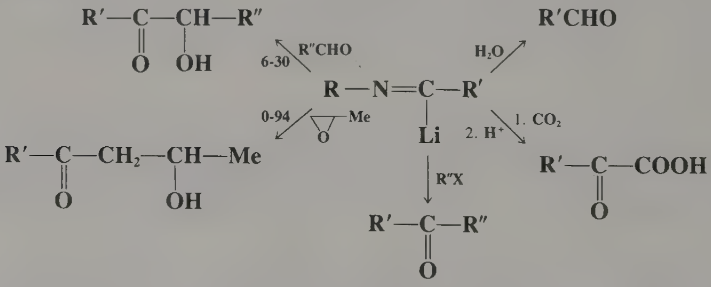
6-71 The Formation of Metalated Aldimines

1/1/Lithio-alkyl-addition



$$R-\overset{\oplus}{N}\equiv\overset{\ominus}{\bar{C}} + R'Li \longrightarrow R-N=\underset{\displaystyle Li}{\underset{|}{C}}-R'$$

Isonitriles that do not contain an α-hydrogen react with alkyllithium compounds, as well as with Grignard reagents, to give lithium (or magnesium) aldimines.[634] These metalated aldimines are versatile nucleophiles and react with various substrates as follows (see also **8-27**):



The reaction therefore constitutes a method for converting an organometallic compound R′M to an aldehyde R′CHO (see also **2-31**), an α-keto acid,[635] a ketone R′COR (see also **2-31**), an α-hydroxy ketone, or a β-hydroxy ketone. In each case the C=N bond is hydrolyzed to a C=O bond (reaction **6-2**).

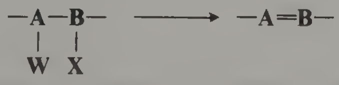
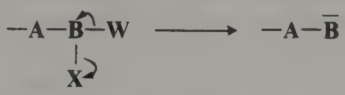
ELIMINATIONS

When two groups are lost from adjacent atoms so that a new double (or triple) bond is formed the



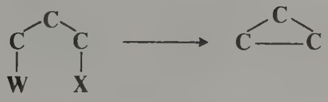
$$\underset{\substack{|\\W}}{-A}-\underset{\substack{|\\X}}{B}- \longrightarrow -A{=}B-$$

reaction is called β *elimination;* one atom is the α-, the other the β-atom. In an α elimination both groups are lost from the same atom to give a carbene (or a nitrene):



$$-A-\underset{\substack{|\\X}}{B}-W \longrightarrow -A-\overline{B}$$

In a γ elimination, a three-membered ring is formed:



Some of these processes were discussed in Chapter 10. Another type of elimination involves the expulsion of a fragment from within a chain or ring (X—Y—Z → X—Z + Y). Such reactions are called *extrusion reactions*. This chapter discusses β elimination and (beginning on p. 937) extrusion reactions; however, β eliminations in which X and W are both hydrogen are oxidation reactions and are treated in Chapter 19.

MECHANISMS AND ORIENTATION

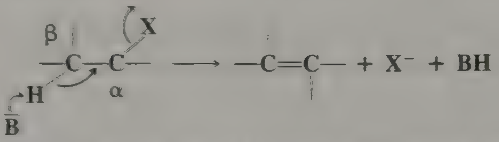
β elimination reactions may be divided into two types; one type taking place largely in solution, the other (pyrolytic eliminations) mostly in the gas phase. In the reactions in solution one group leaves with its electrons and the other without, the latter most often being hydrogen. In these cases we refer to the former as the leaving group or nucleofuge. For pyrolytic eliminations there are two principal mechanisms, one pericyclic and the other a free-radical pathway. A few photochemical eliminations are also known (the most important is Norrish type II cleavage of ketones, p. 214), but these are not generally of synthetic importance[1] and will not be discussed further. In most β eliminations the new bonds are C═C or C≡C; our discussion of mechanisms is largely confined to these cases.[2] Mechanisms in solution (E2, E1, E1cB) are discussed first.

---

[1] For synthetically useful examples of Norrish type II cleavage, see Neckers, Kellogg, Prins, and Schoustra, *J. Org. Chem.* **36**, 1838 (1971).

The E2 Mechanism

In the E2 mechanism (elimination, bimolecular), the two groups depart simultaneously, with the proton being pulled off by a base:



The mechanism thus takes place in one step and kinetically is second order: first order in substrate and first order in base. It is analogous to the SN2 mechanism (p. 256) and often competes with it. With respect to the substrate, the difference between the two pathways is whether the species with the unshared pair attacks the carbon (and thus acts as a nucleophile) or the hydrogen (and thus acts as a base). As in the case of the SN2 mechanism, the leaving group may be positive or neutral and the base may be negatively charged or neutral.

Among the evidence for the existence of the E2 mechanism are: (1) the reaction displays the proper second-order kinetics; (2) when the leaving hydrogen is replaced by deuterium in second-order eliminations, there is an isotope effect of from 3 to 8, consistent with breaking of this bond in the rate-determining step.[3] However, neither of these results alone could prove an E2 mechanism, since both are compatible with other mechanisms also (e.g., see E1cB p. 882). The most compelling evidence for the E2 mechanism is found in stereochemical studies.[4] As will be illustrated in the examples below, the E2 mechanism is stereospecific: the five atoms involved (including the base) in the transition state must be in one plane. There are two ways for this to happen. The H and X may be trans to one another (**A**) with a dihedral angle of 180°, or they may be cis (**B**) with a dihedral angle of 0°.[5] Conformation **A** is called *anti-periplanar*, and this type of elimination, in

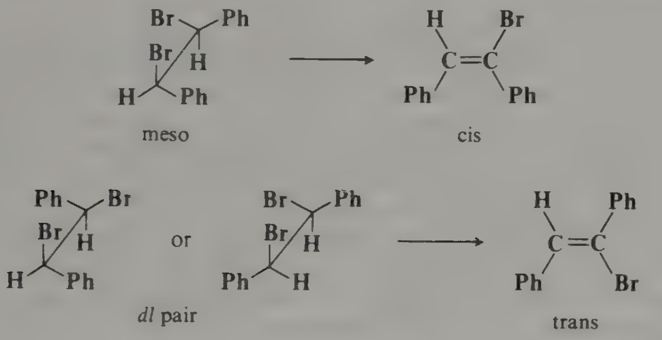
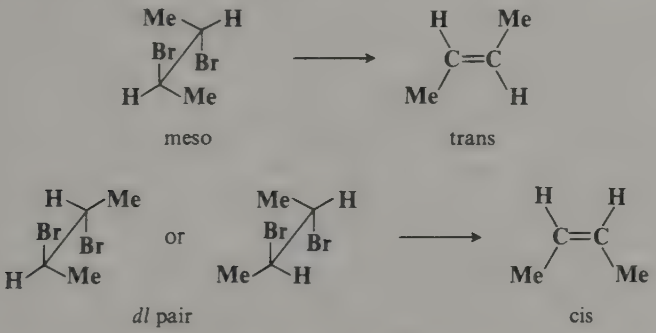
[5] DePuy, Morris, Smith and Smat, *J. Am. Chem. Soc.* **87**, 2421(1965).

which H and X depart in opposite directions, is called *anti elimination*. Conformation **B** is *syn-periplanar*, and this type of elimination, with H and X leaving in the same direction, is called *syn elimination*. Many examples of both kinds have been discovered. In the absence of special effects (discussed below) anti elimination is usually greatly favored over syn elimination, probably because **A** is a staggered conformation (p. 121) and the molecule requires less energy to reach this transition state than it does to reach the eclipsed transition state **B.** A few of the many known examples of predominant or exclusive anti elimination follow.

1. Elimination of HBr from *meso*-1,2-dibromo-1,2-diphenylethane gave *cis*-2-bromostilbene, while the (+) or (−) isomer gave the trans olefin. This stereospecific result, which was obtained



in 1904,[6] demonstrates that in this case elimination is anti. Many similar examples have been discovered since. Obviously, this type of experiment need not be restricted to compounds that have a meso form. Anti elimination requires that an erythro *dl* pair (or either isomer) give the cis olefin, and the threo *dl* pair (or either isomer) give the trans isomer, and this has been found many times. Anti elimination has also been demonstrated in cases where the positive leaving group is not hydrogen. In the reaction of 2,3-dibromobutane with iodide ion, the two bromines are removed (**7-29**). In this case the meso compound gave the trans olefin and the *dl* pair the cis:[7]



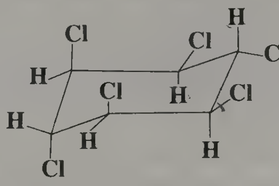
2. In open-chain compounds the molecule can usually adopt that conformation in which H and X are anti-periplanar. However, in cyclic systems this is not always the case. There are nine stereoisomers of 1,2,3,4,5,6-hexachlorocyclohexane: seven meso forms and a *dl* pair (see p. 113).

---

[6] Pfeiffer, Z. *Phys. Chem.* **48,** 40 (1904).

[7] Winstein, Pressman, and Young, *J. Am. Chem. Soc.* **61,** 1645 (1939).

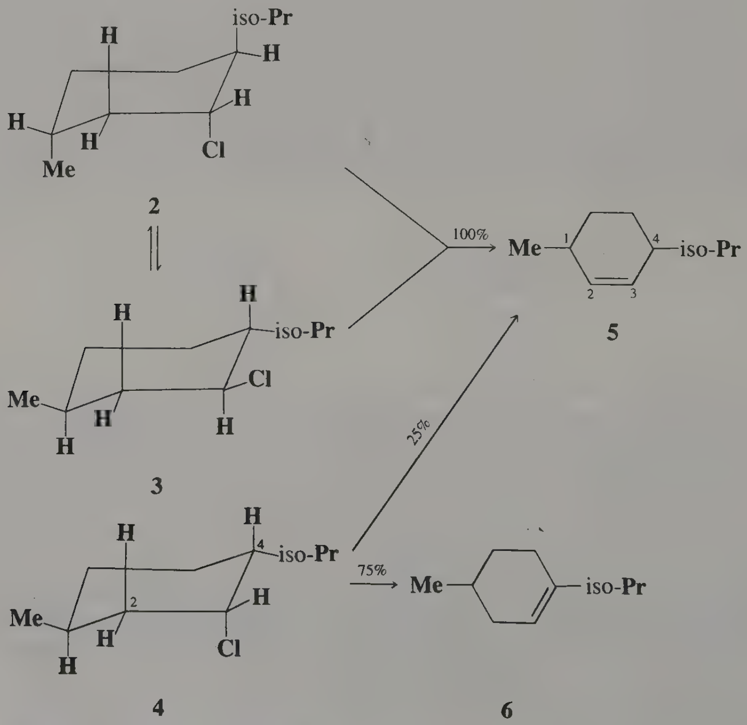
Four of the meso compounds and the *dl* pair (all that were then known) were subjected to elimination of HCl. Only one of these (**1**) has no Cl trans to an H. Of the other isomers, the fastest elimination



1

rate was about three times as fast as the slowest, but the rate for **1** was 7000 times slower than that of the slowest of the other isomers.[8] This result demonstrates that with these compounds anti elimination is greatly favored over syn elimination, though the latter must be taking place on **1**, very slowly, to be sure.

3. The preceding result shows that elimination of HCl in a six-membered ring proceeds best when the H and X are trans to each other. However, there is an additional restriction. Adjacent trans groups on a six-membered ring can be diaxial or diequatorial (p. 125) and the molecule is generally free to adopt either conformation, though one may have a higher energy than the other. Anti-periplanarity of the leaving groups requires that they be diaxial, even if this is the conformation of higher energy. The results with menthyl and neomenthyl chlorides are easily interpretable on this basis. Menthyl chloride has two chair conformations, **2** and **3**. **3**, in which the three substituents



---

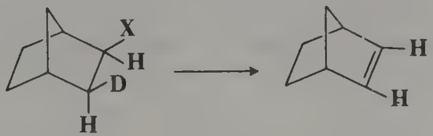
[8] Cristol, *J. Am. Chem. Soc.* **69**, 338 (1947); Cristol, Hause, and Meek, *J. Am. Chem. Soc.* **73**, 674 (1951).

are all equatorial, is the more stable. The more stable chair conformation of neomenthyl chloride is **4,** in which the chlorine is axial; there are axial hydrogens on both C-2 and C-4. The results are: neomenthyl chloride gives rapid E2 elimination and the olefin produced is predominantly **6** (**6**/**5** ratio is about 3:1) in accord with Zaitsev's rule (p. 889). Since an axial hydrogen is available on both sides, this factor does not control the direction of elimination and Zaitsev's rule is free to operate. However, for menthyl chloride, elimination is much slower and the product is entirely the anti-Zaitsev **5.** It is slow because the unfavorable conformation **2** has to be achieved before elimination can take place, and the product is **5** because only on this side is there an axial hydrogen.[9]

4. That anti elimination also occurs in the formation of triple bonds is shown by elimination from *cis*- and *trans*-HOOC—CH═CCl—COOH. In this case the product in both cases is HOOCC≡CCOOH, but the trans isomer reacts about 50 times faster than the cis compound.[10]

Some examples of syn elimination have been found in molecules where H and X could not achieve an anti-periplanar conformation.

1. The deuterated norbornyl bromide (**7**, X = Br) gave 94% of the product containing no deuterium.[11] Similar results were obtained with other leaving groups and with bicyclo[2.2.2] compounds.[12] In these cases the exo X group cannot achieve a dihedral angle of 180° with the endo β-hydrogen because of the rigid structure of the molecule. The dihedral angle here is about 120°. These leaving groups prefer syn elimination with a dihedral angle of about 0° to anti elimination with an angle of about 120°.



7

2. The molecule **8** is a particularly graphic example of the need for a planar transition state. In **8** each Cl has an adjacent hydrogen trans to it, and if planarity of leaving groups were not

[12] For example, see Bird, Cookson, Hudec, and Williams, *J. Chem. Soc.* 410 (1963); Stille, Sonnenberg, and Kinstle, *J. Am. Chem. Soc.* **88,** 4922 (1966); Coke and Cooke, *J. Am. Chem. Soc,* **89,** 6701 (1967); DePuy, Naylor, and Beckman, *J. Org. Chem.* **35,** 2750 (1970); Brown and Liu, *J. Am. Chem. Soc.* **92,** 200 (1970); Sicher, Pánkova, Závada, Kniežo, and Orahovats, *Collect. Czech. Chem. Commun.* **36,** 3128 (1971).

required, anti elimination could easily take place. However, the crowding of the rest of the molecule forces the dihedral angle to be about 120°, and elimination of HCl from **8** is much slower than from corresponding nonbridged compounds.[13] (Note that syn elimination from **8** is even less likely than anti elimination.) Syn elimination can take place from the trans isomer of **8** (dihedral angle about 0°); this isomer reacted about eight times faster than **8.**[13]

The examples so far given illustrate two points. (1) Anti elimination *requires* a dihedral angle of 180°. When this angle cannot be achieved, anti elimination is greatly slowed or prevented entirely. (2) For the simple systems so far discussed syn elimination is not found to any significant extent unless anti elimination is greatly diminished by failure to achieve the 180° angle.

As noted in Chapter 4 (p. 135), six-membered rings are the only ones among rings of four to thirteen members in which strain-free anti-periplanar conformations can be achieved. It is not surprising, therefore, that syn elimination is least common in six-membered rings. Cooke and Coke subjected cycloalkyltrimethylammonium hydroxides to elimination (**7-6**) and found the following percentages of syn elimination with ring size: four-membered, 90%; five-membered, 46%; six-membered, 4%; seven-membered, 31 to 37%.[14] It should be noted that the NMe_3^+ group has a greater tendency to syn elimination than do other common leaving groups such as OTs, Cl, and Br.

Other examples of syn elimination have been found in medium-ring compounds, where both cis and trans olefins are possible (p. 111). As an illustration, we can look at experiments performed by Závada, Svoboda, and Sicher.[15] These workers subjected 1,1,4,4-tetramethyl-7-cyclodecyltrimethylammonium chloride (**9**) to elimination and obtained mostly *trans*- but also some *cis*-tetramethylcyclodecenes as products. (Note that *trans*-cyclodecenes, though stable, are less stable than the cis isomers). In order to determine the stereochemistry of the reaction, they repeated the elimination, this time using deuterated substrates. They found that when **9** was deuterated in the trans position (H_t = D), there was a substantial isotope effect in the formation of *both* cis and trans olefins, but when **9** was deuterated in the cis position (H_c = D), there was *no* isotope effect in the formation of either olefin. Since an isotope effect is expected for an E2 mechanism,[16] these results indicated that *only* the trans hydrogen (H_t) was lost, whether the product was the cis or the trans isomer.[17] This in turn means that *the cis isomer must have been formed by anti elimination and the trans isomer by syn elimination.* (Anti elimination could take place from approximately the conformation shown, but for syn elimination the molecule must twist into a conformation in which the C—H_t and C—NMe_3^+ bonds are syn-periplanar.) This remarkable result, called the *syn–anti dichotomy,* has also been demonstrated by other types of evidence.[18] The fact that syn

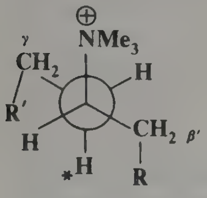
[16] Other possible mechanisms, such as E1cB (p. 882) or α′,β elimination (p. 908), were ruled out in all these cases by other evidence.

[17] This conclusion has been challenged by Coke, Ref. 4.

[18] Sicher, Závada, and Krupička, *Tetrahedron Lett.* 1619 (1966); Sicher and Závada, *Collect. Czech. Chem. Commun.* **32,** 2122 (1967); Závada and Sicher, *Collect. Czech. Chem. Commun.* **32,** 3701 (1967). For a review, see Bartsch and Závada, Ref. 4.

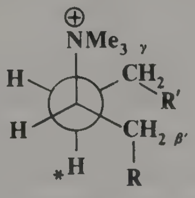
elimination in this case predominates over anti (as indicated by the formation of trans isomer in greater amounts than cis) has been explained by conformational factors.[19] The syn–anti dichotomy has also been found in other medium-ring systems (8- to 12-membered),[20] though the effect is greatest for 10-membered rings. With leaving groups,[21] the extent of this behavior decreases in the order $\text{NMe}_3^+ > \text{OTs} > \text{Br} > \text{Cl}$, which parallels steric requirements. When the leaving group is uncharged, syn elimination is favored by strong bases and by weakly ionizing solvents.[22]

Syn elimination and the syn–anti dichotomy have also been found in open-chain systems, though to a lesser extent than in medium-ring compounds. For example, in the conversion of 3-hexyl-4-*d*-trimethylammonium ion to 3-hexene with potassium *sec*-butoxide, about 67% of the reaction followed the syn–anti dichotomy.[23] The effects of leaving group, base strength, and solvents are similar. In general syn elimination in open-chain systems is only important in cases where certain types of steric effect are present. One such type is compounds in which substituents are found on both the β′- and the γ-carbons (the unprimed letter refers to the branch in which the elimination takes place). The factors that cause these results are not completely understood, but the following conformational effects have been proposed as a partial explanation.[24] The two anti- and two syn-periplanar conformations are, for a quaternary ammonium salt:



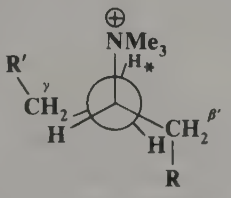
C

anti ⟶ trans



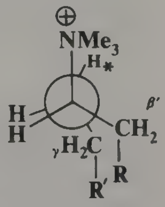
D

anti ⟶ cis



E

syn ⟶ trans



F

syn ⟶ cis

In order for an E2 mechanism to take place a base must approach the proton marked *. In **C** this proton is shielded on both sides by R and R′. In **D** the shielding is on only one side. Therefore, when anti elimination does take place in such systems, it should give more cis product than trans. Also, when the normal anti elimination pathway is hindered sufficiently to allow the syn pathway to compete, the anti → trans route should be diminished more than the anti → cis route. When syn elimination begins to appear, it seems clear that **E**, which is less eclipsed than **F**, should be the favored pathway and syn elimination should generally give the trans isomer. In general, deviations from the syn–anti dichotomy are greater on the trans side than on the cis. Thus, trans olefins are formed partly or mainly by syn elimination, but cis olefins are formed entirely by anti elimination. Predominant syn elimination has also been found in compounds of the form

---

[19] For discussions, see Ref. 4.

[20] For example, see Coke and Mourning, *J. Am. Chem. Soc.* **90,** 5561 (1968), where the experiment was performed on cyclooctyltrimethylammonium hydroxide, and *trans*-cyclooctene was formed by a 100% syn mechanism, and *cis*-cyclooctene by a 51% syn and 49% anti mechanism.

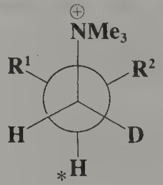
[21] For examples with other leaving groups, see Závada, Krupička, and Sicher, *Chem. Commun.* 66 (1967), *Collect. Czech. Chem. Commun.* **33,** 1393 (1968); Sicher, Jan, and Schlosser, *Angew. Chem. Int. Ed. Engl.* **10,** 926 (1971) [*Angew. Chem.* **83,** 1012]; Závada and Pánková, *Collect. Czech. Chem. Commun.* **45,** 2171 (1980).

[22] See, for example, Sicher and Závada, *Collect. Czech. Chem. Commun.* **33,** 1278 (1968).

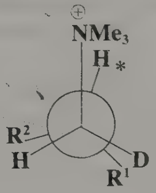
[23] Bailey and Saunders, *Chem. Commun.* 1598 (1968), *J. Am. Chem. Soc.* **92,** 6904 (1970). For other examples of syn elimination and the syn–anti dichotomy in open-chain systems, see Pánková, Sicher, and Závada, *Chem. Commun.* 394 (1967); Pánková, Vítek, Vašíčková, Řeřicha, and Závada, *Collect. Czech. Chem. Commun.* **37,** 3456 (1972); Schlosser and An, *Helv. Chim. Acta* **62,** 1194 (1979); Sugita, Nakagawa, Nishimoto, Kasai, and Ichikawa, *Bull. Chem. Soc. Jpn.* **52,** 871 (1979); Pánková, Kocián, Krupička, and Závada, *Collect. Czech. Chem. Commun.* **48,** 2944 (1983).

[24] Bailey and Saunders, Ref. 23; Chiao and Saunders, *J. Am. Chem. Soc.* **99,** 6699 (1977).

$R^1R^2CHCHDNMe_3^+$, where R^1 and R^2 are both bulky.[25] In this case also the conformation leading to syn elimination (**H**) is less strained than **G**, which gives anti elimination. **G** has three bulky groups (including NMe_3^+) in the gauche position to each other.

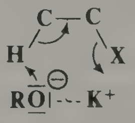


G



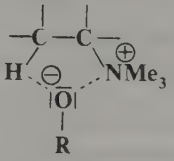
H

It was mentioned above that weakly ionizing solvents promote syn elimination when the leaving group is uncharged. This is probably caused by ion pairing, which is greatest in nonpolar solvents.[26] Ion pairing can cause syn elimination with an uncharged leaving group by means of the transition state shown in **10.**



10

This effect was graphically illustrated by elimination from 1,1,4,4-tetramethyl-7-cyclodecyl bromide.[27] The ratio of syn to anti elimination when this compound was treated with *t*-BuOK in the nonpolar benzene was 55.0. But when the crown ether dicyclohexano-18-crown-6 (p. 77) was added (this compound selectively removes K^+ from the *t*-BuO^- K^+ ion pair and thus leaves *t*-BuO^- as a free ion), the syn/anti ratio decreased to 0.12. Large decreases in the syn/anti ratio on addition of the crown ether were also found with the corresponding tosylate and with other nonpolar solvents.[28] However, with positively charged leaving groups the effect is reversed. Here, ion pairing *increases* the amount of anti elimination.[29] In this case a relatively free base (e.g., PhO^-) can be attracted to the leaving group, putting it in a favorable position for attack on the syn β-hydrogen, while ion pairing would reduce this attraction.



We can conclude that anti elimination is generally favored in the E2 mechanism, but that steric (inability to form the anti-periplanar transition state), conformational, ion-pairing, and other factors cause syn elimination to intervene (and even predominate) in some cases.

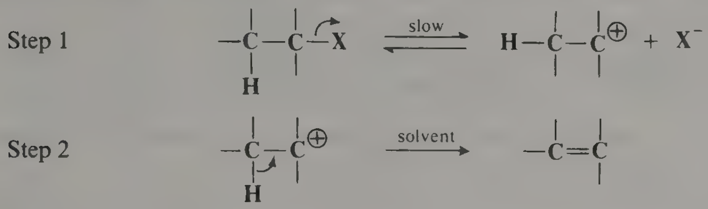
The E1 Mechanism

The E1 mechanism is a two-step process in which the rate-determining step is ionization of the substrate to give a carbocation that rapidly loses a β-proton to a base, usually the solvent:

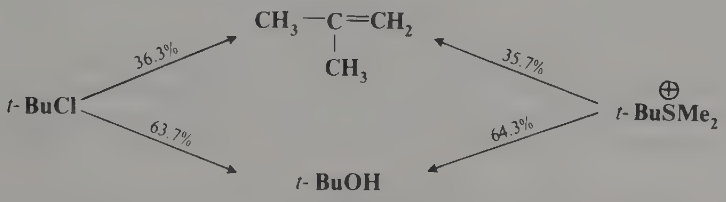


The E1 mechanism normally operates without an *added* base. Just as the E2 mechanism is analogous to and competes with the SN2, so is the E1 mechanism related to the SN1. In fact, the first step of the E1 is exactly the same as that of the SN1 mechanism. The second step differs in that the solvent pulls a proton from the β-carbon of the carbocation rather than attacking it at the positively charged carbon, as in the SN1 process. In a pure E1 reaction (i.e., without ion pairs, etc.) the product should be completely nonstereospecific, since the carbocation is free to adopt its most stable conformation before giving up the proton.

Some of the evidence for the E1 mechanism is as follows:

1. The reaction exhibits first-order kinetics (in substrate) as expected. Of course the solvent is not expected to appear in the rate equation, even if it were involved in the rate-determining step (p. 194), but this point can be easily checked by adding a small amount of the conjugate base of the solvent. It is generally found that such an addition does not increase the rate of the reaction. If this more powerful base does not enter into the rate-determining step, it is unlikely that the solvent does. An example of an E1 mechanism with a rate-determining second step (proton transfer) has been reported.[30]

2. If the reaction is performed on two molecules that differ only in the leaving group (for example, t-BuCl and t-Bu$\overset{\oplus}{S}$Me$_2$), the rates should obviously be different, since they depend on the ionizing ability of the molecule. However, once the carbocation is formed, if the solvent and the temperature are the same, it should suffer the same fate in both cases, since the nature of the leaving group does not affect the second step. This means that *the ratio of elimination to substitution should be the same*. The compounds mentioned in the example were solvolyzed at 65.3°C in 80% aqueous ethanol with the following results:[31]



Although the rates were greatly different (as expected with such different leaving groups), the product ratios were the same, within 1%. If this had taken place by a second-order mechanism, the nucleophile would not be expected to have the same ratio of preference for attack at the β-hydrogen compared to attack at a *neutral* chloride as for attack at the β-hydrogen compared to attack at a *positive* SMe_2 group.

[31] Cooper, Hughes, Ingold, and MacNulty, *J. Chem. Soc.* 2038 (1948).

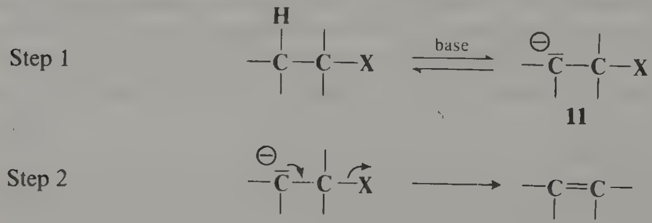
3. Many reactions carried out under first-order conditions on systems where E2 elimination is anti proceed quite readily to give olefins where a cis hydrogen must be removed, often in preference to the removal of a trans hydrogen. For example, menthyl chloride (**2**, p. 876), which by the E2 mechanism gave only **5**, under E1 conditions gave 68% **6** and 32% **5**, since the steric nature of the hydrogen is no longer a factor here, and the more stable olefin (Zaitsev's rule, p. 889) is predominantly formed.

4. If carbocations are intermediates, we should expect rearrangements with suitable substrates. These have often been found in elimination reactions performed under E1 conditions.

E1 reactions can involve ion pairs, just as is true for SN1 reactions (p. 263).[32] This effect is naturally greatest for nondissociating solvents: it is least in water, greater in ethanol, and greater still in acetic acid. It has been proposed that the ion-pair mechanism (p. 266) extends to elimination reactions too, and that the SN1, SN2, E1, and E2 mechanisms possess in common an ion-pair intermediate, at least occasionally.[33]

The E1cB Mechanism[34]

In the E1 mechanism, X leaves first and then H. In the E2 mechanism the two groups leave at the same time. There is a third possibility: the H leaves first and then the X. This is a two-step process, called the *E1cB mechanism*, or the *carbanion mechanism*, since the intermediate is a carbanion:



The name E1cB comes from the fact that it is the conjugate base of the substrate that is giving up the leaving group (see the SN1cB mechanism, p. 314). We can distinguish three limiting cases: (1) The carbanion returns to starting material faster than it forms product: step 1 is reversible. (2) Step 1 is the slow step, and formation of product is faster than return of the carbanion to starting material. In this case step 1 is essentially irreversible. (3) Step 1 is rapid, and the carbanion goes slowly to product. This case occurs only with the most stable carbanions. Here, too, step 1 is essentially irreversible. These cases have been given the designations: (1) $(E1cB)_R$, (2) $(E1cB)_I$, and (3) $(E1)_{anion}$. Their characteristics are listed in Table 1.[35] Investigations of the reaction order are generally not very useful (except for case 3 which is first order), because cases 1 and 2 are second order and thus difficult or impossible to distinguish from the E2 mechanism by this pro-

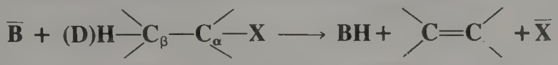
TABLE 1 Kinetic predictions for base-induced β-eliminations[35]



$$\bar{B} + (D)H{-}C_\beta{-}C_\alpha{-}X \longrightarrow BH + C{=}C + \bar{X}$$

Mechanism	Kinetic order[a]	β-hydrogen exchange faster than elimination	General or specific base catalysis	k_H/k_D	Electron withdrawal at C_β[d]	Electron release at C_α[d]	Leaving-group isotope effect or element effect
$(E1)_{anion}$	1	Yes	General[c]	1.0	Rate decrease	Rate increase	Substantial
$(ElcB)_R$	2	Yes	Specific	1.0	Small rate increase	Small rate increase	Substantial
$(E1cB)_{ip}$	2	No	General[e]	$1.0 \rightarrow 1.2$	Small rate increase	Small rate increase	Substantial
$(E1cB)_I$	2	No	General	$2 \rightarrow 8$	Rate increase	Little effect	Small to negligible
E2[b]	2	No	General	$2 \rightarrow 8$	Rate increase	Small rate increase	Small

[a] All mechanisms exhibit first-order kinetics in substrate.

[b] Only transition states with considerable carbanion character considered in this table.

[c] Specific base catalysis predicted if extent of substrate ionization reduced from almost complete.

[d] Effect on rate assuming no change in mechanism is caused; steric factors upon substitution at C_α and C_β have not been considered. The rate predictions are geared to substituent effects such as these giving rise to Hammett reaction constants on β- and α-aryl substitution.

[e] Depends on whether ion pair assists in removal of leaving group.

cedure.[36] We would expect the greatest likelihood of finding the E1cB mechanism in substrates that have (a) a poor nucleofuge and (b) an acidic hydrogen, and most investigations have concerned such substrates. The following is some of the evidence in support of the E1cB mechanism.

1. The first step of the $(ElcB)_R$ mechanism involves a reversible exchange of protons between the substrate and the base. In that case, if deuterium is present in the base, then recovered starting material should contain deuterium. This was found to be the case in the treatment of $Cl_2C{=}CHCl$ with NaOD to give $ClC{\equiv}CCl$. When the reaction was stopped before completion, there *was* deuterium in the recovered olefin.[37] A similar result was found for pentahaloethanes.[38] These substrates are relatively acidic. In both cases the electron-withdrawing halogens increase the acidity of the hydrogen, and in the case of trichloroethylene there is the additional factor that a hydrogen on an sp^2 carbon is more acidic than one on an sp^3 carbon (p. 234). Thus, the ElcB mechanism is more likely to be found in eliminations yielding triple bonds than in those giving double bonds. Another likely place for the E1cB mechanism should be in reaction of a substrate like $PhCH_2CH_2Br$, since the carbanion is stabilized by resonance with the phenyl group. Nevertheless, no deuterium exchange was found here.[39] If this type of evidence is a guide, then it may be inferred that the

---

[36] $(E1cB)_I$ cannot be distinguished from E2 by this means, because it has the identical rate law: Rate = k[substrate][B^-]. The rate law for $(ElcB)_R$ is different: Rate = k[substrate][B^-]/[BH], but this is often not useful because the only difference is that the rate is also dependent (inversely) on the concentration of the conjugate acid of the base, and this is usually the solvent, so that changes in its concentration cannot be measured.

[37] Houser, Bernstein, Miekka, and Angus, *J. Am. Chem. Soc.* **77,** 6201 (1955).

[38] Hine, Wiesboeck, and Ghirardelli, *J. Am. Chem. Soc.* **83,** 1219 (1961); Hine, Wiesboeck, and Ramsay, *J. Am. Chem. Soc.* **83,** 1222 (1961).

[39] Skell and Hauser, *J. Am. Chem. Soc.* **67,** 1661 (1945).

$(E1cB)_R$ mechanism is quite rare, at least for eliminations with common leaving groups such as Br. Cl, or OTs, which yield $C{=}C$ double bonds.

2. When the reaction

$$p\text{-}NO_2C_6H_4\text{—}CH_2\text{—}CH_2\text{—}NR_3^+ + B^- \longrightarrow p\text{-}NO_2C_6H_4\text{—}CH{=}CH_2 + BH + NR_3$$

was carried out in water containing acetohydroxamate buffers, a plot of the rate against the buffer concentration was curved and the rate leveled off at high buffer concentrations, indicating a change in rate-determining step.[40] This rules out an E2 mechanism, which has only one step. When D_2O was used instead of H_2O as solvent, there was an initial inverse solvent isotope effect of 7.7 (the highest inverse solvent isotope effect yet reported). That is, the reaction took place faster in D_2O than in H_2O. This is compatible only with an E1cB mechanism in which the proton-transfer step is not entirely rate-determining. The isotope effect arises from a partitioning of the carbanion intermediate **11.** This intermediate either can go to product or it can revert to starting compound, which requires taking a proton from the solvent. In D_2O the latter process is slower (because the O—D bond of D_2O cleaves less easily than the O—H bond of H_2O), reducing the rate at which **11** returns to starting compound. With the return reaction competing less effectively, the rate of conversion of **11** to product is increased.

3. We have predicted that the E1cB mechanism would be most likely to be found with substrates containing acidic hydrogens and poor leaving groups. Compounds of the type ZCH_2CH_2OPh, where Z is an electron-withdrawing group (e.g., NO_2, SMe_2^+, $ArSO_2$, CN, COOR, etc.), belong to this category, because OPh is a very poor leaving group (p. 311). There is much evidence to show that the mechanism here is indeed E1cB.[41] Isotope effects, measured for $MeSOCD_2CH_2OPh$ and $Me_2\overset{\oplus}{S}CD_2CH_2OPh$ with NaOD in D_2O, are about 0.7. This is compatible with an $(E1cB)_R$ mechanism, but not with an E2 mechanism for which an isotope effect of perhaps 5 might be expected (of course, an E1 mechanism is precluded by the extremely poor nucleofugal ability of OPh). The fact that k_H/k_D is less than the expected value of 1 is attributable to solvent and secondary isotope effects. Among other evidence for an E1cB mechanism in these systems is that changes in the identity of Z had a dramatic effect on the relative rates: a span of 10^{11} between NO_2 and COO^-. Note that elimination from substrates of the type $RCOCH_2CH_2Y$ is the reverse of Michael-type addition to $C{=}C$ bonds. We have seen (p. 664) that such addition involves initial attack by a nucleophile Y and subsequent attack by a proton. Thus the initial loss of a proton from substrates of this type (i.e., an E1cB mechanism) is in accord with the principle of microscopic reversibility.[42] It has been suggested that all base-initiated elimination reactions wherein the proton is activated by strong electron-withdrawing groups proceed by carbanion mechanisms.[43] It may also be recalled that benzyne formation (p. 581) can also occur by such a process.

Of the three cases of the E1cB mechanism, the one most difficult to distinguish from E2 is $(E1cB)_I$. One way to make this distinction is to study the effect of a change in leaving group. This was done in the case of the three acenaphthylenes **12,** where it was found that (1) the three rates were fairly similar, the largest being only about four times that of the smallest, and (2) in compound c (X = Cl, Y = F), the only product contained Cl and no F, i.e., only the poorer nucleofuge F departed while Cl remained.[44] Result (1) rules out all the E1cB mechanisms except $(E1cB)_I$, because the others should all have considerable leaving group effects (Table 1). An ordinary E2 mechanism

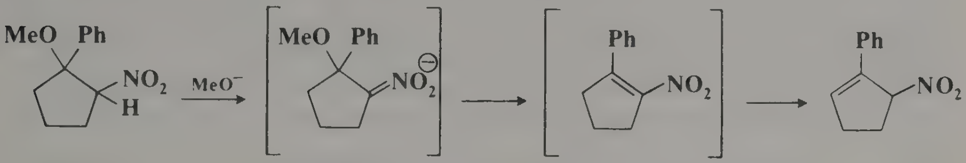
12

	X	Y
a	Br	Cl
b	Cl	Cl
c	Cl	F

should also have a large leaving group effect, but an E2 mechanism with substantial carbanionic character (see the next section) might not. However, no E2 mechanism can explain result (2), which can be explained by the fact that an α-Cl is more effective than an α-F in stabilizing the planar carbanion that remains when the proton is lost. Thus (as in the somewhat similar case of aromatic nucleophilic substitution, see p. 587), when X^- leaves in the second step, the one that leaves is not determined by which is the better nucleofuge, but by which has had its β hydrogen removed.[45]

4. An example of an $(E1)_{anion}$ mechanism has been found with the substrate **13**, which when treated with methoxide ion undergoes elimination to **15**, which is unstable under the reaction

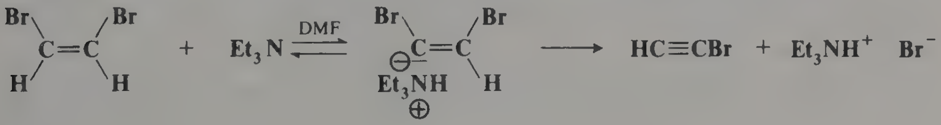


13 **14** **15**

conditions and rearranges as shown.[46] Among the evidence for the proposed mechanism in this case were kinetic and isotope-effect results, as well as the spectral detection of **14**.[47]

5. In many eliminations to form C=O and C≡N bonds the initial step is loss of a positive group (normally a proton) from the oxygen or nitrogen. These may also be regarded as E1cB processes.

There is evidence that some E1cB mechanisms may involve carbanion ion pairs, e.g.,[48]



---

[45] For other evidence for the existence of the $(E1cB)_I$ mechanism, see Bordwell, Vestling, and Yee, Ref. 43; Fedor and Glave, *J. Am. Chem. Soc.* **93,** 985 (1971); Redman, Thomas, and Stirling, *J. Chem. Soc., Perkin Trans. 2* 1135 (1978); Thibblin, *Chem. Scr.* **15,** 121 (1980); Carey, More O'Ferrall, and Vernon, *J. Chem. Soc., Perkin Trans. 2* 1581 (1982); Baciocchi, Ruzziconi, and Sebastiani, *J. Am. Chem. Soc.* **105,** 6114 (1983). The $(E1cB)_I$ mechanism has also been claimed for DDT and some of its analogs [McLennan and Wong, *J. Chem. Soc., Perkin Trans. 2* 526, 1373 (1974), *Aust. J. Chem.* **29,** 787 (1976); McLennan, *J. Chem. Soc., Perkin Trans. 2* 932 (1976)], but this has been challenged: MacLaury and Saracino, *J. Org. Chem.* **44,** 3344 (1979). See also Jarczewski, Schroeder, and Leffek, *Pol. J. Chem.* **56,** 521 (1982).

[46] Bordwell, Yee, and Knipe, *J. Am. Chem. Soc.* **92,** 5945 (1970).

This case is designated $(E1cB)_{ip}$; its characteristics are shown in Table 1.

We have seen that in the E2 mechanism the hydrogen and nucleofuge must be either anti or syn; a perpendicular arrangement does not give the reaction. There is evidence that this is also true for the E1cB mechanism; i.e., after the hydrogen has left, a nucleofuge that is frozen into a perpendicular arrangement will not leave.[49]

The E1–E2–E1cB Spectrum

In the three mechanisms so far considered the similarities are greater than the differences. In each case there is a leaving group that comes off with its pair of electrons and another group (usually hydrogen) that comes off without them. The only difference is in the order of the steps. It is now generally accepted that there is a spectrum of mechanisms ranging from one extreme, in which the leaving group departs well before the proton (pure E1), to the other extreme, in which the proton comes off first and then, after some time, the leaving group follows (pure E1cB). The *pure* E2 case would be somewhere in the middle, with both groups leaving simultaneously. However, most E2 reactions are not exactly in the middle, but somewhere to one side or the other. For example, the nucleofuge might depart just before the proton. This case may be described as an E2 reaction with a small amount of E1 character. The concept may be expressed by the question: In the transition state, which bond (C—H or C—X) has undergone more cleavage?[50]

One way to determine just where a given reaction stands on the E1–E2–E1cB spectrum is to study isotope effects, which ought to tell something about the behavior of bonds in the transition state.[51] For example, $CH_3CH_2\overset{\oplus}{N}Me_3$ showed a nitrogen isotope effect (k^{14}/k^{15}) of 1.017, while $PhCH_2CH_2\overset{\oplus}{N}Me_3$ gave a corresponding value of 1.009.[52] It would be expected that the phenyl group would move the reaction toward the E1cB side of the line, which means that for this compound the C—N bond is not so greatly broken in the transition state as it is for the unsubstituted one. The isotope effect bears this out, for it shows that in the phenyl compound, the mass of the nitrogen has less effect on the reaction rate than it does in the unsubstituted compound. Similar results have been obtained with $\overset{\oplus}{S}R_2$ leaving groups by the use of $^{32}S/^{34}S$ isotope effects[53] and with Cl ($^{35}Cl/^{37}Cl$).[54] The position of reactions along the spectrum has also been studied from the other side of the newly forming double bond by the use of H/D and H/T isotope effects,[55] although interpretation of these results is clouded by the fact that β-hydrogen isotope effects are expected to change smoothly from small to large to small again as the degree of transfer of the β-hydrogen from the β-carbon to the base increases[56] (recall—p. 198—that isotope effects are greatest when the proton is half-transferred in the transition state), by the possibility of secondary isotope effects (e.g., the presence of a β-deuterium or tritium may cause the leaving group to depart more slowly), and by the possibility of tunneling[57] (see footnote 35 in Chapter 6). Other isotope-effect studies have involved labeled α- or β-carbon, labeled α-hydrogen, or labeled base.[51]

[54] Grout, McLennan, and Spackman, *J. Chem. Soc., Perkin Trans. 2* 1758 (1977).

[55] For example, see Saunders and Edison, *J. Am. Chem. Soc.* **82,** 138 (1960); Hodnett and Sparapany, *Pure Appl. Chem.* **8,** 385, 537 (1964); Finley and Saunders, *J. Am. Chem. Soc.* **89,** 898 (1967); Ghanbarpour and Willi, *Liebigs Ann. Chem.* 1295 (1975); Simon and Müllhofer, Ref. 52.

[56] There is controversy as to whether such an effect has been established in this reaction: See Cockerill, *J. Chem. Soc. B* 964 (1967); Blackwell, *J. Chem. Soc., Perkin Trans. 2* 488 (1976).

Another way to study the position of a given reaction on the spectrum involves the use of β-aryl substitution. Since a positive Hammett ρ value is an indication of a negatively charged transition state, the ρ value for substituted β-aryl groups should increase as a reaction moves from E1-like to E1cB-like along the spectrum. This has been shown to be the case in a number of studies;[58] e.g., ρ values of $ArCH_2CH_2X$ increase as the leaving-group ability of X decreases. A typical set of ρ values was: X = I, 2.07; Br, 2.14; Cl, 2.61; SMe_2^+, 2.75; F, 3.12.[59] As we have seen, decreasing leaving-group ability correlates with increasing E1cB character.

Still another method measures volumes of activation.[60] These are negative for E2 and positive for E1cB mechanisms. Measurement of the activation volume therefore provides a continuous scale for deciding just where a reaction lies on the spectrum.

The E2C Mechanism[61]

Certain alkyl halides and tosylates undergo E2 eliminations faster when treated with such weak bases as Cl^- in polar aprotic solvents or PhS^- than with the usual E2 strong bases such as RO^- in ROH.[62] In order to explain these results Parker and co-workers have proposed[63] that there is a spectrum[64] of E2 transition states in which the base may interact in the transition state with the α-carbon as well as with the β-hydrogen. At one end of this spectrum is a mechanism (called E2C) in which, in the transition state, the base interacts mainly with the carbon. The E2C mechanism is characterized by strong nucleophiles that are weak bases. At the other extreme is the normal E2 mechanism, here called E2H to distinguish it from E2C, characterized by strong bases. **16** represents

[64] This is apart from the E1–E2–E1cB spectrum.

a transition state between these extremes. Additional evidence[65] for the E2C mechanism is derived from Brönsted equation considerations (p. 226), from substrate effects, from isotope effects, and from the effects of solvents on rates.

However, the E2C mechanism has been criticized, and it has been contended that all the experimental results can be explained by the normal E2 mechanism.[66] McLennan has suggested that the transition state is that shown as **17.**[67] An ion-pair mechanism has also been proposed.[68] Although the actual mechanisms involved may be a matter of controversy, there is no doubt that a class of elimination reactions exists that is characterized by second-order attack by weak bases.[69] These reactions also have the following general characteristics:[70] (1) they are favored by good leaving groups; (2) they are favored by polar aprotic solvents; (3) the reactivity order is tertiary > secondary > primary, which is the opposite of the normal E2 order (p. 894); (4) the elimination is always anti (syn elimination is not found), but in cyclohexyl systems, a diequatorial anti elimination is about as favorable as a diaxial anti elimination (unlike the normal E2 reaction, p. 876); (5) they follow Zaitsev's rule (p. 889), where this does not conflict with the requirement for anti elimination.

Orientation of the Double Bond

With some substrates, a β-hydrogen is present on only one carbon and (barring rearrangements) there is no doubt as to the identity of the product. For example, $PhCH_2CH_2Br$ can give only $PhCH{=}CH_2$. However, in many other cases two or three olefinic products are possible. In the simplest such case, a *sec*-butyl compound may give either 1-butene or 2-butene. There are a number of rules that enable us to predict, in many instances, which product will predominantly form.[71]

1. No matter what the mechanism, a double bond does not go to a bridgehead carbon unless the ring sizes are large enough (Bredt's rule, see p. 138). This means, for example, not only that **18** gives only **19** and not **20** (indeed **20** is not a known compound), but also that **21** does not undergo elimination.

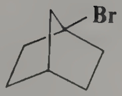
20



21

2. No matter what the mechanism, if there is a double bond (C═C or C═O) already in the molecule that can be in conjugation with the new double bond, then the conjugated product usually predominates, sometimes even when the stereochemistry is unfavorable (for an exception, see p. 892).

3. In the E1 mechanism the leaving group is gone before the choice is made as to which direction the new double bond takes. Therefore the direction is determined almost entirely by the relative stabilities of the two (or three) possible olefins. In such cases *Zaitsev's rule*[72] *operates.* This rule states that *the double bond goes mainly toward the most highly substituted carbon.* That is, a *sec*-butyl compound gives more 2-butene than 1-butene, and 3-bromo-2,3-dimethylpentane gives more 2,3-dimethyl-2-pentene than either 3,4-dimethyl-2-pentene or 2-ethyl-3-methyl-1-butene. Thus Zaitsev's rule predicts that the olefin predominantly formed will be the one with the largest possible number of alkyl groups on the C═C carbons, and in most cases this is what is found. From heat of combustion data (see p. 22) it is known that olefin stability increases with alkyl substitution, though just why this should be is a matter of conjecture. The most common explanation is hyperconjugation. For E1 eliminations Zaitsev's rule governs the orientation, whether the leaving group is neutral or positive, since, as already mentioned, the leaving group is not present when the choice of direction is made. This statement does not hold for E2 eliminations, and it may be mentioned here, for contrast with later results, that E1 elimination of $Me_2CHCHMe\overset{\oplus}{S}Me_2$ gave 91% of the Zaitsev product and 9% of the other.[73] However, there *are* cases in which the leaving group affects the direction of the double bond in E1 eliminations.[74] This may be attributed to ion pairs; that is, the leaving group is not completely gone when the hydrogen departs. Zaitsev's rule breaks down in cases where the non-Zaitsev product is more stable for steric reasons. For example, E1 or E1-like eliminations of 1,2-diphenyl-2-X-propanes $PhMeCXCH_2Ph$ were reported to give about 50% $CH_2{=}CPhCH_2Ph$, despite the fact that the double bond of the Zaitsev product (PhMeC═CHPh) is conjugated with two benzene rings.[75]

4. For the anti E2 mechanism a trans β-proton is necessary; if this is available in only one direction, that is the way the double bond will form. Because of the free rotation in acyclic systems (except where steric hindrance is great), this is a factor only in cyclic systems. Where trans β-hydrogens are available on two or three carbons, two types of behavior are found, depending on substrate structure and the nature of the leaving group. Some compounds follow Zaitsev's rule and give predominant formation of the most highly substituted olefin, but others follow *Hofmann's rule: the double bond goes mainly toward the least highly substituted carbon.* Though many exceptions are known, the following general statements can be made: In most cases, compounds containing uncharged nucleofuges (those that come off as negative ions) follow Zaitsev's rule, just as they do in E1 elimination, no matter what the structure of the substrate. However, elimination from compounds with charged nucleofuges, e.g., NR_3^+, SR_2^+ (those that come off as neutral molecules), follow Hofmann's rule if the substrate is acyclic,[76] but Zaitsev's rule if the leaving group is attached to a six-membered ring.[77]

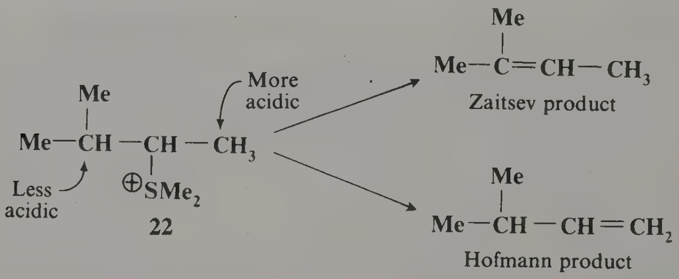
Much work has been devoted to searching for the reasons for the differences in orientation. Since Zaitsev orientation almost always gives the thermodynamically more stable isomer, what needs to be explained is why in some cases the less stable Hofmann product predominates. Three explanations have been offered for the change in orientation in acyclic systems with a change from uncharged to charged nucleofuges. The first of these, by Hughes and Ingold,[78] is that Hofmann orientation is caused by the fact that the acidity of the β-hydrogen is decreased by the presence of the electron-donating alkyl groups. For example, under E2 conditions $Me_2CHCHMe\overset{\oplus}{S}Me_2$ (**22**) gives more of the Hofmann product; it is the more acidic hydrogen that is removed by the base.



Of course, the CH_3 hydrogens would still be more acidic than the Me_2CH hydrogen even if a neutral leaving group were present, but the explanation of Hughes and Ingold is that acidity matters with charged and not with neutral leaving groups, because the charged groups exert a strong electron-withdrawing effect, making differences in acidity greater than they are with the less electron-withdrawing neutral groups.[78] The explanation of Bunnett[79] is similar. According to this, the change to a positive leaving group causes the mechanism to shift toward the E1cB end of the spectrum, where there is more C—H bond breaking in the rate-determining step and where, consequently, acidity is more important. In this view, when there is a neutral leaving group, the mechanism is more E1-like, C—X bond breaking is more important, and olefin stability determines the direction of the new double bond. The third explanation, by H. C. Brown, is completely different. In this picture, field effects are unimportant, and the difference in orientation is largely a steric effect caused by the fact that charged groups are usually larger than neutral ones. A CH_3 group is more open to attack than a CH_2R group and a CHR_2 group is still less easily attacked. Of course, these considerations also apply when the leaving group is neutral, but, according to Brown, they are much less important here because the neutral groups are smaller and do not block access to the hydrogens as much. Brown was able to show that Hofmann elimination increases with the size of the leaving group. Thus the percentage of 1-ene obtained from $CH_3CH_2CH_2CHXCH_3$ was as follows (X listed in order of increasing size): Br, 31%; I, 30%; OTs, 48%; $\overset{\oplus}{S}Me_2$, 87%; SO_2Me, 89%; $\overset{\oplus}{N}Me_3$, 98%.[80] Hofmann elimination was also shown to increase with increase in bulk of the substrate.[81] With large enough compounds, Hofmann orientation can be obtained even with halides, e.g., *t*-amyl bromide gave 89% of the Hofmann product. Even those who believe in the acidity explanations concede that these steric factors operate in extreme cases.[82]

---

[76] An example of an acyclic quaternary ammonium salt that follows Zaitsev's rule is found in Feit and Saunders, *J. Am. Chem. Soc.* **92,** 5615 (1970).

[77] For examples where Zaitsev's rule is followed with charged leaving groups in cyclohexyl systems, see Gent and McKenna, *J. Chem. Soc* 137 (1959); Hughes and Wilby, *J. Chem. Soc.* 4094 (1960); Brownlee and Saunders, *Proc. Chem. Soc.* 314 (1961); Booth, Franklin, and Gidley, *J. Chem. Soc C* 1891 (1968). For a discussion of the possible reasons for this, see Saunders and Cockerill, Ref. 2, pp. 192–193.

[78] For summaries of this position, see Ingold, *Proc. Chem. Soc.* 265–274 (1962); Banthorpe, Hughes, and Ingold, *J. Chem. Soc.* 4054 (1960); Banthorpe, Ref. 2, pp. 55–59.

[79] Bunnett, Ref. 2.

There is one series of results incompatible with the steric explanation—E2 elimination from the four 2-halopentanes gave the following percentages of 1-pentene: F, 83%; Cl, 37%; Br, 25%; I, 20%.[83] The same order was found for the four 2-halohexanes.[84] Although there is some doubt about the relative steric requirements of Br, Cl, and I, there is no doubt that F is the smallest of the halogens, and if the steric explanation were the only valid one, the fluoroalkanes could not give predominant Hofmann orientation. Another result that argues against the steric explanation is the effect of changing the nature of the base. An experiment in which the effective size of the base was kept constant while its basicity was increased (by using as bases a series of $XC_6H_4O^-$ ions) showed that the percentage of Hofmann elimination increased with increasing base strength, though the size of the base did not change.[85] These results are in accord with the explanation of Bunnett, since an increase in base strength moves an E2 reaction closer to the E1cB end of the spectrum. In further experiments, a large series of bases of different kinds was shown to obey linear free-energy relationships between basicity and percentage of Hofmann elimination,[86] though certain very large bases (e.g., 2,6-di-*t*-butyl-phenoxide) did not obey the relationships, steric effects becoming important in these cases. How large the base must be before steric effects are observed depends on the pattern of alkyl substitution in the substrate, but not on the nucleofuge.[87] Steric effects of the base can also become important in cases where the effective size of the base is increased by base association, when the leaving group is halogen or OTs.[88] Such base association effects are unimportant when the leaving group is NMe_3^+.[89]

5. Only a few investigations on the orientation of syn E2 eliminations have been carried out, but these show that Hofmann orientation is greatly favored over Zaitsev.[90]

6. In the E1cB mechanism the question of orientation seldom arises because the mechanism is generally found only where there is an electron-withdrawing group in the β-position, and that is where the double bond goes.

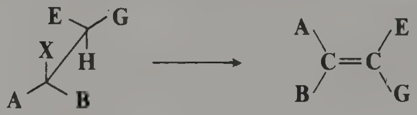
7. As already mentioned, E2C reactions show a strong preference for Zaitsev orientation.[91] In some cases this can be put to preparative use. For example, the compound $PhCH_2CHOTsCHMe_2$ gave about 98% $PhCH{=}CHCHMe_2$ under the usual E2 reaction conditions (*t*-BuOK in *t*-BuOH). In this case the double bond goes to the side with more hydrogens because on that side it will be able to conjugate with the benzene ring. However, with the weak base $Bu_4N^+ Br^-$ in acetone the Zaitsev product $PhCH_2CH{=}CMe_2$ was formed in 90% yield.[92]

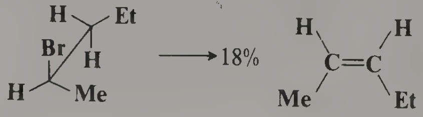
8. In cases where large isotope effects exist, the orientation can be changed by putting D in the substrate instead of H. For example, dehydration of an alcohol $RR'COHCH_3$ gave primarily $RR'C{=}CH_2$, but when $RR'COHCD_3$ was used, the double bond went the other way.[93]

Steric Orientation of the Double Bond

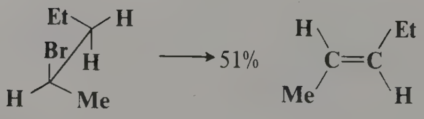
When elimination takes place on a compound of the form CH_3—CABX or CHAB—CGGX, the new olefin does not have cis–trans isomerism, but for compounds of the form CHEG—CABX (E and G *not* H) (**23**) and CH_2E—CABX (**24**), cis and trans isomers are possible. When the anti E2 mechanism is in operation, **23** gives the isomer arising from trans orientation of X and H and, as we have seen before (p. 875), an erythro compound gives the cis olefin and a threo compound the trans. For **24** two conformations are possible for the transition state; these lead to different isomers and often both are obtained. However, the one that predominates is often determined by an eclipsing effect.[94] For example, Zaitsev elimination from 2-bromopentane can occur as follows:



23



25



26

However, in **25** the ethyl group is between Br and Me, while in **26** it is between Br and H. This means that **26** is more stable, and most of the elimination should occur from this conformation. This is indeed what happens, and 51% of the trans isomer is formed (with KOEt) compared to

---

[91] For example, see Lloyd and Parker, *Tetrahedron Lett.* 637 (1971); Ono, *Bull. Chem. Soc. Jpn.* **44,** 1369 (1971); Bailey and Saunders, *J. Org. Chem.* **38,** 3363 (1973); Muir and Parker, *J. Org. Chem.* **41,** 3201 (1976).

[93] Miyano, *J. Org. Chem.* **46,** 1854 (1981).

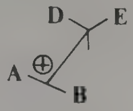
[94] See Cram, Greene, and DePuy, *J. Am. Chem. Soc.* **78,** 790 (1956); Cram, in Newman, "Steric Effects in Organic Chemistry," pp. 338–345, Wiley, New York, 1956.

18% of the cis (the rest is the Hofmann product).[95] These effects become larger with increasing size of A, B, and E.

However, eclipsing effects are not the only factors that affect the cis/trans ratio in anti E2 eliminations. Other factors are the nature of the leaving group, the base, the solvent, and the substrate. Not all these effects are completely understood.[96]

For syn E2 elimination, we have seen (p. 879) that formation of the trans olefin should be greatly preferred to that of the cis isomer because of eclipsing effects. In accord with this, very high trans/cis ratios, higher than would be expected on the basis of olefin stabilities alone, have been found for syn elimination of the 5-decyltrimethylammonium ion.[97]

For E1 eliminations, if there is a free carbocation (**27**), then it is free to rotate, and no matter what the geometry of the original compound, the more stable situation is the one where the larger



27

(**D** may be **H**)

of the D–E pair is opposite the smaller of the A–B pair and the corresponding olefin should form. If the carbocation is not completely free, then to that extent, E2-type products are formed. Similar considerations apply in E1cB eliminations.[98]

REACTIVITY

In this section we examine the effects of changes in the substrate, base, leaving group, and medium on (1) overall reactivity, (2) E1 vs. E2 vs. E1cB,[99] and (3) elimination vs. substitution.

Effect of Substrate Structure

1. *Effect on overall activity.* We refer to the carbon containing the nucleofuge (X) as the α-carbon and to the carbon that loses the proton (or other positive species) as the β-carbon. Groups attached to the α- or β-carbons can exert at least four kinds of influence:

a. They may stabilize or destabilize the incipient double bond (α- or β-groups may do this).

b. They may stabilize or destabilize an incipient negative charge, affecting the acidity of the proton (β-groups only).

c. They may stabilize or destabilize an incipient positive charge (α-groups only).

d. They may exert steric effects (e.g., eclipsing effects) (both α- and β-groups).

Effects a and d can apply in all three mechanisms, though steric effects are greatest for the E2 mechanism. Effect b does not apply in the E1 mechanism, and effect c does not apply in the E1cB mechanism. Groups such as Ar and C=C increase the rate by any mechanism, whether they are α or β (effect a). Electron-withdrawing groups increase the acidity when in the β position, but have little effect in the α position unless they also conjugate with the double bond. Thus Br, Cl, CN, Ts, NO_2, CN, SR in the β position all increase the rate of E2 eliminations.

[99] For discussions, see Cockerill and Harrison, Ref. 2, pp. 178–189.

2. *Effect on E1 vs. E2 vs. E1cB.* α-Alkyl and α-aryl groups increase the extent of E1 elimination, since they stabilize the carbocation character of the transition state. That is, they shift the spectrum toward the E1 end. β-Alkyl groups also shift the mechanism toward E1, since they *decrease* the acidity of the hydrogen. However, β-aryl groups shift the mechanism the other way (toward E1cB) by stabilizing the carbanion. Indeed, as we have seen (p. 884), all electron-withdrawing groups in the β position shift the mechanism toward E1cB.[100] α-Alkyl groups also increase the extent of elimination with weak bases (E2C reactions).

3. *Effect on elimination vs. substitution.* Under second-order conditions α branching increases elimination, to the point where tertiary substrates undergo few SN2 reactions, as we saw in Chapter 10. For example, Table 2 shows results on some simple alkyl bromides. Similar results were obtained with $\overset{\oplus}{\mathrm{S}}\mathrm{Me}_2$ as the leaving group.[104] Two reasons may be presented for this trend. One is statistical: as α branching increases, there are usually more hydrogens for the base to attack. The other is that α branching presents steric hindrance to attack of the base at the carbon. Under first-order conditions, increased α branching also increases the amount of elimination (E1 vs. SN1), though not so much, and usually the substitution product predominates. For example, solvolysis of *t*-butyl bromide gave only 19% elimination[103] (compare with Table 2). β branching also increases the amount of E2 elimination with respect to SN2 substitution (Table 2), not because elimination is faster but because the SN2 mechanism is so greatly slowed (p. 298). Under first-order conditions too, β branching favors elimination over substitution, probably for steric reasons.[105] However, E2 eliminations from compounds with charged leaving groups are slowed by β branching. This is related to Hofmann's rule (p. 890). Electron-withdrawing groups in the β position not only increase the rate of E2 eliminations and shift the mechanisms toward the E1cB end of the spectrum but also increase the extent of elimination as opposed to substitution.

TABLE 2 The effect of α and β branching on the rate of E2 elimination and the amount of olefin formed

The reactions were between the alkyl bromide and OEt⁻. The rate for isopropyl bromide was actually greater than that for ethyl bromide, if the temperature difference is considered. Neopentyl bromide, the next compound in the β-branching series, cannot be compared because it has no β-hydrogen and cannot give an elimination product without rearrangement

Substrate	Temperature, °C	Olefin, %	Rate × 10^5 of E2 reaction	Reference
CH_3CH_2Br	55	0.9	1.6	101
$(CH_3)_2CHBr$	25	80.3	0.237	102
$(CH_3)_3CBr$	25	97	4.17	103
$CH_3CH_2CH_2Br$	55	8.9	5.3	101
 $CH_3\underset{CH_3}{\underset{\vert}{C}}HCH_2Br$	55	59.5	8.5	101

Effect of the Attacking Base

1. *Effect on E1 vs. E2 vs. E1cB.* In the E1 mechanism, an external base is generally not required: The solvent acts as the base. Hence, when external bases are added, the mechanism is shifted toward E2. Stronger bases and higher base concentrations cause the mechanism to move toward the E1cB end of the E1–E2–E1cB spectrum.[106] However, weak bases in polar aprotic solvents can also be effective in elimination reactions with certain substrates (the E2C reaction, p. 887). Normal E2 elimination has been accomplished with the following bases:[107] H_2O, NR_3, OH^-, OAc^-, OR^-, OAr^-, NH_2^-, CO_3^{2-}, $LiAlH_4$, I^-, CN^-, and organic bases. However, the only bases of preparative importance in the normal E2 reaction are OH^-, OR^-, and NH_2^-, usually in the conjugate acid as solvent. Weak bases effective in the E2C reaction are Cl^-, Br^-, F^-, OAc^-, and RS^-. These bases are often used in the form of their R_4N^+ salts.

2. *Effect on elimination vs. substitution.* Strong bases not only benefit E2 as against E1, but also benefit elimination as against substitution. With a high concentration of strong base in a nonionizing solvent, bimolecular mechanisms are favored and E2 predominates over SN2. At low base concentrations, or in the absence of base altogether, in ionizing solvents, unimolecular mechanisms are favored, and the SN1 mechanism predominates over the E1. In Chapter 10, it was pointed out that some species are strong nucleophiles though weak bases (p. 307). The use of these obviously favors substitution, except that, as we have seen, elimination can predominate if polar aprotic solvents are used. It has been shown for the base CN^- that in polar aprotic solvents, the less the base is encumbered by its counterion in an ion pair (i.e., the freer the base), the more substitution is favored at the expense of elimination.[108]

Effect of the Leaving Group

1. *Effect on reactivity.* The leaving groups in elimination reactions are similar to those in nucleophilic substitution. E2 eliminations have been performed with the following groups: NR_3^+, PR_3^+, SR_2^+, OHR^+, SO_2R, OSO_2R, OCOR, OOH, OOR, NO_2,[109] F, Cl, Br, I, and CN (*not* OH_2^+). E1 eliminations have been carried out with: NR_3^+, SR_2^+, OH_2^+, OHR^+, OSO_2R, OCOR, Cl, Br, I, and N_2^+.[110] However, the only important leaving groups for preparative purposes are OH_2^+ (always by E1) and Cl, Br, I, and NR_3^+ (usually by E2).

2. *Effect on E1 vs. E2 vs. E1cB.* Better leaving groups shift the mechanism toward the E1 end of the spectrum, since they make ionization easier. This effect has been studied in various ways. One way already mentioned was a study of ρ values (p. 887). Poor leaving groups and positively charged leaving groups shift the mechanism toward the E1cB end of the spectrum because the strong electron-withdrawing field effects increase the acidity of the β-hydrogen.[111] The E2C reaction is favored by good leaving groups.

3. *Effect on elimination vs. substitution.* As we have already seen (p. 881), for first-order reactions the leaving group has nothing to do with the competition between elimination and substitution, since it is gone before the decision is made as to which path to take. However, where ion pairs are involved, this is not true, and results have been found where the nature of the leaving group does affect the product.[112] In second-order reactions, the elimination/substitution ratio is not greatly dependent on a halide leaving group, though there is a slight increase in elimination in the order I > Br > Cl. When OTs is the leaving group, there is usually much more substitution. For example, n-$C_{18}H_{37}Br$ treated with t-BuOK gave 85% elimination, while n-$C_{18}H_{37}OTs$ gave, under the same conditions, 99% substitution.[113] On the other hand, positively charged leaving groups increase the amount of elimination.

Effect of the Medium

1. *Effect of solvent on E1 vs. E2 vs. E1cB.* With any reaction a more polar environment enhances the rate of mechanisms that involve ionic intermediates. For neutral leaving groups, it is expected that E1 and E1cB mechanisms will be aided by increasing polarity of solvent and by increasing ionic strength. With certain substrates, polar aprotic solvents promote elimination with weak bases (the E2C reaction). Crown ethers have been used to assure that elimination of tosylates takes place entirely by E2 without incursion by E1 mechanisms.[114]

2. *Effect of solvent on elimination vs. substitution.* Increasing polarity of solvent favors SN2 reactions at the expense of E2. In the classical example, alcoholic KOH is used to effect elimination, while the more polar aqueous KOH is used for substitution. Charge-dispersal discussions, similar to those on p. 316,[115] only partially explain this. In most solvents SN1 reactions are favored over E1. E1 reactions compete best in polar solvents that are poor nucleophiles.

3. *Effect of temperature.* Elimination is favored over substitution by increasing temperature, whether the mechanism is first order or second order.[116] The reason is that the activation energies of eliminations are higher than those of substitutions (because eliminations have greater changes in bonding), so at higher temperatures there is a larger degree of elimination.

MECHANISMS AND ORIENTATION IN PYROLYTIC ELIMINATIONS

Mechanisms[117]

A number of types of compound undergo elimination on heating, with no other reagent present. Reactions of this type are often run in the gas phase. The mechanisms are obviously different from those already discussed, since all those require a base (which may be the solvent) in one of the steps, and there is no base or solvent present in pyrolytic elimination. Two mechanisms have been found to operate. One involves a cyclic transition state, which may be four-, five-, or six-membered.

Rev.* **69,** 33–60 (1969).

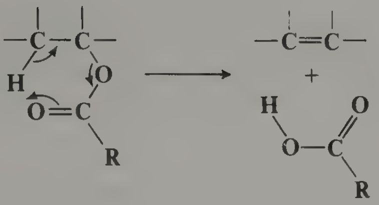
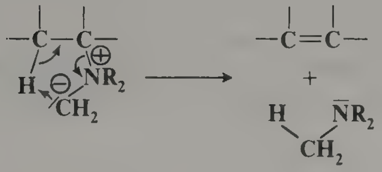
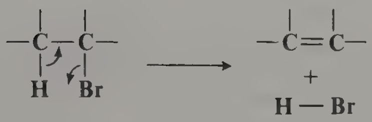
Examples of each size are:



(7-3)

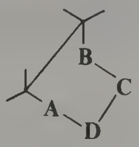


(7-7)



(7-14)

In this mechanism, which is called the *Ei mechanism,* the two groups leave at about the same time and bond to each other as they are doing so. The elimination must be syn and, for the four- and five-membered transition states, the four or five atoms making up the ring must be coplanar. Coplanarity is not required for the six-membered transition state, since there is room for the outside atoms when the leaving atoms are staggered (**28**).



28

As in the E2 mechanism, it is not necessary that the C—H and C—X bond be equally broken in the transition state. In fact, there is also a spectrum of mechanisms here, ranging from a mechanism in which C—X bond breaking is a good deal more advanced than C—H bond breaking to one in which the extent of bond breaking is virtually identical for the two bonds. Evidence for the existence of the Ei mechanism is:

1. The kinetics are first order, so that only one molecule of the substrate is involved in the reaction (that is, if one molecule attacked another, the kinetics would be second order in substrate).[118]

2. Free-radical inhibitors do not slow the reactions, so that no free-radical mechanism is involved.[119]

3. The mechanism predicts exclusive syn elimination, and this behavior has been found in many cases.[120] The evidence is inverse to that for the anti E2 mechanism and generally involves the following facts: (1) an erythro isomer gives a trans olefin and a threo isomer gives a cis olefin; (2) the reaction takes place only when a cis β-hydrogen is available; (3) if, in a cyclic compound, a cis hydrogen is available on only one side, the elimination goes in that direction. Another piece of evidence involves a pair of steroid molecules. In 3β-acetoxy-(*R*)-5α-methylsulfinylcholestane (**29** shows rings A and B of this compound) and in 3β-acetoxy-(*S*)-5α-methylsulfinylcholestane

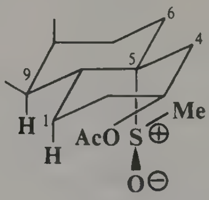
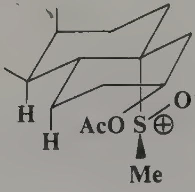
[119] Barton, Head, and Williams, *J. Chem. Soc.* 1715 (1953).

[120] In a few instances anti or nonstereoselective elimination has been found; this behavior is generally ascribed to the intervention of other mechanisms. For example, see Bordwell and Landis, *J. Am. Chem. Soc.* **80,** 2450, 6383 (1958); Briggs and Djerassi, *J. Org. Chem.* **33,** 1625 (1968); Smissman, Li, and Creese, *J. Org. Chem.* **35,** 1352 (1970).



29



30

(7-13)

(**30:** rings A and B), the *only* difference is the configuration of oxygen and methyl about the sulfur. Yet pyrolysis of **29** gave only elimination to the 4-side (86% 4-ene), while **30** gave predominant elimination to the 6-side (65% 5-ene and 20% 4-ene).[121] Models show that interference from the 1- and 9-hydrogens causes the two groups on the sulfur to lie *in front of it* with respect to the rings, rather than behind it. Since the sulfur is chiral, this means that in **29** the oxygen is near the 4-hydrogen, while in **30** it is near the 6 hydrogen. This experiment is compatible only with syn elimination.[122]

4. ^{14}C isotope effects for the Cope elimination (**7-8**) show that both the C—H and C—N bonds have been extensively broken in the transition state.[123]

5. Some of these reactions have been shown to exhibit negative entropies of activation, indicating that the molecules are more restricted in geometry in the transition state than they are in the starting compound.[118]

Where a pyrolytic elimination lies on the mechanistic spectrum seems to depend mostly on the leaving group. When this is halogen, all available evidence suggests that in the transition state the C—X bond is cleaved to a much greater extent that the C—H bond, i.e., there is a considerable amount of carbocation character in the transition state. This is in accord with the fact that a completely nonpolar four-membered cyclic transition state violates the Woodward–Hoffmann rules (see the similar case of **5-48**). Evidence for the carbocation-like character of the transition state when halide is the leaving group is that relative rates are in the order I > Br > Cl[124] (see p. 310), and that the effects of substituents on reaction rates are in accord with such a transition state.[125] Rate ratios for pyrolysis of some alkyl bromides at 320°C were: ethyl bromide, 1; isopropyl bromide, 280; *t*-butyl bromide, 78,000. Also, α-phenylethyl bromide had about the same rate as *t*-butyl bromide. On the other hand, β-phenylethyl bromide was only slightly faster than ethyl bromide. This indicates that C—Br cleavage was much more important in the transition state than C—H cleavage, since the incipient carbocation was stabilized by α-alkyl and α-aryl substitution, while there was no incipient carbanion to be stabilized by β-aryl substitution. These substituent effects, as well as those for other groups, are very similar to the effects found for the SN1 mechanism and thus in very good accord with a carbocation-like transition state. In certain cases, neighboring-group effects, similar to those discussed in Chapter 10, have been reported.[126]

[123] Wright, Sims, and Fry, *J. Am. Chem. Soc.* **105,** 3714 (1983).

[124] Maccoll, Ref. 2, pp. 215–216.

[125] For reviews of such studies, see Maccoll, Ref. 2, Ref. 117.

For esters, the rate ratios were much smaller,[127] though still in the same order, so that this reaction is closer to a pure Ei mechanism, though the transition state still has some carbocationic character. Other evidence for a greater initial C—O cleavage with esters is that of a series of 1-arylethylacetates followed σ^+ rather than σ, showing carbocationic character at the 1 position.[128] The extent of E1 character in the transition state increases in the following order of ester types: acetate < phenylacetate < benzoate < carbamate < carbonate.[129] Cleavage of xanthates (**7-4**), cleavage of sulfoxides (**7-13**), the Cope reaction (**7-8**), and reaction **7-7** are probably very close to straight Ei mechanisms.[130]

The second type of pyrolysis mechanism is completely different from the Ei mechanism and involves free radicals. Initiation occurs by pyrolytic homolytic cleavage. The remaining steps may vary, and a few are shown:

$$\begin{array}{lll}
\text{Initiation} & R_2CHCH_2X & \longrightarrow R_2CHCH_2\bullet + X\bullet \\
\text{Propagation} & R_2CHCH_2X + X\bullet & \longrightarrow R_2\underset{\bullet}{C}CH_2X + HX \\
 & R_2\underset{\bullet}{C}CH_2X & \longrightarrow R_2C{=}CH_2 + X\bullet
\end{array}$$

Termination (disproportionation)

$$2R_2\underset{\bullet}{C}CH_2X \longrightarrow R_2C{=}CH_2 + R_2CXCH_2X$$

Free-radical mechanisms are mostly found in pyrolyses of polyhalides and of primary monohalides,[131] though they also have been postulated in pyrolysis of certain esters.[132] Much less is known about these mechanisms and we shall not consider them further. Free-radical eliminations in solution are also known but are rare.[133]

Orientation in Pyrolytic Eliminations

As in the E1–E2–E1cB mechanistic spectrum, Bredt's rule applies; and if a double bond is present, a conjugated system will be preferred, if sterically possible (p. 888). Apart from these considerations, the following statements can be made for Ei eliminations:

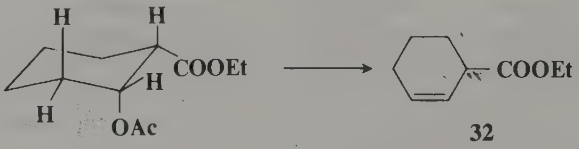
[132] For example, see Rummens, *Recl. Trav. Chim. Pays-Bas* **83,** 901 (1964); Louw and Kooyman, *Recl. Trav. Chim. Pays-Bas* **84,** 1511 (1965).

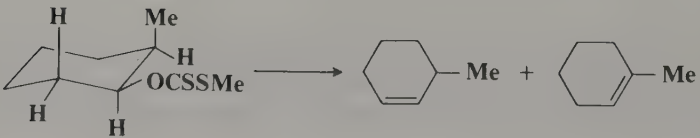
[133] For examples, see Kampmeier, Geer, Meskin, and D'Silva, *J. Am. Chem. Soc.* **88,** 1257 (1966); Kochi, Singleton, and Andrews, *Tetrahedron* **24,** 3503 (1968); Hepinstall and Kampmeier, *J. Am. Chem. Soc.* **95,** 1904 (1973); Lythgoe and Waterhouse, *Tetrahedron Lett.* 4223 (1977); Boothe, Greene, and Shevlin, *J. Org. Chem.* **45,** 794 (1980); Stark, Nelson, and Jensen, *J. Org. Chem.* **45,** 420 (1980); Kochi, "Organic Mechanisms and Catalysis," pp. 346–349, Academic Press, New York, 1978.

1. In the absence of considerations mentioned below, orientation is statistical and is determined by the number of β-hydrogens available (therefore *Hofmann's rule* is followed). For example, *sec*-butyl acetate gives 55 to 62% 1-butene and 38 to 45% 2-butene,[134] which is close to the 3:2 distribution predicted by the number of hydrogens available.[135]

2. A cis β-hydrogen is required. Therefore in cyclic systems, if there is a cis hydrogen on only one side, the double bond will go that way. However, when there is a six-membered transition state, this does not necessarily mean that the leaving groups must be cis to each other, since such transition states need not be completely coplanar. If the leaving group is axial, then the hydrogen obviously must be equatorial (and consequently cis to the leaving group), since the transition state cannot be realized when the groups are both axial. But if the leaving group is equatorial, it can form a transition state with a β-hydrogen which is either axial (hence, cis) or equatorial (hence, trans). Thus **31**, in which the leaving group is most likely axial, does not form a double bond in the direction of the carbethoxyl group, even though that would be conjugated, because there is no equatorial hydrogen on that side. Instead it gives 100% **32**.[136]



31 **32** (7-3)



33 (7-4)

On the other hand, **33**, with an equatorial leaving group, gives about 50% of each olefin, even though, for elimination to the 1-ene, the leaving group must go off with a trans hydrogen.[137]

3. In some cases, especially with cyclic compounds, the more stable olefin forms and Zaitsev's rule applies. For example, menthyl acetate gives 35% of the Hofmann product and 65% of the Zaitsev, even though a cis β-hydrogen is present on both sides and the statistical distribution is the other way. A similar result was found for the pyrolysis of menthyl chloride.[138]

4. There are also steric effects. In some cases the direction of elimination is determined by the need to minimize steric interactions in the transition state or to relieve steric interactions in the ground state.[139]

1,4 Conjugate Eliminations

1,4 eliminations of the type

$$\mathrm{H{-}C{-}C{=}C{-}C{-}X \longrightarrow C{=}C{-}C{=}C}$$

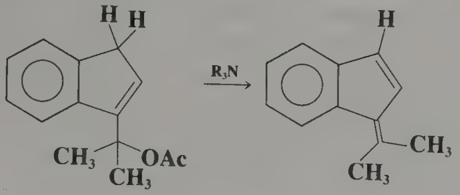
are much rarer than conjugate additions (Chapter 15), but some examples are known.[140] One such is[141]



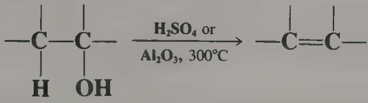
REACTIONS

First we consider reactions in which a C=C or a C≡C bond is formed. From a synthetic point of view, the most important reactions for the formation of double bonds are **7-1** (usually by an E1 mechanism), **7-6, 7-14,** and **7-29** (usually by an E2 mechanism), and **7-3, 7-4,** and **7-8** (usually by an Ei mechanism). The only synthetically important method for the formation of triple bonds is **7-14.**[142] In the second section we treat reactions in which C≡N bonds and C=N bonds are formed, and then eliminations that give C=O bonds and diazoalkanes. Finally, we discuss extrusion reactions.

Reactions in Which C=C and C≡C Bonds are Formed

A. Reactions in Which Hydrogen is Removed from One Side. In **7-1** to **7-5** the other leaving atom is oxygen. In reactions **7-6** to **7-11** it is nitrogen. For reactions in which hydrogen is removed from both sides, see **9-1** to **9-6.**

7-1 Dehydration of Alcohols
Hydro-hydroxy-elimination



$$-\underset{H}{\overset{|}{\underset{|}{C}}}-\underset{OH}{\overset{|}{\underset{|}{C}}}- \xrightarrow[\text{Al}_2\text{O}_3,\ 300^\circ\text{C}]{\text{H}_2\text{SO}_4\text{ or}} -\overset{|}{C}=\overset{|}{C}-$$

Dehydration of alcohols can be accomplished in several ways. H_2SO_4 and H_3PO_4 are common reagents, but in many cases these lead to rearrangement products and to ether formation (**0-18**). If the alcohol can be evaporated, then vapor-phase elimination over Al_2O_3 is an excellent method since side reactions are greatly reduced. This method has even been applied to such high-molecular-weight alcohols as 1-dodecanol.[143] Other metallic oxides (e.g., Cr_2O_3, TiO_2, WO_3) have also been used, as have been sulfides, other metallic salts, and zeolites. Another method of avoiding side reactions is the conversion of alcohols to esters, and the pyrolysis of these (**7-3** to **7-5**). The ease of dehydration increases with α branching, and tertiary alcohols are dehydrated so easily with even a trace of acid that it sometimes happens even when the investigator desires otherwise. It may also be recalled that the initial alcohol products of many base-catalyzed condensations dehydrate spontaneously (Chapter 16) because the new double bond can be in conjugation with one already there. Many other dehydrating agents have been used on occasion: P_2O_5, I_2, $ZnCl_2$, BF_3-etherate, dimethyl sulfoxide, $KHSO_4$, KOH, anhydrous $CuSO_4$,[144] and phthalic ahydride, among others. Secondary and tertiary alcohols can also be dehydrated, without rearrangements, simply on refluxing in HMPT.[145] With nearly all reagents, dehydration follows Zaitsev's rule. An exception involves the passage of hot alcohol vapors over thorium oxide at 350 to 450°C, under which conditions Hofmann's rule is followed,[146] and the mechanism is probably different.

---

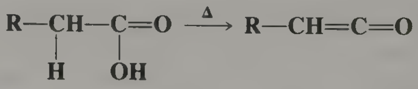
[140] For a discussion of the stereochemistry of 1,4 eliminations, see Hill and Bock, *J. Am. Chem. Soc.* **100,** 637 (1978). For a review of certain types of 1,4 and 1,6 eliminations, see Wakselman, *Nouveau J. Chem.* **7,** 439–447 (1983).

[141] Thibblin, Onyido, and Ahlberg, *Chem. Scr.* **19,** 145 (1982).

[142] For reviews of methods for preparing alkynes, see Friedrich, in Patai and Rappoport, "The Chemistry of Functional Groups, Supplement C," pt. 2, pp. 1376–1384, Wiley, New York, 1983; Ben-Efraim, in Patai, "The Chemistry of the Carbon–Carbon Triple Bond," pt. 2, pp. 755–790, Wiley, New York, 1978. For a comparative study of various methods, see Mesnard, Bernadou, and Miginiac, *J. Chem. Res., Synop.* 270 (1981), and previous papers in this series.

[143] For example, see Spitzin, Michailenko, and Pirogowa, *J. Prakt. Chem.* [4] **25,** 160 (1964); Bertsch, Greiner, Kretzschmar, and Falk, *J. Prakt. Chem.* [4] **25,** 184 (1964).

Carboxylic acids can be dehydrated by pyrolysis, the product being a ketene:

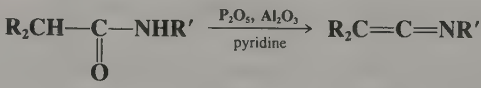


$$\underset{\text{H}}{\text{R—}\underset{|}{\text{CH}}}\text{—}\underset{\text{OH}}{\underset{|}{\text{C}}}\text{=O} \xrightarrow{\Delta} \text{R—CH=C=O}$$

Ketene itself is commercially prepared in this manner. In a similar reaction, carbon suboxide is produced by heating malonic acid with P_2O_5:

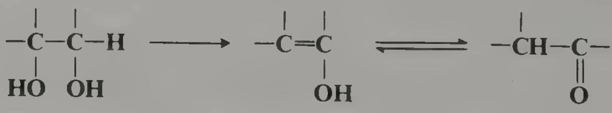
$$\text{HOOC—CH}_2\text{—COOH} \longrightarrow \text{O=C=C=C=O}$$

Analogously, amides can be dehydrated with P_2O_5, pyridine, and Al_2O_3 to give ketenimines:[147]



$$\text{R}_2\text{CH—}\underset{\text{O}}{\underset{\|}{\text{C}}}\text{—NHR}' \xrightarrow[\text{pyridine}]{P_2O_5,\ Al_2O_3} \text{R}_2\text{C=C=NR}'$$

There is no way in which dehydration of alcohols can be used to prepare triple bonds: *gem*-diols and vinyl alcohols do not exist and *vic*-diols[148] give either conjugated dienes or lose only 1 mole of water to give an aldehyde or ketone:



$$-\underset{\text{HO}}{\overset{|}{\underset{|}{\text{C}}}}-\underset{\text{OH}}{\overset{|}{\underset{|}{\text{C}}}}-\text{H} \longrightarrow -\overset{|}{\text{C}}=\underset{\text{OH}}{\overset{|}{\underset{|}{\text{C}}}} \rightleftharpoons -\overset{|}{\text{CH}}-\underset{\text{O}}{\underset{\|}{\text{C}}}-$$

However, triple-bond compounds have been formed, in low-to-moderate yields, by dehydration of aryl ketones ($ArCOCH_2R \rightarrow ArC{\equiv}CR$) upon treatment with the reagent 2-chloro-3-ethylbenzoxazolium tetrafluoroborate in excess Et_3N.[149]

When proton acids catalyze alcohol dehydration, the mechanism is E1.[150] The principal process involves conversion of ROH to ROH_2^+ and cleavage of the latter to R^+ and H_2O, though with some acids a secondary process probably involves conversion of the alcohol to an inorganic ester and ionization of *this* (illustrated for H_2SO_4):

[148] For a review on the dehydration of 1,2 and 1,3 diols, see Bartók and Molnár, in Patai, "The Chemistry of Functional Groups, Supplement E," pt. 2, pp. 721–760, Wiley, New York, 1980.

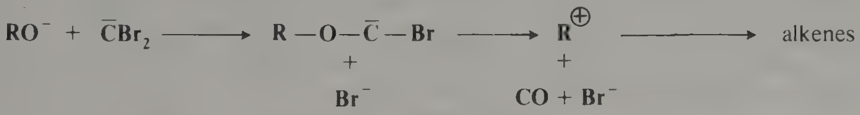
[149] Tsuji, Watanabe, and Mukaiyama, *Chem. Lett.* 481 (1979); See also Harrison, *J. Org. Chem.* **44,** 3578 (1979).

[150] For reviews of dehydration mechanisms, see Saunders and Cockerill, Ref. 2, pp. 221–274, 317–331; Banthorpe, Ref. 2, pp. 145–158; Knözinger, in Patai, "The Chemistry of the Hydroxyl Group," pt. 2, pp. 641–718, Interscience, New York, 1971.

$$\mathrm{ROH} \xrightarrow{\mathrm{H_2SO_4}} \mathrm{ROSO_2OH} \longrightarrow \mathrm{R^+ + HSO_4^-}$$

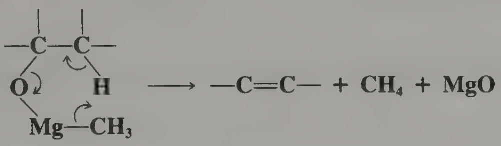
Note that these mechanisms are the reverse of those involved in the acid-catalyzed hydration of double bonds (**5-2**), in accord with the principle of microscopic reversibility. With anhydrides, such as P_2O_5 or phthalic anhydride, as well as with some other reagents such as HMPT,[151] it is likely that an ester is formed, and the leaving group is the conjugate base of the corresponding acid. In these cases the mechanism may be E1 or E2. The mechanism with Al_2O_3 and other solid catalysts has been studied extensively but is poorly understood.[152]

Dehydration of alcohols has also been accomplished by treating the *alkoxide* form of the alcohol with bromoform.[153] This reaction is called *deoxidation*. It is known that bromoform in basic solution gives rise to dibromocarbene, and the following mechanism is likely:



$$\mathrm{RO^- + \overline{C}Br_2} \longrightarrow \underset{\mathrm{Br^-}}{\overset{}{\mathrm{R{-}O{-}\overline{C}{-}Br}}\atop +} \longrightarrow \underset{\mathrm{CO + Br^-}}{\mathrm{R^{\oplus}}\atop +} \longrightarrow \text{alkenes}$$

Note that the cleavage of the intermediate ROCBr is analogous to cleavage of RN_2^+ (p. 313) and the product distribution is similar.[154] Magnesium alkoxides (formed by ROH + $Me_2Mg \rightarrow$ ROMgMe) have been decomposed thermally, by heating at 195–340°C to give the alkene, CH_4, and MgO.[155] Syn elimination is found and an Ei mechanism is likely:



Similar decomposition of aluminum and zinc alkoxides has also been accomplished.[156]

OS **I,** 15, 183, 226, 280, 345, 430, 473, 475; **II,** 12, 368, 408, 606; **III,** 22, 204, 237, 312, 313, 353, 560, 729, 786; **IV,** 130, 444, 771; **V,** 294; **50,** 66; **52,** 96; **60,** 101; **61,** 56. [156] Ref. 155; Brieger, Watson, Barar, and Shene, *J. Org. Chem.* **44,** 1340 (1979).

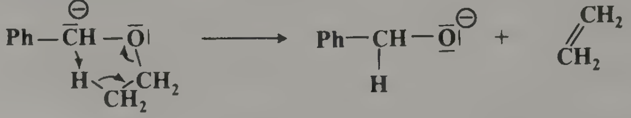
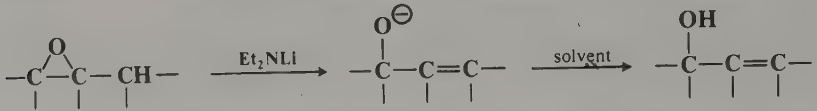
Olefins can be formed by the treatment of ethers with very strong bases, such as alkylsodium or alkyllithium compounds or sodium amide,[157] though there are usually side reactions too. The reaction is aided by electron-withdrawing groups in the β-position, and, for example, $EtOCH_2CH(COOEt)_2$ can be converted to $CH_2{=}C(COOEt)_2$ without any bse at all, but simply on heating.[158] *t*-Butyl ethers are cleaved more easily than others. Several mechanisms are possible for the elimination. In many cases the mechanism is probably E1cB or on the E1cB side of the mechanistic spectrum,[159] since the base required is so strong, but it has been shown (by the use of $PhCD_2OEt$) that $PhCH_2OEt$ reacts by the five-membered Ei mechanism:[160]

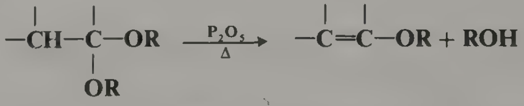


Epoxides can be converted to allylic alcohols[160a] by treatment with several reagents, including



lithium diethylamide,[161] *t*-butyldimethylsilyl iodide,[162] a dialkylboryl triflate,[163] and a diethylaluminum dialkylamide R_2NAlEt.[164] An alternative procedure is given in **7-13.**

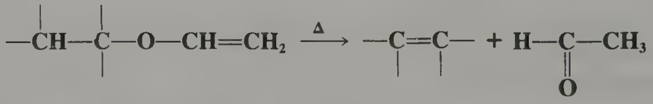
Ethers have also been converted to olefins and alcohols by passing vapors over hot P_2O_5 or Al_2O_3 (this method is similar to **7-1**), but this is not a general reaction. However, acetals can be converted to vinyl ethers in this manner:



$$-\overset{|}{C}H-\underset{OR}{\underset{|}{\overset{|}{C}}}-OR \xrightarrow[\Delta]{P_2O_5} -\overset{|}{C}=\overset{|}{C}-OR + ROH$$

This can also be done at room temperature by treatment with Me_3SiI in the presence of hexamethyldisilazane.[165]

Vinyl ethers can be pyrolyzed to olefins and aldehydes in a manner similar to that of reaction **7-3:**



$$-\overset{|}{C}H-\underset{|}{\overset{|}{C}}-O-CH=CH_2 \xrightarrow{\Delta} -\underset{|}{C}=\underset{|}{C}- + H-\underset{\underset{O}{\|}}{C}-CH_3$$

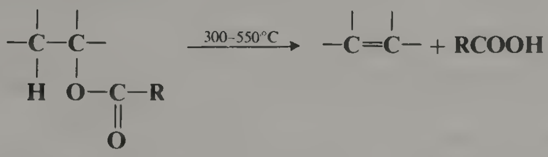
The rate of this reaction for R—O—CH═CH$_2$ increased in the order Et < i-Pr < *t*-Bu.[166] The mechanism is probably similar to that of **7-3.**

OS **IV,** 298, 404; **V,** 25, 642, 859, 1145; **53,** 17, 116; **54,** 19, 74, 77; **57,** 65.

7-3 Pyrolysis of Esters of Carboxylic Acids
Hydro-acyloxy-elimination



$$\text{H}-\overset{|}{\text{C}}-\overset{|}{\text{C}}-\text{O}-\underset{\text{O}}{\underset{\|}{\text{C}}}-\text{R} \xrightarrow{300\text{–}550^\circ\text{C}} -\overset{|}{\text{C}}=\overset{|}{\text{C}}- + \text{RCOOH}$$

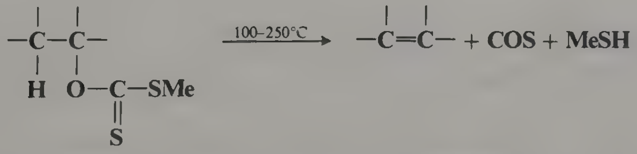
Esters in which the alkyl group has a β-hydrogen can be pyrolyzed, most often in the gas phase, to give the corresponding acid and an olefin.[167] No solvent is required. Since rearrangement and other side reactions are few, the reaction is synthetically very useful and is often carried out as an indirect method of accomplishing **7-1.** The yields are excellent and the workup is easy. Many olefins have been prepared in this manner. For higher olefins (above about C$_{10}$) a better method is to pyrolyze the *alcohol* in the presence of acetic anhydride.[168]

The mechanism is Ei (see p. 897). Lactones can be pyrolyzed to give unsaturated acids, provided that the six-membered transition state required for Ei reactions is available (it is not available for five- and six-membered lactones, but it is for larger rings[169]). Amides give a similar reaction but require higher temperatures.

Allylic acetates give dienes when heated with O,N-bis(trimethylsilyl)acetamide and molybdenum hexacarbonyl.[170]

OS **III,** 30; **IV,** 746; **V,** 235.

7-4 The Chugaev Reaction



$$\text{H}-\overset{|}{\text{C}}-\overset{|}{\text{C}}-\text{O}-\underset{\text{S}}{\underset{\|}{\text{C}}}-\text{SMe} \xrightarrow{100\text{–}250^\circ\text{C}} -\overset{|}{\text{C}}=\overset{|}{\text{C}}- + \text{COS} + \text{MeSH}$$

Methyl xanthates are prepared by treatment of alcohols with NaOH and CS$_2$ to give RO—CS—SNa, followed by treatment of this with methyl iodide. Pyrolysis of the xanthate to give the olefin, COS, and the mercaptan is called the *Chugaev reaction.*[171] The reaction is thus, like **7-3,** an indirect method of accomplishing **7-1.** Elimination is easier with xanthates than with ordinary esters and the temperatures required are lower, which is advantageous because possible isomerization of the resulting olefin is minimized. The Chugaev reaction is used even more often than **7-3.** The mechanism is Ei, similar to that of **7-3.** For a time there was doubt as to which sulfur atom closed the ring, but now there is much evidence, including the study of ^{34}S and ^{13}C isotope effects, to show that it is the C=S sulfur:[172]

---

[166] McEwen and Taylor, *J. Chem. Soc., Perkin Trans. 2* 1179 (1982).

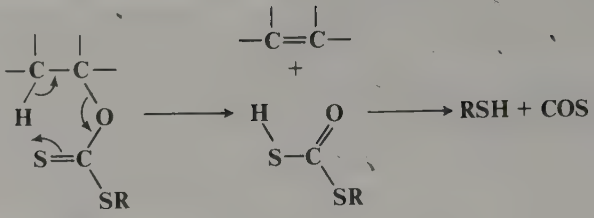
[167] For a review, see DePuy and King, Ref. 117, pp. 432–444.

[168] Aubrey, Barnatt, and Gerrard, *Chem. Ind.* (*London*) 681 (1965).

[169] See, for example, Bailey and Bird, Ref. 122.

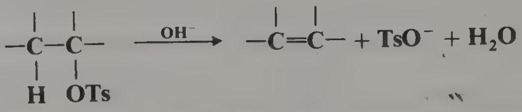
[170] Trost, Lautens, and Peterson, *Tetrahedron Lett.* **24,** 4525 (1983).

[171] For reviews, see DePuy and King, Ref. 117, pp. 444–448; Nace, *Org. React.* **12,** 57–100 (1962).



The mechanism is thus exactly analogous to that of **7-3**.

7-5 Decomposition of Other Esters
Hydro-tosyloxy-elimination

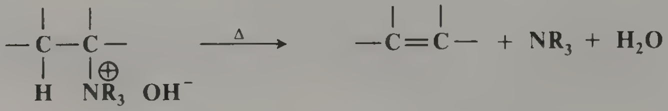


$$\underset{\displaystyle \text{H}}{\overset{|}{\text{—C}}}\text{—}\underset{\displaystyle \text{OTs}}{\overset{|}{\text{C—}}} \xrightarrow{\text{OH}^-} \text{—}\overset{|}{\text{C}}\text{=}\overset{|}{\text{C}}\text{—} + \text{TsO}^- + \text{H}_2\text{O}$$

Several types of inorganic esters can be cleaved to olefins by treatment with bases. Esters of sulfuric, sulfurous, and other acids undergo elimination in solution by E1 or E2 mechanisms, as do tosylates and other esters of sulfonic acids. It has been shown that bis(tetra-*n*-butylammonium) oxalate $(Bu_4N^+)_2\ (COO^-)_2$ is an excellent reagent for inducing tosylates to undergo elimination rather than substitution[173] (see p. 896). High yields of olefins are obtained by heating arylsulfonates in such solvents as dimethyl sulfoxide or HMPT.[174]

OS **50,** 84.

7-6 Cleavage of Quaternary Ammonium Hydroxides
Hydro-trialkylammonio-elimination[175]



$$\underset{\displaystyle \text{H}}{\overset{|}{\text{—C}}}\text{—}\underset{\displaystyle \text{NR}_3\ \text{OH}^-}{\overset{|}{\text{C—}}}{}^{\oplus} \xrightarrow{\Delta} \text{—}\overset{|}{\text{C}}\text{=}\overset{|}{\text{C}}\text{—} + \text{NR}_3 + \text{H}_2\text{O}$$

Cleavage of quaternary ammonium hydroxides is the final step of the process known as *Hofmann exhaustive methylation or Hofmann degradation.*[176] In the first step, a primary, secondary, or tertiary amine is treated with enough methyl iodide to convert it to the quaternary ammonium iodide (**0-45**). In the second step, the iodide is converted to the hydroxide by treatment with silver oxide. In the cleavage step an aqueous or alcoholic solution of the hydroxide is distilled, often under reduced pressure. The decomposition generally takes place at a temperature between 100 and 200°C. Alternatively, the solution can be concentrated to a syrup by distillation or freeze-drying.[177] When the syrup is heated at low pressures, the cleavage reaction takes place at lower temperatures than are required for the reaction in the ordinary solution, probably because the base (OH^- or RO^-) is less solvated.[178] The reaction has not been used a great deal as a synthetic tool for synthesizing olefins, though some cyclic olefins are best prepared in this way. The principal importance of the method, especially in earlier years, was for structural determination of unknown amines. The reaction was extremely useful, especially in the alkaloid field. In many of these compounds the nitrogen is in a ring, or even at a ring junction, and in such cases the olefin still contains nitrogen. Repetitions of the process are required to remove the nitrogen completely, e.g.,

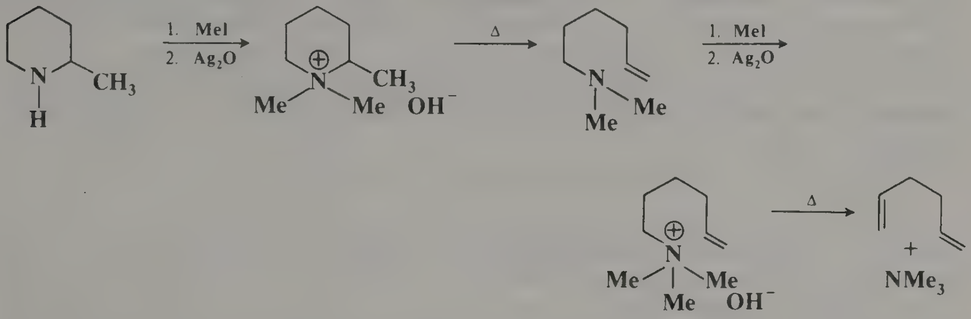
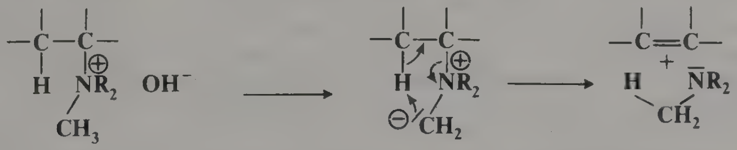
[177] Archer, *J. Chem. Soc. C* 1327 (1971).



A side reaction involving nucleophilic substitution to give an alcohol ($R_4N^+ OH^- \rightarrow ROH + R_3N$) generally accompanies the normal elimination reaction[179] but seldom causes trouble. However, when none of the four groups on the nitrogen has a β-hydrogen, then substitution is the only reaction possible. On heating $Me_4N^+ OH^-$ in water, methanol is obtained, though without a solvent the product is not methanol but dimethyl ether.[180]

The mechanism is usually E2; Hofmann's rule is generally obeyed by acyclic and Zaitsev's rule by cyclohexyl substrates (p. 890). In certain cases, where the molecule is highly hindered, a five-membered Ei mechanism, similar to that in **7-7**, has been shown to operate. That is, the OH^- in these cases does not attract the β-hydrogen, but instead removes one of the methyl hydrogens:



The obvious way to distinguish between this mechanism and the ordinary E2 mechanism is by use of deuterium labeling. For example, if the reaction is carried out on a quaternary hydroxide deuterated on the β-carbon ($R_2CDCH_2NMe_3^+ OH^-$), then the fate of the deuterium indicates the mechanism. If the E2 mechanism is in operation, the trimethylamine produced would contain no deuterium (which would be found only in the water). But if the mechanism is Ei, the amine would contain deuterium. In the case of the highly hindered compound $(Me_3C)_2CDCH_2NMe_3^+ OH^-$, the deuterium did appear in the amine, demonstrating an Ei mechanism for this case.[181] With simpler compounds, the mechanism is E2, since here the amine was deuterium-free.[182] This is also true in the case of the *cis*-norbornyl compound **7** (X = NMe_3^+) (p. 877), where a maximum of 6% of the elimination takes place by the Ei mechanism.[183] The mechanism here is chiefly syn E2.

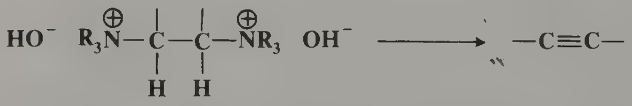
[182] Cope, LeBel, Moore, and Moore, *J. Am. Chem. Soc.* **83,** 3861 (1961).

When the nitrogen bears more than one group possessing a β-hydrogen, which group cleaves? The Hofmann rule says that *within* a group the hydrogen on the least alkylated carbon cleaves. This tendency is also carried over to the choice of which group cleaves: thus ethyl with three β-hydrogens cleaves more readily than any longer *n*-alkyl group, all of which have two β-hydrogens. "The β-hydrogen is removed most readily if it is located on a methyl group, next from RCH_2, and least readily from R_2CH."[184] In fact, the Hofmann rule as first stated[185] in 1851 applied only to which group cleaved, not to the orientation within a group; the latter could not have been specified in 1851, since the structural theory of organic compounds was not formulated until 1857–1860. Of course, the Hofmann rule (applied to which group cleaves *or* to orientation within a group) is superseded by conjugation possibilities. Thus $PhCH_2CH_2NMe_2Et^+\ OH^-$ gives mostly styrene instead of ethylene.

Triple bonds have been prepared by pyrolysis of 1,2-bis salts.[186]



$$HO^-\ R_3\overset{\oplus}{N}-\underset{H}{\overset{|}{C}}-\underset{H}{\overset{|}{C}}-\overset{\oplus}{N}R_3\ \ OH^- \longrightarrow -C\equiv C-$$

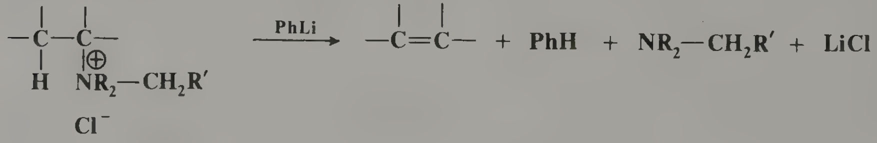
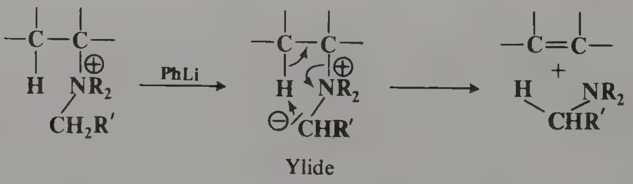
7-7 Cleavage of Quaternary Ammonium Salts with Strong Bases



$$-\underset{H}{\overset{|}{C}}-\underset{\substack{NR_2-CH_2R'\\ Cl^-}}{\overset{|}{\underset{\oplus}{C}}}- \xrightarrow{PhLi} -\overset{|}{C}=\overset{|}{C}- + PhH + NR_2-CH_2R' + LiCl$$

When quaternary ammonium halides are treated with strong bases (e.g., PhLi, KNH_2 in liquid NH_3[187]), an elimination may occur that is similar in products, though not in mechanism, to **7-6.**[188] This represents an alternative to **7-6** and is done on the quaternary ammonium halide, so that it is not necessary to convert this to the hydroxide. The mechanism is Ei:



An α′-hydrogen is obviously necessary so that the ylide can be formed. This type of mechanism is called α′,β elimination, since a β-hydrogen is removed by the α′-carbon. The mechanism has been confirmed by labeling experiments similar to those described at **7-6**.[189] and by isolation of the intermediate ylides.[190] An important synthetic difference between this and most instances of **7-6** is that syn elimination is observed here and anti elimination in **7-6**, so that products of opposite configuration are formed when the olefin exhibits cis–trans isomerism.

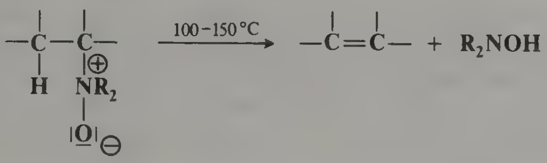
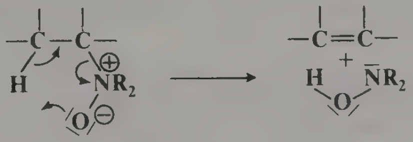
An alternative procedure that avoids the use of a very strong base is heating the salt with KOH in polyethylene glycol monomethyl ether.[191]

7-8 Cleavage of Amine Oxides
Hydro-(Dialkyloxidoammonio)-elimination



Cleavage of amine oxides to produce an alkene and a hydroxylamine is called the *Cope reaction* (not to be confused with the Cope *rearrangement*, **8-36**). It is an alternative to **7-6** and **7-7**.[192] The reaction is usually performed with a mixture of amine and oxidizing agent (see **9-29**) without isolation of the amine oxide. Because of the mild conditions side reactions are few, and the olefins do not usually rearrange. The reaction is thus very useful for the preparation of many olefins. However, it does not open 6-membered rings containing hetero nitrogen, though it does open rings of 5 and 7 to 10 members.[193] Rates of the reaction increase with increasing size of α- and β-substituents.[194] The reaction can be carried out at room temperature in dry Me_2SO or THF.[195] The elimination is a stereoselective syn process,[196] and the five-membered Ei mechanism operates:



Almost all evidence indicates that the transition state must be planar.[197] Deviations from planarity as in **7-3** (see p. 897) are not found here, and indeed this is why six-membered heterocyclic nitrogen compounds do not react. Because of the stereoselectivity of this reaction and the lack of rearrangement of the products, it is useful for the formation of trans cycloolefins (eight-membered and higher).

[192] For reviews, see Cope and Trumbull, Ref. 176, pp. 361–370; DePuy and King, Ref. 117, pp. 448–451.

[193] Cope and LeBel, *J. Am. Chem. Soc.* **82**, 4656 (1960); Cope, Ciganek, Howell, and Schweizer, *J. Am. Chem. Soc.* **82**, 4663 (1960).

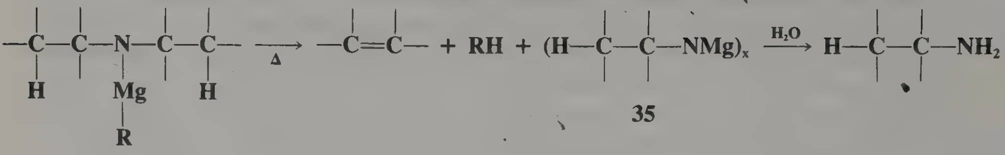
[194] Závada, Pánková, and Svoboda, *Collect. Czech. Chem. Commun.* **38**, 2102 (1973).

[195] Cram, Sahyun, and Knox, *J. Am. Chem. Soc.* **84**, 1734 (1962).

[196] See, for example, Bach, Andrzejewski, and Dusold, *J. Org. Chem.* **38**, 1742 (1973).

[197] There is evidence from isotope-effect studies that the C---H---O portion of the transition state is nonlinear: Kwart, George, Louw, and Ultee, *J. Am. Chem. Soc.* **100**, 3927 (1978); Kwart and Brechbiel, *J. Am. Chem. Soc.* **103**, 4650 (1981). This has led to the postulate that the five-membered transition state is nonplanar. However, a planar transition state could still have a nonlinear C---H---O portion.

7-9 Cleavage of Other Amine Derivatives
Hydro-magnesioalkylamino-elimination

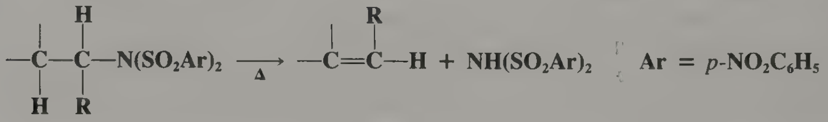


$$-\underset{H}{\overset{|}{\underset{|}{C}}}-\overset{|}{\underset{|}{C}}-\underset{\underset{R}{|}}{\overset{|}{\underset{|}{\underset{Mg}{N}}}}-\overset{|}{\underset{|}{C}}-\underset{H}{\overset{|}{\underset{|}{C}}}- \xrightarrow[\Delta]{} -\overset{|}{C}=\overset{|}{C}- + RH + (H-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-NMg)_x \xrightarrow{H_2O} H-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-NH_2$$

34 **35**

Secondary amines can be converted to magnesium amides (**34**) by treatment with a Grignard reagent RMgX. When heated either in the solid state or in an inert diluent such as *n*-dodecane, **34** decompose to give the alkene, RH, and an amide residue (represented as **35**) that is hydrolyzable to a primary amine.[198] Like the similar cleavage of magnesium alkoxides, mentioned at the end of **7-1**, the elimination is syn and an Ei mechanism is likely. Zinc and aluminum analogs of **34** react in a similar manner.

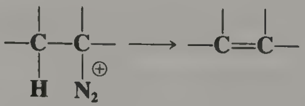
Primary amines with secondary alkyl groups can be cleaved by pyrolyzing their bis(*p*-nitrobenzenesulfonyl) derivatives.[199]



$$-\underset{H}{\overset{|}{\underset{|}{C}}}-\underset{R}{\overset{H}{\underset{|}{\overset{|}{C}}}}-N(SO_2Ar)_2 \xrightarrow[\Delta]{} -\overset{|}{C}=\overset{R}{\overset{|}{C}}-H + NH(SO_2Ar)_2 \qquad Ar = p\text{-}NO_2C_6H_5$$

The nucleofuge in this reaction, $N(SO_2Ar)_2$, is similar to the NTs_2 leaving group mentioned on p. 312. The reaction fails for amines with primary alkyl groups (R = H), but such amines, as well as those with secondary alkyl groups, can be cleaved after conversion to certain pyridium salts[200] (similar to the pyrylium salts shown on p. 313).

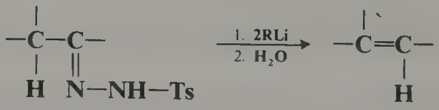
7-10 Olefins from Aliphatic Diazonium Salts
Hydro-diazonio-elimination



$$-\underset{H}{\overset{|}{\underset{|}{C}}}-\underset{N_2}{\overset{|}{\underset{|\oplus}{C}}}- \longrightarrow -\overset{|}{C}=\overset{|}{C}-$$

The treatment of aliphatic amines with nitrous acid is not a useful method for the preparation of olefins any more than it is for the preparation of alcohols (**0-5**), though some olefin is usually formed in such reactions.

7-11 Decomposition of Toluene-*p*-sulfonylhydrazones



$$-\underset{H}{\overset{|}{\underset{|}{C}}}-\underset{N-NH-Ts}{\underset{\|}{C}}- \xrightarrow[2.\ H_2O]{1.\ 2RLi} -\overset{|}{C}=\underset{H}{\underset{|}{C}}-$$

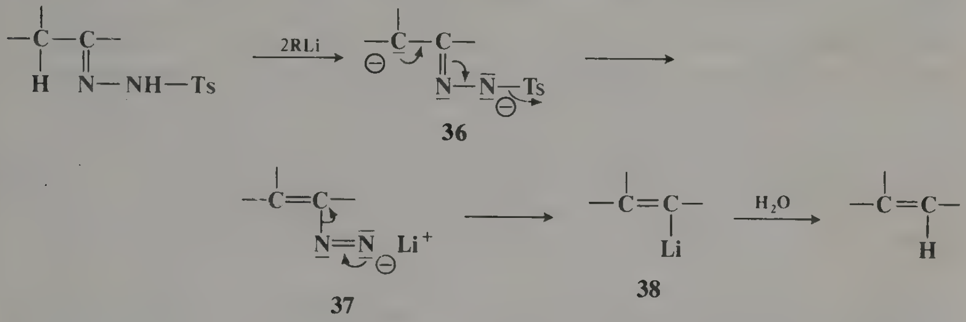
Treatment of the tosylhydrazone of an aldehyde or a ketone with a strong base leads to the formation of an olefin, the reaction being formally an elimination accompanied by a hydrogen shift.[201] The reaction (the *Shapiro reaction*) has been applied to tosylhydrazones of many aldehydes and ketones. The most useful method synthetically involves treatment of the substrate with at least two equivalents of an organolithium compound[202] (usually MeLi) in ether, hexane, or tetramethylenediamine.[203] This procedure gives good yields of alkenes without side reactions and, where a choice is possible, predominantly gives the less highly substituted olefin. Tosylhydrazones of α,β-unsaturated ketones give conjugated dienes.[204] The mechanism[205] has been formulated as:



Evidence for this mechanism is: (1) two equivalents of RLi are required; (2) the hydrogen in the product comes from the water and not from the adjacent carbon, as shown by deuterium labeling;[206] and (3) the intermediates **36, 37,** and **38** have been trapped.[207] This reaction, when performed in tetramethylenediamine, can be a synthetically useful method[208] of generating vinyllithiums (**38**), which can be trapped by various electrophiles such as D_2O (to give deuterated alkenes), CO_2 (to give α,β-unsaturated carboxylic acids—**6-35**), or DMF (to give α,β-unsaturated aldehydes—**0-107**).

The reaction also takes place with other bases (e.g., NaOMe,[209] LiH,[210] Na in ethylene glycol, NaH, $NaNH_2$[211]) or with smaller amounts of RLi, but in these cases side reactions are common and the orientation of the double bond is in the other direction (to give the more highly substituted olefin). The reaction with Na in ethylene glycol is called the *Bamford–Stevens reaction.*[212] For these reactions two mechanisms are possible—a carbenoid and a carbocation mechanism.[213] The side reactions found are those expected of carbenes and carbocations. In general, the carbocation mechanism is chiefly found in protic solvents and the carbenoid mechanism in aprotic solvents.

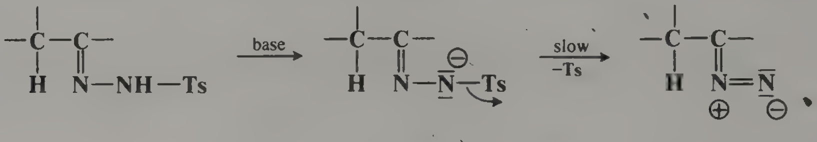
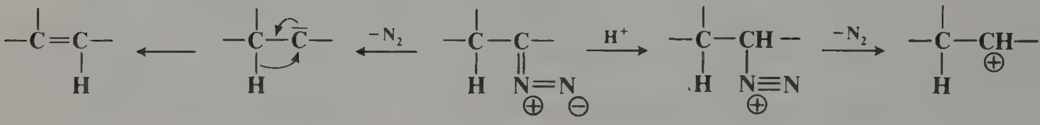
Both routes involve formation of a diazo compound (**39**) which in some cases has been isolated.[214]



39

In the absence of protic solvents **39** loses N_2, and hydrogen migrates, to give the olefin product. The migration of hydrogen may immediately follow, or be simultaneous with, the loss of N_2. In a protic solvent, **39** becomes protonated to give the diazonium ion **40** which loses N_2 to give the corresponding carbocation which may then undergo elimination (**7-10**) or give other reactions characteristic of carbocations. The reaction has been used as a synthetic method for the preparation of diazo compounds **39.**[215]



39 **40**

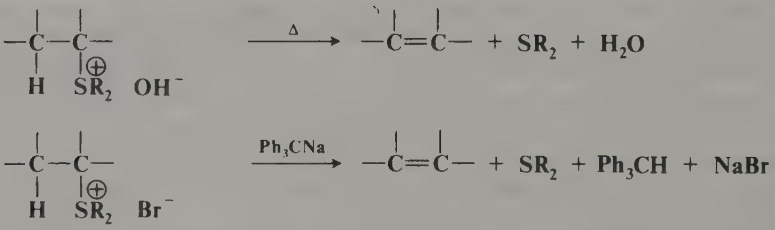
OS **51,** 66; **61,** 141.

7-12 Cleavage of Sulfonium Compounds
Hydro-dialkylsulfonio-elimination



Sulfonium compounds undergo elimination similar to that of their ammonium counterparts (**7-6** and **7-7**) in scope and mechanism. The decomposition by heat of sulfonium hydroxides has been known for many years.[216] The ylide reaction was discovered more recently.[217] Neither is important synthetically.

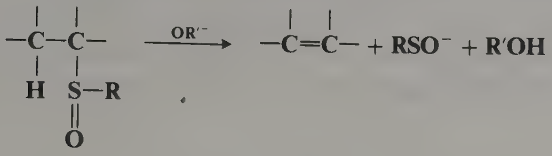
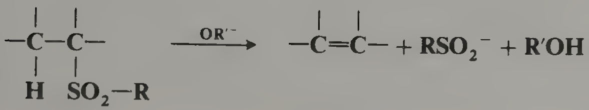
7-13 Cleavage of Sulfoxides, Selenoxides, and Sulfones



$$-\underset{\displaystyle H}{\overset{|}{C}}-\underset{\underset{\displaystyle O}{\overset{\|}{\displaystyle S-R}}}{\overset{|}{C}}- \xrightarrow{OR'^-} -\overset{|}{C}{=}\overset{|}{C}- + RSO^- + R'OH$$

Hydro-alkylsulfinyl-elimination

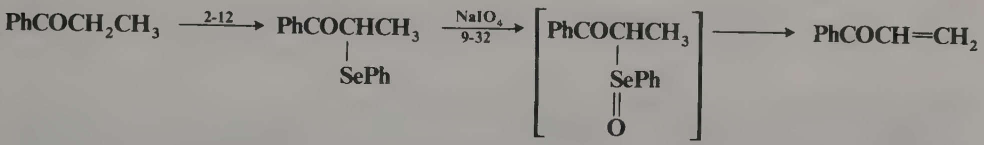


$$-\underset{\displaystyle H}{\overset{|}{C}}-\underset{\displaystyle SO_2-R}{\overset{|}{C}}- \xrightarrow{OR'^-} -\overset{|}{C}{=}\overset{|}{C}- + RSO_2^- + R'OH$$

Hydro-alkylsulfonyl-elimination

Sulfones and sulfoxides with a β-hydrogen undergo elimination on treatment with an alkoxide or, for sulfones,[218] even with OH^-.[219] In mechanism, these reactions belong on the E1–E2–E1cB spectrum.[220] Although the leaving groups are uncharged, the orientation follows Hofmann's rule, not Zaitsev's. Sulfoxides (but not sulfones) also undergo elimination on pyrolysis at about 80°C in a manner analogous to **7-8.** The mechanism is also analogous, being the five-membered Ei mechanism with syn elimination.[221] Selenoxides[222,223] and sulfinate esters $R_2CH—CHR—SO—OMe$[224] also undergo elimination by the Ei mechanism, the selenoxide reaction taking place at room temperature.[225] The reaction with selenoxides has been extended to the formation of triple bonds.[226]

Both the selenoxide[227] and sulfoxide[228] reactions have been used in a method for the conversion of ketones, aldehydes, and esters to their α,β-unsaturated derivatives (illustrated for the selenoxide).



$$PhCOCH_2CH_3 \xrightarrow{2\text{-}12} \underset{\displaystyle SePh}{PhCOCHCH_3} \xrightarrow[9\text{-}32]{NaIO_4} \left[\underset{\underset{\displaystyle O}{\overset{\|}{\displaystyle SePh}}}{PhCOCHCH_3}\right] \longrightarrow PhCOCH{=}CH_2$$

Because of the mildness of the procedure, this is probably the best means of accomplishing this conversion. The selenoxide reaction has been used in a procedure for the conversion of epoxides to allylic alcohols.[229]

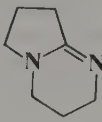
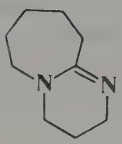
[236] This name also applies to reaction **7-15.**

The elimination of HX from an alkyl halide is a very general reaction and can be accomplished with chlorides, fluorides, bromides, and iodides.[236a] Hot alcoholic KOH is the most frequently used base, though stronger bases[237] (OR^-, NH_2^-, etc.) or weaker ones (e.g., amines) are used where warranted. The bicyclic amidines 1,5-diazabicyclo[3.4.0]nonene-5 (DBN)[238] and 1,8-diazabicyclo-[5.4.0]undecene-7 (DBU)[239] are good reagents for difficult cases.[240] Phase transfer catalysis has been used with OH^- as base.[241] As previously mentioned (p. 887), certain weak bases in polar aprotic solvents are effective reagents for dehydrohalogenation. Among those most often used for synthetic purposes are LiCl or LiBr-$LiCO_3$ in DMF.[242] Dehydrohalogenation has also been effected by heating of the alkyl halide in HMPT with no other reagent present.[243]



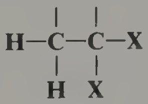
DBN



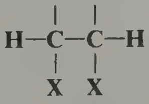
DBU

Tertiary halides undergo elimination most easily. Eliminations of chlorides, bromides, and iodides follow Zaitsev's rule, except for a few cases where steric effects are important (for an example, see p. 891). Eliminations of fluorides follow Hofmann's rule (p. 891).

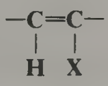
This reaction is by far the most important way of introducing a triple bond into a molecule.[244] This may be accomplished with substrates of the types:



$$\mathrm{H{-}\overset{|}{\underset{\underset{H}{|}}{C}}{-}\overset{|}{\underset{\underset{X}{|}}{C}}{-}X}$$



$$\mathrm{H{-}\overset{|}{\underset{\underset{X}{|}}{C}}{-}\overset{|}{\underset{\underset{X}{|}}{C}}{-}H}$$



$$\mathrm{{-}\underset{\underset{H}{|}}{C}{=}\underset{\underset{X}{|}}{C}{-}}$$

The most commonly used base for triple-bond formation is $NaNH_2$. This base causes 1-alkynes to predominate (where possible), because it forms the salt of the alkyne, shifting any equilibrium between 1- and 2-alkynes. When the base is OH^- or OR^-, the equilibrium tends to be shifted to the internal alkyne, which is thermodynamically more stable. If another hydrogen is suitably located (e.g., $—CRH—CX_2—CH_2—$), then allene formation can compete, though alkynes are usually more stable.

Dehydrohalogenation is generally carried out in solution, with a base, and the mechanism is usually E2, though the E1 mechanism has been demonstrated in some cases. However, elimination of HX may also be accomplished by pyrolysis of the halide, in which case the mechanism is the Ei mechanism (p. 897) or, in some instances, the free-radical mechanism (p. 899). Pyrolysis is normally performed without a catalyst at about 400°C. The pyrolysis reaction is not generally useful synthetically, because of its reversibility. Less work has been done on pyrolysis with a catalyst[245] (usually a metallic oxide or salt), but the mechanisms here are probably E1 or E2.

[236a] For a review of eliminations involving the carbon-halogen bond, see Baciocchi, in Patai and Rappoport, "The Chemistry of Functional Groups, Supplement D," pt. 2, pp. 1173-1227, Wiley, New York, 1983.

[237] Triphenylmethylpotassium rapidly dehydrohalogenates secondary alkyl bromides and iodides, in over 90% yields, at 0°C: Anton and Crabtree, *Tetrahedron Lett.* **24**, 2449 (1983).

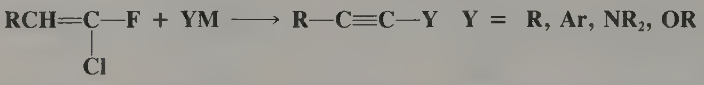
[244] For reviews, see Ben-Efraim, Ref. 142; Köbrich and Buck, in Viehe, "Acetylenes," pp. 100–134, Marcel Dekker, New York, 1969; Ref. 186, pp. 391–397; Köbrich, Ref. 2, pp. 50–53.

A combination elimination and substitution reaction has been used to synthesize alkynes. In this reaction a compound RCH=CFCl is treated with YM, where M is a metal and Y may be alkyl, aryl, NR_2, or OR:



$$\mathrm{RCH{=}\underset{\displaystyle Cl}{\underset{|}{C}}{-}F + YM \longrightarrow R{-}C{\equiv}C{-}Y \qquad Y = R, Ar, NR_2, OR}$$

Alkynes, ynamines, and acetylenic ethers can be prepared in this manner.[246] In a similar reaction, trifluoro ethers and sulfides are converted to acetylenic ethers and thioethers: $CF_3CH_2—YR + R'Li \rightarrow R'—C{\equiv}C—YR$ (Y = O or S).[247]

See also OS **56,** 118.

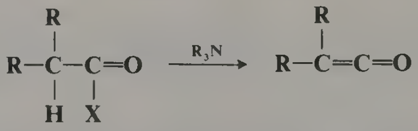
7-15 Dehydrohalogenation of Acyl Halides and Sulfonyl Halides



$$\mathrm{R{-}\overset{\displaystyle R}{\overset{|}{\underset{\displaystyle H}{\underset{|}{C}}}}{-}\underset{\displaystyle X}{\underset{|}{C}}{=}O \xrightarrow{R_3N} R{-}\overset{\displaystyle R}{\overset{|}{C}}{=}C{=}O}$$

Ketenes can be prepared by treatment of acyl halides with tertiary amines. The scope is broad, and most acyl halides possessing an α-hydrogen give the reaction, but if at least one R is hydrogen, only the ketene dimer, not the ketene, is isolated. However, if it is desired to use a reactive ketene in a reaction with a given compound, the ketene may be generated in situ in the presence of the given compound.[248]

Closely related is the reaction of tertiary amines with sulfonyl halides that contain an α-hydrogen. In this case the initial product is the highly reactive sulfene, which cannot be isolated but reacts further to give various products, one of which may be the alkene that is the dimer of RCH.[249] Here too, reactions of sulfenes in situ are common (for example, see **6-64**).

$$\mathrm{RCH_2SO_2Cl \xrightarrow{R_3N} \underset{Sulfene}{[RCH{=}SO_2]} \longrightarrow RCH{=}CHR} + \text{other products}$$

OS **IV,** 560; **V,** 294, 877; **52,** 36; **57,** 117.

7-16 Elimination of Boranes
Hydro-boranetriyl-elimination

$$\mathrm{(R_2CH{-}CH_2)_3B} + 3\ \text{1-decene} \rightleftharpoons \mathrm{3R_2C{=}CH_2 + [CH_3(CH_2)_8CH_2]_3B}$$

---

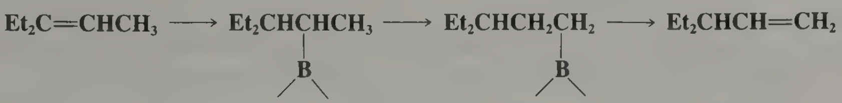
[249] For reviews of sulfenes, see Chapter 10, Ref. 1377.

Trialkylboranes are formed from an olefin and BH_3 (**5-13**). When the resulting borane is treated with another olefin, an exchange reaction occurs.[250] This is an equilibrium process that can be shifted by using a large excess of olefin, by using an unusually reactive olefin, or by using an olefin with a higher boiling point than the displaced olefin and removing the latter by distillation. The reaction is useful for shifting a double bond in the direction opposite to that resulting from normal isomerization methods (**2-2**). This cannot be accomplished simply by treatment of a borane such as **42** with an olefin, because elimination in this reaction follows Zaitsev's rule: It is in the direction of the most stable olefin, and the product would be **41**, not **44.** However, if it is desired to convert **41** to **44,** this can be accomplished by converting **41** to **42,** isomerizing **42** to **43** (**8-13**)



$$Et_2C{=}CHCH_3 \longrightarrow Et_2CH\underset{\underset{\diagup\;\diagdown}{B}}{\underset{|}{C}}HCH_3 \longrightarrow Et_2CHCH_2\underset{\underset{\diagup\;\diagdown}{B}}{\underset{|}{C}}H_2 \longrightarrow Et_2CHCH{=}CH_2$$

41 **42** **43** **44**

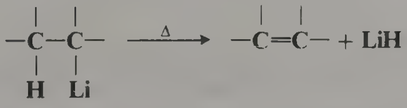
and then subjecting **43** to the exchange reaction with a higher-boiling olefin, e.g., 1-decene, whereupon **44** is produced. In the usual isomerizations (**2-2**), **44** could be isomerized to **41,** but not the other way around. The reactions **42** → **43** and **43** → **44** proceed essentially without rearrangement. The mechanism is probably the reverse of borane addition (**5-13**).

A similar reaction, but irreversible, has been demonstrated for alkynes.[251]

$$(R_2CH{-}CH_2)_3B + R'C{\equiv}CR' \longrightarrow 3R_2C{=}CH_2 + (R'CH{=}CR')_3B$$

Treatment of trialkylboranes (especially B-alkyl-9-BBN compounds) with benzaldehyde results in cleavage of one of the alkyl groups to give an olefin.[252]

7-17 Pyrolysis of Alkali-Metal Organometallic Compounds
Hydro-metallo-elimination



$$-\underset{H}{\underset{|}{\overset{|}{C}}}-\underset{Li}{\underset{|}{\overset{|}{C}}}- \xrightarrow{\Delta} -\overset{|}{C}{=}\overset{|}{C}- + LiH$$

Solid lithium hydride and an olefin can be obtained by heating alkyllithium compounds containing a β-hydrogen.[253] With *sec*-BuLi the orientation followed Zaitsev's rule, although formation of *cis*-2-butene predominated over formation of the trans isomer.[254] The reaction has also been applied to alkylsodium and alkylpotassium compounds.[255] Grignard reagents gave olefins when thermally decomposed in nonsolvating solvents, e.g., cumene.[256] Alkenes have also been obtained from RLi and RMgX in solution, by treatment with ethylene and $NiCl_2$ or with certain other reagents.[257]

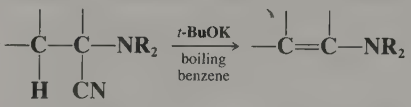
Nitroalkenes have been obtained by cleavage of H and HgCl from β-nitro mercuric halides[258] (prepared by nitromercuration—see **5-8**). The mechanism is generally believed to be a four-centered pericyclic one (Ei).[259]

7-18 Dehydrocyanation
Hydro-cyano-elimination



$$-\underset{\mathrm{H}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\underset{\mathrm{CN}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\mathrm{NR_2} \xrightarrow[\text{boiling benzene}]{t\text{-BuOK}} -\overset{|}{\mathrm{C}}=\overset{|}{\mathrm{C}}-\mathrm{NR_2}$$

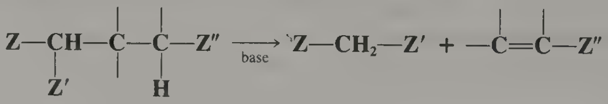
Enamines can be prepared from α-cyano tertiary amines by treatment with KOH or *t*-BuOK in boiling benzene or toluene, or in *t*-butyl methyl ether at room temperature.[260]

7-19 Decarbonylation of Acyl Halides
Hydro-chloroformyl-elimination

$$\mathrm{RCH_2CH_2COCl + RhCl(Ph_3P)_3 \xrightarrow{\Delta} RCH{=}CH_2 + HCl + RhClCO(Ph_3P)_2}$$

Acyl chlorides containing an α-hydrogen are smoothly converted to olefins, with loss of HCl and CO, on heating with chlorotris(triphenylphosphine)rhodium, with metallic platinum, or with certain other catalysts.[261] The mechanism probably involves conversion of $\mathrm{RCH_2CH_2COCl}$ to $\mathrm{RCH_2CH_2{-}RhCO(Ph_3P)_2Cl_2}$ followed by a concerted syn elimination of Rh and H.[262] See also **4-40** and **9-13.**

7-20 Reversal of the Michael Reaction
Hydro-bis(ethoxycarbonyl)methyl-elimination, etc.

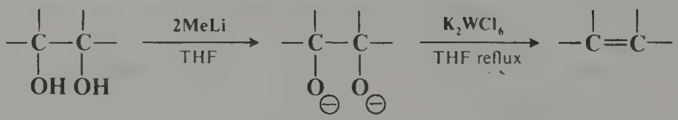


$$\mathrm{Z{-}\underset{Z'}{\underset{|}{CH}}{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{\underset{H}{|}}{C}}{-}Z''} \xrightarrow[\text{base}]{} \mathrm{Z{-}CH_2{-}Z'} + -\overset{|}{\mathrm{C}}=\overset{|}{\mathrm{C}}-\mathrm{Z''}$$

Olefins can be formed on base cleavage of Michael adducts. (See **5-17.** Z is defined on p. 664.) In some cases cleavage occurs simply on heating, without basic catalysis.

B. Reactions in Which Neither Leaving Atom is Hydrogen

7-21 Deoxygenation of Vicinal Diols
Dihydroxy-elimination



$$-\underset{\mathrm{OH}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\underset{\mathrm{OH}}{\overset{|}{\underset{|}{\mathrm{C}}}}- \xrightarrow[\text{THF}]{\text{2MeLi}} -\underset{\mathrm{O^{\ominus}}}{\overset{|}{\underset{|}{\mathrm{C}}}}-\underset{\mathrm{O^{\ominus}}}{\overset{|}{\underset{|}{\mathrm{C}}}}- \xrightarrow[\text{THF reflux}]{\mathrm{K_2WCl_6}} -\overset{|}{\mathrm{C}}=\overset{|}{\mathrm{C}}-$$

---

[258] Corey and Estreicher, *J. Am. Chem. Soc.* **100,** 6294 (1978).

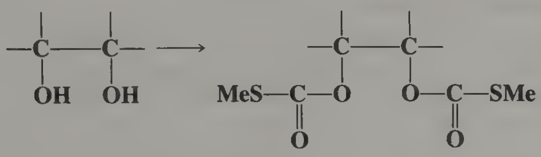
[261] Tsuji and Ohno, *J. Am. Chem. Soc.* **88,** 3452 (1966), **90,** 94, (1968); Ohno and Tsuji, *J. Am. Chem. Soc.* **90,** 99 (1968). For a review, see Tsuji and Ohno, *Synthesis* 157–169 (1969).

[262] Lau, Becker, Huang, Baenziger, and Stille, *J. Am. Chem. Soc.* **99,** 5664 (1977).

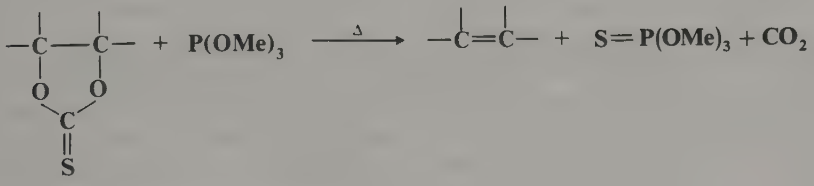
vic-Diols can be deoxygenated by treatment of the dilithium dialkoxide with the tungsten halide K_2WCl_6, or with certain other tungsten reagents, in refluxing THF.[263] Tetrasubstituted diols react most rapidly. The elimination is largely, but not entirely, syn. Several other methods have been reported, in which the diol is deoxygenated directly, without conversion to the dialkoxide. These include treatment with titanium metal,[264] with Me_3SiCl-NaI,[265] with Ph_3P-imidazole-I_2 in toluene,[266] and with PBr_3-CuBr-ether at low temperatures, followed by zinc powder.[267]

vic-Diols can also be deoxygenated indirectly, through sulfonate ester derivatives. For example, *vic*-dimesylates and *vic*-ditosylates have been converted to alkenes by treatment, respectively, with naphthalene–sodium[268] and with NaI in dimethylformamide.[269] In another procedure, the diols are converted to bisdithiocarbonates (bis xanthates), which undergo elimination (probably by a free-radical mechanism) when treated with tri-*n*-butylstannane in toluene or benzene.[270] *vic*-Diols can also be dehydrogenated through cyclic derivatives (**7-22**).



2-Ene-1,4-diols give 1,4-elimination  $(HO-\overset{|}{\underset{|}{C}}-\overset{|}{C}=\overset{|}{C}-\overset{|}{\underset{|}{C}}-OH \rightarrow -\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=\overset{|}{C}-)$ when treated with $TiCl_3$ and $LiAlH_4$.[271]

7-22 Cleavage of Cyclic Thionocarbonates



45

Cyclic thionocarbonates (**45**) can be cleaved to olefins (the *Corey–Winter reaction*)[272] by heating with trimethyl phosphite[273] or other trivalent phosphorus compounds[274] or by treatment with bis(1,5-

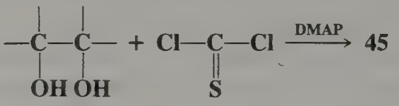
[272] For reviews, see Block, *Org. React.* **30,** 457–566 (1984); Sonnet, *Tetrahedron* **36,** 557–604 (1980), pp. 593–598; Mackie, in Cadogan, "Organophosphorus Reagents in Organic Synthesis," pp. 354–359, Academic Press, New York, 1979; Block, Ref. 217, pp. 229–235.

[273] Corey and Winter, *J. Am. Chem. Soc.* **85,** 2677 (1963).

[274] Corey, *Pure Appl. Chem.* **14,** 19–37 (1967), pp. 32–33.

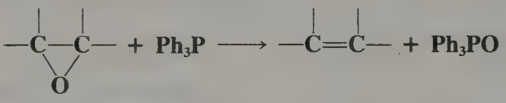
cyclooctadiene)nickel.[275] The thionocarbonates can be prepared by treatment of 1,2-diols with thiophosgene and 4-dimethylaminopyridine (DMAP):[276]



$$-\underset{\text{OH}}{\overset{|}{\text{C}}}-\underset{\text{OH}}{\overset{|}{\text{C}}}- + \text{Cl}-\underset{\text{S}}{\overset{}{\underset{\|}{\text{C}}}}-\text{Cl} \xrightarrow{\text{DMAP}} \mathbf{45}$$

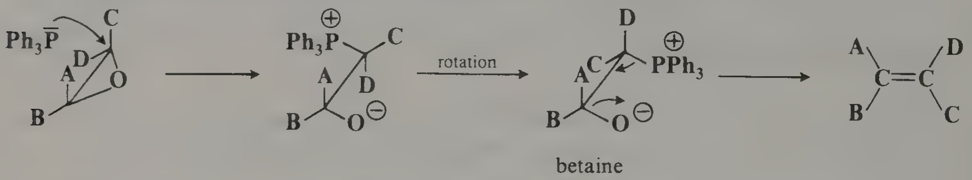
The elimination is of course syn, so the product is sterically controlled. Olefins that are not sterically favored can be made this way in high yield, e.g., *cis*-$PhCH_2CH{=}CHCH_2Ph$.[277] Certain other 5-membered cyclic derivatives of 1,2-diols can also be converted to alkenes.[278]

7-23 The Conversion of Epoxides to Olefins



$$-\overset{|}{\text{C}}-\overset{|}{\text{C}}- + Ph_3P \longrightarrow -\overset{|}{\text{C}}=\overset{|}{\text{C}}- + Ph_3PO$$

Epoxides can be converted to olefins[279] by treatment with triphenylphosphine[280] or triethyl phosphite $P(OEt)_3$.[281] The first step of the mechanism is nucleophilic substitution (**0-51**), followed by a four-center elimination. Since inversion accompanies the substitution, the overall elimination is anti, i.e., if two groups A and C are cis in the epoxide, they will be trans in the olefin:



Alternatively, the epoxide can be treated with lithium diphenylphosphide Ph_2PLi, and the product quaternized with methyl iodide.[282] For another method of preparing the betaine, and hence olefins, see the Wittig reaction (**6-47**). Olefins have also been obtained from epoxides by reaction with a large number of reagents, among them[283] Li in THF,[284] TsOH and NaI,[285] trimethylsilyl iodide,[286] dimethyl diazomalonate,[286a] 3-methyl-2-selenoxobenzothiazole,[287] PI_3,[288] P_2I_4,[289] alkylmanganese compounds,[289a] $Fe(CO)_5$,[290] F_3CCOI,[291] sodium (cyclopentadienyl)ferrate,[292] $TiCl_3$-$LiAlH_4$,[293] $FeCl_3$-BuLi,[294] the tungsten reagents mentioned in **7-21,**[263] and NaI-NaOAc-Zn-AcOH.[295] The last-mentioned method is actually a variation of **7-31,** since iodohydrins are intermediates. Some of these methods give syn elimination.

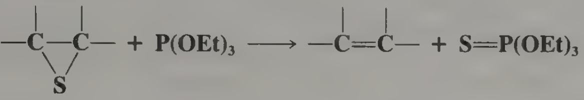
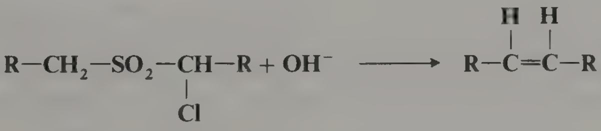
7-24 The Conversion of Episulfides to Olefins



Episulfides[296] can be converted to olefins in a reaction similar in appearance to **7-23.**[297] However, in this case the elimination is syn, so that the mechanism cannot be the same as that of **7-23.** The phosphite attacks not the carbon, but the sulfur. Among other reagents that convert episulfides to olefins are phenyllithium, Bu_3SnH,[298] P_2I_4,[298] lithium aluminum hydride[299] (this compound behaves quite differently with epoxides, see **0-81**), and methyl iodide.[300] Episulfoxides can be converted to olefins and sulfur monoxide simply by heating.[301]

7-25 The Ramberg–Bäcklund Reaction



$$R-CH_2-SO_2-\underset{Cl}{\underset{|}{CH}}-R + OH^- \longrightarrow R-\overset{H}{\overset{|}{C}}=\overset{H}{\overset{|}{C}}-R$$

The reaction of an α-halo sulfone with a base to give an olefin is called the *Ramberg–Bäcklund reaction.*[302] The reaction is quite general for α-halo sulfones with an α′-hydrogen, despite the unreactivity of α-halo sulfones in normal SN2 reactions (p. 303). Halogen reactivity is in the order I > Br ≫ Cl. Phase transfer catalysis has been used.[303] In general, mixtures of cis and trans isomers are obtained, but usually the less stable cis isomer predominates. The mechanism involves formation

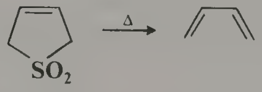
[303] Hartman and Hartman, *Synthesis* 504 (1982).

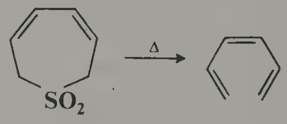
of an episulfone and then elimination of SO_2. There is much evidence for this mechanism,[304] including the preparation of episulfones in other ways and the demonstration that they give olefins under the reaction conditions faster than the corresponding α-halo sulfones.[305] Episulfones synthesized in other ways (e.g., **6-64**) are reasonably stable compounds but eliminate SO_2 to give olefins when heated or treated with base. A comparison of the reactivity of $PhCH_2SO_2CH_2OTs$ with that of $PhCH_2SO_2CH_2Cl$ showed that the tosylate reacted a great deal slower than the chloride,[306] despite the fact that OTs is normally a much better nucleofuge (p. 312).

If the reaction is run on the unsaturated bromo sulfones $RCH_2CH{=}CHSO_2CH_2Br$ (prepared by reaction of $BrCH_2SO_2Br$ with $RCH_2CH{=}CH_2$ followed by treatment with Et_3N), the dienes $RCH{=}CHCH{=}CH_2$ are produced in moderate-to-good yields.[307]

2,5-Dihydrothiophene-1,1-dioxides (**46**) and 2,7-dihydrothiepin-1,1-dioxides (**47**) undergo analogous 1,4 and 1,6 eliminations, respectively (see also **7-51**). These are concerted reactions and,



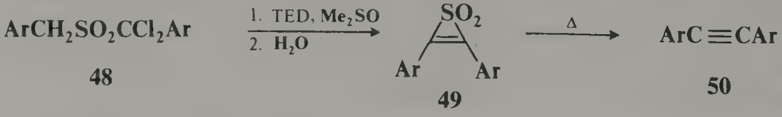
46



47

as predicted by the orbital-symmetry rules (p. 756), the former[308] is a suprafacial process and the latter[309] an antarafacial process. The rules also predict that elimination of SO_2 from episulfones cannot take place by a concerted mechanism (except antarafacially, which is unlikely for such a small ring), and the evidence shows that this reaction occurs by a nonconcerted pathway.[310] The eliminations of SO_2 from **46** and **47** are examples of *cheletropic reactions,*[311] which are defined as reactions in which two σ bonds that terminate at a single atom (in this case the sulfur atom) are made or broken in concert.[312]

α,α-Dichlorobenzyl sulfones (**48**) react with an excess of the base triethylenediamine in dimethyl sulfoxide at room temperature to give 2,3-diarylthiiren-1,1-dioxides (**49**), which can be isolated.[313]



48 **49** **50**

Thermal decomposition of **49** gives the alkynes **50**.[314] Alternatively, α,α-dichlorobenzyl sulfides $ArCH_2SCCl_2Ar$ can be converted to **50** by treatment with triphenylphosphine and *t*-BuOK in THF.[315]

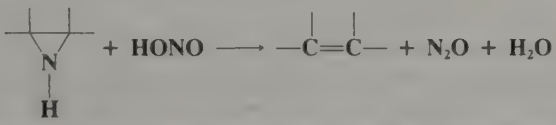
[315] Mitchell, *J. Chem. Soc., Chem. Commun.* 955 (1973).

A Ramberg–Bäcklund-type reaction has been carried out on the α-halo *sulfides* $ArCHClSCH_2Ar$, which react with *t*-BuOK and PPh_3 in refluxing tetrahydrofuran to give the alkenes $ArCH{=}CHAr$.[316] Another analogous reaction is treatment of α-bromo ketones $R_2CBrCOCHR_2$ with base and hydrogen peroxide to give olefins $R_2C{=}CR_2$.[317] This reaction involves a cyclopropanone intermediate (see the Favorskii rearrangement, **8-8**) which loses CO on reaction with H_2O_2.

The Ramberg–Bäcklund reaction can be regarded as a type of extrusion reaction (see p. 937).

OS **V,** 877; **50,** 43, 65.

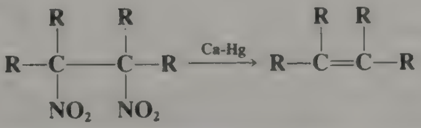
7-26 The Conversion of Aziridines to Olefins



Aziridines not substituted on the nitrogen atom react with nitrous acid to produce olefins.[318] An N-nitroso compound is an intermediate (**2-50**); other reagents that produce such intermediates also give olefins. The reaction is stereospecific: cis aziridines give cis olefins and trans aziridines give trans olefins.[319] Aziridines carrying N-alkyl substituents can be converted to olefins by treatment with ferrous iodide[320] or with *m*-chloroperbenzoic acid.[321] An N-oxide intermediate (**9-29**) is presumably involved in the latter case.

7-27 Conversion of Vicinal Dinitro Compounds to Olefins

Dinitro-elimination

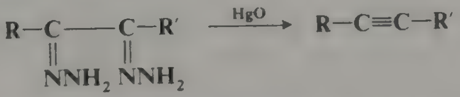


$$R-\underset{NO_2}{\overset{R}{C}}-\underset{NO_2}{\overset{R}{C}}-R \xrightarrow{\text{Ca-Hg}} R-\overset{R}{C}=\overset{R}{C}-R$$

Tetrasubstituted *vic*-dinitro compounds are converted to olefins by treatment with amalgamated calcium.[322] Various functional groups, such as CN and COOR, did not affect the reaction. Other reagents that have been used include sodium sulfide in DMF,[323] Bu_3SnH,[324] and $SnCl_2$.[325] Radical-ion mechanisms are likely in all these cases. *vic*-Dinitro compounds can be prepared by the reaction between an α,α-dinitro compound and the salt of a nitro paraffin (p. 415).

7-28 The Conversion of Dihydrazones to Alkynes

Dihydrazono-bielimination



$$R-\underset{NNH_2}{\underset{\|}{C}}-\underset{NNH_2}{\underset{\|}{C}}-R' \xrightarrow{\text{HgO}} R-C\equiv C-R'$$

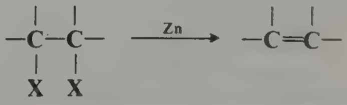
1,2-Dihydrazones can be made to lose two moles of nitrogen to give alkynes by treatment with HgO, Ag_2O, $CuCl_2$-O_2-pyridine, or certain other reagents. R and R′ may be alkyl or aryl. Highly strained seven- and eight-membered cycloalkynes (see p. 137), as well as large cycloalkynes, have been obtained by this reaction.[326]

OS **IV**, 377. See also OS **55**, 73.

7-29 Dehalogenation of Vicinal Dihalides

Dihalo-elimination[327]



$$-\underset{X}{\overset{|}{\underset{|}{C}}}-\underset{X}{\overset{|}{\underset{|}{C}}}- \xrightarrow{Zn} -\overset{|}{C}=\overset{|}{C}-$$

Dehalogenation has been accomplished with many reagents, the most common being zinc, magnesium, and iodide ion.[327a] Among reagents used less frequently have been phenyllithium, phenylhydrazine, chromous chloride $CrCl_2$, naphthalene–sodium,[328] Na-NH_3,[329] Na_2S in DMF,[330] and lithium aluminum hydride.[331] Though the reaction gives good yields, it is not very useful because the best way to prepare *vic*-dihalides is by the addition of halogen to a double bond (**5-27**). One useful feature of this reaction is that there is no doubt about the *position* of the new double bond, so that it can be used to give double bonds exactly where they are wanted. For example, allenes, which are not easily prepared by other methods, can be prepared from X—C—CX_2—C—X or X—C—CX=C— systems.[332] Cumulenes have been obtained from 1,4 elimination:

$$\mathbf{BrCH_2{-}C{\equiv}C{-}CH_2Br + Zn \longrightarrow CH_2{=}C{=}C{=}CH_2}$$

Triple bonds can be prepared from X—C=C—X or X_2C—CX_2 systems,[333] but availability considerations are even more extreme here.

The reaction can be carried out for any combination of halogens, except where one is fluorine. Mechanisms are often complex and depend on the reagent and reaction conditions.[334] For different reagents, mechanisms involving carbocations, carbanions, and free-radical intermediates, as well as concerted mechanisms, have been proposed. The reaction with I^- was found to proceed with stereospecific anti orientation (p. 875); from this fact an E2 mechanism was assumed in this case, but more recent work[335] shows that the reaction is not always stereospecifically anti and the mechanism is more complicated. When the reagent is zinc, anti stereospecificity has been observed in some cases,[336] but not in others.[337]

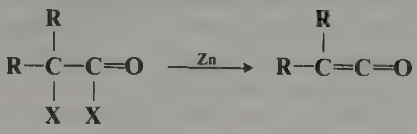
7-30 Dehalogenation of α-Halo Acyl Halides

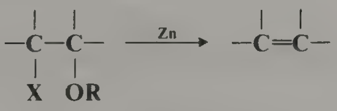


$$\mathrm{R{-}\overset{R}{\underset{X}{C}}{-}\underset{X}{C}{=}O \xrightarrow{Zn} R{-}\overset{R}{C}{=}C{=}O}$$

Ketenes can be prepared by dehalogenation of α-halo acyl halides with zinc or with triphenylphosphine,[338] analogously to **7-2.** The reaction generally gives good results when the two R groups are aryl or alkyl, but not when either one is hydrogen.[339]

OS **IV,** 348.

7-31 Elimination of a Halogen and a Hetero Group
Alkoxy-halo-elimination

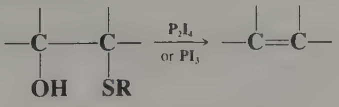


$$\mathrm{{-}\underset{X}{\overset{|}{C}}{-}\underset{OR}{\overset{|}{C}}{-} \xrightarrow{Zn} {-}\overset{|}{C}{=}\overset{|}{C}{-}}$$

The elimination of OR and halogen from β-halo ethers is called the *Boord reaction.* It can be carried out with zinc, magnesium, or sodium. The yields are high and the reaction is of broad scope. β-Halo acetals readily yield vinyl ethers: $\mathrm{X{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{C}(OR)_2 \rightarrow {-}\overset{|}{C}{=}\overset{|}{C}{-}OR}$. Besides β-halo ethers, the reaction can also be carried out on compounds of the formula $\mathrm{X{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}Z}$, where X is halogen and Z is OCOR, OTs,[340] NR_2,[341] or SR.[342] Z may also be OH, but then X is limited to Br and I. Like **7-29,** this method ensures that the new double bond will be in a specific position. The fact that magnesium causes elimination in these cases limits the preparation of Grignard reagents from these compounds. It has been shown that treatment of β-halo ethers and esters with zinc gives nonstereospecific elimination,[343] so that the mechanism was not E2. It was postulated that the mechanism is E1cB, because of the poor leaving-group ability of OR and OCOR. Bromohydrins can be converted to olefins (elimination of Br, OH) in high yields by treatment with $LiAlH_4$-$TiCl_3$.[344]

OS **III,** 698; **IV,** 748; **55,** 62.

7-32 Cleavage of β-Hydroxy Sulfides, Selenides, and Related Compounds
Hydroxy-alkylthio-elimination, etc.



$$\mathrm{{-}\underset{OH}{\overset{|}{C}}{-}\underset{SR}{\overset{|}{C}}{-} \xrightarrow[\text{or } PI_3]{P_2I_4} {-}\overset{|}{C}{=}\overset{|}{C}{-}}$$

---

[338] Darling and Kidwell, *J. Org. Chem.* **33,** 3974 (1968).

[339] For a procedure that gives 60 to 65% yields when one R = H, see McCarney and Ward, *J. Chem. Soc., Perkin Trans. 1* 1600 (1975).

[340] Cristol and Rademacher, *J. Am. Chem. Soc.* **81,** 1600 (1959). This reaction has also been accomplished with PhMgBr: Reeve, Brown, and Steckel, *J. Am. Chem. Soc.* **93,** 4607 (1971).

[341] Gurien, *J. Org. Chem.* **28,** 878 (1963).

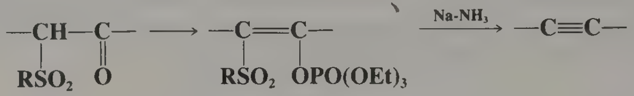
[344] McMurry and Hoz, *J. Org. Chem.* **40,** 3797 (1975).

β-Hydroxy sulfides can be converted to alkenes by treatment with P_2I_4, PI_3, or (for tetrasubstituted alkenes) $SOCl_2$.[345] Other reagents have also been used.[346] An analogous reaction for β-hydroxy selenides uses $SOCl_2$ or $MeSO_2Cl$ and Et_3N[347] or Me_3SiCl.[348] It was mentioned at **6-42** (p. 838) that β-hydroxysulfinamides, on heating, undergo a syn elimination.[349]

Triple-bond compounds can be prepared by elimination from β-keto sulfones by first converting them to the enol phosphorinates **51** and treatment of these with Na in liquid NH_3[350] or with Na-Hg in THF-Me_2SO.[351]

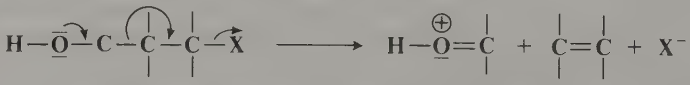


$$\underset{RSO_2}{\text{—}\underset{|}{\text{CH}}}\text{—}\underset{O}{\underset{\|}{\text{C}}}\text{—} \longrightarrow \text{—}\underset{RSO_2}{\underset{|}{\text{C}}}\text{=}\underset{OPO(OEt)_3}{\underset{|}{\text{C}}}\text{—} \xrightarrow{\text{Na-NH}_3} \text{—C}\equiv\text{C—}$$

51

Fragmentations

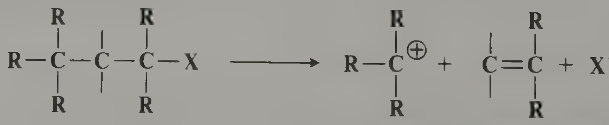
When carbon is the positive leaving group (the electrofuge) in an elimination, the reaction is called *fragmentation*.[352] These processes occur on substrates of the form W—C—C—X, where X is a normal nucleofuge (e.g., halogen, OH_2^+, OTs, NR_3^+, etc.) and W is a positive-carbon electrofuge. In most of the cases W is HO—C— or R_2N—C—, so that the positive charge on the carbon atom is stabilized by the unshared pair of the oxygen or nitrogen, e.g.,



$$H\text{—}\underline{\bar{O}}\text{—}C\text{—}C\text{—}C\text{—}X \longrightarrow H\text{—}\overset{\oplus}{\underline{O}}\text{=}C + C\text{=}C + X^-$$

The mechanisms are mostly E1 or E2. We shall discuss only a few fragmentations, since many are possible and not much work has been done on most of them. Reactions **7-33** to **7-39** and **7-41** may be considered fragmentations. See also **9-13** and **9-14.**

7-33 Fragmentation of γ-Branched Alcohols and Halides
Alkyl-halo-elimination



$$R\text{—}\underset{R}{\overset{R}{C}}\text{—}C\text{—}\underset{R}{\overset{R}{C}}\text{—}X \longrightarrow R\text{—}\underset{R}{\overset{R}{C}}{}^{\oplus} + C\text{=}\underset{R}{\overset{R}{C}} + X^-$$

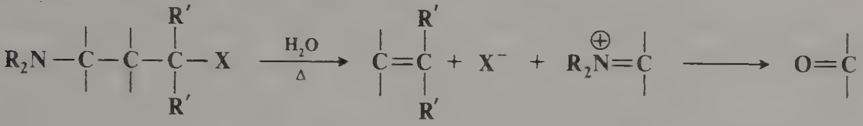
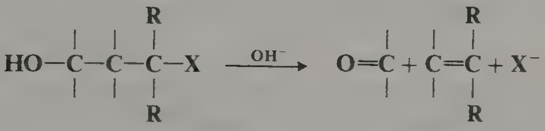
[352] For reviews, see Becker and Grob, in Patai, Ref. 2, pt. 2, pp. 653–723; Grob, *Angew. Chem. Int. Ed. Engl.* **8,** 535–546 (1969) [*Angew. Chem.* **81,** 543–554]; Grob and Schiess, *Angew. Chem. Int. Ed. Engl.* **6,** 1–15 (1967) [*Angew. Chem.* **79,** 1–14].

When alkyl halides or alcohols with both α and γ branching are subjected to solvolysis, they may undergo fragmentation to give an olefin and a carbocation. The carbocation then undergoes further elimination or substitution, depending on the conditions. This is of course an E1 process, with the first step being ionization of the halide or the protonated alcohol. This is another way of saying that carbocations of the form  $R_3C-\overset{|}{\underset{|}{C}}-\overset{\oplus}{C}R_2$ find it easy to lose a relatively stable R_3C^+ ion rather than H^+. As expected for a carbocation mechanism, these fragmentations occur to the greatest extent for tertiary substrates, to a smaller extent for secondary, and essentially not at all for primary substrates, even with γ branching. Even with apparently favorable substrates, fragmentation is not always observed.[353]

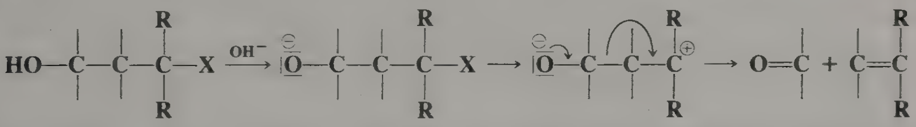
7-34 Fragmentation of γ-Amino and γ-Hydroxy Halides

Dialkylaminoalkyl-halo-elimination, etc.





γ-Dialkylamino halides undergo fragmentation when heated with water to give an olefin and an iminium salt, which under the reaction conditions is hydrolyzed to an aldehyde or ketone (**6-2**).[354] γ-Hydroxy halides and tosylates are fragmented with base. In this instance the base does not play its usual role in elimination reactions but instead serves to remove a proton from the OH group, which enables the carbon leaving group to come off more easily:



The mechanism of these reactions is often E1 and the side reactions are similar to those in **7-33.** However, in at least some cases, an E2 mechanism operates.[355] It has been shown that stereoisomers of cyclic γ-amino halides and tosylates in which the two leaving groups can assume an anti-periplanar conformation react by the E2 mechanism, while those isomers in which the groups cannot assume such a conformation either fragment by the E1 mechanism or do not undergo fragmentation at all, but in either case give rise to side products characteristic of carbocations.[356]

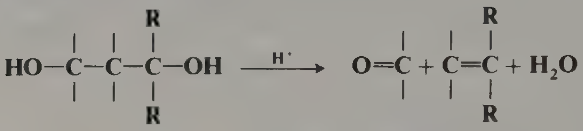
Chim. Acta* **50,** 416 (1967); Geisel, Grob, and Wohl, *Helv. Chim. Acta* **52,** 2206 (1969). See also Gleiter, Stohrer, and Hoffmann, *Helv. Chim. Acta* **55,** 893 (1972).

In certain cases (electron-withdrawing groups in the β-position, or the use of poor nucleofuges such as ArCOO) an E1cB mechanism has been shown.[357]

γ-Dialkylamino alcohols do not give fragmentation, since for ionization the OH group must be converted to OH_2^+ and this would convert NR_2 to NR_2H^+, which does not have the unshared pair necessary to form the double bond with the carbon.[358]

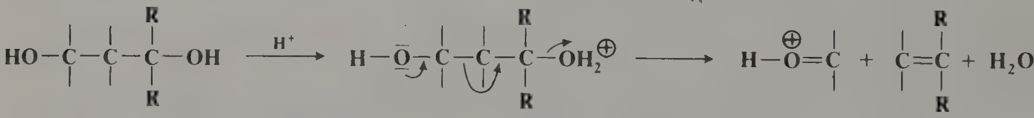
7-35 Fragmentation of 1,3-Diols

Hydroxyalkyl-hydroxy-elimination



$$HO-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{R}{\underset{R}{C}}-OH \xrightarrow{H^+} O=\overset{|}{\underset{|}{C}} + \overset{|}{\underset{|}{C}}=\overset{R}{\underset{R}{C}} + H_2O$$

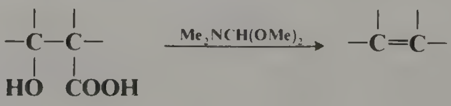
1,3-Diols in which at least one OH group is tertiary or is located on a carbon with aryl substituents can be cleaved by acid treatment.[359] At least in some cases the mechanism seems to be E2 since anti elimination is found:[360]



However, in other cases the mechanism is E1. Suitable β-hydroxy acids also give the reaction. As already mentioned (in **7-34**), γ-dialkylamino alcohols do not give fragmentation, but non-N-substituted γ-amino alcohols do give the reaction, when treated with nitrous acid, and give the same products as the corresponding 1,3-diol.[361] Here the mechanism is undoubtedly E1.

7-36 Decarboxylation of β-Hydroxy Carboxylic Acids and of β-Lactones

Carboxy-hydroxy-elimination



$$-\overset{|}{\underset{HO}{C}}-\overset{|}{\underset{COOH}{C}}- \xrightarrow{Me_2NCH(OMe)_2} -\overset{|}{C}=\overset{|}{C}-$$

An OH and a COOH group can be eliminated from β-hydroxy carboxylic acids by refluxing with excess dimethylformamide dimethyl acetal.[362] Mono-, di-, tri-, and tetrasubstituted olefins have been prepared by this method in good yields.[363] There is evidence that the mechanism involves E1 or E2 elimination from the zwitterionic intermediate $^-O_2C-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OCH=\overset{\oplus}{N}Me_2$.[364] The reaction has also been accomplished under extremely mild conditions (a few seconds at 0°C) with PPh_3 and ethyl azodicarboxylate EtOOC—N=N—COOEt.[365] In a related procedure, β-lactones undergo thermal decarboxylation to give olefins in high yields. The reaction has been shown to be a

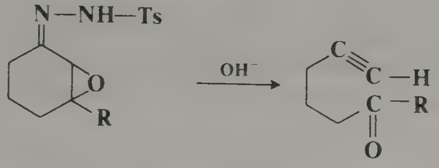
stereospecific syn elimination.[366] There is evidence that this reaction also involves a zwitterionic intermediate.[367]

7-37 Fragmentation of α,β-Epoxy Hydrazones



Cyclic α,β-unsaturated ketones[368] can be cleaved by treatment with base of their epoxy tosylhydrazone derivatives to give acetylenic ketones.[369] The reaction can be applied to the formation of acetylenic aldehydes (R = H) by using the corresponding 2,4-dinitrotosylhydrazone derivatives.[370] Hydrazones (e.g., **52**) prepared from epoxy ketones and ring-substituted N-aminoaziridines undergo similar fragmentation when heated.[371]

On heating, bicyclo[2.2.1]heptenones (**53**) usually lose CO to give cyclohexadienes,[372] in a type of reverse Diels–Alder reaction. Bicyclo[2.2.1]heptadienones (**54**) undergo the reaction so readily (because of the stability of the benzene ring produced) that they cannot generally be isolated. **53** and **54** can be prepared by Diels–Alder reactions between a cyclopentadienone and an alkyne or olefin, so that this reaction is a useful method for the preparation of specifically substituted benzene ring and cyclohexadienes.[373] Unsaturated bicyclic lactones of the type **55** can also undergo the reaction, losing CO_2. See also **7-50.**

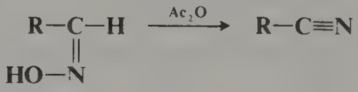
Reactions in Which C≡N or C=N Bonds Are Formed

7-40 Dehydration of Aldoximes and Similar Compounds
C-Hydro-*N*-hydroxy-elimination



$$\underset{\substack{\| \\ \text{HO—N}}}{\text{R—C—H}} \xrightarrow{Ac_2O} \text{R—C≡N}$$

Aldoximes can be dehydrated to nitriles[374] by many dehydrating agents, of which acetic anhydride is the most common. Among reagents that are effective under mild conditions[375] (room temperature) are diphenyl hydrogen phosphonate[376] $(PhO)_2PHO$, ethyl orthoformate and H^+,[377] 2,4,6-trichloro-*s*-triazine,[378] trifluoromethane sulfonic anhydride,[379] P_2I_4,[283] SeO_2,[380] CS_2 under phase transfer conditions,[381] Cl_3COCl-Et_3N,[382] chloromethylene dimethylammonium chloride $Me_2N{=}CHCl^+\ Cl^-$,[383] and dicyclohexylcarbodiimide in the presence of Et_3N and Cu(II) ions.[384] The reaction is most successful when the H and OH are trans. Various alkyl and acyl derivatives of aldoximes, for example, $RCH{=}NOR$, $RCH{=}NOCOR$, $RCH{=}NOSO_2Ar$, etc., also give nitriles, as do chlorimines $RCH{=}NCl$ (the latter with base treatment).[385] N,N-dichloro derivatives of primary amines give nitriles on pyrolysis: $RCH_2NCl_2 \rightarrow RCN$.[386]

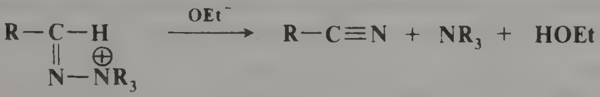
Quaternary hydrazonium salts (derived from aldehydes) give nitriles when treated with OEt^-:[387]



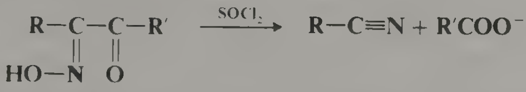
$$\underset{\underset{N-\overset{\oplus}{N}R_3}{\|}}{R-C-H} \xrightarrow{OEt^-} R-C\equiv N + NR_3 + HOEt$$

as do dimethylhydrazones $RCH{=}NNMe_2$ when treated with Et_2NLi and HMPT.[388] All these are methods of converting aldehyde derivatives to nitriles. For the conversion of aldehydes directly to nitriles, without isolation of intermediates, see **6-22.**

OS **II,** 622; **III,** 690.

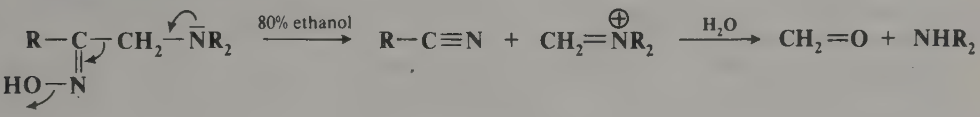
7-41 The Conversion of Ketoximes to Nitriles

C-Acyl-N-hydroxy-elimination



$$R-\underset{\underset{HO-N}{\|}}{C}-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{SOCl_2} R-C\equiv N + R'COO^-$$

Certain ketoximes can be converted to nitriles by the action of proton or Lewis acids.[389] Among these are oximes of α-diketones (illustrated above), α-keto acids, α-dialkylamino ketones, α-hydroxy ketones, β-keto ethers, and similar compounds.[390] These are fragmentation reactions, analogous to **7-34** and **7-35.** For example, α-dialkylamino ketoximes also give amines and aldehydes or ketones in addition to nitriles:[391]



$$R-\underset{\underset{HO-N}{\|}}{C}-CH_2-NR_2 \xrightarrow{\text{80\% ethanol}} R-C\equiv N + CH_2{=}\overset{\oplus}{N}R_2 \xrightarrow{H_2O} CH_2{=}O + NHR_2$$

The reaction that normally occurs on treatment of a ketoxime with a Lewis or proton acid is the Beckmann rearrangement (**8-20**); fragmentations are considered side reactions, often called "abnormal" or second-order" Beckmann rearrangements.[392] Obviously, the substrates mentioned are much more susceptible to fragmentation than are ordinary ketoximes, since in each case an unshared pair is available to assist in removal of the group cleaving from the carbon. However, fragmentation is a side reaction even with ordinary ketoximes[393] and, in cases where a particularly stable carbocation may be cleaved, may be the main reaction:[394]

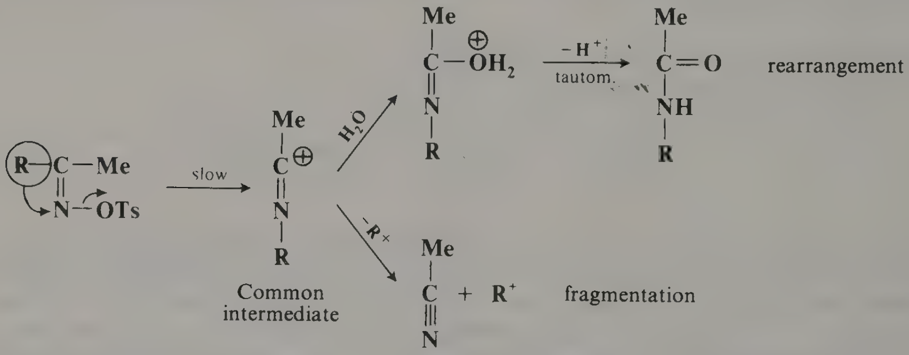
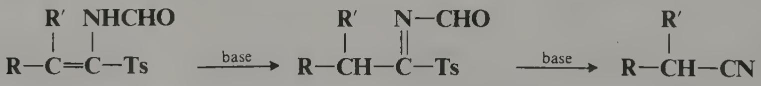
$$Ar_2CH-\underset{\underset{N-OH}{\|}}{C}-Me \xrightarrow{PCl_5} Me-C\equiv N + Ar_2CHCl$$

There are indications that the mechanism at least in some cases first involves a rearrangement and then cleavage. The ratio of fragmentation to Beckmann rearrangement of a series of oxime tosylates RC(=NOTs)Me was not related to the solvolysis rate but *was* related to the stability of R^+ (as determined by the solvolysis rate of the corresponding RCl), which showed that fragmentation did not take place in the rate-determining step.[395] It may be postulated then that the first step in the fragmentation and in the rearrangement is the same and that this is the rate-determining step. The product is determined in the second step:



However, in other cases the simple E1 or E2 mechanisms operate.[396] The fragmentation of certain ketoximes to nitriles has also been carried out with tetrakis(triphenylphosphine)palladium $Pd(PPh_3)_4$.[397] In this case the other product is the aldehyde R′CHO.

The fragmentation of N-(1-tosyl-1-alkenyl)formamides (**56**) by refluxing with NaOMe in MeOH



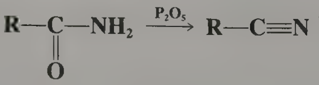
56

$$R-\overset{\overset{R'}{|}}{C}=\overset{\overset{NHCHO}{|}}{C}-Ts \xrightarrow{\text{base}} R-\overset{\overset{R'}{|}}{C}H-\overset{\overset{N-CHO}{\|}}{C}-Ts \xrightarrow{\text{base}} R-\overset{\overset{R'}{|}}{C}H-CN$$

is a step in the conversion of a ketone to a nitrile,[398] since **56** can be prepared by treatment of ketones with $TsCH_2NC$ (p. 840). The overall conversion is RR′C=O to RR′CHCN.

OS **V**, 266.

7-42 Dehydration of Unsubstituted Amides
***NN*-Dihydro-*C*-oxo-bielimination**



$$R-\underset{\underset{O}{\|}}{C}-NH_2 \xrightarrow{P_2O_5} R-C\equiv N$$

Unsubstituted amides can be dehydrated to nitriles.[399] Phosphorus pentoxide is the most common dehydrating agent for this reaction, but many others, including $POCl_3$, PCl_5, CCl_4-Ph_3P,[400] $TiCl_4$-base,[401] $CHCl_3$-$PhCH_2NEt_3^+$ Cl^--base,[402] HMPT,[403] trifluoroacetic anhydride-pyridine,[404] cyanuric chloride,[405] $Me_2N{=}CHCl^+$ Cl^-,[406] trimethylsilyl polyphosphate,[407] phosphorus tris(diethylamide) $P(NEt_2)_3$,[408] and $SOCl_2$ have also been used. It is possible to convert an acid to the nitrile, without isolation of the amide, by heating its ammonium salt with the dehydrating agent.[409] Acyl halides can also be directly converted to nitriles by heating with sulfamide $(NH_2)_2SO_2$.[410] The reaction may be formally looked on as a β-elimination from the enol form of the amide  $\underset{\displaystyle \mathrm{OH}}{\mathrm{R{-}\underset{|}{C}{=}NH}}$, in which case it is like **7-40**, except that H and OH have changed places. In some cases, for example, with $SOCl_2$, the mechanism probably *is* through the enol form, with the dehydrating agent forming an ester with the OH group, for example,  $\underset{\displaystyle \mathrm{OSOCl}}{\mathrm{R{-}\underset{|}{C}{=}NH}}$, which undergoes elimination by the E1 or E2 mechanism.[411] N,N-Disubstituted ureas give cyanamides ($R_2N{-}CO{-}NH_2 \rightarrow R_2N{-}CN$) when dehydrated with $CHCl_3$-NaOH under phase transfer conditions.[412]

N-Alkyl-substituted amides can be converted to nitriles and alkyl chlorides by treatment with PCl_5. This reaction is called the *von Braun reaction* (not to be confused with the other von Braun reaction, **0-74**). In a similar reaction, treatment of N-alkyl-substituted amides with chlorotris(triphenylphosphine)rhodium $RhCl(PPh_3)_3$ or certain other catalysts give nitriles and the corresponding alcohols.[413] N-Sulfo chloride derivatives of amides (prepared by treatment of carboxylic acids or ketones with chlorosulfonyl isocyanate $ClSO_2NCO$) can be converted to nitriles by treatment with dimethylformamide[414] or with triethylamine.[415]

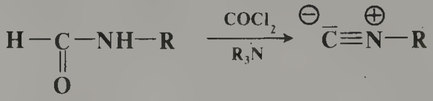
7-43 Conversion of Primary Nitro Compounds to Nitriles

$$\mathrm{RCH_2{-}NO_2} \xrightarrow[\text{pyridine}]{\mathrm{PCl_3}} \mathrm{RC{\equiv}N}$$

Nitriles can be obtained in one step by treatment of primary nitro compounds with PCl_3 and pyridine.[416] R may be alkyl or aryl and may contain C=C double bonds or various functional groups. Yields are moderate to good. The reaction has also been carried out with Me_3N-SO_2 and with HMPT.[417] Primary azides RCH_2N_3 have been converted to nitriles RCN with Pd metal.[418]

7-44 Conversion of N-Alkylformamides to Isonitriles
***CN*-Dihydro-*C*-oxo-bielimination**

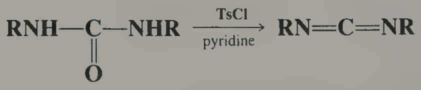


$$\mathrm{H{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R} \xrightarrow[\mathrm{R_3N}]{\mathrm{COCl_2}} \overset{\ominus}{\bar{\mathrm{C}}}{\equiv}\overset{\oplus}{\mathrm{N}}{-}\mathrm{R}$$

Isonitriles can be prepared by elimination of water from N-alkylformamides with phosgene and a tertiary amine.[419] Other reagents, among them TsCl in quinoline, $POCl_3$ and a tertiary amine, $Me_2N{=}CHCl^+\ Cl^-$,[420] diphosgene $ClCOOCCl_3$,[421] 2-chloro-3-ethylbenzoxazolium tetrafluoroborate,[422] Ph_3P-CCl_4-Et_3N,[423] and Ph_3PBr_2-Et_3N[424] have also been employed.

OS **V,** 300, 772; **51,** 31; **57,** 102; **59,** 183. See also OS **61,** 14.

7-45 Dehydration of N,N′-Disubstituted Ureas and Thioureas
1/*N*,3/*N*-Dihydro-2/*C*-oxo-bielimination



$$\mathrm{RNH{-}\underset{\underset{O}{\|}}{C}{-}NHR} \xrightarrow[\text{pyridine}]{\mathrm{TsCl}} \mathrm{RN{=}C{=}NR}$$

Carbodiimides[425] can be prepared by the dehydration of N,N′-disubstituted ureas with various dehydrating agents, among which are TsCl in pyridine, $POCl_3$, PCl_5, P_2O_5-pyridine, and Ph_3PBr_2-Et_3N.[424] H_2S can be removed from the corresponding thioureas by treatment with HgO, NaOCl, organolithium or -magnesium compounds,[426] 2-chloro-1-methylpyridinium iodide–Et_3N,[427] phosgene,[428] or diethyl azodicarboxylate–triphenylphosphine.[429]

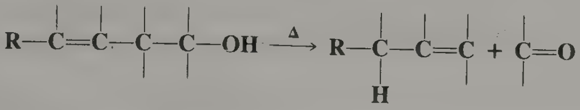
Reactions in Which C=O Bonds Are Formed

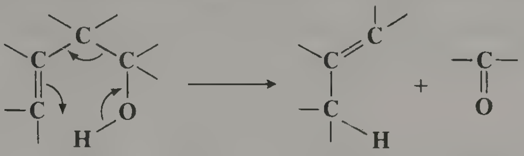
Many elimination reactions in which C=O bonds are formed were considered in Chapter 16, along with their more important reverse reactions. Also see **2-39** and **2-40.**

7-46 Pyrolysis of β-Hydroxy Olefins
O-Hydro-C-allyl-elimination



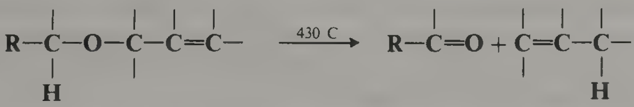
$$\mathrm{R{-}C{=}C{-}C{-}C{-}OH \xrightarrow{\Delta} R{-}\underset{H}{C}{-}C{=}C + C{=}O}$$

β-Hydroxy olefins are cleaved when pyrolyzed to give olefins and aldehydes or ketones.[430] Olefins produced this way are quite pure, since there are no side reactions. The mechanism has been shown to be Ei, primarily by observations that the kinetics are first order[431] and that, for ROD, the deuterium



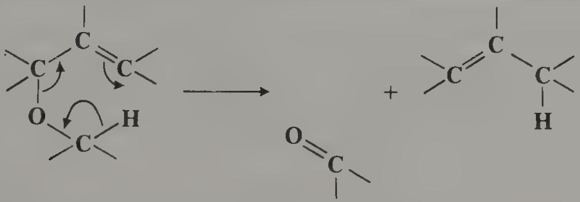
appeared in the allylic position of the new olefin.[432] β-Hydroxyacetylenes react similarly to give the corresponding allenes and carbonyl compounds.[433] The mechanism is the same despite the linear geometry of the triple bonds.

7-47 Pyrolysis of Allyl Ethers
C-Hydro-O-allyl-elimination



$$\mathrm{R{-}\underset{H}{C}{-}O{-}C{-}C{=}C{-} \xrightarrow{430\ C} R{-}C{=}O + C{=}C{-}\underset{H}{C}{-}}$$

Pyrolysis of allyl ethers that contain at least one α-hydrogen gives olefins and aldehydes or ketones. The reaction is closely related to reaction **7-46,** and the mechanism is also Ei, though not exactly



analogous.[434] Note that this mechanism is the reverse of that of the ene synthesis (**5-16**). Homoallylic ethers can be pyrolytically cleaved via an eight-membered cyclic transition state to give an aldehyde and two alkenes.[435]

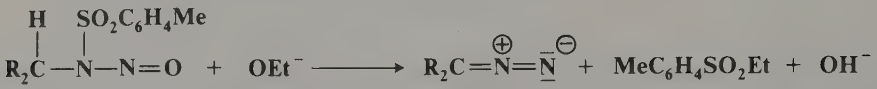
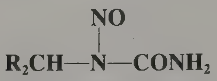
Reactions in Which N=N Bonds Are Formed

7-48 Eliminations to Give Diazoalkanes



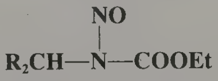
$$R_2\overset{\displaystyle H}{\overset{|}{C}}-\overset{\displaystyle SO_2C_6H_4Me}{\overset{|}{N}}-N{=}O + OEt^- \longrightarrow R_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{\underline{N}} + MeC_6H_4SO_2Et + OH^-$$

Various N-nitroso-N-alkyl compounds undergo elimination to give diazoalkanes.[436] One of the most convenient methods for the preparation of diazomethane involves base treatment of N-nitroso-N-methyl-*p*-toluenesulfonamide (illustrated above, with R = H).[437] However, other compounds commonly used are (base treatment is required in all cases):



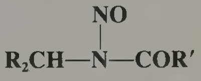
$$R_2CH-\overset{\displaystyle NO}{\overset{|}{N}}-CONH_2$$

N-nitroso-N-alkylureas



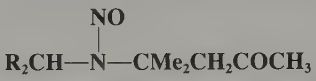
$$R_2CH-\overset{\displaystyle NO}{\overset{|}{N}}-COOEt$$

N-nitroso-N-alkylcarbamates



$$R_2CH-\overset{\displaystyle NO}{\overset{|}{N}}-COR'$$

N-nitroso-N-alkyl amides

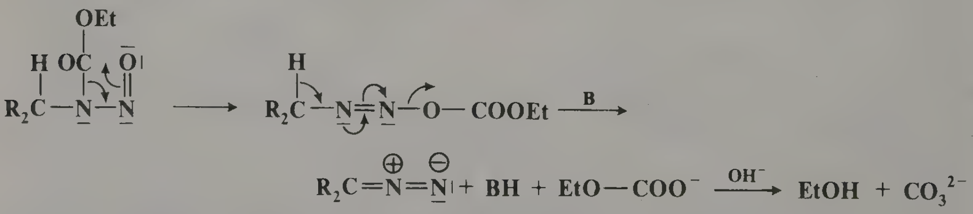


$$R_2CH-\overset{\displaystyle NO}{\overset{|}{N}}-CMe_2CH_2COCH_3$$

N-nitroso-N-alkyl-4-amino-4-methyl-2-pentanones

All these compounds can be used to prepare diazomethane, though the sulfonamide, which is commercially available, is most satisfactory. (N-Nitroso-N-methylcarbamate and N-nitroso-N-methylurea give good yields, but are highly irritating and carcinogenic.[438]) For higher diazoalkanes the preferred substrates are nitrosoalkylcarbamates.

Most of these reactions probably begin with a 1,3 nitrogen-to-oxygen rearrangement, followed by the actual elimination (illustrated for the carbamate):



OS **II,** 165; **III,** 119, 244; **IV,** 225, 250; **V,** 351; **57,** 95.

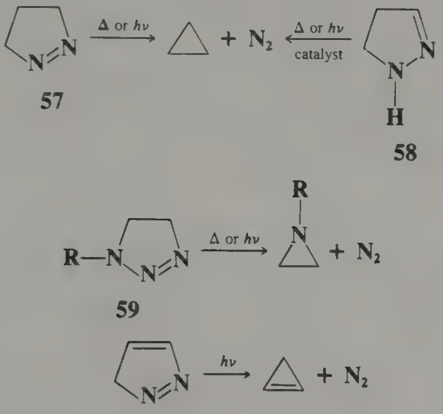
Extrusion Reactions

We consider an *extrusion reaction*[439] to be one in which an atom or group Y connected to two other atoms X and Z is lost from a molecule, leading to a product in which X is bonded directly to Z.

$$\text{X}-\text{Y}-\text{Z} \longrightarrow \text{X}-\text{Z} + \text{Y}$$

Reactions **4-40** and **7-25** also fit this definition. Reaction **7-39** does not fit the definition, but is often also classified as an extrusion reaction. An extrusibility scale has been developed, showing that the ease of extrusion of the common Y groups is in the order: $-\text{N}{=}\text{N}- > -\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{O}- > -\text{SO}_2- > -\text{CO}-$[440]

7-49 Extrusion of N_2 from Pyrazolines, Pyrazoles, and Triazolines



57 58 59 60

1-Pyrazolines (**57**) can be converted to cyclopropanes and N_2 on photolysis[441] or pyrolysis.[442] The tautomeric 2-pyrazolines (**58**), which are more stable than **57**, also give the reaction, but in this case an acidic or basic catalyst is required, the function of which is to convert **58** to **57**.[443] In the absence of such catalysts, **58** do not react.[444] In a similar manner, triazolines (**59**) are converted to aziridines.[445] Side reactions are frequent with both **57** and **59**, and some substrates do not give the reaction at all. However, the reaction has proved synthetically useful in many cases. In general, photolysis gives better yields and fewer side reactions than pyrolysis with both **57** and **59**. 3*H*-

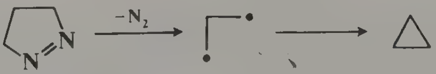
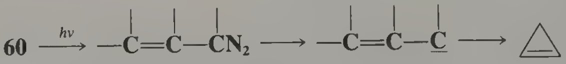
Pyrazoles[445a] (**60**) are stable to heat, but in some cases can be converted to cyclopropenes on photolysis,[446] though in other cases other types of products are obtained.

There is much evidence that the mechanism[447] of the 1-pyrazoline reactions generally involves diradicals, though the mode of formation and detailed structure (e.g., singlet vs. triplet) of these



radicals may vary with the substrate and reaction conditions. The reactions of the 3*H*-pyrazoles have been postulated to proceed through a diazo compound that loses N_2 to give a vinylcarbene.[448]



$$60 \xrightarrow{h\nu} -\overset{|}{C}{=}\overset{|}{C}-\overset{|}{C}N_2 \longrightarrow -\overset{|}{C}{=}\overset{|}{C}-\overset{|}{\underline{C}} \longrightarrow \triangle$$

Δ^2-Tetrazolines can be photolyzed to diaziridines.[449]

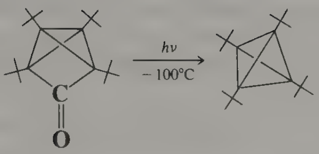
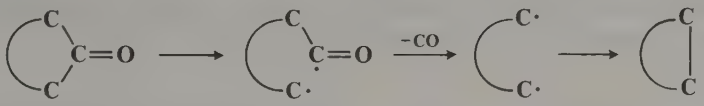
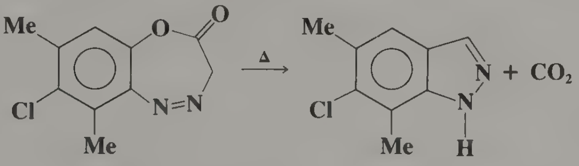
[451] Cava and Mangold, *Tetrahedron Lett.* 1751 (1964).



The mechanism probably involves a Norrish type I cleavage (p. 213), loss of CO from the resulting radical, and recombination of the radical fragments.

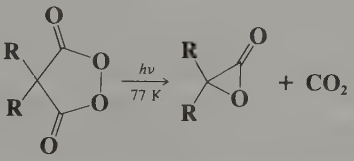


Certain lactones extrude CO_2 on heating or on irradiation, examples being pyrolysis of 7-chloro-6,8-dimethyl-1,4,5-benzoxadiazepin-2-one (**63**) to give the corresponding indazole **64**,[453]



63 **64**

and the formation of α-lactones by photolysis of 1,2-dioxolane-3,5-diones.[454]



Decarboxylation of β-lactones (see **7-36**) may be regarded as a degenerate example of this reaction. Certain diaryl carbonates give diaryl ethers when heated with base: Ar—O—CO—O—Ar → Ar—O—Ar.[455] See also **7-39** and **7-54.**

There are no OS references, but see OS **57,** 45 for a related reaction.

7-51 Extrusion of SO_2

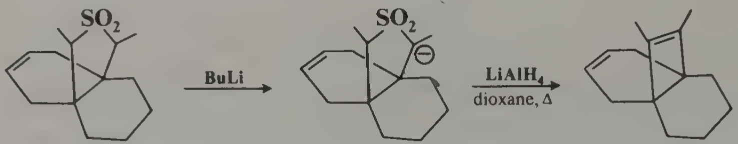
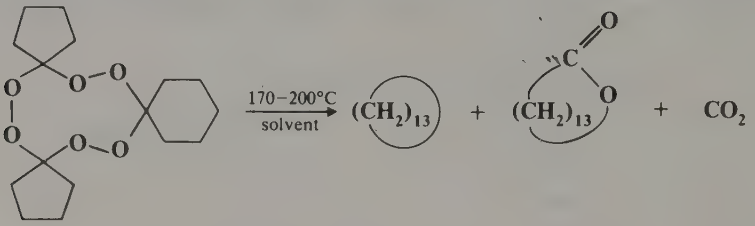
In a reaction similar to **7-50**, certain cyclic sulfones extrude SO_2 on heating or photolysis to give ring-contracted products.[456] An example is the preparation of naphtho(*b*)cyclobutene shown above.[457] In a different kind of reaction, five-membered cyclic sulfones can be converted to cyclobutenes by treatment with butyllithium followed by $LiAlH_4$,[458] e.g.,



This method is most successful when both the α and α′ positions of the sulfone bear alkyl substituents. See also **7-25.**

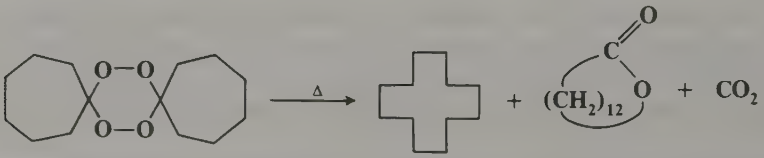
OS **50,** 53.

7-52 The Story Synthesis



65

When cycloalkylidene peroxides (e.g., **65**) are heated in an inert solvent (e.g., decane), extrusion of CO_2 takes place; the products are the cycloalkane containing three carbon atoms less than the starting peroxide and the lactone containing two carbon atoms less[459] (the *Story synthesis*).[460] The two products are formed in comparable yields, usually about 15 to 25% each. Although the yields are low, the reaction is useful because there are not many other ways to prepare large rings. The reaction is versatile, having been used to prepare rings of every size from 8 to 33 members. The method is also applicable to dimeric cycloalkylidene peroxides, in which case the cycloalkane and lactone products result from loss of two molecules and one molecule of CO_2, respectively, e.g.,



Both dimeric and trimeric cycloalkylidene peroxides can be synthesized[461] by treatment of the corresponding cyclic ketones with H_2O_2 in acid solution,[462] or in the presence of an ion-exchange resin.[463] The trimeric peroxide is formed first and is subsequently converted to the dimeric compound.[464]

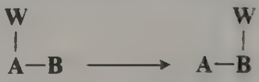
18

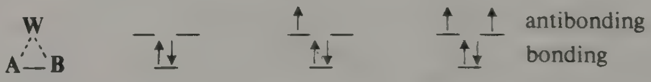
REARRANGEMENTS

In a rearrangement reaction a group moves from one atom to another in the same molecule.[1] Most are migrations from an atom to an adjacent one (called 1,2 shifts), but some are over longer distances. The migrating group (W) may move with its electron pair (these may be called *nucleophilic* or *anionotropic* rearrangements; the migrating group may be regarded as a nucleophile), without its electron pair (*electrophilic* or *cationotropic* rearrangements; in the case of migrating hydrogen, *prototropic* rearrangements), or with just one electron (free-radical rearrangements). The atom A is called the *migration origin* and B is the *migration terminus*. However, there are some rearrangements that do not lend themselves to neat categorization in this manner. Among these are those with cyclic transition states (**8-31** to **8-43**).



$$\overset{\mathbf{W}}{\mathbf{A}}\!-\!\mathbf{B} \longrightarrow \mathbf{A}\!-\!\overset{\mathbf{W}}{\mathbf{B}}$$

As we shall see, nucleophilic 1,2 shifts are much more common than electrophilic or free-radical 1,2 shifts. The reason for this can be seen by a consideration of the transition states (or in some cases intermediates) involved. We represent the transition state or intermediate for all three cases by **1**, in which the two-electron A—W bond overlaps with the orbital on atom B, which contains zero, one, and two electrons, in the case of nucleophilic, free-radical, and electrophilic migration, respectively. The overlap of these orbitals gives rise to three new orbitals, which have an energy relationship similar to those on p. 49 (one bonding and two degenerate antibonding orbitals). In a nucleophilic migration, where only two electrons are involved, both can go into the bonding orbital and **1** is a low-energy transition state; but in a free-radical or electrophilic migration, there are, respectively, three or four electrons that must be accommodated and antibonding orbitals must be occupied. It is not surprising therefore that, when 1,2-electrophilic or free-radical shifts are found, the migrating group W is usually aryl or some other group that can accommodate the extra one or two electrons and thus effectively remove them from the three-membered transition state or intermediate (see **37** on p. 956).



1 Nucleophilic Free radical Electrophilic

In any rearrangement we can in principle distinguish between two possible modes of reaction: In one of these the group W becomes completely detached from A and may end up on the B atom of a different molecule (*intermolecular* rearrangement); in the other W goes from A to B in the

---

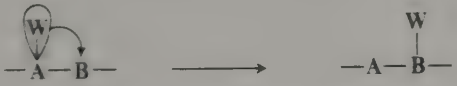
[1] For books, see Mayo, "Rearrangements in Ground and Excited States," 3 vols., Academic Press, New York, 1980 [we will refer to this as Mayo-RGES]; Mayo, "Molecular Rearrangements," 2 vols., Interscience, New York, 1963 [Mayo-MR]; Stevens and Watts, "Selected Molecular Rearrangements," Van Nostrand Reinhold, London, 1973. For a review of many of these rearrangements, see Collins and Eastham, in Patai, "The Chemistry of the Carbonyl Group," vol. 1, pp. 761–821, Interscience, New York, 1966. See also the series *Mechanisms of Molecular Migrations*.

same molecule (*intramolecular* rearrangement), in which case there must be some continuing tie holding W to the A—B system, preventing it from coming completely free. Strictly speaking, only the intramolecular type fits our definition of a rearrangement, but the general practice, which is followed here, is to include under the title "rearrangement" all net rearrangements whether they are inter- or intramolecular. It is usually not difficult to tell whether a given rearrangement is intramolecular or not. The most common method involves the use of *crossover* experiments. In this type of experiment, rearrangement is carried out on a mixture of W—A—B and V—A—C, where V is closely related to W (say, methyl vs. ethyl) and B to C. In an intramolecular process only A—B—W and A—C—V are recovered, but if the reaction is intermolecular, then not only will these two be found, but also A—B—V and A—C—W.

MECHANISMS

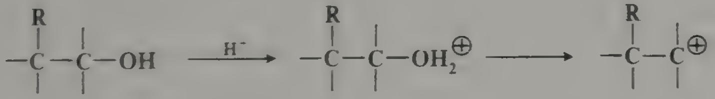
Nucleophilic Rearrangements[2]

Broadly speaking, such rearrangements consist of three steps, of which the actual migration is the second:



This process is sometimes called the Whitmore 1,2 shift.[3] Since the migrating group carries the electron pair with it, the migration terminus B must be an atom with only six electrons in its outer shell (an open sextet). The first step therefore is creation of a system with an open sextet. Such a system can arise in various ways, but two of these are the most important:

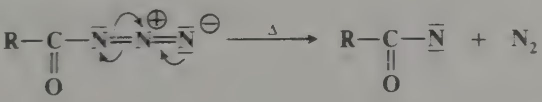
1. *Formation of a carbocation.* These can be formed in a number of ways (see p. 149), but one of the most common methods when a rearrangement is desired is the acid treatment of an alcohol:



2

These two steps are of course the same as the first two steps of the SN1cA or the E1 reactions of alcohols.

2. *Formation of a nitrene.* The decomposition of acyl azides is one of several ways in which nitrenes are formed (see p. 176):



3

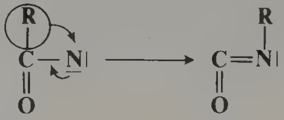
---

[2] For reviews, see Shubin, *Top. Curr. Chem.* **116**-**117**, 267–341 (1984); Saunders, Chandrasekhar, and Schleyer, in Mayo-RGES, Ref. 1, vol. 1, pp. 1–53; Kirmse, *Top. Curr. Chem.* **80**, 89–124 (1979); Wheland, "Advanced Organic Chemistry," 3d ed., pp. 550–619, Wiley, New York, 1960. For a review of rearrangements in vinyl cations, see Shchegolev and Kanishchev, *Russ. Chem. Rev.* **50**, 553–564 (1981).

[3] It was first postulated by Whitmore, *J. Am. Chem. Soc.* **54**, 3274 (1932).

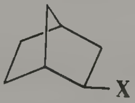
After the migration has taken place, the atom at the migration origin (A) must necessarily have an open sextet. In the third step this atom acquires an octet. In the case of carbocations, the most common third steps are combinations with a nucleophile (rearrangement with substitution) and loss of a hydrogen (rearrangement with elimination).

Though we have presented this mechanism as taking place in three steps, and some reactions do take place in this way, in many cases two or all three steps are simultaneous. For instance, in the nitrene example above, as the R migrates, an electron pair from the nitrogen moves into the C—N bond to give a stable isocyanate:



In this example, the second and third steps are simultaneous. It is also possible for the second and third steps to be simultaneous even when the "third" step involves more than just a simple motion of a pair of electrons. Similarly, there are many reactions in which the first two steps are simultaneous; that is, there is no actual formation of a species such as **2** or **3.** In these instances it may be said that R assists in the removal of the leaving group, with migration of R and the removal of the leaving group taking place simultaneously. Many investigations have been carried out in attempts to determine, in various reactions, whether such intermediates as **2** or **3** actually form, or whether the steps are simultaneous (see, for example, the discussions on pp. 946, 982), but the difference between the two possibilities is often subtle, and the question is not always easily answered.

Evidence for this mechanism is that rearrangements of this sort occur under conditions where we have previously encountered carbocations: SN1 conditions, Friedel–Crafts alkylation, etc. Solvolysis of neopentyl bromide leads to rearrangement products, and the rate increases with increasing ionizing power of the solvent but is unaffected by concentration of base,[4] so that the first step is carbocation formation. The same compound under SN2 conditions gave no rearrangement, but only ordinary substitution, though slowly. Thus with neopentyl bromide, formation of a carbocation leads only to rearrangement. Carbocations usually rearrange to more stable carbocations. Thus the direction of rearrangement is usually primary → secondary → tertiary. Neopentyl (Me_3CCH_2), neophyl ($PhCMe_2CH_2$), and norbornyl (e.g., **4**) type systems are especially prone to carbocation rearrangement reactions. It has been shown that the rate of migration increases with the degree of electron deficiency at the migration terminus.[5]



4

We have previously mentioned (p. 142) that stable tertiary carbocations can be obtained, in solution, at very low temperatures. Nmr studies have shown that when these solutions are warmed, rapid migrations of hydride and of alkyl groups take place, resulting in an equilibrium mixture of structures.[6] For example, the *t*-pentyl cation (**5**)[7] equilibrates as follows:

$$\underset{\mathbf{5}}{\mathrm{CH_3{-}\overset{CH_3}{\underset{\oplus}{C}}{-}CH_2{-}CH_3}} \underset{\text{of H}}{\overset{\text{migration}}{\rightleftharpoons}} \underset{\mathbf{6}}{\mathrm{CH_3{-}\overset{CH_3}{CH}{-}\underset{\oplus}{CH}{-}CH_3}} \underset{\text{of CH}_3}{\overset{\text{migration}}{\rightleftharpoons}}$$

$$\underset{\mathbf{6'}}{\mathrm{CH_3{-}\underset{\oplus}{CH}{-}\overset{CH_3}{CH}{-}CH_3}} \underset{\text{of H}}{\overset{\text{migration}}{\rightleftharpoons}} \underset{\mathbf{5'}}{\mathrm{CH_3{-}CH_2{-}\overset{CH_3}{\underset{\oplus}{C}}{-}CH_3}}$$

Carbocations that rearrange to give products of identical structure (e.g., $\mathbf{5} \rightleftharpoons \mathbf{5'}$, $\mathbf{6} \rightleftharpoons \mathbf{6'}$, or **64** or **65** on p. 286) are called *degenerate carbocations* and such rearrangements are *degenerate rearrangements*. Many examples are known.[8]

The Actual Nature of the Migration

Most nucleophilic 1,2 shifts are intramolecular. W does not become free but always remains connected in some way to the substrate. Apart from the evidence from crossover experiments, the strongest evidence is that when the group W is chiral, the configuration is *retained* in the product. For example, (+)-PhCHMeCOOH was converted to (−)-$\mathrm{PhCHMeNH_2}$ by the Curtius (**8-17**), Hofmann (**8-16**), Lossen (**8-18**), and Schmidt (**8-19**) reactions.[9] In these reactions the extent of retention varied from 95.8 to 99.6%. Retention of configuration in the migrating group has been shown many times since.[10] Another experiment demonstrating retention was the easy conversion of **7** to **8**.[11] Neither inversion nor racemization could take place at a bridgehead. There is much other evidence that retention of configuration usually occurs in W, and inversion never.[12] However, this is not the state of affairs at A and B. In many reactions, of course, the structure of W—A—B

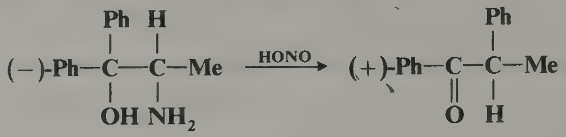
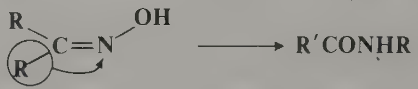
[12] See Cram, in Newman, "Steric Effects in Organic Chemistry," pp. 251–254, Wiley, New York, 1956; Wheland, Ref. 2, pp. 597–604.

is such that the product has only one steric possibility at A or B or both, and in most of these cases nothing can be learned. But in cases where the steric nature of A or B can be investigated, the results are mixed. It has been shown that either inversion or racemization can occur at A or B. Thus the following conversion proceeded with inversion at B:[13]



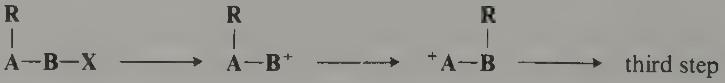
$$(-)\text{-Ph}-\underset{\text{OH}}{\overset{\text{Ph}}{C}}-\underset{\text{NH}_2}{\overset{\text{H}}{C}}-\text{Me} \xrightarrow{\text{HONO}} (+)\text{-Ph}-\underset{\text{O}}{\overset{}{\underset{\|}{C}}}-\underset{\text{H}}{\overset{\text{Ph}}{C}}-\text{Me} \qquad (8\text{-}2)$$

and inversion at A has been shown in other cases.[13] However, in many other cases, racemization occurs at A or B or both.[14] It is not always necessary for the product to have two steric possibilities in order to investigate the stereochemistry at A or B. Thus, in most Beckmann rearrangements (**8-20**), only the group trans (usually called *anti*) to the hydroxyl group migrates:



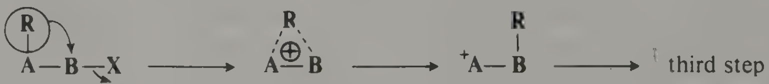
showing inversion at B.

This information tells us about the degree of concertedness of the three steps of the rearrangement. First we shall look at the migration terminus B. If racemization is found at B, then it is probable that the first step takes place before the second and that a positively charged carbon (or other sextet atom) is present at B:



$$\overset{\text{R}}{\underset{|}{\text{A}}}-\text{B}-\text{X} \longrightarrow \overset{\text{R}}{\underset{|}{\text{A}}}-\text{B}^{+} \longrightarrow {}^{+}\text{A}-\overset{\text{R}}{\underset{|}{\text{B}}} \longrightarrow \text{third step}$$

With respect to B this is an SN1-type process. If inversion occurs at B, then it is likely that the first two steps are concerted, that a carbocation is *not* an intermediate, and that the process is SN2-like:



9

In this case participation by R assists in removal of X in the same way that neighboring groups do (p. 268). Indeed, R *is* a neighboring group here. The only difference is that, in the case of the neighboring-group mechanism of nucleophilic substitution, R never becomes detached from A, while in a rearrangement the bond between R and A is broken. In either case, the anchimeric assistance results in an increased rate of reaction. Of course, for such a process to take place, R must be in a favorable geometrical position (R and X anti-periplanar). **9** may be a true intermediate or only a transition state, depending on what migrates. In certain cases of the SN1-type process, it is possible for migration to take place with net retention of configuration at the migrating terminus because of conformational effects in the carbocation.[15]

[13] For inversion at B, see Bernstein and Whitmore, *J. Am. Chem. Soc.* **61,** 1324 (1939). For inversion at A, see Meerwein and van Emster, *Ber.* **53,** 1815 (1920), **55,** 2500 (1922); Meerwein and Gérard, *Liebigs Ann. Chem.* **435,** 174 (1923).

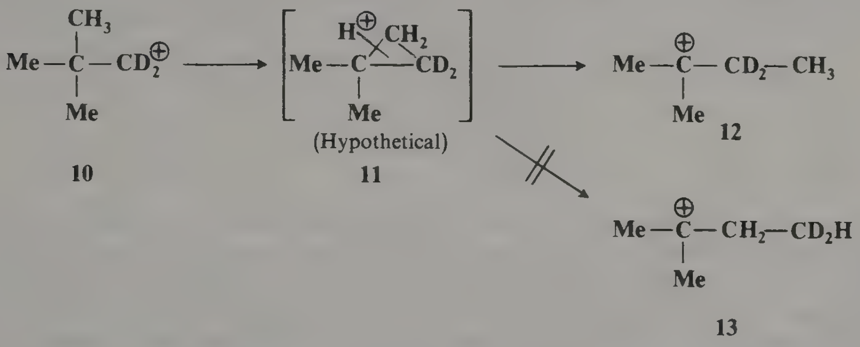
[14] For example, see Winstein and Morse, *J. Am. Chem. Soc.* **74,** 1133 (1952).

[15] Benjamin and Collins, *J. Am. Chem. Soc.* **83,** 3662 (1961); Collins, Staum, and Benjamin, *J. Org. Chem.* **27,** 3525 (1962); Collins and Benjamin, *J. Org. Chem.* **37,** 4358 (1972).

We may summarize a few conclusions:

1. The SN1-type process occurs mostly when B is a tertiary atom or has one aryl group and at least one other alkyl or aryl group. In other cases, the SN2-type process is more likely. Inversion of configuration (indicating an SN2-type process) has been shown for a neopentyl substrate by the use of the chiral neopentyl-1-*d* alcohol.[16] On the other hand, there is other evidence that neopentyl systems undergo rearrangement by a carbocation (SN1-type) mechanism.[17]

2. The question as to whether **9** is an intermediate or a transition state has been much debated. When R is aryl or vinyl, then **9** is probably an intermediate and the migrating group lends anchimeric assistance[18] (see p. 279 for resonance stabilization of this intermediate when R is aryl). When R is alkyl, **9** is a protonated cyclopropane (edge- or corner-protonated; see p. 678). There is much evidence that in simple migrations of a methyl group, the bulk of the products formed do not arise from protonated cyclopropane *intermediates*. Evidence for this statement has already been given (p. 285). Further evidence was obtained from experiments involving labeling. Rearrangement of the neopentyl cation labeled with deuterium in the 1 position (**10**) gave only *t*-pentyl products with the label in the 3 position (derived from **12**), though if **11** were an intermediate, the cyclopropane ring could just as well cleave the other way to give *t*-pentyl derivatives labeled in the 4 position (derived from **13**).[19]



10 **11** **12** **13**

Another experiment that led to the same conclusion was the generation, in several ways, of $\mathrm{Me_3C^{13}CH_2^+}$. In this case the only *t*-pentyl products isolated were labeled in C-3, that is, $\mathrm{Me_2\overset{\oplus}{C}{-}{}^{13}CH_2CH_3}$ derivatives; no derivatives of $\mathrm{Me_2\overset{\oplus}{C}{-}CH_2{}^{13}CH_3}$ were found.[20] Though the bulk of the products are not formed from protonated cyclopropane intermediates, there is considerable evidence that at least in 1-propyl systems, a small part of the product can in fact arise from such intermediates.[21] Among this evidence is the isolation of 10 to 15% cyclopropanes (mentioned on p. 285). Additional evidence comes from propyl cations generated by diazotization of labeled amines ($CH_3CH_2CD_2^+$, $CH_3CD_2CH_2^+$, $CH_3CH_2{}^{14}CH_2^+$), where isotopic distribution in the products indicated that a small amount (about 5%) of the product had to be formed from protonated cyclopropane intermediates, e.g.,[22]

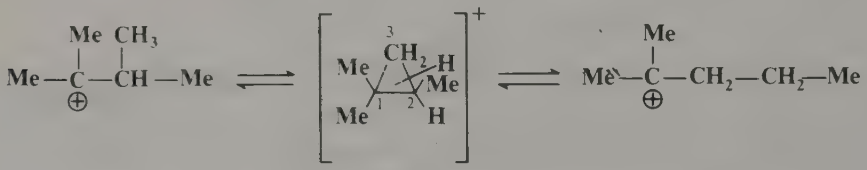
$$CH_3CH_2CD_2NH_2 \xrightarrow{HONO} \sim 1\%\ C_2H_4D{-}CHD{-}OH$$

$$CH_3CD_2CH_2NH_2 \xrightarrow{HONO} \sim 1\%\ C_2H_4D{-}CHD{-}OH$$

$$CH_3CH_2{}^{14}CH_2NH_2 \xrightarrow{HONO} \sim 2\%\ {}^{14}CH_3CH_2CH_2OH + \sim 2\%\ CH_3{}^{14}CH_2CH_2OH$$

Even more scrambling was found in trifluoroacetolysis of 1-propyl-1-^{14}C-mercuric perchlorate.[23] However, protonated cyclopropane intermediates accounted for less than 1% of the products from diazotization of labeled isobutylamine[24] and from formolysis of labeled 1-propyl tosylate.[25]

It is likely that protonated cyclopropane transition states or intermediates are also responsible for certain non-1,2 rearrangements. For example, in super-acid solution, the dimethylisopropylcarbonium ion (**14**) is an equilibrium with the dimethyl-*n*-propylcarbonium ion (**16**). It is not possible for these to interconvert solely by 1,2 alkyl or hydride shifts unless primary carbocations (which are highly unlikely) are intermediates. However, the reaction can be explained[26] by postulating that (in the forward reaction) it is the 1,2 bond of the intermediate or transition state **15** that opens up rather than the 2,3 bond, which is the one that would open if the reaction were a normal 1,2 shift of a methyl group. In this case opening of the 1,2 bond produces a tertiary cation, while opening of the 2,3 bond would give a secondary cation. (In the reaction **16** → **14,** it is of course the 1,3 bond which opens.)



14 **15** **16**

3. There has been much discussion of H as migrating group. There is no conclusive evidence for the viewpoint that **9** in this case is or is not a true intermediate, though both positions have been argued (see p. 285).

The stereochemistry at the migration origin A is less often involved, since in most cases it does not end up as a tetrahedral atom; but when there is inversion here, there is an SN2-type process at the beginning of the migration. This may or may not be accompanied by an SN2 process at the migration terminus B:

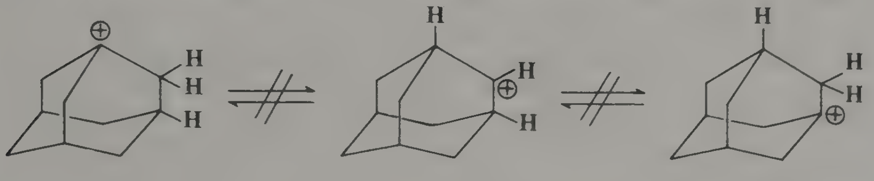
inversion at A and B

inversion at A only

In some cases it has been found that, when H is the migrating species, the configuration at A may be *retained*.[27]

There is evidence that the configuration of the molecule may be important even where the leaving group is gone long before migration takes place. For example, the 1-adamantyl cation (**17**) does not equilibrate intramolecularly, even at temperatures up to 130°C,[28] though open-chain (e.g., **5** ⇌ **5′**) and cyclic tertiary carbocations undergo such equilibration at 0°C or below. On the basis of this and other evidence it has been concluded that for a 1,2 shift of hydrogen or methyl to proceed as smoothly as possible, the vacant *p* orbital of the carbon bearing the positive charge and the sp^3 orbital carrying the migrating group must be coplanar,[28] which is not possible for **17.**



17 **17′**

Migratory Aptitudes[29]

In many reactions there is no question about which group migrates. For example, in the Hofmann, Curtius, and similar reactions there is only one possible migrating group in each molecule, and one can measure migratory aptitudes only by comparing the relative rearrangement rates of different compounds. In other instances there are two or more potential migrating groups, but which migrates is settled by the geometry of the molecule. The Beckmann rearrangement (**8-20**) provides an example. As we have seen, only the group trans to the OH migrates. In compounds whose geometry is not restricted in this manner, there still may be eclipsing effects (see p. 892), so that the choice of migrating group is largely determined by which group is in the right place in the most stable conformation of the molecule.[30] However, in some reactions, especially the Wagner–Meerwein

---

Chem.* **199,** 700 (1971); Kirmse and Arold, *Chem. Ber.* **104,** 1800 (1971); Kirmse, Ratajczak, and Rauleder, *Chem. Ber.* **110,** 2290 (1977).

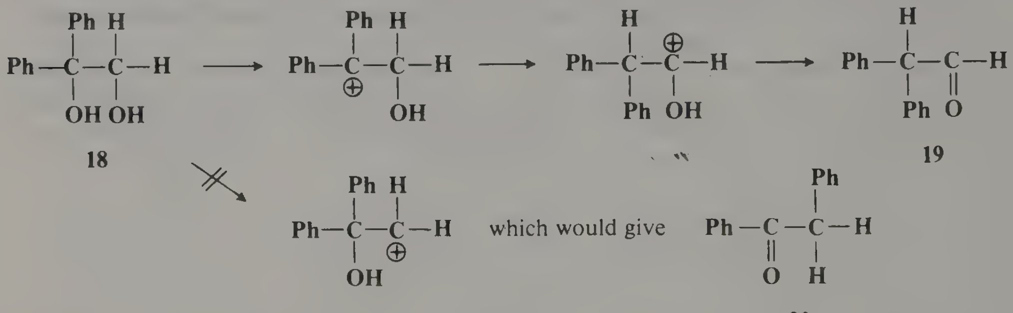
[28] Brouwer and Hogeveen, *Recl. Trav. Chim. Pays-Bas* **89,** 211 (1970); Majerski, Schleyer, and Wolf, *J. Am. Chem. Soc.* **92,** 5731 (1970).

[29] For discussions, see Koptyug and Shubin, *J. Org. Chem. USSR* **16,** 1685–1714 (1980); Wheland, Ref. 2, pp. 573–597.

[30] For a discussion, see Cram, Ref. 12, pp. 270–276. For an interesting example, see Nickon and Weglein, *J. Am. Chem. Soc.* **97,** 1271 (1975).

(**8-1**) and the pinacol (**8-2**) rearrangements, the molecule may contain several groups that, geometrically at least, have approximately equal chances of migrating, and these reactions have often been used for the direct study of relative migratory aptitudes. In the pinacol rearrangement there is the additional question of which OH group leaves and which does not, since a group can migrate only if the OH group on *the other* carbon is lost.

We deal with the second question first. To study this question, the best type of substrate to use is one of the form  $\underset{\text{HO}}{\text{R}_2\text{C}}\text{—}\underset{\text{OH}}{\text{CR}_2'}$, since the only thing that determines migratory aptitude is which OH group comes off. Once the OH group is gone, the migrating group is determined. As might be expected, the OH that leaves is the one whose loss gives rise to the more stable carbocation. Thus 1,1-diphenylethanediol (**18**) gives diphenylacetaldehyde (**19**), not phenylacetophenone (**20**).



21 **20**

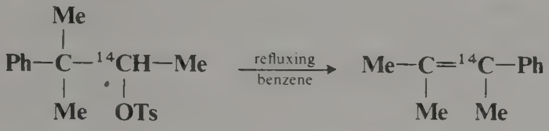
Obviously, it does not matter in this case whether phenyl has a greater inherent migratory aptitude than hydrogen or not. Only the hydrogen can migrate because **21** is not formed. As we have already seen, carbocation stability is enhanced by groups in the order aryl > alkyl > hydrogen, and this normally determines which side loses the OH group. However, exceptions are known, and which group is lost may depend on the reaction conditions (for an example, see the reaction of **40,** p. 963).

In order to answer the question about inherent migratory aptitudes, the obvious type of substrate to use (in the pinacol rearrangement) is  $\underset{\text{HO}}{\text{RR}'\text{C}}\text{—}\underset{\text{OH}}{\text{CRR}'}$, since the same carbocation is formed no matter which OH leaves, and it would seem that a direct comparison of the migratory tendencies of R and R′ is possible. On closer inspection, however, we can see that several factors are operating. Apart from the question of possible conformational effects, already mentioned, there is also the fact that whether the group R or R′ migrates is determined not only by the relative inherent migrating abilities of R and R′ but also by whether the group which does *not* migrate is better at stabilizing the positive charge which will now be found at the migration origin.[31] Thus, migration of R gives rise to the cation $\text{R}'\overset{\oplus}{\text{C}}\text{(OH)CR}_2\text{R}'$, while migration of R′ gives the cation $\text{R}\overset{\oplus}{\text{C}}\text{(OH)CRR}_2'$, and these cations have different stabilities. It is possible that in a given case R might be found to migrate less than R′, not because it actually has a lower inherent migrating tendency, but because it is much better at stabilizing the positive charge. In addition to this factor, migrating ability of a group is also related to its capacity to render anchimeric assistance to the departure of the nucleofuge.

---

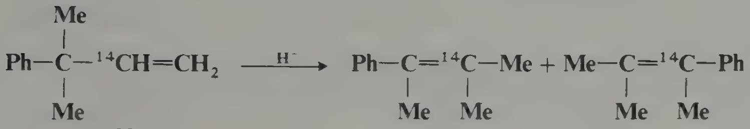
[31] For example, see Howells and Warren, *J. Chem. Soc., Perkin Trans. 2* 1645 (1973); McCall, Townsend and Bonner, *J. Am. Chem. Soc.* **97,** 2743 (1975); Brownbridge, Hodgson, Shepherd, and Warren, *J. Chem. Soc., Perkin Trans. 1* 2024 (1976).

An example of this effect is the finding that in the decomposition of the tosylate **22** only the phenyl group migrates, while in acid treatment of the corresponding alkene **23**, there is competitive



$$\mathrm{Ph{-}\overset{Me}{\underset{Me}{C}}{-}{}^{14}\underset{OTs}{C}H{-}Me \xrightarrow[\text{benzene}]{\text{refluxing}} Me{-}\underset{Me}{C}{=}{}^{14}\underset{Me}{C}{-}Ph}$$

22



$$\mathrm{Ph{-}\overset{Me}{\underset{Me}{C}}{-}{}^{14}CH{=}CH_2 \xrightarrow{H^+} Ph{-}\underset{Me}{C}{=}{}^{14}\underset{Me}{C}{-}Me + Me{-}\underset{Me}{C}{=}{}^{14}\underset{Me}{C}{-}Ph}$$

23

migration of both methyl and phenyl (in these reactions ^{14}C labeling is necessary to determine which group has migrated).[32] **22** and **23** give the same carbocation; the differing results must be caused by the fact that in **22** the phenyl group can assist the leaving group, while no such process is possible for **23.** This example clearly illustrates the difference between migration to a relatively free terminus and one that proceeds with the migrating group lending anchimeric assistance.[33]

It is not surprising therefore that clear-cut answers as to relative migrating tendencies are not available. More often than not migratory aptitudes are in the order aryl > alkyl, but exceptions are known, and the position of hydrogen in this series is often unpredictable. In some cases migration of hydrogen is preferred to aryl migration; in other cases migration of alkyl is preferred to that of hydrogen. Mixtures are often found, and the isomer that predominates often depends on conditions. For example, the comparison between methyl and ethyl has been made many times in various systems, and in some cases methyl migration and in others ethyl migration has been found to predominate.[34] However, it can be said that among aryl migrating groups, electron-donating substituents in the para and meta positions increase the migratory aptitudes, while the same substituents in the ortho positions decrease them. Electron-withdrawing groups decrease migrating ability in all positions. The following are a few of the relative migratory aptitudes determined for aryl groups by Bachmann and Ferguson:[35] *p*-anisyl, 500; *p*-tolyl, 15.7; *m*-tolyl, 1.95; phenyl, 1.00; *p*-chlorophenyl, 0.7; *o*-anisyl, 0.3. For the *o*-anisyl group, the poor migrating ability probably has a steric cause, while for the others there is a fair correlation with activation or deactivation of electrophilic aromatic substitution, which is what the process is with respect to the benzene ring.

Memory Effects[36]

Solvolysis of the endo bicyclic compound **24** (X = ONs, p. 312, or Br) gave mostly the bicyclic allylic alcohol **27,** along with a smaller amount of the tricyclic alcohol **31,** while solvolysis of the exo isomers **28** gave mostly **31,** with smaller amounts of **27.**[37] Thus the two isomers gave entirely different ratios of products, though the carbocation initially formed (**25** or **29**) seems to be the same for each. In the case of **25,** a second rearrangement (a shift of the 1,7 bond) follows, while with **29** it is an intramolecular addition of the positive carbon to the double bond that follows. It seems as if **25** and **29** "remember" how they were formed before they go on to give the second step. Such effects are called *memory effects* and other such cases are also known.[38] The causes of these effects are not well understood, though there has been much discussion. One possible cause is differential solvation of the apparently identical ions **25** and **29.** Other possibilities are: (1) that the ions have geometrical structures that are twisted in opposite senses (e.g., a twisted **29** might have its positive carbon closer to the double bond than a twisted **25**); (2) that ion pairing is responsible;[39] and (3) that nonclassical carbocations are involved.[40] One possibility that has been ruled out is that the steps **24** → **25** → **26** and **28** → **29** → **30** are concerted, so that **25** and **29** never exist at all. This possibility has been excluded by several kinds of evidence, including the fact that **24** gives not only **27,** but also some **31;** and **28** gives some **27** along with **31.** This means that some of the **25** and **29** ions interconvert, a phenomenon known as *leakage.*

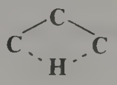
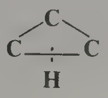
Longer Nucleophilic Rearrangements

The question as to whether a group can migrate with its electron pair from A to C in W—A—B—C or over longer distances has been much debated. Although claims have been made that alkyl groups can migrate in this way, the evidence is that such migration is extremely rare, if it occurs at all. One experiment that demonstrated this was the generation of the 3,3-dimethyl-1-butyl cation $Me_3CCH_2CH_2^+$. If 1,3 methyl migrations are possible, this cation would appear to be a favorable substrate for them, since such a migration would convert a primary cation into the tertiary 2-methyl-2-pentyl cation $Me_2\overset{\oplus}{C}CH_2CH_2CH_3$, while the only possible 1,2 migration (of hydride) would give only a secondary cation. However, no products arising from the 2-methyl-2-pentyl cation were found, the only rearranged products being those formed by the 1,2 hydride migration.[41] 1,3 Migration of bromine has been reported.[42]

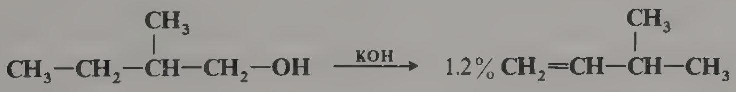
However, most of the debate over the possibility of 1,3 migrations has concerned not methyl or bromine but 1,3 hydride shifts.[43] There is no doubt that *apparent* 1,3 hydride shifts take place (many instances have been found), but the question is whether they are truly direct hydride shifts or whether they occur by another mechanism. There are at least two ways in which indirect 1,3 hydride shifts can take place: (1) by successive 1,2 shifts or (2) through the intervention of protonated cyclopropanes (see p. 948). A direct 1,3 shift would have the transition state **A**, while the transition state for a 1,3 shift involving a protonated cyclopropane intermediate would resemble **B**. The evidence is that most reported 1,3 hydride shifts are actually the result of successive 1,2 migrations,[44] but that in some cases small amounts of products cannot be accounted for in this way. For example, the reaction of 2-methyl-1-butanol with KOH and bromoform gave a mixture of olefins, nearly all of which could have arisen from simple elimination or 1,2 shifts of hydride or alkyl. However, 1.2% of the product was 3-methyl-1-butene (**32**):[45]



A



B



$$CH_3-CH_2-\overset{\displaystyle CH_3}{\overset{|}{CH}}-CH_2-OH \xrightarrow{KOH} 1.2\%\ CH_2{=}CH-\overset{\displaystyle CH_3}{\overset{|}{CH}}-CH_3$$

32

Hypothetically, **32** could have arisen from a 1,3 shift (direct or through a protonated cyclopropane) or from two successive 1,2 shifts:

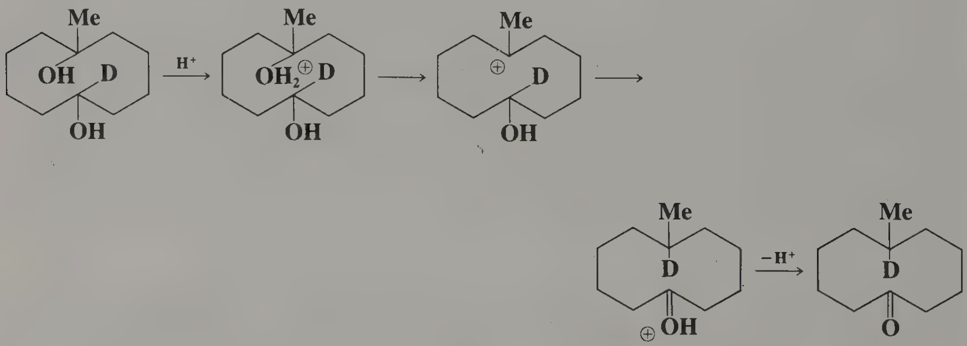
33 **34** **35**

However, the same reaction applied to 2-methyl-2-butanol gave no **32,** which demonstrated that **35** was not formed from **34.** The conclusion was thus made that **35** was formed directly from **33.** This experiment does not answer the question as to whether **35** was formed by a direct shift or through a protonated cyclopropane, but from other evidence[46] it appears that 1,3 hydride shifts that do not result from successive 1,2 migrations usually take place through protonated cyclopropane intermediates (which, as we saw on p. 947, account for only a small percentage of the product in any case). However, there is evidence that direct 1,3 hydride shifts by way of **A** may take place in super-acid solutions.[47]

Although direct nucleophilic rearrangements over distances greater than 1,2 are rare (or perhaps nonexistent) when the migrating atom or group must move along a chain, this is not so for a shift across a ring of 8 to 11 members. Many such transannular rearrangements are known.[48] Several examples are given on p. 135. We look at the mechanism of one of these:[49]



It is noteworthy that the *methyl* group does not migrate in this system. It is generally true that alkyl groups do not undergo transannular migration. In most cases it is hydride that undergoes this type of migration, though a small amount of phenyl migration has also been shown.[50]

---

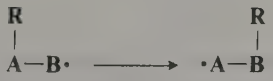
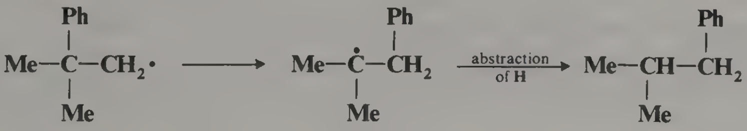
Free-Radical Rearrangements[51]

1,2-Free-radical rearrangements are much less common than the nucleophilic type previously considered, for the reasons mentioned on p. 942. Where they do occur, the general pattern is similar. There must first be generation of a free radical, and then the actual migration in which the migrating group moves with one electron:



$$\overset{R}{\overset{|}{A}}{-}B\cdot \longrightarrow \cdot A{-}\overset{R}{\overset{|}{B}}$$

Finally, the new free radical must stabilize itself by a further reaction. The order of radical stability leads us to predict that here too, as with carbocation rearrangements, any migrations should be in the order primary → secondary → tertiary, and that the logical place to look for them should be in neopentyl and neophyl systems. The most common way of generating free radicals for the purpose of detection of rearrangements is by decarbonylation of aldehydes (**4-40**). In this manner it was found that neophyl radicals *do* undergo rearrangement. Thus, $PhCMe_2CH_2CHO$ treated with di-*t*-butyl peroxide gave about equal amounts of the normal product $PhCMe_2CH_3$ and the product arising from migration of phenyl:[52]



$$Me{-}\underset{Me}{\underset{|}{\overset{Ph}{\overset{|}{C}}}}{-}CH_2\cdot \longrightarrow Me{-}\underset{Me}{\underset{|}{\dot{C}}}{-}\overset{Ph}{\overset{|}{CH_2}} \xrightarrow[\text{of H}]{\text{abstraction}} Me{-}\underset{Me}{\underset{|}{CH}}{-}\overset{Ph}{\overset{|}{CH_2}}$$

Many other cases of free-radical migration of aryl groups have also been found.[53]

It is noteworthy that the extent of migration is much less than with the corresponding carbocations: thus in the example given, there was only about 50% migration, whereas the carbocation would have given much more. Also noteworthy is that there was no migration of the methyl group. In general it may be said that free-radical migration of alkyl groups does not occur at ordinary temperatures. Many attempts have been made to detect such migration on the traditional neopentyl and bornyl types of substrates. However, alkyl migration is not observed, even in substrates where the corresponding carbocations undergo facile rearrangement.[54] Another type of migration that is very common for carbocations, but which is not observed for free radicals, is 1,2 migration of hydrogen. We confine ourselves to a few examples of the lack of migration of alkyl groups and hydrogen:

1. 3,3-Dimethylpentanal($EtCMe_2CH_2CHO$) gave no rearranged products on decarbonylation.[55]

Chem. Rev.* **31,** 1–18 (1962); Walling, in Mayo-MR, Ref. 1, pp. 407–455.

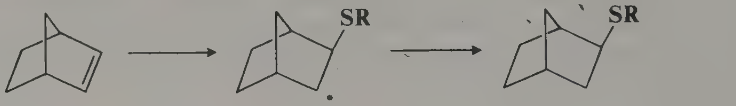
[52] Winstein and Seubold, *J. Am. Chem. Soc.* **69,** 2916 (1947); Seubold, *J. Am. Chem. Soc.* **75,** 2532 (1953). For the observation of this rearrangement by esr, see Hamilton and Fischer, *Helv. Chim. Acta* **56,** 795 (1973).

[53] For example, see Curtin and Hurwitz, *J. Am. Chem. Soc.* **74,** 5381 (1952); Wilt and Philip, *J. Org. Chem.* **24,** 441 (1959), **25,** 891 (1960); Pines and Goetschel, *J. Am. Chem. Soc.* **87,** 4207 (1965); Goerner, Cote, and Vittimberga, *J. Org. Chem.* **42,** 19 (1977); Collins, Roark, Raaen, and Benjamin, *J. Am. Chem. Soc.* **101,** 1877 (1979); Walter and McBride, *J. Am. Chem. Soc.* **103,** 7069, 7074 (1981).

[54] For a summary of unsuccessful attempts, see Slaugh, Magoon, and Guinn, *J. Org. Chem.* **28,** 2643 (1963).

[55] Seubold, *J. Am. Chem. Soc.* **76,** 3732 (1954).

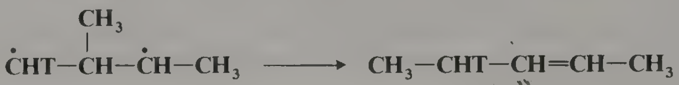
2. Addition of RSH to norbornene gave only *exo*-norbornyl sulfides, though **36** is an intermediate, and the corresponding carbocation cannot be formed without rearrangement.[56]



36

3. It was shown[57] that no rearrangement of isobutyl radical to *t*-butyl radical (which would involve the formation of a more stable radical by a hydrogen shift) took place during the chlorination of isobutane.

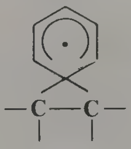
However, 1,2 migration of alkyl groups has been shown to occur in certain *diradicals*.[58] For example, the following rearrangement has been established by tritium labeling.[59]



$$\dot{C}HT-\underset{}{\overset{CH_3}{\overset{|}{C}}}H-\dot{C}H-CH_3 \longrightarrow CH_3-CHT-CH=CH-CH_3$$

In this case the fact that migration of the methyl group leads directly to a compound in which all electrons are paired undoubtedly contributes to the driving force of the reaction.

The fact that aryl groups migrate, but alkyl groups and hydrogen generally do not, leads to the proposition that **37**, in which the odd electron is not found in the three-membered ring, may



37

be an intermediate. There has been much controversy on this point, but the bulk of the evidence indicates that **37** is a transition state, not an intermediate. Among the evidence is the failure to observe **37** either by esr[60] or CIDNP.[61] Both of these techniques can detect free radicals with extremely short lifetimes (pp. 162–163).[62]

Besides aryl, vinyl[63] and acetoxy groups[64] also migrate. Vinyl groups migrate by way of a cyclopropylcarbinyl radical intermediate,[65] while the migration of acetoxy groups may involve the charge-separated structure shown.[66] In addition, migration has been observed for chloro (and to a much lesser extent bromo) groups. For example, in the reaction of $Cl_3CCH{=}CH_2$ with bromine under the influence of peroxides, the products were 47% $Cl_3CCHBrCH_2Br$ (the normal addition product) and 53% $BrCCl_2CHClCH_2Br$, which arose by rearrangement:

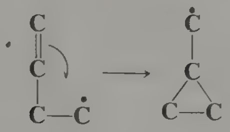
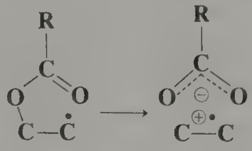
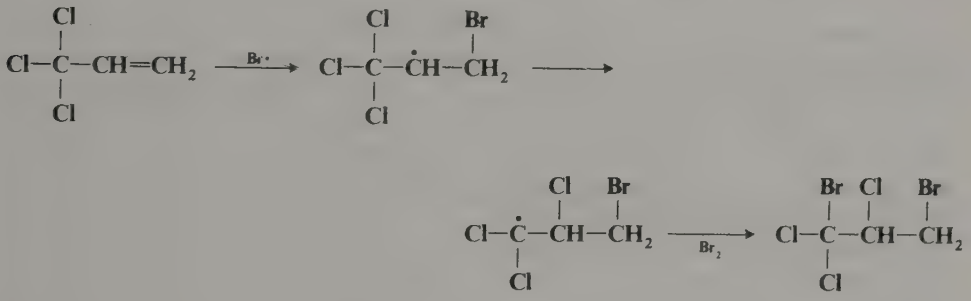
[62] For other evidence, see Martin, *J. Am. Chem. Soc.* **84,** 1986 (1962); Rüchardt and Hecht, *Tetrahedron Lett.* 957 (1962), *Chem. Ber.* **98,** 2460, 2471 (1965); Rüchardt and Trautwein, *Chem. Ber.* **98,** 2478 (1965).

[63] For example, see Slaugh, Mullineaux, and Raley, *J. Am. Chem. Soc.* **85,** 3180 (1963); Slaugh, *J. Am. Chem. Soc.* **87,** 1522 (1965).

[64] Surzur and Teissier, *C. R. Acad. Sci., Ser. C* **264,** 1981 (1967); *Bull. Soc. Chim. Fr.* 3060 (1970); Tanner and Law, *J. Am. Chem. Soc.* **91,** 7535 (1969); Julia and Lorne, *C. R. Acad. Sci., Ser. C* **273,** 174 (1971); Lewis, Miller, and Winstein, *J. Org. Chem.* **37,** 1478 (1972).







$$Cl_3C{-}CH{=}CH_2 \xrightarrow{Br\cdot} Cl_3C{-}\dot{C}H{-}CH_2Br \longrightarrow Cl_2\dot{C}{-}CHCl{-}CH_2Br \xrightarrow{Br_2} BrCCl_2{-}CHCl{-}CH_2Br$$

In this particular case the driving force for the rearrangement is the particular stability of dichloroalkyl free radicals. Nesmeyanov, Freidlina, and co-workers have extensively studied reactions of this sort.[67] It has been shown that the 1,2 migration of Cl readily occurs if the migration origin is tertiary and the migration terminus primary.[68] Migration of Cl and Br could take place by a transition state in which the odd electron is accommodated in a vacant *d* orbital of the halogen.

In summary then, 1,2 free-radical migrations are much less prevalent than the analogous carbocation processes, and are important only for aryl, vinyl, acetoxy, and halogen migrating groups. The direction of migration is normally toward the more stable radical, but "wrong-way" rearrangements are also known.[69]

Despite the fact that hydrogen atoms do not migrate 1,2, longer free-radical migrations of hydrogen are known.[70] The most common are 1,5 shifts, but 1,6 and longer shifts have also been found. The possibility of 1,3 hydrogen shifts has been much investigated, but it is not certain if any actually occur. If they do they are rare, presumably because the most favorable geometry for

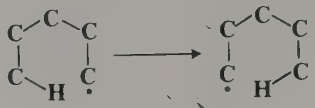
[70] For a discussion, see Freidlina and Terent'ev, *Acc. Chem. Res.* **10,** 9–15 (1977).

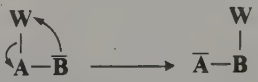
C---H---C in the transition state is linear and this geometry cannot be achieved in a 1,3 shift. 1,4 shifts are definitely known, but are still not very common. These long shifts may be regarded as internal abstractions of hydrogen (for reactions involving them, see **4-7** and **8-44**):



Transannular shifts of hydrogen atoms have also been observed.[71] A few shifts longer than 1,2 have been noted for aryl, but not for alkyl or halogen groups.

Electrophilic Rearrangements[72]

Rearrangements in which a group migrates without its electrons are much rarer than the two kinds previously considered, but the general principles are the same. A carbanion (or other negative ion) is created first, and the actual rearrangement step involves migration of a group without its electrons:



The product of the rearrangement may be stable or may react further, depending on its nature (see also pp. 962–963).

REACTIONS

The reactions in this chapter are classified into three main groups. 1,2 Shifts are considered first. Within this group, reactions are classified according to (1) the identity of the substrate atoms A and B and (2) the nature of the migrating group W. In the second group are the cyclic rearrangements. The third group consists of rearrangements that cannot be fitted into either of the first two categories.

Reactions in which the migration terminus is on an aromatic ring have been treated under aromatic substitution. These are **1-32** to **1-38, 1-42, 3-26** to **3-29,** and, partially, **1-39, 1-44,** and **1-45.** Double-bond shifts have also been treated in other chapters, though they may be considered rearrangements (p. 287, p. 520, and **2-2**). Another reaction that may be regarded as a rearrangement is the Willgerodt reaction (**9-73**).

(if $R^4 = H$)

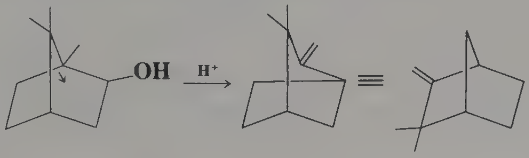
(if R^2 has an α hydrogen)

R = alkyl, aryl, or hydrogen

When alcohols are treated with acids, simple substitution (e.g., **0-68**) or elimination (**7-1**) usually accounts for most or all of the products. But in many cases, especially where two or three alkyl or aryl groups are on the β-carbon, some or all of the product is rearranged. These rearrangements are called *Wagner–Meerwein rearrangements.*[73] As pointed out previously, the carbocation that is a direct product of the rearrangement must stabilize itself, and most often it does this by the loss of a hydrogen β to it, so that the rearrangement product is usually an olefin. The proton lost may be R^4 (if this is a hydrogen) or an α-proton from R^2 (if it has one). If there is a choice of protons, Zaitsev's rule (p. 889) governs the direction, as we might expect. Sometimes a different positive group is lost instead of a proton.[74] Less often, the new carbocation stabilizes itself by combining with a nucleophile instead of losing a proton. The nucleophile may be the water which is the original leaving group, so that the product is a rearranged alcohol, or it may be some other species present, which we have called Y. Rearrangement is usually predominant in neopentyl and neophyl types of substrates, and with these types normal nucleophilic substitution is difficult (normal elimination of course impossible). Under SN2 conditions, substitution is extremely slow;[75] under SN1 conditions, carbocations are formed that rapidly rearrange. However, free-radical substitution, unaccompanied by rearrangement, can be carried out on neopentyl systems, though, as we have seen (p. 955), neophyl systems undergo rearrangement as well as substitution.

Wagner–Meerwein rearrangements were first discovered in the bicyclic terpenes, and most of the early development of this reaction was with these compounds.[76] An example is

Example *a*



isoborneol camphene

---

[73] For a review, see Pocker, in Mayo-MR, Ref. 1, vol. 1, pp. 6–15. See also Ref. 2.

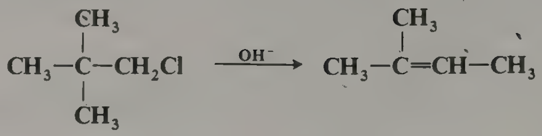
[74] For example, see Grob, Hoegerle, and Ohta, *Helv. Chim. Acta* **45,** 1823 (1962).

[75] See, however, Chapter 10, Ref. 226.

[76] For reviews of rearrangements in bicyclic systems, see Hogeveen and van Kruchten, *Top. Curr. Chem.* **80,** 89–124 (1979); Berson, in Mayo-MR, Ref. 1, pp. 111–231. For reviews of the Wagner–Meerwein rearrangement applied to natural products, see Mayo-MR, Ref. 1, as follows: King and Mayo, pp. 813–840 (terpenes); Warnhoff, pp. 842–879 (alkaloids); Wendler, pp. 1020–1028 (steroids). For reviews concerning caranes and pinanes see, respectively, Arbuzov and Isaeva, *Russ. Chem. Rev.* **45,** 673–683 (1976); Banthorpe and Whittaker, *Q. Rev., Chem. Soc.* **20,** 373–387 (1966).

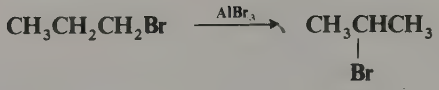
Examples in simpler systems are:

Example *b*



$$CH_3-\overset{\overset{\displaystyle CH_3}{|}}{\underset{\underset{\displaystyle CH_3}{|}}{C}}-CH_2Cl \xrightarrow{OH^-} CH_3-\overset{\overset{\displaystyle CH_3}{|}}{C}=CH-CH_3$$

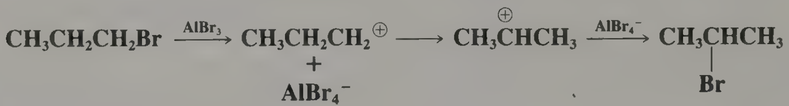
Example *c*



$$CH_3CH_2CH_2Br \xrightarrow{AlBr_3} CH_3\underset{\underset{\displaystyle Br}{|}}{C}HCH_3$$

These examples illustrate the following points:

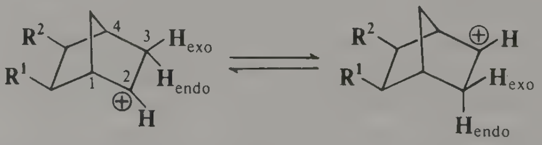
1. Hydride ion can migrate. In example *c*, it was hydride that shifted, not bromide:



$$CH_3CH_2CH_2Br \xrightarrow{AlBr_3} \underset{\displaystyle AlBr_4^-}{\underset{+}{CH_3CH_2CH_2^{\oplus}}} \longrightarrow CH_3\overset{\oplus}{C}HCH_3 \xrightarrow{AlBr_4^-} CH_3\underset{\underset{\displaystyle Br}{|}}{C}HCH_3$$

2. The leaving group does not have to be H_2O, but can be any departing species whose loss creates a carbocation, including N_2 from aliphatic diazonium ions[77] (see the section on leaving groups in nucleophilic substitution, p. 310). Also, rearrangement may follow when the carbocation is created by addition of a proton or other positive species to a double bond. Even alkanes give rearrangements when heated with Lewis acids, provided some species is initially present to form a carbocation from the alkane.
3. Example *c* illustrates that the last step may be substitution instead of elimination.
4. Example *b* illustrates that the new double bond is formed in accord with Zaitsev's rule.

2-Norbornyl cations, besides displaying the 1,2 shifts of a CH_2 group previously illustrated for the isoborneol → camphene conversion, are also prone to rapid hydride shifts from the 3 to the 2 position (known as 3,2 shifts). These 3,2 shifts usually take place from the exo side;[78] that is, the



3-exo hydrogen migrates to the 2-exo position.[79] This stereoselectivity is analogous to the behavior we have previously seen for norbornyl systems, namely, that nucleophiles attack norbornyl cations from the exo side (p. 281) and that addition to norbornenes is also usually from the exo direction (p. 676).

The direction of rearrangement is usually towards the most stable carbocation (or free radical), which is tertiary > secondary > primary, but rearrangements in the other direction have also been found,[80] and often the product is a mixture corresponding to an equilibrium mixture of the possible carbocations.

---

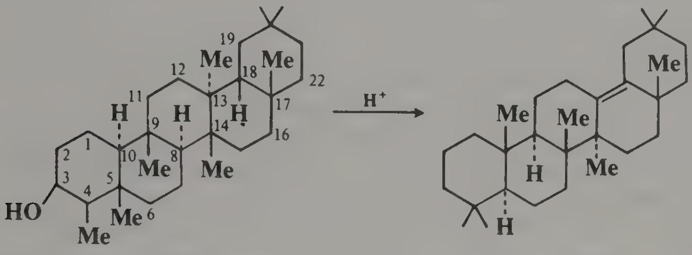
[77] For reviews of rearrangements arising from diazotization of aliphatic amines, see, in Patai, "The Chemistry of the Amino Group," Interscience, New York, 1968, the articles by White and Woodcock, pp. 407–497 (pp. 473–483) and by Banthorpe, pp. 585–667 (pp. 586–612).

[78] For example, see Kleinfelter and Schleyer, *J. Am. Chem. Soc.* **83,** 2329 (1961); Collins, Cheema, Werth, and Benjamin, *J. Am. Chem. Soc.* **86,** 4913 (1964); Berson, Hammons, McRowe, Bergman, Remanick, and Houston, *J. Am. Chem. Soc.* **89,** 2590 (1967).

[79] For examples of 3,2 endo shifts, see Bushell and Wilder, *J. Am. Chem. Soc.* **89,** 5721 (1967); Wilder and Hsieh, *J. Org. Chem.* **36,** 2552 (1971).

The term "Wagner–Meerwein rearrangement" is not precise. Some use it to refer to all the rearrangements in this section and in **8-2.** Others use it only when an alcohol is converted to a rearranged olefin. Terpene chemists call the migration of a methyl group the *Nametkin rearrangement*. The term *retropinacol rearrangement* is often applied to some or all of these. Fortunately, this disparity in nomenclature does not seem to cause much confusion.

Sometimes several of these rearrangements occur in one molecule, either simultaneously or in rapid succession. A spectacular example is found in the triterpene series. Friedelin is a triterpenoid ketone found in cork. Reduction gives 3β-friedelanol (**38**). When this compound is treated with acid, 13(18)-oleanene (**39**) is formed.[81] In this case *seven* 1,2 shifts take place. On removal of H_2O



38 **39**

from position 3 to leave a positive charge, the following shifts occur: hydride from 4 to 3; methyl from 5 to 4; hydride from 10 to 5; methyl from 9 to 10; hydride from 8 to 9; methyl from 14 to 8; and methyl from 13 to 14. This leaves a positive charge at position 13, which is stabilized by loss of the proton at the 18 position to give the 13(18)-ene. Until the elimination, each time a positive charge is formed, migration of a hydride or a methyl moves in to fill it, leaving another positive charge, which must be filled in its turn. All these shifts are stereospecific, the group always migrating on the side of the ring system on which it is located; that is, a group above the "plane" of the ring system (indicated by a solid line in **39**) moves above the plane, and a group below the plane (dashed line) moves below it. It is probable that the seven shifts are not all concerted, though some of them may be, for intermediate products can be isolated.[82] As an illustration of point 2 (p. 960), it may be mentioned that friedelene, derived from dehydration of **38,** also gives **39** on treatment with acid.[83]

It was mentioned above that even alkanes undergo Wagner–Meerwein rearrangements if treated with Lewis acids and a small amount of initiator. An interesting application of this reaction is the conversion of tricyclic molecules to adamantane and its derivatives.[84] It has been found that *all* tricyclic alkanes containing 10 carbons are converted to adamantane by treatment with a Lewis acids such as $AlCl_3$. If the substrate contains more than 10 carbons, alkyl-substituted adamantanes are produced. Some examples are

Diamantane

If 14 or more carbons are present, the product may be diamantane or a substituted diamantane.[85] These reactions are successful because of the high thermodynamic stability of adamantane, diamantane, and similar diamond-like molecules. The most stable of a set of C_nH_m isomers (called the *stabilomer*) will be the end product if the reaction reaches equilibrium.[86] Best yields are obtained by the use of ''sludge'' catalysts[87] (i.e., a mixture of AlX_3 and *t*-butyl bromide or *sec*-butyl bromide) or by passing the substrate in the gas phase through a tube containing a chlorinated platinum–alumina catalyst.[88] Though it is certain that these adamantane-forming reactions take place by nucleophilic 1,2 shifts, the exact pathways are not easy to unravel because of their complexity.[89] Treatment of adamantane-2-^{14}C with $AlCl_3$ results in total carbon scrambling on a statistical basis.[90]

As already indicated, the mechanism of the Wagner–Meerwein rearrangement is usually nucleophilic. Free-radical rearrangements are also known (see the mechanism section of this chapter), though virtually only with aryl migration. However, carbanion mechanisms (electrophilic) have also been found.[72] Thus Ph_3CCH_2Cl treated with sodium gave Ph_2CHCH_2Ph along with unrearranged products.[91] The intermediate is $Ph_3C\overline{C}H_2^{\ominus}$, and the phenyl moves without its electron pair. There is evidence that the reaction involves a tight ion pair.[92] Only aryl and not alkyl groups migrate by the electrophilic mechanism (p. 942) and a transition state analogous to **37** is likely.[93]

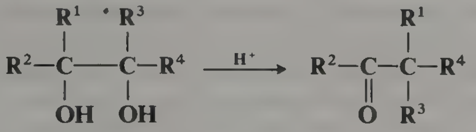
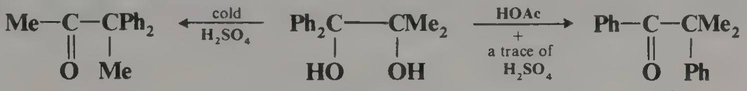
8-2 The Pinacol Rearrangement



R = alkyl, aryl, or hydrogen

When *vic*-diols (glycols) are treated with acids, they can be rearranged to give aldehydes or ketones, though elimination without rearrangement can also be accomplished. This reaction is called the *pinacol rearrangement;* the reaction gets its name from the typical compound pinacol $Me_2COHCOHMe_2$, which is rearranged to pinacolone Me_3CCOCH_3.[94] The reaction has been accomplished many times, with alkyl, aryl, hydrogen, and even ethoxycarbonyl (COOEt)[95] as migrating groups. In most cases each carbon has at least one alkyl or aryl group, and the reaction is most often carried out with tri- and tetrasubstituted glycols. As mentioned earlier, glycols in which the four R groups are not identical can give rise to more than one product, depending on which group migrates (see p. 950 for a discussion of migratory aptitudes). Mixtures are often produced, and which group preferentially migrates may depend on the reaction conditions as well as on the nature of the substrate. Thus the action of cold, concentrated sulfuric acid on **40** produces mainly the ketone **41** (methyl migration),



41 **40** **42**

while treatment of **40** with acetic acid containing a trace of sulfuric acid gives mostly **42** (phenyl migration).[96] If at least one R group is hydrogen, aldehydes can be produced as well as ketones. Generally, aldehyde formation is favored by the use of mild conditions (lower temperatures, weaker acids), because under more drastic conditions the aldehydes may be converted to ketones (**8-4**).

The mechanism involves a simple 1,2 shift. The ion **43** (where all four R groups are Me) has been trapped by the addition of tetrahydrothiophene.[97] It may seem odd that a migration takes place

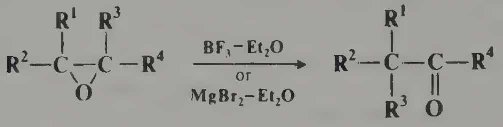
when the positive charge is already at a tertiary position, but carbocations stabilized by an oxygen atom are even more stable than tertiary alkyl cations (p. 146). There is also the driving force supplied by the fact that the new carbocation can immediately stabilize itself by losing a proton.

It is obvious that other compounds in which a positive charge can be placed on a carbon α to one bearing an OH group can also give this rearrangement. This is true for β-amino alcohols, which rearrange on treatment with nitrous acid (this is called the *semipinacol* rearrangement), iodohydrins, for which the reagent is mercuric oxide or silver nitrate, and allylic alcohols, which can rearrange on treatment with a strong acid that protonates the double bond. A similar rearrangement is given by epoxides, when treated with acidic[98] reagents such as BF_3-etherate or $MgBr_2$-etherate, or sometimes by heat alone.[99] It has been shown that epoxides are intermediates in the pinacol rearrangements of certain glycols.[100] Among the evidence[101] for the mechanism given is that $Me_2COHCOHMe_2$, $Me_2COHCNH_2Me_2$, and $Me_2COHCClMe_2$ gave the reaction at different rates (as expected) but yielded the *same mixture* of two products—pinacol and pinacolone—indicating a common intermediate.[102]



R = alkyl, aryl, or hydrogen

Epoxides can also be rearranged to aldehydes or ketones on treatment with certain transition-metal catalysts.[103] A good way to prepare β-diketones consists of heating α,β-epoxy ketones at 80–140°C in toluene with small amounts of $(Ph_3P)_4Pd$ and 1,2-bis(diphenylphosphino)ethane.[104]

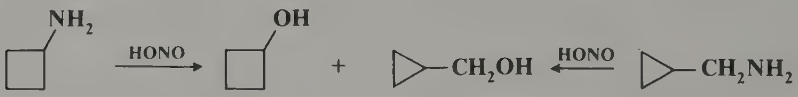
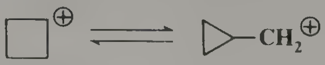
8-3 Expansion and Contraction of Rings



When a positive charge is formed on an alicyclic carbon, migration of an alkyl group can take place to give ring contraction, producing a ring that is one carbon smaller than the original.



Note that this change involves conversion of a secondary to a primary carbocation. In a similar manner, when a positive charge is placed on a carbon α to an alicyclic ring, ring expansion can take place.[105] The new carbocation, and the old one, may then give products by combination with a nucleophile (e.g., the alcohols shown above), or by elimination, so that this reaction is really a special case of **8-1.** Often, both rearranged and unrearranged products are formed, so that, for example, cyclobutylamine and cyclopropylmethylamine give similar mixtures of the two alcohols shown above on treatment with nitrous acid (a small amount of 3-buten-1-ol is also produced). When the carbocation is formed by diazotization of an amine, the reaction is called the *Demyanov rearrangement,*[106] but of course similar products are formed when the carbocation is generated in other ways. The expansion reaction has been performed on rings of C_3 to C_8,[107] but yields are best with the smaller rings, where relief of small-angle strain provides a driving force for the reaction. The contraction reaction has been applied to four-membered rings and to rings of C_6 to C_8, but contraction of a cyclopentyl cation to a cyclobutylmethyl system is generally not feasible because of the additional strain involved. Strain is apparently much less of a factor in the cyclobutyl–cyclopropylmethyl interconversion (for a discussion of this interconversion, see p. 283).

---

[98] Epoxides can also be rearranged with basic catalysts, though the products are usually different. For a review, see Yandovskii and Ershov, *Russ. Chem. Rev.* **41,** 403–410 (1972).

[99] For a review, see Parker and Isaacs, *Chem. Rev.* **59,** 737–799 (1959), pp. 772–778.

[100] See, for example, Matsumoto, *Tetrahedron* **24,** 6851 (1968); Pocker and Ronald, *J. Am. Chem. Soc.* **92,** 3385 (1970), *J. Org. Chem.* **35,** 3362 (1970); Tamura and Moriyoshi, *Bull. Chem. Soc. Jpn.* **47,** 2942 (1974).

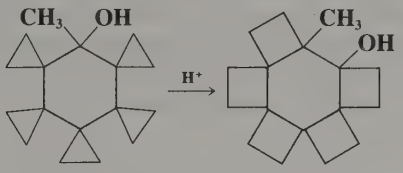
[101] See also Herlihy, *Aust. J. Chem.* **34,** 107 (1981).

[102] Pocker, *Chem. Ind.* (*London*) 332 (1959).

[103] For example, see Alper, Des Roches, Durst, and Legault, *J. Org. Chem.* **41,** 3611 (1976); Milstein, Buchman, and Blum, *J. Org. Chem.* **42,** 2299 (1977).

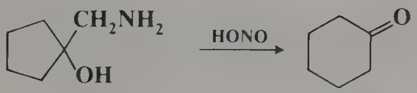
[104] Suzuki, Watanabe, and Noyori, *J. Am. Chem. Soc.* **102,** 2095 (1980).

An interesting example of a cascade of ring expansions, similar to the friedelin example described in **8-1,** is the conversion of 16-methylpentaspiro[2.0.2.0.2.0.2.0.2.1]hexadecan-16-ol (**44**) to 2-methylhexacyclo[12.2.0.$0^{2,5}$.$0^{5,8}$.$0^{8,11}$.$0^{11,14}$]hexadecan-1-ol (**45**) on treatment with *p*-toluenesulfonic acid in acetone–water.[108] The student may wish to write out the mechanism as an exercise.

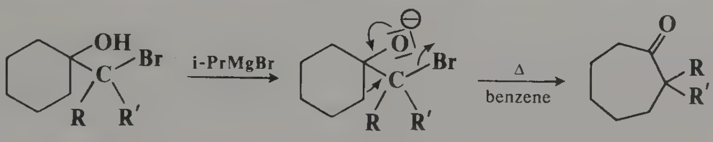


44 **45**

Ring expansions of certain hydroxyamines, e.g.,



are analogous to the semipinacol rearrangement (**8-2**). This reaction is called the *Tiffeneau–Demyanov ring expansion.* These have been performed on rings of C_4 to C_8 and the yields are better than for the simple Demyanov ring expansion. A similar reaction has been used to expand rings of from five to eight members.[109] In this case, a cyclic bromohydrin of the form **46** is treated with



46 **47**

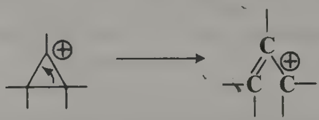
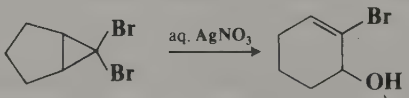
a Grignard reagent which, acting as a base, removes the OH proton to give the alkoxide **47.** Refluxing of **47** brings about the ring enlargement. The reaction has been accomplished for **46,** in which at least one R group is phenyl or methyl,[110] but fails when both R groups are hydrogen.[111]

A positive charge generated on a three-membered ring gives "contraction" to an allylic cation.[112]



We have previously seen (p. 304) that this is the reason nucleophilic substitutions are not feasible at a cyclopropyl substrate. The reaction is often used to convert cyclopropyl halides and tosylates to allylic products, especially for the purpose of ring expansion, an example being[113]



The stereochemistry of these cyclopropyl cleavages is governed by the principle of orbital symmetry conservation (for a discussion, see p. 1011).

Three-membered rings can also be cleaved to unsaturated products in at least two other ways. (1) On pyrolysis, cyclopropanes may undergo "contraction" to propenes.[114] In the simplest case, cyclopropane gives propene when heated to 400 to 500°C. The mechanism is generally regarded[115] as involving a diradical intermediate[116] (recall that free-radical 1,2 migration is possible for diradicals, p. 956). (2) The generation of a carbene or carbenoid carbon in a three-membered ring can lead to allenes, and allenes are often prepared in this way.[117] One way to generate such a species is treatment of a 1,1-dihalocyclopropane with an alkyllithium compound (**2-38**).[118] In

[114] For reviews, see Berson, in Mayo-RGES, Ref. 1, vol. 1, pp. 324–352, *Ann. Rev. Phys. Chem.* **28,** 111–132 (1977); Bergman, in Kochi, Ref. 51, vol. 1, pp. 191–237; Frey, *Adv. Phys. Org. Chem.* **4,** 147–193 (1966), pp. 148–170; Breslow, in Mayo-MR, Ref. 1, pp. 234–245.

[115] For evidence that diradical intermediates may not be involved, at least in some cases, see Fields, Haszeldine, and Peter, *Chem. Commun.* 1081 (1967); Parry and Robinson, *Chem. Commun.* 1083 (1967); Holbrook and Parry, *J. Chem. Soc. B* 1019 (1970); Clifford and Holbrook, *J. Chem. Soc., Perkin Trans. 2* 1972 (1972); Baldwin and Grayston, *J. Am. Chem. Soc.* **96,** 1629, 1630 (1974).

[116] We have seen before that such diradicals can close up to give cyclopropanes (**7-49**). Therefore, pyrolysis of cyclopropanes can produce not only propenes but also isomerized (cis → trans or optically active → inactive) cyclopropanes. See, for example, Berson and Balquist, *J. Am. Chem. Soc.* **90,** 7343 (1968); Bergman and Carter, *J. Am. Chem. Soc.* **91,** 7411 (1969).

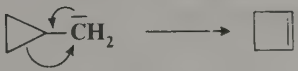
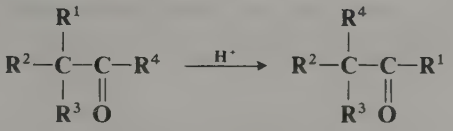
[118] See Baird and Baxter, *J. Chem. Soc., Perkin Trans. 1* 2317 (1979), and references cited therein.

contrast, the generation of a carbene or carbenoid at a cyclopropylmethyl carbon gives ring expansion.[119]



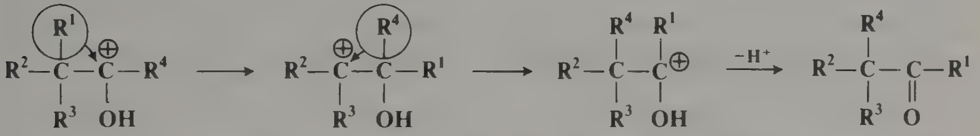
OS **III,** 276; **IV,** 221, 957; **V,** 306, 320; **51,** 60; **56,** 32; **60,** 6, 20, 25.

8-4 Acid-Catalyzed Rearrangements of Aldehydes and Ketones

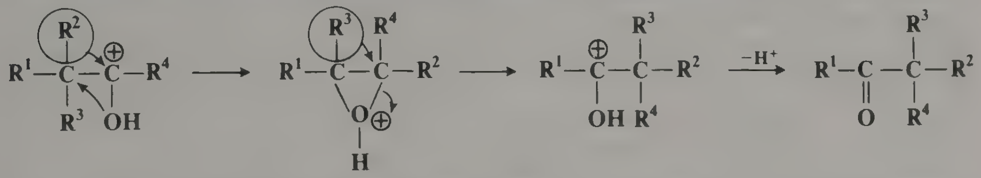


$$R^2-\overset{\overset{\Large R^1}{|}}{\underset{\underset{\Large R^3}{|}}{C}}-\underset{\underset{\Large O}{\|}}{C}-R^4 \xrightarrow{H^+} R^2-\overset{\overset{\Large R^4}{|}}{\underset{\underset{\Large R^3}{|}}{C}}-\underset{\underset{\Large O}{\|}}{C}-R^1$$

Rearrangements of this type, where a group α to a carbonyl "changes places" with a group attached to the carbonyl carbon, occur when migratory aptitudes are favorable.[120] R^2, R^3, and R^4 may be alkyl or hydrogen. Certain aldehydes have been converted to ketones, and ketones to other ketones (though more drastic conditions are required for the latter), but no rearrangement of a ketone to an aldehyde (R^1 = H) has so far been reported. There are two mechanisms,[121] each beginning with protonation of the oxygen and each involving two migrations. In one mechanism, the migrations are in opposite directions:[122]



In the other pathway the migrations are in the same direction. The actual mechanism of this pathway is not certain, but an epoxide (protonated) intermediate[123] is one possibility:[124]



If the reaction is carried out with ketone labeled in the C=O group with ^{14}C, then the first pathway predicts that the product will contain all the ^{14}C in the C=O carbon, while in the second pathway the label will be in the α-carbon (demonstrating migration of oxygen). The results of such experiments[125] have shown that in some cases only the C═O carbon was labeled, in other cases only the α-carbon, while in still others both carbons bore the label, indicating that in these cases both pathways were in operation. With α-hydroxy aldehydes and ketones, the process may stop after only one migration (this is called the *α-ketol rearrangement*).

---

[120] For reviews, see Fry, *Mech. Mol. Migr.* **4,** 113–196 (1971); Collins and Eastham, in Patai, Ref. 1, pp. 771–790.

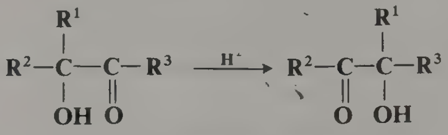
[121] Favorskii and Chilingaren, *C. R. Acad. Sci.* **182,** 221 (1926).

[122] Raaen and Collins, *J. Am. Chem. Soc.* **80,** 1409 (1958); Kendrick, Benjamin, and Collins, *J. Am. Chem. Soc.* **80,** 4057 (1958); Rothrock and Fry, *J. Am. Chem. Soc.* **80,** 4349 (1958); Collins and Bowman, *J. Am. Chem. Soc.* **81,** 3614 (1959).

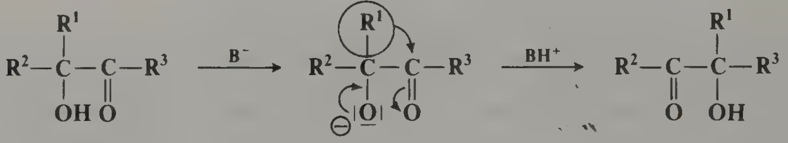
[123] Zook, Smith, and Greene, *J. Am. Chem. Soc.* **79,** 4436 (1957).

[124] Some such pathway is necessary to account for the migration of oxygen that is found. It may involve a protonated epoxide, a 1,2-diol, or simply a 1,2 shift of an OH group.

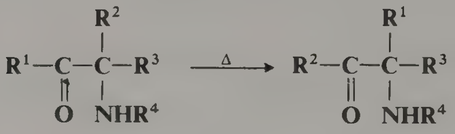
[125] See, for example, Barton and Porter, *J. Chem. Soc.* 2483 (1956); Fry, Carrick, and Adams, *J. Am. Chem. Soc.* **80,** 4743 (1958); Oka and Fry, *J. Org. Chem.* **35,** 2801 (1970); Zalesskaya and Remizova, *J. Gen. Chem. USSR* **35,** 29 (1965); Oka, Hinton, Fry, and Whaley, *J. Org. Chem.* **44,** 3545 (1979); Fry and Oka, *J. Am. Chem. Soc.* **101,** 6353 (1979).



The α-ketol rearrangement can also be brought about by base catalysis, but only if the alcohol is tertiary, since if R^1 or R^2 = hydrogen, enolization of the substrate is more favored than rearrangement.

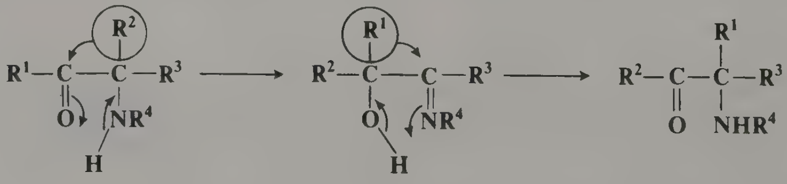


8-5 Thermal Rearrangement of Amino Ketones



R = alkyl, aryl

When heated, ketones containing an α secondary amino group may undergo a rearrangement,[126] similar in appearance to **8-4**, in which two R groups "change places."[127] R may be alkyl or aryl. The mechanism is different from that of **8-4**, though it also involves two migrations in opposite directions. In this case the 1,2 migrations of R are accompanied by 1,4 migration of hydrogen between O and N:



48

The mechanism predicts that when heated, α-hydroxy imines (**48**) in which the OH group is tertiary should rearrange to α-amino ketones; this has been found to be the case.

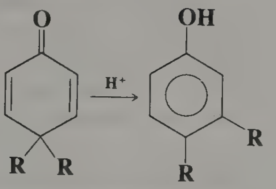
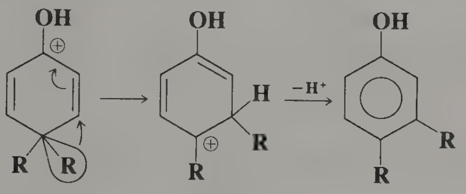
8-6 The Dienone–Phenol Rearrangement

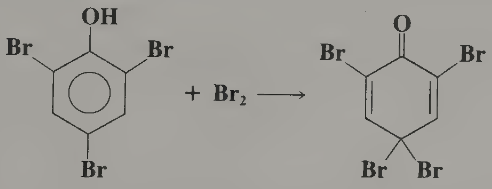


Compounds in which a cyclohexadienone has two alkyl groups in the 4 position undergo, on acid treatment, 1,2 migration of one of these groups:

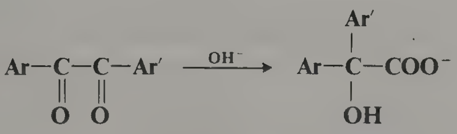


49 **50**

The driving force in the overall reaction (the *dienone–phenol rearrangement*) is of course creation of an aromatic system.[128] It may be noted that ions **49** and **50** are arenium ions (p. 448), the same as those generated by attack of an electrophile on a phenol.[129] Sometimes, in the reaction of a phenol with an electrophile, a kind of reverse rearrangement (called the *phenol–dienone rearrangement*) takes place, though without an actual migration.[130] An example is



8-7 The Benzil–Benzilic Acid Rearrangement



$$\text{Ar}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\underset{\underset{\text{O}}{\|}}{\text{C}}-\text{Ar}' \xrightarrow{\text{OH}^-} \text{Ar}-\overset{\overset{\text{Ar}'}{|}}{\underset{\underset{\text{OH}}{|}}{\text{C}}}-\text{COO}^-$$

When treated with base, α-diketones rearrange to give the salts of α-hydroxy acids, a reaction known as the *benzil–benzilic acid rearrangement* (benzil is PhCOCOPh; benzilic acid is

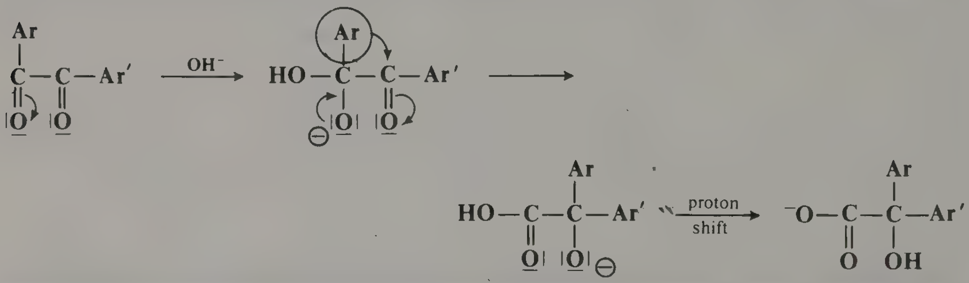
---

[128] For reviews, see Perkins and Ward, *Mech. Mol. Migr.* **4,** 55–112 (1971), pp. 90–103; Miller, *Mech. Mol. Migr.* **1,** 247–313 (1968); Shine, "Aromatic Rearrangements," pp. 55–68, American Elsevier, New York, 1967; Waring, *Adv. Alicyclic Chem.* **1,** 129–256 (1966), pp. 207–223. For a review of other rearrangements of cyclohexadienones, see Miller, *Acc. Chem. Res.* **8,** 245–256 (1975).

[129] For evidence that these ions are indeed intermediates in this rearrangement, see Vitullo, *J. Org. Chem.* **34,** 224 (1969), *J. Org. Chem.* **35,** 3976 (1970); Vitullo and Grossman, *J. Am. Chem. Soc.* **94,** 3844 (1972).

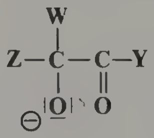
[130] For a review, see Ershov, Volod'kin, and Bogdanov, *Russ. Chem. Rev.* **32,** 75–93 (1963).

$Ph_2COHCOOH$).[131] Though the reaction is usually illustrated with aryl groups, it can also be applied to aliphatic diketones and to α-keto aldehydes. The use of alkoxide ion instead of OH^- gives the corresponding ester directly,[132] though alkoxide ions that are readily oxidized (such as OEt^- or $OCHMe_2^-$) are not useful here, since they reduce the benzil to a benzoin. Aroxide ions (OAr^-) are not strong enough bases for the reaction. The mechanism is similar to the rearrangements in **8-1** to **8-4,** but there is a difference: The migrating group does not move to a carbon with an open sextet. The carbon has an octet but can still accept a group with its pair of electrons by releasing a π pair of electrons from the C=O bond to the oxygen. The first step is attack of the base at the carbonyl group, the same as the first step of the tetrahedral mechanism of nucleophilic substitution (p. 290) and of many additions to the C=O bond (Chapter 16):



The mechanism has been intensively studied,[131] and there is much evidence for it.[133] The reaction is irreversible. There is evidence that the oxygen atom of the C=O group that is attacked by OH^- is first coordinated to the Na^+ or K^+ of NaOH or KOH.[134]

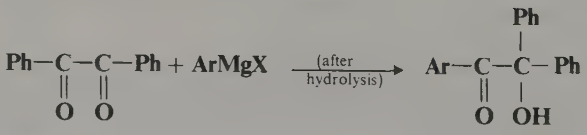
There are other related reactions in which an intermediate of the form



$$\begin{array}{c}W\\|\\Z-C-C-Y\\\ \ \ |\ \ \ \ \ \|\\\ \ {}^{\ominus}O\ \ \ O\end{array}$$

51

is formed and then rearrangement follows. An example is



$$\underset{\ \ \ O\ \ O}{\overset{}{Ph-\overset{}{C}-C-Ph}} + ArMgX \xrightarrow[\text{hydrolysis)}]{\text{(after}} Ar-\underset{O}{\overset{}{C}}-\underset{OH}{\overset{Ph}{C}}-Ph$$

In the intermediate **51,** for the benzilic acid rearrangement, Z = OH, W and Y = R, Ar, or H; for the benzilic ester case, Z = OR, W and Y = R or Ar; for the Grignard example shown, Z, W, and Y all = Ar. In other cases, W and Z may be ArNH, ArCO, RCO, etc. and Y may be OH, RCO, etc. The base-catalyzed α-ketol rearrangement (**8-4**) also belongs to this group of reactions, with W and Z = R or Ar; Y = R, Ar, or H.

OS **I,** 89.

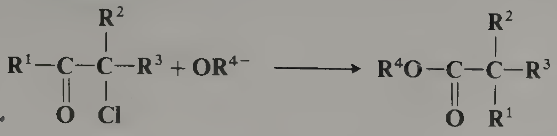
[132] Doering and Urban, *J. Am. Chem. Soc.* **78,** 5938 (1956).

[133] However, some evidence for an SET pathway has been reported: Screttas, Micha-Strettas, and Cazianis, *Tetrahedron Lett.* **24,** 3287 (1983).

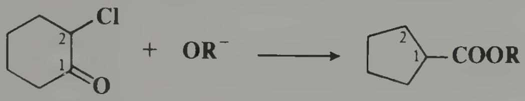
[134] Poonia, Porwal, and Sen, *Bull. Soc. Chim. Belg.* **90,** 247 (1981).

8-8 The Favorskii Rearrangement



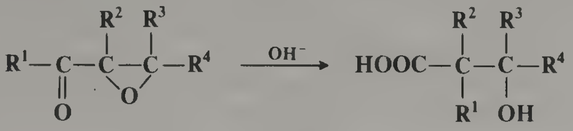
$$R^1-\underset{\underset{O}{\|}}{C}-\overset{\overset{R^2}{|}}{\underset{\underset{Cl}{|}}{C}}-R^3 + OR^{4-} \longrightarrow R^4O-\underset{\underset{O}{\|}}{C}-\overset{\overset{R^2}{|}}{\underset{\underset{R^1}{|}}{C}}-R^3$$

The reaction of α-halo ketones (chloro, bromo, or iodo) with alkoxide ions[135] to give rearranged esters is called the *Favorskii rearrangement*.[136] The use of hydroxide ions or amines as bases leads to the free acid (salt) or amide, respectively, instead of the ester. Cyclic α-halo ketones give ring contraction:



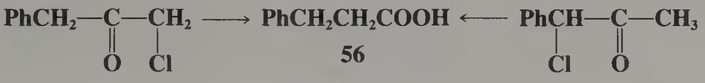
52 **53**

The reaction has also been carried out on α-hydroxy ketones[137] and on α,β-epoxy ketones:[138]



The fact that an epoxide gives a reaction analogous to a halide indicates that the oxygen and halogen are leaving groups in a nucleophilic substitution step.

Through the years, the mechanism[139] of the Favorskii rearrangement has been the subject of much investigation; at least five different mechanisms have been proposed. However, the finding[140] that **54** and **55** *both* give **56** (this behavior is typical) shows that any mechanism where the halogen leaves and R^1 takes its place is invalid, since in such a case **54** would be expected to give **56** (with $PhCH_2$ migrating), but **55** should give PhCHMeCOOH (with CH_3 migrating). That is, in the case of **55**, it was PhCH that migrated and not methyl. Another important result was determined by radioactive labeling. **52**, in which C-1 and C-2 were equally labeled with ^{14}C, was converted to **53**. The product was found to contain 50% of the label on the carbonyl carbon, 25% on C-1, and 25% on C-2.[141] Now the carbonyl carbon, which originally carried half of the radioactivity, still



$$PhCH_2-\underset{\underset{O}{\|}}{C}-\underset{\underset{Cl}{|}}{CH_2} \longrightarrow \underset{\textbf{56}}{PhCH_2CH_2COOH} \longleftarrow Ph\underset{\underset{Cl}{|}}{CH}-\underset{\underset{O}{\|}}{C}-CH_3$$

54 **55**

---

[135] The reaction has also been reported to take place with $BF_3 \cdot MeOH$ and Ag^+: Giordano, Castaldi, Casagrande, and Abis, *Tetrahedron Lett.* **23,** 1385 (1982).

[136] For reviews, see Hunter, Stothers, and Warnhoff, in Mayo-RGES, vol. 1, pp. 437–461; Chenier, *J. Chem. Educ.* **55,** 286–291 (1978); Rappe, in Patai, "The Chemistry of the Carbon–Halogen Bond," pt. 2, pp. 1084–1101, Wiley, New York, 1973; Redmore and Gutsche, Ref. 105, pp. 46–69; Akhrem, Ustynyuk, and Titov, *Russ. Chem. Rev.* **39,** 732–746 (1970); Kende, *Org. React.* **11,** 261–316 (1960).

[137] Craig, Dinner, and Mulligan, *J. Org. Chem.* **37,** 3539 (1972).

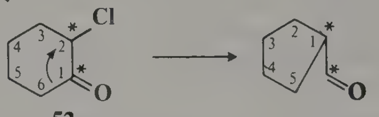
[138] See, for example, House and Gilmore, *J. Am. Chem. Soc.* **83,** 3972 (1961); Mouk, Patel, and Reusch, *Tetrahedron* **31,** 13 (1975).

[139] For a review of the mechanism, see Baretta and Waegell, *React. Intermed. (Plenum)* **2,** 527–585 (1982).

[140] McPhee and Klingsberg, *J. Am. Chem. Soc.* **66,** 1132 (1944); Bordwell, Scamehorn, and Springer, *J. Am. Chem. Soc.* **91,** 2087 (1969).

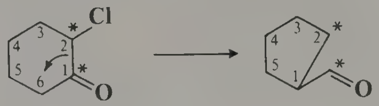
[141] Loftfield, *J. Am. Chem. Soc.* **73,** 4707 (1951).

had this much, so that the rearrangement did not directly affect *it*. However, if the C-6 carbon had migrated to C-2, then the other half of the radioactivity would be only on C-1 of the product:



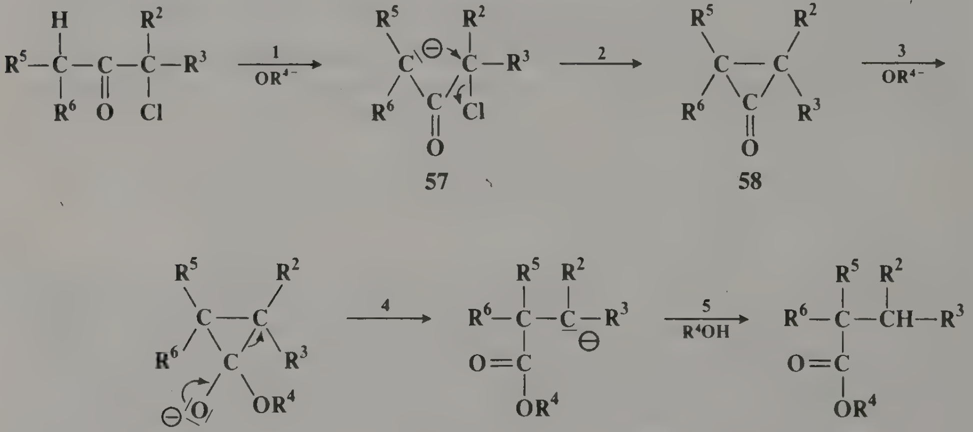
52

On the other hand, if the migration had gone the other way—if the C-2 carbon had migrated to C-6—then this half of the radioactivity would be found solely on C-2 of the product:



52

The fact that C-1 and C-2 were found to be equally labeled showed that *both migrations occurred,* and with equal probability. Since C-2 and C-6 of **52** are not equivalent, this means that there must be a symmetrical intermediate.[142] The type of intermediate that best fits the circumstances is a cyclopropanone,[143] and the mechanism (for the general case) is formulated (replacing R^1 of our former symbolism with CHR^5R^6, since it is obvious that for this mechanism an α-hydrogen is required on the nonhalogenated side of the carbonyl):



57

58

The intermediate corresponding to **58** in the case of **52** is a symmetrical compound, and the three-membered ring can be opened with equal probability on either side of the carbonyl, accounting for the results with ^{14}C. In the general case, **58** is not symmetrical and should open on the side that gives the more stable carbanion.[144] This accounts for the fact that **54** and **55** give the same product.

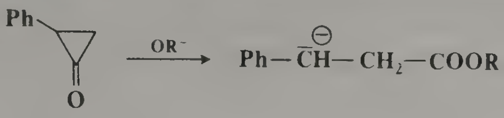
---

[142] A preliminary migration of the chlorine from C-2 to C-6 was ruled out by the fact that recovered **52** had the same isotopic distribution as the starting **52**.

[143] Although cyclopropanones are very reactive compounds, several of them have been isolated. For reviews of cyclopropanone chemistry, see Wasserman, Clark, and Turley, *Top. Curr. Chem.* **47,** 73–156 (1974); Turro, *Acc. Chem. Res.* **2,** 25–32 (1969).

[144] Factors other than carbanion stability (including steric factors) may also be important in determining which side of an unsymmetrical **58** is preferentially opened. See, for example, Rappe and Knutsson, *Acta Chem. Scand.* **21,** 2205 (1967); Rappe, Knutsson, Turro, and Gagosian, *J. Am. Chem. Soc.* **92,** 2032 (1970).

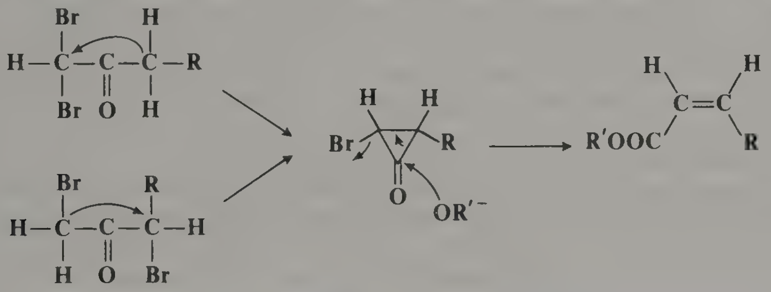
The intermediate in both cases is **59**, which always opens to give the carbanion stabilized by



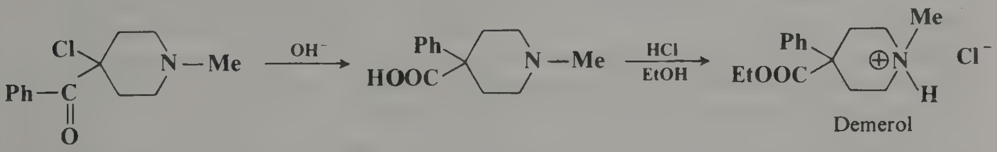
59

resonance. The cyclopropanone intermediate (**58**) has been isolated in the case where $R^2 = R^5 = t$-Bu and $R^3 = R^6 = H$,[145] and it has also been trapped.[146] Also, cyclopropanones synthesized by other methods have been shown to give Favorskii products on treatment with NaOMe or other bases.[147]

When the Favorskii rearrangement is applied to α,α-dihalo ketones containing an α′-hydrogen[148] or to α,α′-dihalo ketones containing an α-hydrogen,[149] the product is an α,β-unsaturated ester. In either case the same cyclopropanone is formed. Ring opening is different here, involving simultaneous elimination of halide ion:



The mechanism discussed is in accord with all the facts when the halo ketone contains an α-hydrogen on the other side of the carbonyl group. However, ketones that do not have a hydrogen there also rearrange to give the same type of product. This is usually called the *quasi-Favorskii rearrangement*. An example is found in the preparation of Demerol:[150]



The quasi-Favorskii rearrangement obviously cannot take place by the cyclopropanone mechanism. The mechanism that is generally accepted (called the *semibenzilic mechanism*[151]) is a base-catalyzed pinacol rearrangement–type mechanism similar to that of **8-7**. This mechanism requires inversion at the migration terminus and this has been found.[152] It has been shown that even where there *is* an appropriately situated α-hydrogen, the semibenzilic mechanism may still operate. One such example is the ring contraction of α-halocyclobutanones[153] (for these substrates, boiling water may be all that is necessary; a stronger base is not always required). The semibenzilic mechanism has been shown for these compounds by experiments involving deuterium labeling, as well as by other experiments.[154] In at least one case it has been shown that an α-halo ketone with an α′-hydrogen can give the Favorskii reaction by either the cyclopropanone or the semibenzilic mechanism, depending on the experimental conditions.[155]

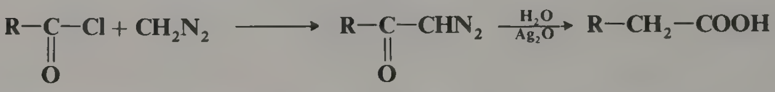
8-9 The Arndt–Eistert Synthesis



$$R-\underset{\underset{O}{\|}}{C}-Cl + CH_2N_2 \longrightarrow R-\underset{\underset{O}{\|}}{C}-CHN_2 \xrightarrow[Ag_2O]{H_2O} R-CH_2-COOH$$

In the *Arndt–Eistert synthesis* an acyl halide is converted to a carboxylic acid with one additional carbon.[156] The first step of this process is reaction **0-115.** The actual rearrangement occurs in the second step on treatment of the diazo ketone with water and silver oxide or with silver benzoate and triethylamine. This rearrangement is called the *Wolff rearrangement.* It is the best method of increasing a carbon chain by one if a *carboxylic acid* is available (**0-103** and **6-35** begin with alkyl halides). If an alcohol R′OH is used instead of water, the ester RCH_2COOR' is isolated directly. Similarly, ammonia gives the amide. Other catalysts are sometimes used, e.g., colloidal platinum, copper, etc., but occasionally the diazo ketone is simply heated or photolyzed in the presence of water, an alcohol, or ammonia, with no catalyst at all. The photolysis method[157] often gives better results than the silver catalysis method. Of course, diazo ketones prepared in any other way also give the rearrangement.[158] The reaction is of wide scope. R may be alkyl or aryl and may contain many functional groups including unsaturation, but not including groups acidic enough to react with CH_2N_2 or diazo ketones (e.g., **0-6** and **0-28**). Sometimes the reaction is performed with other diazoalkanes (that is, $R'CHN_2$) to give RCHR′COOH. The reaction has been used for ring contraction of cyclic diazo ketones,[159] e.g.,[160]

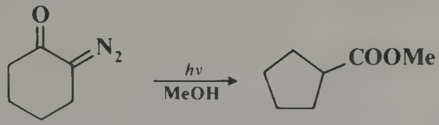
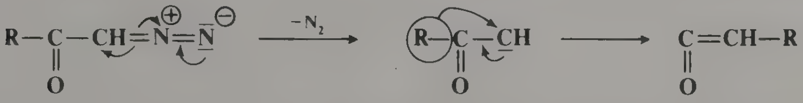
[157] For a review of the photolysis method, see Ando, in Patai, Ref. 156, pp. 458–475.

[158] For a method of conducting the reaction with trimethylsilyldiazomethane instead of CH_2N_2, see Aoyama and Shioiri, *Tetrahedron Lett.* **21,** 4461 (1980).

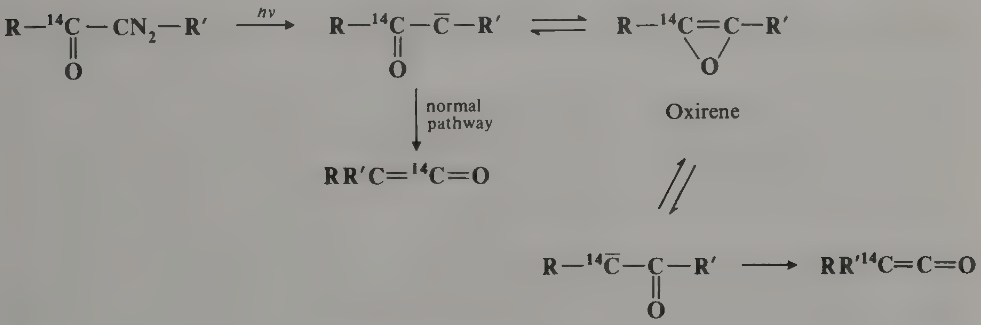


The mechanism is generally regarded to involve formation of a carbene. It is the divalent carbon that has the open sextet and to which the migrating group brings its electron pair:



The actual product of the reaction is thus the ketene, which then reacts with water (**5-2**), an alcohol (**5-4**), or ammonia or an amine (**5-8**). Particularly stable ketenes (e.g., $Ph_2C{=}C{=}O$) have been isolated and others have been trapped in other ways (e.g., as β-lactams,[161] **6-66**). The purpose of the catalyst is not well understood, though many suggestions have been made. This mechanism is strictly analogous to that of the Curtius rearrangement (**8-17**). Although the mechanism as shown above involves a free carbene and there is much evidence to support this,[162] it is also possible that at least in some cases the two steps are concerted and a free carbene is absent.

When the Wolff rearrangement is carried out photochemically, the mechanism is basically the same,[157] but another pathway can intervene. Some of the ketocarbene originally formed can undergo a carbene–carbene rearrangement, through an oxirene intermediate.[163] This was shown by ^{14}C labeling experiments, where diazo ketones labeled in the carbonyl group gave rise to ketenes that



---

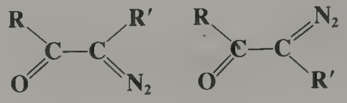
[163] For a review of oxirenes, see Lewars, *Chem. Rev.* **83,** 519–534 (1983).

bore the label at both C=C carbons.[164] In general, the smallest degree of scrambling (and thus of the oxirene pathway) was found when R′ = H. The oxirene pathway is not found in the thermal Wolff rearrangement. It is likely that an excited singlet state of the carbene is necessary for the oxirene pathway to intervene.[165]

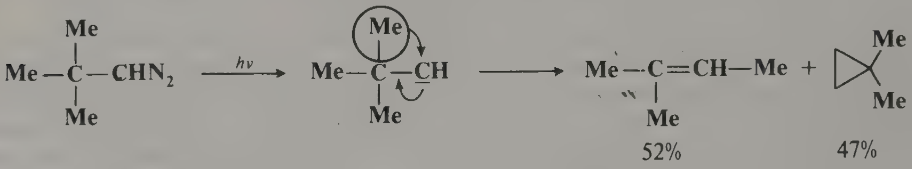
The diazo ketone can exist in two conformations, called *s-E* and *s-Z*. Studies have shown that



s-Z *s-E*

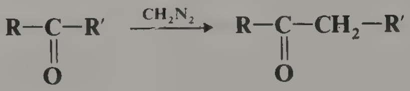
Wolff rearrangement takes place preferentially from the *s-Z* conformation.[166]

Other 1,2 alkyl migrations to a carbene or carbenoid terminus are also known,[167] e.g.,[168]

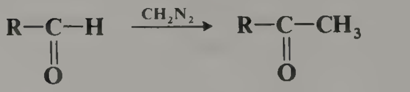


OS **III,** 356; **50,** 77; **52,** 53.

8-10 Homologization of Aldehydes and Ketones



$$\underset{\displaystyle O}{\overset{\|}{R-C-R'}} \xrightarrow{CH_2N_2} \underset{\displaystyle O}{\overset{\|}{R-C-CH_2-R'}}$$



$$\underset{\displaystyle O}{\overset{\|}{R-C-H}} \xrightarrow{CH_2N_2} \underset{\displaystyle O}{\overset{\|}{R-C-CH_3}}$$

Aldehydes and ketones can be converted to their homologs[169] with diazomethane.[170] Formation of the epoxide (**6-63**) is a side reaction. Although this reaction appears superficially to be similar to the insertion of carbenes into C—H bonds (**2-18**), the mechanism is quite different. This reaction is a true rearrangement and no free carbene is involved. The first step is an addition to the C=O bond of the aldehyde or ketone:

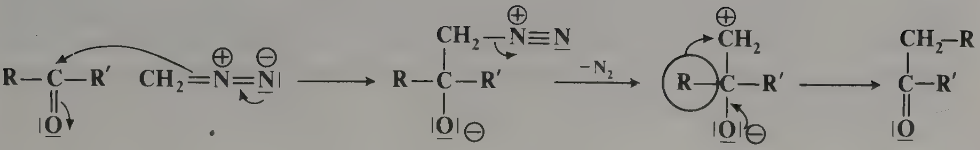
[167] For a review, see Kirmse, Ref. 117, pp. 457–462. See also Kowalski and Fields, *J. Am. Chem. Soc.* **104,** 321 (1982).

[168] Kirmse and Horn, *Chem. Ber.* **100,** 2698 (1967).

[169] Other homologization reagents have also been reported: See Taylor, Chiang, and McKillop, *Tetrahedron Lett.* 1827 (1977); Villieras, Perriot, and Normant, *Synthesis* 968 (1979); Hashimoto, Aoyama, and Shioiri, *Tetrahedron Lett.* **21,** 4619 (1980).

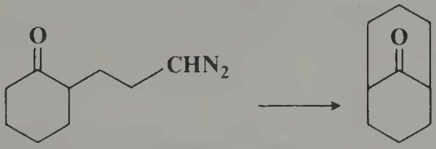
[170] For a review, see Gutsche, *Org. React.* **8,** 364–429 (1954).



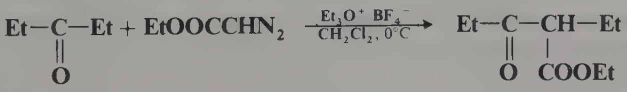
60 **61**

The betaine **60** can sometimes be isolated. As shown on p. 866, **60** can also go to the epoxide. The evidence for this mechanism is summarized in the review by Gutsche.[170] It may be noted that this mechanism is essentially the same as in the apparent ''insertions'' of oxygen (**8-22**) and nitrogen (**8-19**) into ketones.

Aldehydes give fairly good yields of methyl ketones; that is, hydrogen migrates in preference to alkyl. The most abundant side product is not the homologous aldehyde, but the epoxide. However, the yield of aldehyde at the expense of methyl ketone can be increased by the addition of methanol. If the aldehyde contains electron-withdrawing groups, the yield of epoxides is increased and the ketone is formed in smaller amounts, if at all. Ketones give poorer yields of homologous ketones. Epoxides are usually the predominant product here, especially when one or both R groups contain an electron-withdrawing group. The yield of ketones also decreases with increasing length of the chain. The use of boron trifluoride[171] or aluminum chloride[172] increases the yield of ketone.[173] Cyclic ketones,[174] three-membered[175] and larger, behave particularly well and give good yields of ketones with the ring expanded by one.[176] Aliphatic diazo compounds ($RCHN_2$ and R_2CN_2) are sometimes used instead of diazomethane, with the expected results.[177] An interesting example is the preparation of bicyclic compounds from alicyclic compounds with a diazo group in the side chain, e.g.,[178]



Ethyl diazoacetate can be used analogously, in the presence of a Lewis acid or of triethyloxonium fluoroborate,[179] e.g.,



$$\underset{\displaystyle O}{\overset{}{Et-\underset{\|}{C}-Et}} + EtOOCCHN_2 \xrightarrow[CH_2Cl_2,\ 0^\circ C]{Et_3O^+\ BF_4^-} Et-\underset{\underset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle COOEt}{|}}{CH}-Et$$

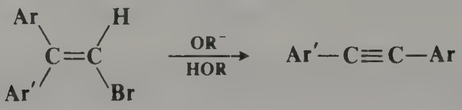
When unsymmetrical ketones were used in this reaction (with BF_3 as catalyst), the less highly substituted carbon preferentially migrated.[180] For unsymmetrical ketones, the reaction can be made regioselective by applying this method to the α-halo ketone, in which case only the other carbon migrates.[181] The ethyl diazoacetate procedure has also been applied to the acetals or ketals of α,β-unsaturated aldehydes and ketones.[182]

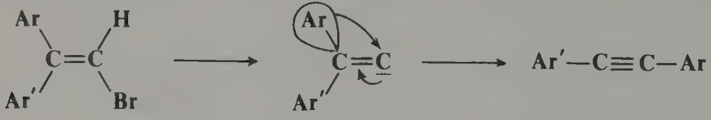
OS **IV**, 225, 780.

8-11 The Fritsch–Buttenberg–Wiechell Rearrangement



The rearrangement of 1,1-diaryl-2-haloethylenes to diarylacetylenes with strong bases[183] is called the *Fritsch–Buttenberg–Wiechell rearrangement*.[184] Alkoxide ions, sodium amide, and alkyl- and aryllithiums have been used as bases. The order of halide reactivity is Br > I ≫ Cl.[185] There are two main side reactions, which may predominate. One is simple nucleophilic substitution of the halide by the base (e.g., $Ar_2C{=}CHBr + OEt^- \rightarrow Ar_2C{=}CHOEt$), and the other, which occurs with alkyl- and aryllithiums, is halogen–metal interchange (**2-38**).

In this rearrangement, a hydrogen and a halogen are removed from the same carbon on treatment with a base, and it is tempting to assume that a carbene intermediate is involved here (see p. 173):



However, a major piece of evidence against this mechanism is that the reaction is stereoselective: the predominant migrating group is the one trans to the halogen. This was determined by the use of two different aryl groups and the labeling of one of the ethylenic carbons with ^{14}C.[186] A free carbene should be symmetrical, and it should not matter which group migrates.[187] Other evidence against the carbene mechanism is that products of carbene insertion or addition are not found. If we reject the carbene mechanism, there are still two major possibilities.[188] The aryl group may migrate with (mechanism *a*) or without (mechanism *b*) its electrons:

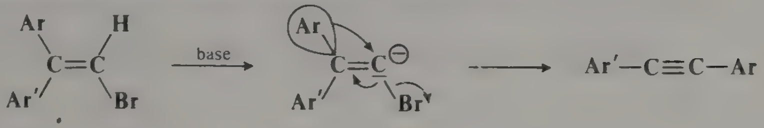
[186] Curtin, Flynn, and Nystrom, *J. Am. Chem. Soc.* **80,** 4599 (1958); Bothner-By, *J. Am. Chem. Soc.* **77,** 3293 (1955).

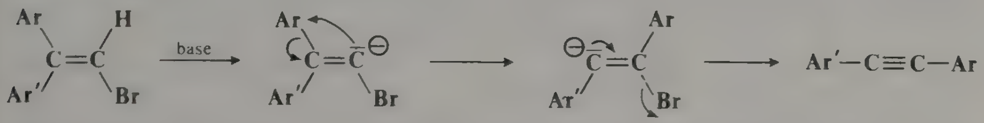
[187] It has been shown [Tadros, Sakla, Ishak, and Armanious, *J. Chem. Soc.* 4218 (1963)] that the reaction of 1-phenyl-1-*p*-anisyl-2-bromoethylene with sodium glycoxide in boiling ethylene glycol is not stereoselective, the anisyl group preferentially migrating, whether cis or trans. It may be that the mechanism in this case is different or, more simply, that here the olefin isomerizes before migration takes place.

[188] An *intermolecular* mechanism was ruled out by crossover experiments and by the fact that a substituent on a migrating ring is found in the same position in the product.

Mechanism *a*



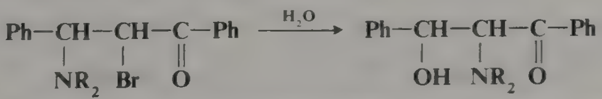
Mechanism *b*



Although we have shown these mechanisms with two and three steps, respectively, it is also possible that two or three of the steps are concerted. The principal way of distinguishing between mechanisms *a* and *b* is the study of the effects of substituents on the migrating group. In mechanism *a* the reaction with respect to the migrating group is electrophilic aromatic substitution, with a transition state in which the ring is positively charged. Electron-donating substituents in the ortho or para position should aid the migration, and withdrawing substituents should hinder it. In mechanism *b* the reaction is nucleophilic aromatic substitution, with a negatively charged transition state, and the effect of substituents should be just the opposite. The results are in accord with mechanism *a*.[189] The question remains as to whether it is a one-step or two-step process. There is evidence that, at least in some cases, there is a two-step mechanism: the intermediate **62** has been isolated as the lithium compound and on heating gave the diarylacetylene;[190] and hydrogen–deuterium exchange has been shown.[185] However, it may be that in other cases the two steps are concerted. The fact that the reaction is stereoselective does not *require* that the reaction be concerted, since vinyl carbanions can hold their configurations (p. 156).

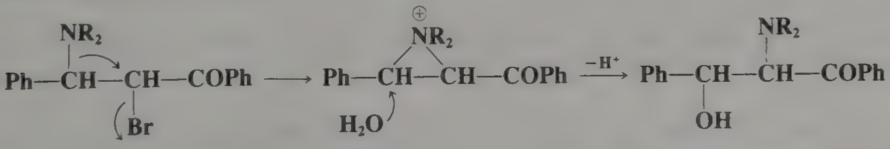
B. Carbon-to-Carbon Migrations of Other Groups

8-12 Migrations of Halogen, Hydroxyl, Amino, etc.



$$\underset{NR_2}{Ph{-}CH}{-}\underset{Br}{CH}{-}\underset{O}{\overset{\|}{C}}{-}Ph \xrightarrow{H_2O} \underset{OH}{Ph{-}CH}{-}\underset{NR_2}{CH}{-}\underset{O}{\overset{\|}{C}}{-}Ph$$

When a nucleophilic substitution is carried out on a substrate that has a neighboring group (p. 268) on the adjacent carbon, then if the cyclic intermediate is opened on the opposite side, the result is migration of the neighboring group. In the example shown above (NR_2 = morpholino),[191] the reaction took place as follows:



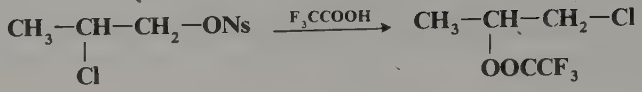
---

[189] Köbrich and Trapp, *Z. Naturforsch.* **18**, 1125 (1963), *Chem. Ber.* **99**, 680 (1966); Jones and Damico, *J. Am. Chem. Soc.* **85**, 2273 (1963); Köbrich, Trapp, and Hornke, *Tetrahedron Lett.* 1131 (1964), *Chem. Ber.* **100**, 961 (1967).

[190] Köbrich and Trapp, Ref. 189.

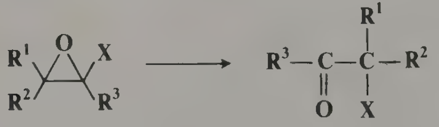
[191] Southwick and Walsh, *J. Am. Chem. Soc.* **77**, 405 (1955). See also Suzuki, Okano, Nakai, Terao, and Sekiya, *Synthesis* 723 (1983).

Another example is[192] (ONs = nosylate, see p. 312):



$$CH_3-\underset{Cl}{CH}-CH_2-ONs \xrightarrow{F_3CCOOH} CH_3-\underset{OOCCF_3}{CH}-CH_2-Cl$$

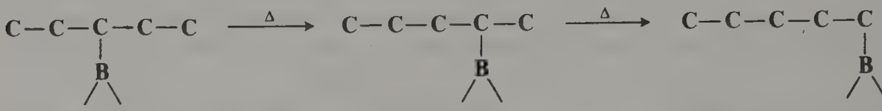
α-Halo and α-acyloxy epoxides undergo ready rearrangement to α-halo and α-acyloxy ketones, respectively.[193] These substrates are very prone to rearrange, and often do so on standing without



X=F, Cl, Br, or OCOR

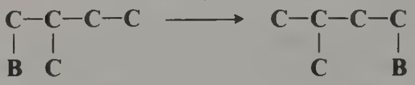
a catalyst, though in some cases an acid catalyst is necessary. The reaction is essentially the same as the rearrangement of epoxides shown in **8-2,** except that in this case halogen or acyloxy is the migrating group (as shown above; however, it is also possible for one of the R groups—alkyl, aryl, or hydrogen—to migrate instead, and mixtures are sometimes obtained).

8-13 Migration of Boron



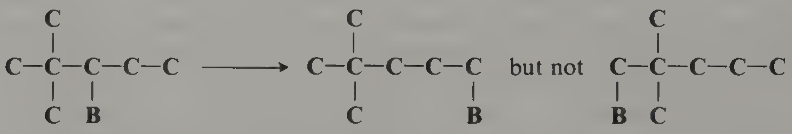
$$C-C-\underset{B}{C}-C-C \xrightarrow{\Delta} C-C-C-\underset{B}{C}-C \xrightarrow{\Delta} C-C-C-C-\underset{B}{C}$$

When a nonterminal borane is heated at temperatures ranging from 100 to 200°C, the boron moves toward the end of the chain.[194] The reaction is catalyzed by small amounts of borane or other species containing B—H bonds. The boron can move past a branch, e.g.,



$$\underset{B}{C}-\underset{C}{C}-C-C \longrightarrow C-\underset{C}{C}-C-\underset{B}{C}$$

but not past a double branch, e.g.,



$$C-\overset{C}{\underset{C}{C}}-\underset{B}{C}-C-C \longrightarrow C-\overset{C}{\underset{C}{C}}-C-C-\underset{B}{C} \quad \text{but not} \quad C-\overset{C}{\underset{B}{C}}-\underset{C}{C}-C-C$$

The reaction is an equilibrium: **63, 64,** and **65** each gave a mixture containing about 40% **63,** 1%

Res.* **11,** 403–406 (1978).

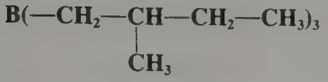
[193] For a review, see McDonald, *Mech. Mol. Migr.* **3,** 67–107 (1971).

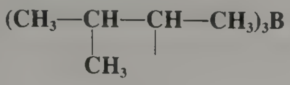
[194] Brown, "Hydroboration," pp. 136–149, W. A. Benjamin, New York, 1962; Brown and Zweifel, *J. Am. Chem. Soc.* **88,** 1433 (1966). See also Brown and Racherla, *J. Organomet. Chem.* **241,** C37 (1982).

64, and 59% **65**. The migration can go quite a long distance. Thus $(C_{11}H_{23}CHC_{11}H_{23})_3B$ was



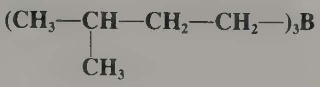
$$\mathrm{B(-CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2-CH_3)_3}$$

63



$$\mathrm{(CH_3-\underset{\displaystyle CH_3}{\underset{|}{CH}}-\underset{|}{CH}-CH_3)_3B}$$

64

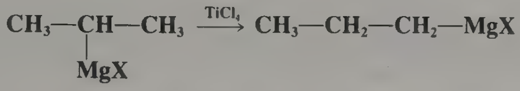


$$\mathrm{(CH_3-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2-CH_2-)_3B}$$

65

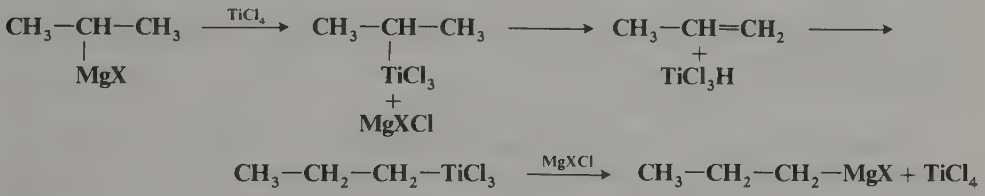
completely converted to $(C_{23}H_{47})_3B$, involving a migration of 11 positions.[195] If the boron is on a cycloalkyl ring, it can move around the ring; if an alkyl chain is also on the ring, the boron may move from the ring to the chain, ending up at the end of the chain.[196] The reaction is useful for the migration of double bonds in a controlled way (see **2-2**). There is evidence that a π complex mechanism is involved in the migration.[197]

8-14 Rearrangement of Grignard Reagents



$$\mathrm{CH_3-\underset{\displaystyle MgX}{\underset{|}{CH}}-CH_3 \xrightarrow{TiCl_4} CH_3-CH_2-CH_2-MgX}$$

The MgX of Grignard reagents[198] can migrate to terminal positions in the presence of small amounts of $TiCl_4$.[199] The proposed mechanism consists of metal exchange (**2-34**), elimination–addition, and metal exchange:

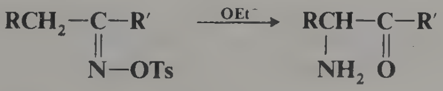


$$\mathrm{CH_3-\underset{\displaystyle MgX}{\underset{|}{CH}}-CH_3 \xrightarrow{TiCl_4} \underset{\displaystyle MgXCl}{\underset{+}{CH_3-\underset{\displaystyle TiCl_3}{\underset{|}{CH}}-CH_3}} \longrightarrow \underset{\displaystyle TiCl_3H}{\underset{+}{CH_3-CH{=}CH_2}} \longrightarrow}$$

$$\mathrm{CH_3-CH_2-CH_2-TiCl_3 \xrightarrow{MgXCl} CH_3-CH_2-CH_2-MgX + TiCl_4}$$

The addition step is similar to **5-13** or **5-14** and follows Markovnikov's rule, so that the positive titanium goes to the terminal carbon.

8-15 The Neber Rearrangement



$$\mathrm{RCH_2-\underset{\displaystyle N-OTs}{\underset{\|}{C}}-R' \xrightarrow{OEt^-} R\underset{\displaystyle NH_2}{\underset{|}{CH}}-\underset{\displaystyle O}{\underset{\|}{C}}-R'}$$

α-Amino ketones can be prepared by treatment of ketoxime tosylates with a base such as ethoxide ion or pyridine.[200] This is called the *Neber rearrangement*. R is usually aryl, though the reaction has been carried out with R = alkyl or hydrogen. R′ may be alkyl or aryl but not hydrogen. The Beckmann rearrangement (**8-20**) and the abnormal Beckmann reaction (elimination to the nitrile, **7-41**) may be side reactions, though these generally occur in acid media. A similar rearrangement is given by N,N-dichloroamines of the type $\mathrm{RCH_2CH(NCl_2)R'}$, where the product is also $\mathrm{RCH(NH_2)COR'}$.[201] The mechanism of the Neber rearrangement is as follows:[202]

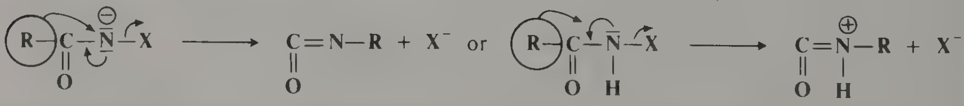
The best evidence for this mechanism is that the azirine intermediate has been isolated.[203] In contrast to the Beckmann rearrangement, this one is sterically indiscriminate:[204] both a syn and an anti ketoxime give the same product. Where there are two possible C—H groups to which the nitrogen can migrate, the more acidic proton is lost. The mechanism as shown above consists of three steps, the last being hydrolysis of an imine (**6-2**). However, it is possible that the first two steps are concerted, and it is also possible that what is shown as the second step is actually two steps: loss of OTs to give a nitrene, and formation of the azirine. In the case of the dichloroamines, HCl is first lost to give $\mathrm{RCH_2}\underset{\underset{\mathrm{NCl}}{\|}}{\mathrm{C}}\mathrm{R'}$, which then behaves analogously.[205] N-Chloroimines prepared in other ways also give the reaction.[206] Analogously, N-chloroimino esters $\mathrm{RCH_2}\underset{\underset{\mathrm{NCl}}{\|}}{\mathrm{C}}\mathrm{OR'}$ give α-amino ortho esters $\mathrm{RCH(NH_2)C(OR')_3}$[207] or α-amino esters $\mathrm{RCH(NH_2)COOR'}$,[208] each of which can be hydrolyzed to α-amino acids.

OS **V**, 909.

C. Carbon-to-Nitrogen Migrations of R and Ar. The reactions in this group are nucleophilic migrations from a carbon to a nitrogen atom. In each case the nitrogen atom either has six electrons in its outer shell (and thus invites the migration of a group carrying an electron pair) or else loses a nucleofuge concurrently with the migration (p. 944). Reactions **8-16** to **8-19** are used to prepare amines from acid derivatives. Reactions **8-19** and **8-20** are used to prepare amines from ketones. The mechanisms of reactions **8-16, 8-17, 8-18,** and **8-19** (with carboxylic acids) are very similar and follow one of two patterns:



Some of the evidence[209] is: (1) configuration is retained in R (p. 945); (2) the kinetics are first order; (3) intramolecular rearrangement is shown by labeling; and (4) no rearrangement occurs *within* the migrating group, e.g., a neopentyl group on the carbon of the starting material is still a neopentyl group on the nitrogen of the product.

[207] Graham, *Tetrahedron Lett.* 2223 (1969).

[208] Baumgarten, Dirks, Petersen, and Zey, *J. Org. Chem.* **31,** 3708 (1966).

[209] For a discussion of this mechanism and the evidence for it, see Smith, in Mayo-MR, Ref. 1, vol. 1, pp. 528–550.

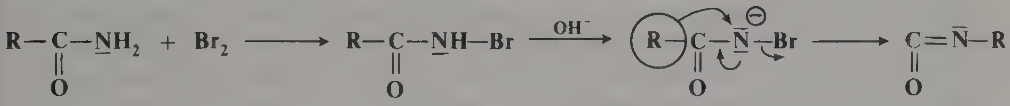
In many cases it is not certain whether the nucleofuge X is lost first, creating an intermediate nitrene[210] or nitrenium ion, or whether migration and loss of the nucleofuge are simultaneous, as shown above.[211] It is likely that both possibilities can exist, depending on the substrate and reaction conditions, and that there is a spectrum of mechanisms.

8-16 The Hofmann Rearrangement

$$\mathrm{RCONH_2 + NaOBr \longrightarrow R{-}N{=}C{=}O \xrightarrow{\text{hydrolysis}} RNH_2}$$

In the *Hofmann rearrangement*, an unsubstituted amide is treated with sodium hypobromite (or sodium hydroxide and bromine, which is essentially the same thing) to give a primary amine that has one carbon fewer than the starting amide.[212] The actual product of the reaction is the isocyanate, but this compound is seldom isolated[213] since it is usually hydrolyzed under the reaction conditions. R may be alkyl or aryl, but if it is an alkyl group of more than about six or seven carbons, low yields are obtained unless Br_2 and NaOMe are used instead of Br_2 and NaOH.[214] Under these conditions the product of addition to the isocyanate is the carbamate RNHCOOMe (**6-8**), which is easily isolated or can be hydrolyzed to the amine. Side reactions when NaOH is the base are formation of ureas RNHCONHR and acylureas RCONHCONHR by addition, respectively, of RNH_2 and $RCONH_2$ to RNCO (**6-17**). If acylureas are desired, they can be made the main products by using only half the usual quantities of Br_2 and NaOH. Another side product, though only from primary R, is the nitrile derived from oxidation of RNH_2 (**9-5**). Imides react to give amino acids, e.g., phthalimide gives *o*-aminobenzoic acid. α-Hydroxy and α-halo amides give aldehydes and ketones by way of the unstable α-hydroxy- or α-haloamines. However, a side product with an α-halo amide is a *gem*-dihalide. Ureas analogously give hydrazines. This reaction is sometimes called the *Hofmann degradation*, but this name is easily confused with **7-6.**

The mechanism follows the pattern outlined on p. 982.



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}\underline{N}H_2 + Br_2 \longrightarrow R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}\underline{N}H{-}Br \xrightarrow{OH^-} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}\overset{\ominus}{\overline{N}}{-}Br \longrightarrow \underset{\underset{\displaystyle O}{\|}}{C}{=}\overline{N}{-}R}$$

66

The first step is an example of **2-54** and the intermediate N-halo amides (**66**) have been isolated. In the second step, **66** lose a proton to the base. **66** are acidic because of the presence of two electron-withdrawing groups (acyl and halo) on the nitrogen. It is possible that the third step is actually two steps: loss of bromide to form a nitrene, followed by the actual migration, but most of the available evidence favors the concerted reaction.[215]

A similar reaction can be effected by the treatment of amides with lead tetraacetate.[216] In this case the initial isocyanate and the amine formed from it react with the acetic acid liberated from the lead tetraacetate to give, respectively, ureas and amides. If the reaction is carried out in the presence of an alcohol, carbamates are formed (**6-8**).

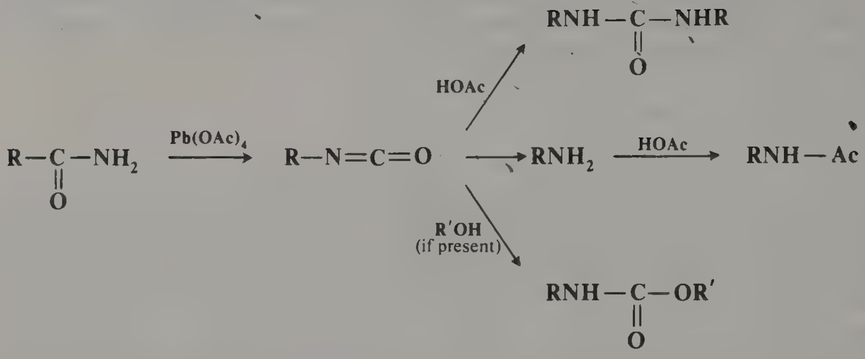
Soc.* **87,** 1141 (1965); Acott, Beckwith, Hassanali, and Redmond, *Tetrahedron Lett.* 4039 (1965); Acott, Beckwith, and Hassanali, *Aust. J. Chem.* **21,** 185, 197 (1968); Baumgarten, Smith, and Staklis, *J. Org. Chem.* **40,** 3554 (1975).



Another reagent that converts $RCONH_2$ to RNH_2 (R = alkyl, but not aryl) is I,I-bis-(trifluoroacetoxy)iodobenzene $PhI(OCOCF_3)_2$.[217]

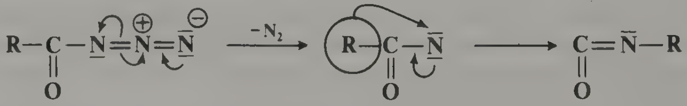
OS **II,** 19, 44, 462; **IV,** 45.

8-17 The Curtius Rearrangement

$$RCON_3 \xrightarrow{\Delta} R{-}N{=}C{=}O$$

The *Curtius rearrangement* involves the pyrolysis of acyl azides to yield isocyanates.[218] The reaction gives good yields of isocyanates, since no water is present to hydrolyze them to the amine. Of course, they can be subsequently hydrolyzed, and indeed the reaction *can* be carried out in water or alcohol, in which case the products are amines, carbamates, or acylureas, as in **8-16.**[219] This is a very general reaction and can be applied to almost any carboxylic acid: aliphatic, aromatic, alicyclic, heterocyclic, unsaturated, and containing many functional groups. Acyl azides can be prepared as in **0-63** or by treatment of acylhydrazines (hydrazides) with nitrous acid (analogous to **2-49**). The Curtius rearrangement is catalyzed by Lewis or protic acids, but these are usually not necessary for good results.

The mechanism is similar to that in **8-16:**



Also note the exact analogy between this reaction and **8-9.** However, in this case, there is no evidence for a free nitrene and it is probable that the steps are concerted.[220]

Alkyl azides can be similarly pyrolyzed to give imines, in an analogous reaction:[221]

$$R_3CN_3 \xrightarrow{\Delta} R_2C{=}NR$$

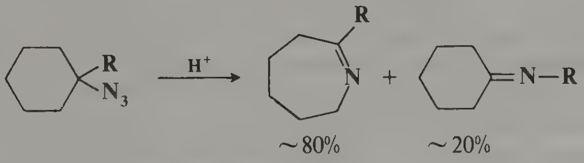
[218] For reviews, see Banthorpe, in Patai, "The Chemistry of the Azido Group," pp. 397–405, Interscience, New York, 1971.

[219] For a variation that conveniently produces the amine directly, see Pfister and Wyman, *Synthesis* 38 (1983).

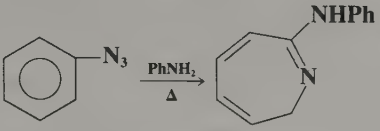
[220] See, for example, Lwowski, *Angew. Chem. Int. Ed. Engl.* **6,** 897–906 (1967) [*Angew. Chem.* **79,** 922–931]; Linke, Tissue, and Lwowski, *J. Am. Chem. Soc.* **89,** 6308 (1967); Smalley and Bingham, *J. Chem. Soc. C* 2481 (1969).

[221] For reviews, see Stevens and Watts, Ref. 1, pp. 45–52; Smith, in Mayo-MR, Ref. 1, vol. 1, pp. 462–479. For reviews of the formation of nitrenes from alkyl and aryl azides, see, in Lwowski, Ref. 211, the chapters by Lewis and Saunders, 47–97, pp. 47–78 and by Smith, pp. 99–162.

The R groups may be alkyl, aryl, or hydrogen, though if hydrogen migrates, the product is the unstable $R_2C{=}NH$. The mechanism is essentially the same as that of the Curtius rearrangement. However, in pyrolysis of tertiary alkyl azides, there is evidence that free alkyl nitrenes are intermediates.[222] The reaction can also be carried out with acid catalysis, in which case lower temperatures can be used, although the acid may hydrolyze the imine (reaction **6-2**). Cycloalkyl azides give ring expansion.[223]

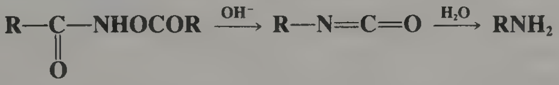


Aryl azides also give ring expansion on heating, e.g.,[224]



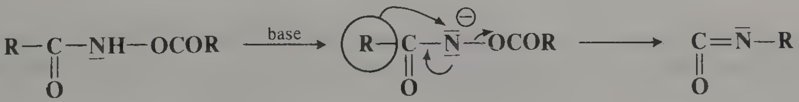
OS **III,** 846; **IV,** 819; **V,** 273; **51,** 48; **59,** 1. Also see OS **55,** 32.

8-18 The Lossen Rearrangement



$$R-\underset{\underset{\displaystyle O}{\|}}{C}-NHOCOR \xrightarrow{OH^-} R-N{=}C{=}O \xrightarrow{H_2O} RNH_2$$

The O-acyl derivatives of hydroxamic acids[225] give isocyanates when treated with bases or sometimes even just on heating,[226] in a reaction known as the *Lossen rearrangement.* The mechanism is similar to that of reactions **8-16** and **8-17:**



This reaction is performed much less often than reactions **8-16, 8-17,** or **8-19,** because hydroxamic acids are not readily available. The reaction can be carried out under particularly mild conditions by treatment of a hydroxamic acid with 1-benzyl-3-dimethylaminopropylcarbodiimide, which is water-soluble.[227] It is possible to convert ArCOOH to $ArNH_2$ in one step by heating the acid with nitromethane in polyphosphoric acid. The hydroxamic acid is an intermediate, and this is actually a Lossen rearrangement.[228] An N-phenyl hydroxamic acid derivative has been reported to give a Lossen rearrangement.[229]

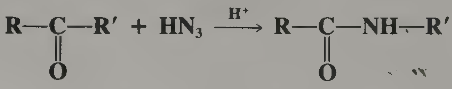
8-19 The Schmidt Reaction

$$\mathrm{RCOOH} + \mathrm{HN_3} \xrightarrow{\mathrm{H^+}} \mathrm{R{-}N{=}C{=}O} \xrightarrow{\mathrm{H_2O}} \mathrm{RNH_2}$$

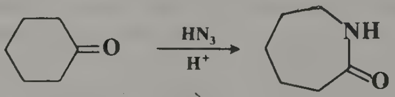
There are actually three reactions called by the name *Schmidt reaction,* involving the addition of hydrazoic acid to carboxylic acids, aldehydes and ketones, and alcohols and olefins.[230] The most common is the reaction with carboxylic acids, illustrated above.[231] Sulfuric acid is the most common catalyst, but Lewis acids have also been used. Good results are obtained for aliphatic R, especially for long chains. When R is aryl, the yields are variable, being best for sterically hindered compounds like mesitoic acid. This method has the advantage over **8-16** and **8-17** that it is just one step (in practice, not in mechanism) from the acid to the amine, but conditions are more drastic.[232] Under the acid conditions employed, the isocyanate is virtually never isolated, though this has been accomplished.[233]

The reaction between a ketone and hydrazoic acid is a method for "insertion" of NH between the carbonyl group and one R group, converting a ketone into an amide.[234]



$$\mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}R'} + \mathrm{HN_3} \xrightarrow{\mathrm{H^+}} \mathrm{R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}NH{-}R'}$$

Either or both of the R groups may be aryl. In general, dialkyl ketones and cyclic ketones react more rapidly than alkyl aryl ketones, and these more rapidly than diaryl ketones. The latter require sulfuric acid and do not react in concentrated HCl, which is strong enough for dialkyl ketones. Dialkyl and cyclic ketones react sufficiently faster than diaryl or aryl alkyl ketones—or carboxylic acids or alcohols—that these functions may be present in the same molecule without interference. Cyclic ketones give lactams:[235]



With alkyl aryl ketones, it is the aryl group that generally migrates to the nitrogen, except when the alkyl group is bulky.[236] The reaction has been applied to a few aldehydes, but rarely. With aldehydes the product is usually the nitrile (**6-22**). Even with ketones, conversion to the nitrile is often a side reaction, especially with the type of ketone that gives **7-41**. Aromatic aldehydes and ketones containing an *o*-hydroxy group give *o*-hydroxy aromatic amides when treated with NaOH and monochloroamine NH_2Cl.[237]

Alcohols and olefins react with HN_3 to give alkyl azides, which in the course of reaction rearrange in the same way as discussed in reaction **8-17**.[221]

There is evidence that the mechanism with carboxylic acids[231] is similar to that of reaction

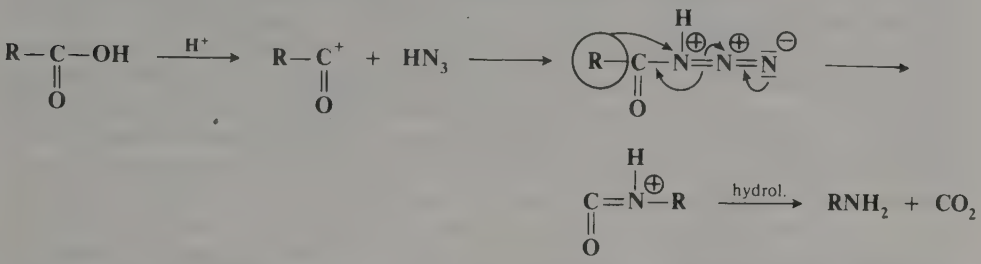
[235] For a review with respect to bicyclic ketones, see Krow, *Tetrahedron* **37,** 1283–1307 (1981).

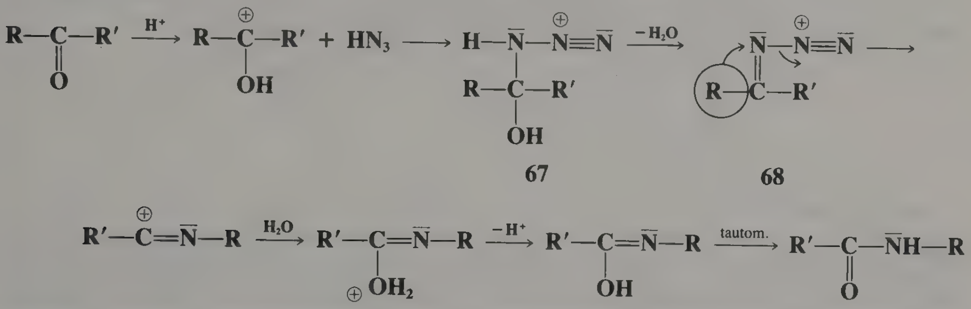
[236] Exceptions to this statement have been noted in the case of cyclic aromatic ketones bearing electron-donating groups in ortho and para positions: Bhalerao and Thyagarajan, *Can. J. Chem.* **46,** 3367 (1968); Tomita, Minami, and Uyeo, *J. Chem. Soc. C* 183 (1969).

[237] Crochet and Kovacic, *J. Chem. Soc., Chem. Commun.* 716 (1973).

8-17, except that it is the protonated azide that undergoes the rearrangement:[238]



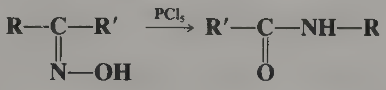
The first step is the same as that of the AAC1 mechanism (**0-11**), which explains why good results are obtained with hindered substrates. The mechanism with ketones is[239]



Note the similarity of this mechanism to those of "insertion" of CH_2 (**8-10**) and of O (**8-22**). The three reactions are essentially analogous, both in products and in mechanism.[240] Also note the similarity of the latter part of this mechanism to that of the Beckmann rearrangement (**8-20**).

OS **V**, 408; **56**, 107. See also OS **V**, 623.

8-20 The Beckmann Rearrangement



$$R{-}\underset{\underset{N-OH}{\|}}{C}{-}R' \xrightarrow{PCl_5} R'{-}\underset{\underset{O}{\|}}{C}{-}NH{-}R$$

When oximes are treated with PCl_5 or a number of other reagents, they rearrange to substituted amides in a reaction called the *Beckmann rearrangement*.[241] Among other reagents used have been concentrated H_2SO_4, formic acid, liquid SO_2, PPh_3-CCl_4,[242] HMPT,[243] 2-chloropyridinium fluorosulfonate,[244] $SOCl_2$,[245] silica gel,[246] P_2O_5-methanesulfonic acid,[247] HCl-HOAc-Ac_2O, and polyphosphoric acid.[248] The group that migrates is generally the one anti to the hydroxyl, and this is often used as a method of determining the configuration of the oxime. However, it is not unequivocal. It is known that with some oximes the syn group migrates and that with others, especially where R and R′ are both alkyl, mixtures of the two possible amides are obtained. However, this behavior does not necessarily mean that the syn group actually undergoes migration. In most cases the oxime undergoes isomerization under the reaction conditions *before* migration takes place.[249] The scope of the reaction is quite broad. R and R′ may be alkyl, aryl, or hydrogen. However, hydrogen very seldom *migrates,* so that the reaction is not generally a means of converting aldoximes to unsubstituted amides $RCONH_2$. This conversion can be accomplished, though, by treatment of the aldoxime with nickel acetate under neutral conditions[250] or by heating the aldoxime for 60 hr at 100°C after it has been adsorbed onto silica gel.[251] As in the case of the Schmidt rearrangement, when the oxime is derived from an alkyl aryl ketone, it is generally the aryl group that preferentially migrates. The oximes of cyclic ketones give ring enlargement,[252] e.g.,

---

[238] There has been some controversy about this mechanism. For a discussion, see Vogler and Hayes, *J. Org. Chem.* **44**, 3682 (1979).

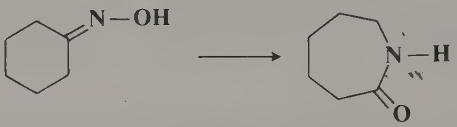
[239] Smith, *J. Am. Chem. Soc.* **70**, 320 (1948); Smith and Antoniades, *Tetrahedron* **9**, 210 (1960. A slightly different mechanism, involving direct rearrangement of **67**, has been shown in certain cases: Fikes and Shechter, *J. Org. Chem.* **44**, 741 (1979). See also Bach and Wolber, *J. Org. Chem.* **47**, 239 (1982).

[240] For evidence for this mechanism, see Koldobskii, Enin, Naumov, Ostrovskii, Tereshchenko, and Bagal, *J. Org. Chem. USSR* **8**, 242 (1972); Ostrovskii, Koshtaleva, Shirokova, Koldobskii, and Gidaspov, *J. Org. Chem. USSR* **10**, 2365 (1974); Ref. 234.

[241] For reviews, see McCarty, in Patai, "The Chemistry of the Carbon–Nitrogen Double Bond," pp. 408–439, Interscience, New York, 1970; Donaruma and Heldt, *Org. React.* **11**, 1–156 (1960); Smith, in Mayo-MR, Ref. 1, vol. 1, pp. 483–507.

[242] Waters, Wakabayashi, and Fields, *Org. Prep. Proced. Int.* **6**, 53 (1974).

[243] Monson and Broline, *Can. J. Chem.* **51**, 942 (1973); Gupton, Idoux, Leonard, and DeCrescenzo, *Synth. Commun.* **13**, 1083 (1983).



Not only do oximes undergo the Beckmann rearrangement, but so also do esters of oximes with many acids, organic and inorganic. A side reaction with many substrates is the formation of nitriles (the "abnormal" Beckmann rearrangement, **7-41**). Cyclic ketones can be converted directly to lactams in one laboratory step by treatment with NH_2OSO_2OH and formic acid (**6-20** takes place first, then the Beckmann rearrangement).[253]

In the first step of the mechanism, the OH group is converted by the reagent to a better leaving group. After that, the mechanism follows a course analogous to that for the Schmidt reaction of ketones (**8-19**) from the formation of **68** on:[254]

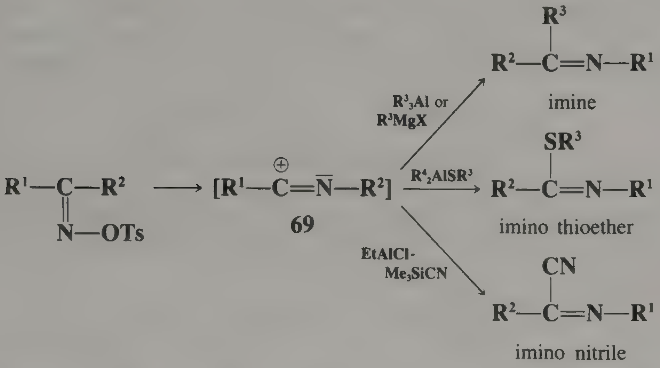
[254] For summaries of the considerable evidence for this mechanism, see Ref. 241: Donaruma and Heldt, pp. 5–14; Smith, pp. 488–493.

The other reagents convert OH to an ester leaving group (e.g., $OPCl_4$ from PCl_5 and OSO_2OH from concentrated H_2SO_4[255]). Alternatively, the attack on **69** can be by the leaving group, if different from H_2O. Intermediates of the form **69** have been detected by nmr and uv spectroscopy.[256] The rearrangement has also been found to take place by a different mechanism, involving formation of a nitrile by fragmentation, and then addition by a Ritter reaction (**6-56**).[257] Beckmann rearrangements have also been carried out photochemically.[258]

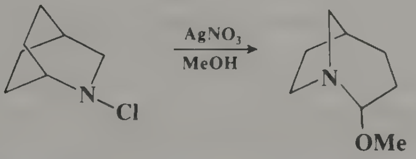
If the rearrangement of oxime sulfonates is induced by organoaluminum reagents, the intermediate **69** is captured by the nucleophile originally attached to the Al. By this means an oxime



can be converted to an imine, an imino thioether, or an imino nitrile[259] (in the last case, the nucleophile comes from added trimethylsilyl cyanide). The imine can be reduced to an amine (**6-27**) or treated with a Grignard reagent (**6-36**) to give a *t*-alkyl secondary amine. The imine-producing reaction can also be accomplished with a Grignard reagent in benzene or toluene.[260]

OS **II,** 76, 371.

8-21 Stieglitz and Related Rearrangements



Besides the reactions discussed at **8-16** to **8-20**, a number of other rearrangements are known in which an alkyl group migrates from C to N. Certain bicyclic N-haloamines, for example N-chloro-2-azabicyclo[2.2.2]octane (above), undergo rearrangement when solvolyzed in the presence of silver nitrate.[261] This reaction is similar to the Wagner–Meerwein rearrangement (**8-1**) and is initiated by the silver-catalyzed departure of the chloride ion.[262] Similar reactions have been used for ring expansions and contractions, analogous to those discussed for reaction **8-3**.[263] An example is the conversion of 1-(N-chloroamino)cyclopropanols to β-lactams.[264]

The name *Stieglitz rearrangement* is generally applied to the rearrangements of trityl N-haloamines and hydroxylamines. These reactions are similar to the rearrangements of alkyl azides

$$Ar_3CNHX \xrightarrow{\text{base}} Ar_2C{=}NAr$$

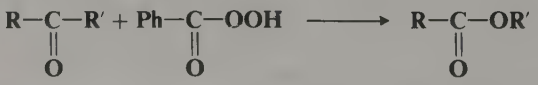
$$Ar_3CNHOH \xrightarrow{PCl_5} Ar_2C{=}NAr$$

(**8-17**), and the name Stieglitz rearrangement is also given to the rearrangement of trityl azides. Another similar reaction is the rearrangement undergone by tritylamines when treated with lead tetraacetate:[265]

$$Ar_3CNH_2 \xrightarrow{Pb(OAc)_4} Ar_2C{=}NAr$$

D. Carbon-to-Oxygen Migrations of R and Ar

8-22 The Baeyer–Villiger Rearrangement



$$\underset{\displaystyle O}{\underset{\|}{R—C—R'}} + \underset{\displaystyle O}{\underset{\|}{Ph—C—OOH}} \longrightarrow \underset{\displaystyle O}{\underset{\|}{R—C—OR'}}$$

The treatment of ketones with peracids such as perbenzoic or peracetic acid, or with other peroxy compounds in the presence of acid catalysts, gives esters by "insertion" of oxygen. The reaction is called the *Baeyer–Villiger rearrangement*.[266] A particularly good reagent is peroxytrifluoroacetic acid. Reactions with this reagent are rapid and clean, giving high yields of product, though it is often necessary to add a buffer such as Na_2HPO_4 to prevent transesterification of the product with trifluoroacetic acid. The reaction is often applied to cyclic ketones to give lactones.[267] For acyclic compounds, R′ must usually be secondary, tertiary, or vinylic, although primary R′ has been rearranged with peroxytrifluoroacetic acid,[268] with BF_3-H_2O_2,[269] and with $K_2S_2O_8$-H_2SO_4.[270] For unsymmetrical ketones the approximate order of migration is tertiary alkyl > secondary alkyl, aryl > primary alkyl > methyl. Since the methyl group has a low migrating ability, the reaction provides a means of cleaving a methyl ketone R′COMe to produce an alcohol or phenol R′OH (by hydrolysis of the ester R′OCOMe). Diaryl ketones give the reaction but are seldom used preparatively. The migrating ability of aryl groups is increased by electron-donating and decreased by electron-withdrawing substituents.[271] Enolizable β-diketones do not react. α-Diketones can be converted to anhydrides. With aldehydes, migration of hydrogen gives the carboxylic acid, and this is a way of accomplishing reaction **4-6.** Migration of the other group would give formates, but this seldom happens, though in some cases aryl aldehydes have been converted to formates[272] (see also the Dakin reaction in **9-12**).

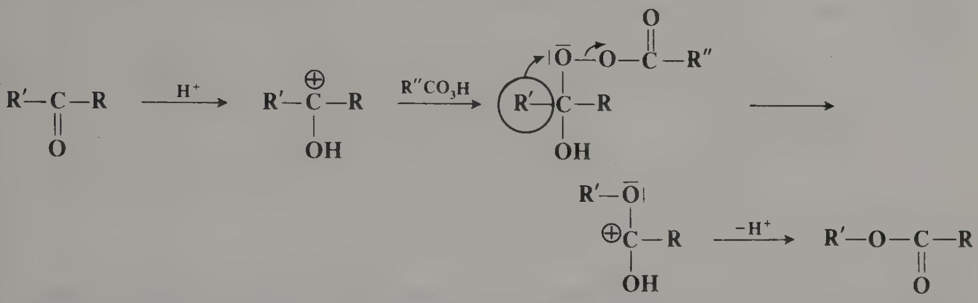
[270] Deno, Billups, Kramer, and Lastomirsky, *J. Org. Chem.* **35,** 3080 (1970).

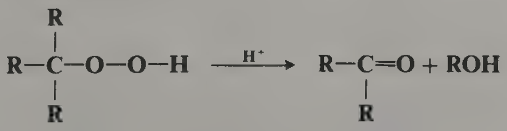
The mechanism[273] is similar to those of the analogous reactions with hydrazoic acid (**8-19** with ketones) and diazomethane (**8-9**):



One important piece of evidence for this mechanism was that benzophenone–^{18}O gave ester entirely labeled in the carbonyl oxygen, with none in the alkoxyl oxygen.[274] Carbon-14 isotope-effect studies on acetophenones have shown that migration of aryl groups takes place in the rate-determining step,[275] demonstrating that migration of Ar is concerted with departure of OCOR″.[276] (It is hardly likely that migration would be the slow step if the leaving group departed first to give an ion with a positive charge on an oxygen atom, which would be a highly unstable species.)

Ketones can be doubly oxidized to dialkyl carbonates [$R_2CO \rightarrow (RO)_2CO$] by treatment with *m*-chloroperoxybenzoic acid.[277]

8-23 Rearrangement of Hydroperoxides



$$R_3C{-}O{-}O{-}H \xrightarrow{H^+} R_2C{=}O + ROH$$

Hydroperoxides (R = alkyl, aryl, or hydrogen) can be cleaved by proton or Lewis acids in a reaction whose principal step is a rearrangement.[278] The reaction has also been applied to peroxy esters $R_3COOCOR'$, but less often. When aryl and alkyl groups are both present, migration of aryl dominates. Among alkyl groups the migratory order is tertiary R > secondary R > Pr ≈ H > Et ≫ Me.[270] It is not necessary actually to prepare and isolate hydroperoxides. The reaction takes place when the alcohols are treated with H_2O_2 and acids. Migration of an alkyl group of a primary hydroperoxide provides a means for converting an alcohol to its next lower homolog ($RCH_2OOH \rightarrow CH_2{=}O + ROH$).[270]

---

[271] For a report of substituent effects in the α, β, and γ positions of alkyl groups, see Noyori, Sato, and Kobayashi, *Bull. Chem. Soc. Jpn.* **56,** 2661 (1983).

[272] For example;, see Godfrey, Sargent, and Elix, *J. Chem. Soc., Perkin Trans. 1* 1353 (1974).

[273] Proposed by Criegee, *Liebigs Ann. Chem.* **560,** 127 (1948).

[274] Doering and Dorfman, *J. Am. Chem. Soc.* **75,** 5595 (1953). For summaries of the other evidence, see Smith, Ref. 266, pp. 578–584.

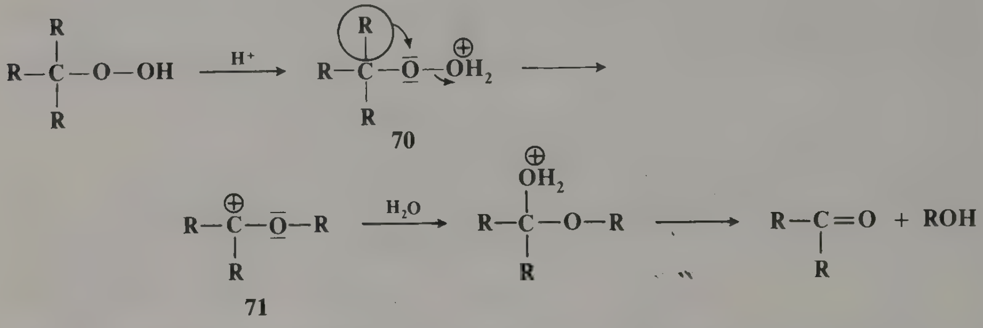
[275] Palmer and Fry, *J. Am. Chem. Soc.* **92,** 2580 (1970). See also Mitsuhashi, Miyadera, and Simamura, *Chem. Commun.* 1301 (1970). For secondary isotope-effect studies, see Winnik, Stoute, and Fitzgerald, *J. Am. Chem. Soc.* **96,** 1977 (1974).

[276] In some cases the rate-determining step has been shown to be the addition of peracid to the substrate [see, for example, Ogata and Sawaki, *J. Org. Chem.* **37,** 2953 (1972)]. Even in these cases it is still highly probable that migration is concerted with departure of the nucleofuge.

[277] Bailey and Shih, *J. Am. Chem. Soc.* **104,** 1769 (1982).

[278] For reviews, see Yablokov, *Russ. Chem. Rev.* **49,** 833–842 (1980); Lee and Uff, Ref. 266, 445–449.

The mechanism is as follows:[279]



70

71

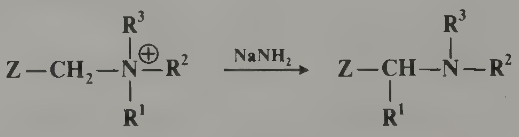
$$R_3C{-}O{-}OH \xrightarrow{H^+} R_3C{-}\overline{O}{-}\overset{\oplus}{O}H_2 \longrightarrow R_2\overset{\oplus}{C}{-}\overline{O}{-}R \xrightarrow{H_2O} R_2C(\overset{\oplus}{O}H_2){-}O{-}R \longrightarrow R_2C{=}O + ROH$$

The last step is hydrolysis of the unstable hemiacetal. Alkoxycarbocation intermediates (**71**, R = alkyl) have been isolated in super-acid solution,[280] at low temperatures, and their structures proved by nmr.[281] The protonated hydroperoxides (**70**) could not be observed in these solutions, evidently reacting immediately on formation.

OS **V**, 818.

E. Nitrogen-to-Carbon, Oxygen-to-Carbon, and Sulfur-to-Carbon Migration

8-24 The Stevens Rearrangement



$$Z{-}CH_2{-}\overset{\oplus}{N}R^1R^2R^3 \xrightarrow{NaNH_2} Z{-}CH(R^1){-}NR^2R^3$$

In the *Stevens rearrangement* a quaternary ammonium salt containing an electron-withdrawing group Z on one of the carbons attached to the nitrogen is treated with a strong base (such as NaOR or $NaNH_2$) to give a rearranged tertiary amine. Z is a group such as RCO, ROOC, phenyl, etc.[282] The most common migrating groups are allyl, benzyl, benzhydryl, 3-phenylpropargyl, and phenacyl, though even methyl migrates to a sufficiently negative center.[283] When an allyl group migrates, it may or may not involve an allylic rearrangement within the migrating group (see **8-39**), depending on the substrate and reaction conditions. In a few cases the reaction has been applied to compounds without a Z group, but stronger bases are required and yields are often low.[284]

---

[279] For a discussion of the transition state involved in the migration step, see Wistuba and Rüchardt, *Tetrahedron Lett.* **22,** 3389 (1981).

[280] For a review of peroxy compounds in super acids, see Olah, Parker, and Yoneda, *Angew. Chem. Int. Ed. Engl.* **17,** 909–931 (1978) [*Angew. Chem.* **90,** 962–984].

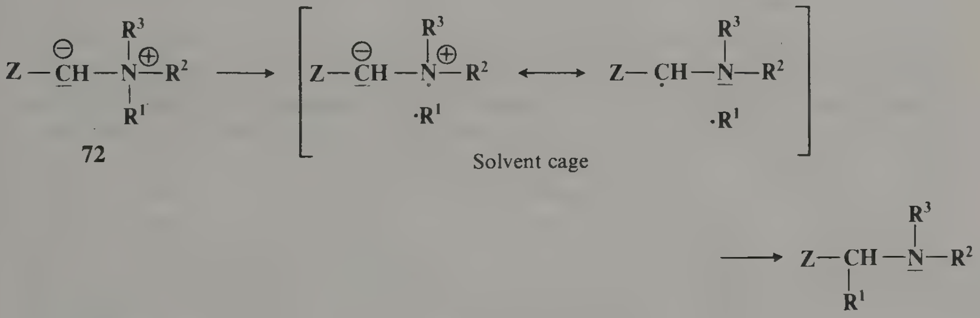
[282] For reviews of the Stevens rearrangement, see Lepley and Giumanini, *Mech. Mol. Migr.* **3,** 297–440 (1971); Pine, *Org. React.* **18,** 403–464 (1970). For reviews of the Stevens and the closely related Wittig rearrangement (**8-26**), see Stevens and Watts, Ref. 1, pp. 81–116; Wilt, in Kochi, Ref. 51, pp. 448–458; Iwai, *Mech. Mol. Migr.* **2,** 73–116 (1969), pp. 105–113; Stevens, *Prog. Org. Chem.* **7,** 48–74 (1968); Zimmerman, in Mayo-MR, Ref. 1, vol. 1, pp. 345–406.

[283] Migration of aryl is rare, but has been reported: Heaney and Ward, *Chem. Commun.* 810 (1969); Truce and Heuring, *Chem. Commun.* 1499 (1969).

The mechanism has been the subject of much study.[285] That the rearrangement is intramolecular was shown by crossover experiments, by ^{14}C labeling,[286] and by the fact that retention of configuration is found at R.[287] The first step is loss of the acidic proton to give the ylide **72,** which has been isolated.[288] The finding[289] that CIDNP spectra[290] (p. 163) could be obtained in many instances shows that in these cases the product is formed directly from a free-radical precursor. The following radical pair mechanism was proposed:[291]

Mechanism *a*



The radicals do not drift apart because they are held together by the solvent cage. According to this mechanism, the radicals must recombine rapidly in order to account for the fact that R^1 does not racemize. Other evidence in favor of mechanism *a* is that in some cases small amounts of coupling products (R^1R^1) have been isolated,[292] which would be expected if some $\cdot R^1$ leaked from the solvent cage. However, not all the evidence is easily compatible with mechanism *a*.[293] It is possible that another mechanism (*b*) similar to mechanism *a*, but involving ion pairs in a solvent cage instead of radical pairs, operates in some cases. A third possible mechanism would be a

Mechanism *b*

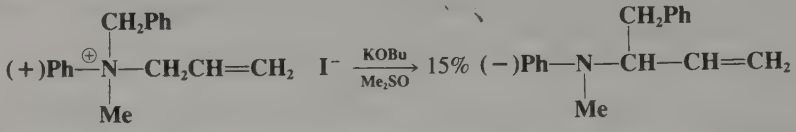
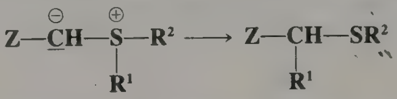
concerted 1,2-shift,[294] but the orbital symmetry principle requires that this take place with inversion at R′.[295] A migration with retention is forbidden (see p. 1019). Since the actual migration takes place with retention, it cannot, according to this argument, proceed by a concerted mechanism.[296] However, in the case where the migrating group is allylic, a concerted mechanism can also operate (**8-39**). An interesting finding which is compatible with all three mechanisms is that optically active allylbenzylmethylphenylammonium iodide (asymmetric nitrogen, see p. 86) gave optically active product:[297]



$$(+)\mathrm{Ph}\overset{\oplus}{-}\underset{\underset{\mathrm{Me}}{|}}{\overset{\overset{\mathrm{CH_2Ph}}{|}}{\mathrm{N}}}-\mathrm{CH_2CH{=}CH_2}\quad \mathrm{I}^- \xrightarrow[\mathrm{Me_2SO}]{\mathrm{KOBu}} 15\%\ (-)\mathrm{Ph}-\underset{\underset{\mathrm{Me}}{|}}{\mathrm{N}}-\overset{\overset{\mathrm{CH_2Ph}}{|}}{\mathrm{CH}}-\mathrm{CH{=}CH_2}$$

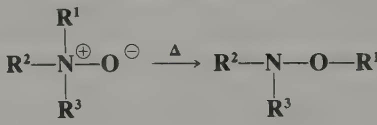
The Sommelet–Hauser rearrangement competes when Z is an aryl group (see **3-27**). Hofmann elimination competes when one of the R groups contains a β-hydrogen atom (**7-6** and **7-7**).

Sulfur ylides containing a Z group give an analogous rearrangement, often also referred to as a Stevens rearrangement.[298] In this case too, there is much evidence (including CIDNP) that a



$$\mathrm{Z}-\overset{\ominus}{\underline{\mathrm{C}}\mathrm{H}}-\underset{\underset{\mathrm{R^1}}{|}}{\overset{\oplus}{\mathrm{S}}}-\mathrm{R^2} \longrightarrow \mathrm{Z}-\underset{\underset{\mathrm{R^1}}{|}}{\mathrm{CH}}-\mathrm{SR^2}$$

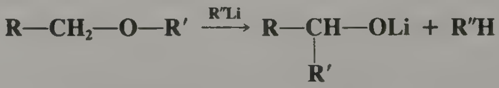
radical-pair cage mechanism is operating,[299] except that when the migrating group is allyl, the mechanism may be different (see **8-39**). Another reaction with a similar mechanism[300] is the *Meisenheimer rearrangement,*[301] in which certain tertiary amine oxides rearrange on heating to give



$$\mathrm{R^2}-\underset{\underset{\mathrm{R^3}}{|}}{\overset{\overset{\mathrm{R^1}}{|}}{\mathrm{N}}}\overset{\oplus}{-}\mathrm{O}^{\ominus} \xrightarrow{\Delta} \mathrm{R^2}-\underset{\underset{\mathrm{R^3}}{|}}{\mathrm{N}}-\mathrm{O}-\mathrm{R^1}$$

substituted hydroxylamines. The migrating group R^1 is almost always allylic or benzilic.[302] R^2 and R^3 may be alkyl or aryl, but if one of the R groups contains a β-hydrogen, the Cope elimination reaction (**7-8**) often competes.

8-25 The Wittig Rearrangement



$$\mathrm{R}-\mathrm{CH_2}-\mathrm{O}-\mathrm{R'} \xrightarrow{\mathrm{R''Li}} \mathrm{R}-\underset{\underset{\mathrm{R'}}{|}}{\mathrm{CH}}-\mathrm{OLi} + \mathrm{R''H}$$

The rearrangement of ethers with alkyllithium is called the *Wittig rearrangement* (not to be confused with the Wittig reaction, **6-47**) and is similar to **8-24.**[282] However, a stronger base is required (e.g., phenyllithium or sodium amide). R and R′ may be alkyl, aryl, or vinyl.[303] Also, one of the hydrogens may be replaced by an alkyl or aryl group, in which case the product is the salt of a tertiary alcohol. Migratory aptitudes here are allyl, benzyl > ethyl > methyl > phenyl.[304] The following radical-pair mechanism[305] (similar to mechanism *a* of **8-24**) is likely, after removal of the proton by the base. One of the radicals in the radical pair is a ketyl radical. Among the evidence for this mechanism is (1) the rearrangement is largely intramolecular; (2) migratory aptitudes are in the order of free-radical stabilities, not of carbanion stabilities[306] (which rules out an ion-pair mechanism similar to mechanism *b* of **8-24**); (3) aldehydes are obtained as side products;[307] (4) partial racemization of R′ has been observed[308] (the remainder of the product retained its configuration); (5) crossover products have been detected;[309] and (6) when ketyl radicals and R· radicals from different precursors were brought together, similar products resulted.[310] However, there is evidence that at least in some cases the radical-pair mechanism accounts for only a portion of the product, and some kind of concerted mechanism can also take place.[311] Most of the above investigations were carried out with systems where R′ is alkyl, but a radical-pair mechanism has also been suggested for the case where R′ is aryl.[312] When R′ is allylic a concerted mechanism can operate (**8-39**).

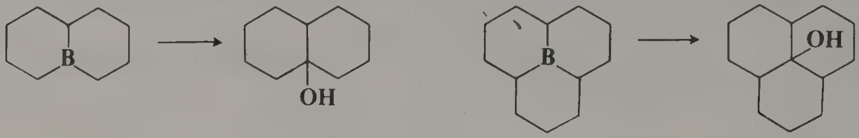
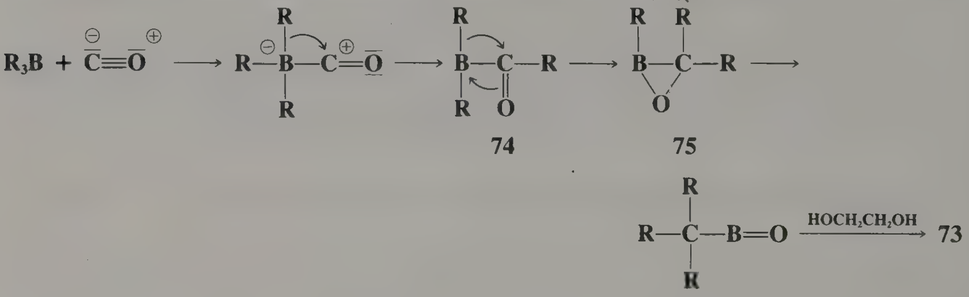
Trialkylboranes (which can be prepared from olefins by **5-13**) react with carbon monoxide[314] at 100 to 125°C in the presence of ethylene glycol to give the 2-bora-1,3-dioxolanes **73,** which are easily oxidized (**2-26**) to tertiary alcohols.[315] The R groups may be primary, secondary, or tertiary, and may be the same or different.[316] Yields are high and the reaction is quite useful, especially for the preparation of sterically hindered alcohols such as tricyclohexylcarbinol and tri-2-norbornylcarbinol, which are difficult to prepare by **6-30.** Heterocycles in which boron is a ring atom react similarly (except that high CO pressures are required), and cyclic alcohols can be obtained from these



substrates.[317] The preparation of such heterocyclic boranes was discussed at **5-13.** The overall conversion of a diene or triene to a cyclic alcohol has been described by H. C. Brown as "stitching" with boron and "riveting" with carbon.

Though the mechanism has not been investigated thoroughly, it has been shown to be intramolecular by the failure to find crossover products when mixtures of boranes are used.[318] The following scheme, involving three boron-to-carbon migrations, has been suggested.



74 **75**

76

The purpose of the ethylene glycol is to intercept the boronic anhydride **76,** which otherwise forms polymers that are difficult to oxidize. As we shall see in **8-27** and **8-28,** it is possible to stop the reaction after only one or two migrations have taken place.

There are two other methods for achieving the conversion $R_3B \rightarrow R_3COH$, which often give better results: (1) treatment with α,α-dichloromethyl methyl ether and the base lithium triethyl-

$$\text{Method 1}\quad R_3B + CHCl_2OMe \xrightarrow[\text{2. } H_2O_2-NaOH]{\text{1. } LiOCEt_3-THF} R_3COH$$

$$\text{Method 2}\quad R_3B + CN^- \xrightarrow{\text{THF}} \underset{\mathbf{77}}{R_3\overset{\ominus}{B}-CN} \xrightarrow[\text{2. } NaOH-H_2O_2]{\text{1. excess } (CF_3CO)_2O} R_3COH$$

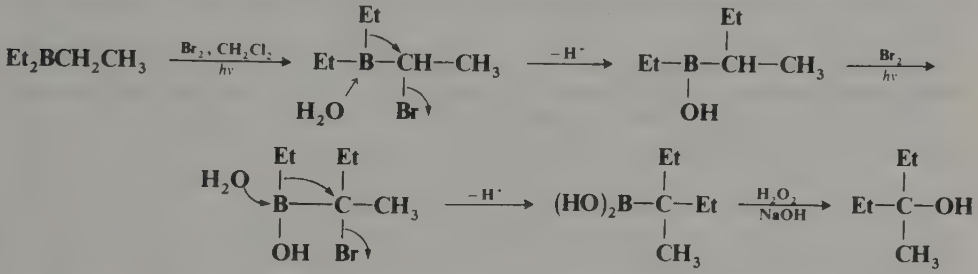
[318] Brown and Rathke, *J. Am. Chem. Soc.* **89,** 4528 (1967).

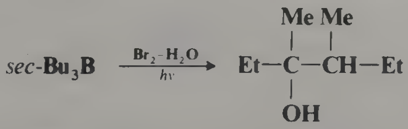
carboxide;[319] (2) treatment with a suspension of sodium cyanide in tetrahydrofuran followed by reaction of the resulting trialkylcyanoborate **77** with an excess (more than 2 moles) of trifluoroacetic anhydride.[320] All the above migrations take place with retention of configuration at the migrating carbon.[321]

Another method converts a trialkylborane to a tertiary alcohol in which only two of the R groups are derived from the borane. In this method the borane is treated with a 1-lithio-1,1-bis(phenylthio)alkane, then with $HgCl_2$, and the product is finally oxidized.[322] This method can be adapted to the preparation of secondary alcohols R_2CHOH ($R' = H$) if three equivalents of $HgCl_2$ are used.[322]

$$\mathbf{R_3B + R'\overset{\ominus}{\bar{C}}(SPh)_2 \longrightarrow R_3\overset{\ominus}{B}—CR'(SPh)_2 \longrightarrow R_2B—CRR'SPh \xrightarrow[\text{2. } H_2O_2\text{-}OH^-]{\text{1. } HgCl_2} R_2R'COH}$$

A different kind of borane-to-tertiary-alcohol conversion involves treatment of a tri-*n*-alkylborane with 2 moles of bromine or N-bromosuccinimide in the presence of water and light, followed by oxidation.[323] In this reaction, illustrated for triethylborane, bromination steps (reaction **4-1**) are followed by migration steps. Tri-*sec*-alkylboranes give corresponding products, but in lower yields. However, when tri-*sec*-alkylboranes are treated with only 1 mole of Br_2, in the presence of water and light, only one migration takes place and the product is a tertiary alcohol derived from two alkyl groups.[324]





$$sec\text{-}\mathbf{Bu_3B} \xrightarrow[h\nu]{Br_2\text{-}H_2O} \mathbf{Et—\underset{OH}{\overset{Me}{C}}—\overset{Me}{C}H—Et}$$

Extension of this reaction to boranes of the form RR′R″B where R″ is thexyl, permits combination of R and R′, since thexyl neither can be α-brominated, nor does it migrate.[325]

Several other methods for the conversion of boranes to tertiary alcohols are also known.[326]

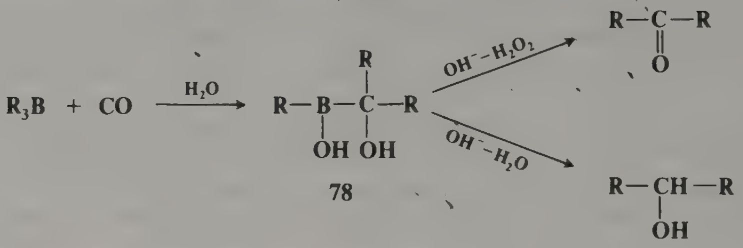
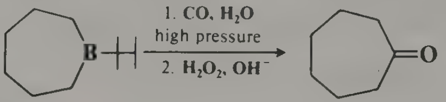
8-27 Conversion of Boranes to Secondary Alcohols or Ketones



78

If the reaction between trialkylboranes and carbon monoxide (**8-26**) is carried out in the presence of water followed by addition of NaOH, the product is a secondary alcohol. If H_2O_2 is added along with the NaOH, the corresponding ketone is obtained instead.[327] Various functional groups (e.g., OAc, COOR, CN) may be present in R without being affected,[328] though if they are in the α or β position relative to the boron atom, difficulties may be encountered. The reaction has been extended to the formation of unsymmetrical ketones by use of a borane of the form $R_2R'B$, where one of the groups migrates much less readily than the other (migratory aptitudes are in the order primary > secondary > tertiary). For example, *n*-alkyldicyclohexylboranes gave good yields of alkyl cyclohexyl ketones.[318] When R′ is thexyl, it is always the other two groups that migrate, so the product from a borane RR′R″B (R″ = thexyl) is the ketone RCOR′.[329] However, the thexyl reaction suffers from the disadvantage that carbonylation of boranes containing a thexyl group requires CO pressures of 70 atm. Cyclic thexylboranes give cyclic ketones,[330] e.g.,



The reaction follows the mechanism shown in **8-26** until formation of the borepoxide **75.** In the presence of water the third boron → carbon migration does not take place, because the water hydrolyzes **75** to the diol **78.**

Trialkylboranes can also be converted to ketones by the cyanoborate procedure, mentioned in **8-26.** In this case the procedure is similar, but use of an equimolar amount of trifluoroacetic

$$R_3\overset{\ominus}{B}—CN \xrightarrow[2.\ H_2O_2\text{-}OH^-]{1.\ (CF_3CO)_2O} RCOR$$

77

anhydride leads to the ketone rather than the tertiary alcohol.[331] By this procedure thexylboranes RR′R″B (R″ = thexyl) can be converted to unsymmetrical ketones RCOR′ without the use of high pressures. Like the carbon monoxide procedure, this method tolerates the presence of various functional groups in R. Another method involves the treatment of borinic acid esters (which can be prepared by treatment of dialkylchloroboranes with alcohols) with α,α-dichloromethyl methyl

$$R_2BCl + R'OH \longrightarrow R_2BOR' \xrightarrow[2.\ H_2O_2\text{-}OH^-]{1.\ CHCl_2OMe,\ LiOCEt_3\ \ THF,\ 25^\circ C} R_2CO$$

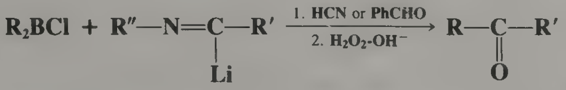
[330] Brown and Negishi, *J. Am. Chem. Soc.* **89,** 5477 (1967), *Chem. Commun.* 594 (1968).

[331] Pelter, Smith, Hutchings, and Rowe, *J. Chem. Soc., Perkin Trans. 1* 129 (1975); Ref. 320. See also Pelter, Hutchings, and Smith, *J. Chem. Soc., Perkin Trans. 1* 142 (1975); Mallison, White, Pelter, Rowe, and Smith, *J. Chem. Res., Synop.* 234 (1978).

ether and lithium triethylcarboxide.[332] This method does not waste an R group and is carried out under mild conditions. In still another procedure ketones are prepared by the reaction between dialkylchloroboranes and lithium aldimines[333] (which can be prepared by **6-71**).



$$R_2BCl + R''\text{—}N{=}\underset{\displaystyle Li}{\underset{|}{C}}\text{—}R' \xrightarrow[\text{2. } H_2O_2\text{-}OH^-]{\text{1. HCN or PhCHO}} R\text{—}\underset{\displaystyle O}{\underset{\|}{C}}\text{—}R'$$

For another conversion of trialkylboranes to ketones, see **8-30.**[334] Other conversions of boranes to secondary alcohols are also known.[335]

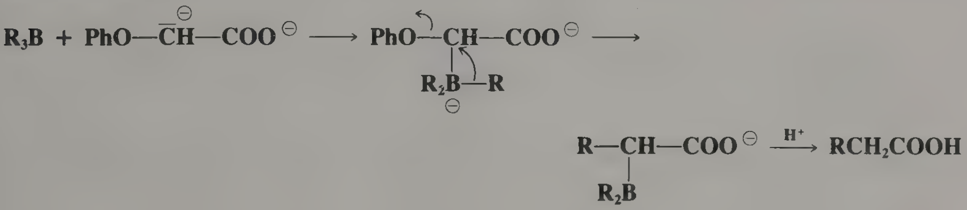
OS **58,** 24.

8-28 Conversion of Boranes to Primary Alcohols, Aldehydes, or Carboxylic Acids

$$R_3B + CO \xrightarrow[\text{2. } H_2O_2\text{-}OH^-]{\text{1. } LiBH_4} RCH_2OH$$

$$R_3B + CO \xrightarrow[\text{2. } H_2O_2\text{-}NaH_2PO_4\text{-}Na_2HPO_4]{\text{1. } LiAl(OMe)_3} RCHO$$

When the reaction between a trialkylborane and carbon monoxide (**8-26**) is carried out in the presence of a reducing agent such as lithium borohydride or potassium triisopropoxyborohydride, the reducing agent intercepts the intermediate **74,** so that only one boron-to-carbon migration takes place, and the product is hydrolyzed to a primary alcohol or oxidized to an aldehyde.[336] This procedure wastes two of the three R groups, but this problem can be avoided by the use of B-alkyl-9-BBN derivatives (p. 426). Since only the 9-alkyl group migrates, this method permits the conversion in high yield of an alkene to a primary alcohol or aldehyde containing one more carbon.[337] When B-alkyl-9-BBN derivatives are treated with CO and lithium tri-*t*-butoxyaluminum hydride,[338] other functional groups (e.g., CN and ester) may be present in the alkyl group without being reduced.[339] Boranes can be directly converted to carboxylic acids by reaction with the dianion of phenoxyacetic acid.[340]



$$R_3B + PhO\text{—}\overset{\ominus}{\bar{C}H}\text{—}COO^{\ominus} \longrightarrow PhO\text{—}\underset{\displaystyle \underset{\ominus}{R_2B}\text{—}R}{\underset{|}{CH}}\text{—}COO^{\ominus} \longrightarrow R\text{—}\underset{\displaystyle R_2B}{\underset{|}{CH}}\text{—}COO^{\ominus} \xrightarrow{H^+} RCH_2COOH$$

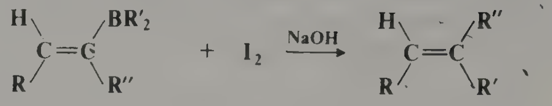
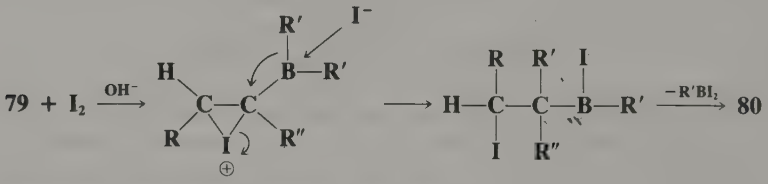
8-29 Conversion of Vinylboranes to Alkenes



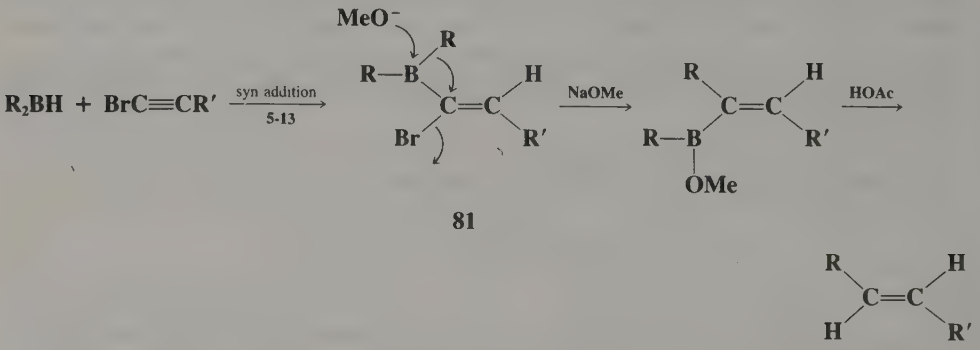
79 **80**

The reaction between trialkylborane and iodine to give alkyl iodides was mentioned at **2-28.** When the substrate contains a vinyl group, the reaction takes a different course, with one of the R′ groups migrating to the carbon, to give alkenes **80.**[341] The reaction is stereospecific in two senses: (1) if the groups R and R″ are cis in the starting compound, they will be trans in the product; (2) there is retention of configuration within the migrating group R′.[342] Since vinylboranes can be prepared from alkynes (**5-13**), this is a method for the addition of R′ and H to a triple bond. If R″ = H, the product is a cis alkene. The mechanism is believed to be



When R′ is vinyl, the product is a conjugated diene.[343]

In another procedure, the addition of a dialkylborane to a 1-haloalkyne produces an α-halovinylborane (**81**).[344] Treatment of this with NaOMe gives the rearrangement shown, and protonolysis



81

of the product produces the *E*-alkene **82.**[342] If R is a vinyl group the product is a 1,3-diene.[345] If one of the groups is thexyl, then the other migrates.[346] This extends the scope of the synthesis, since dialkylboranes where one R group is thexyl are easily prepared.

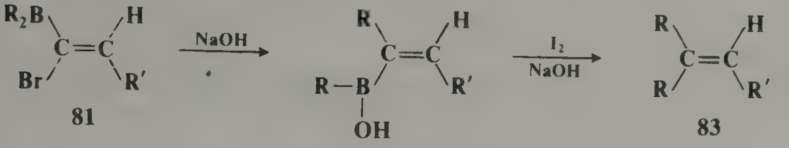
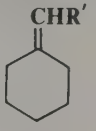
A combination of both of the procedures described above results in the preparation of trisubstituted olefins.[347] The entire conversion of haloalkyne to **83** can be carried out in one reaction vessel, without isolation of intermediates. If R_2BH is a heterocyclic borane, the product is an exocyclic olefin, e.g., **84.**



81 **83**



84

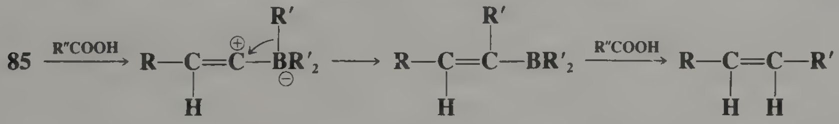
E-alkenes **82** can also be obtained[348] by treatment of **79** ($R'' = H$) with cyanogen bromide or cyanogen iodide in CH_2Cl_2[349] or with $Pd(OAc)_2$-Et_3N.[350]

8-30 Formation of Alkynes, Alkenes, and Ketones from Boranes and Acetylides

$$\mathrm{R'_3B + RC{\equiv}CLi \longrightarrow RC{\equiv}C{-}\overset{\ominus}{B}R'_3\ Li^+ \xrightarrow{I_2} RC{\equiv}CR'}$$

85

A hydrogen directly attached to a triple-bond carbon can be replaced in high yield by an alkyl or an aryl group, by treatment of the lithium acetylide with a trialkyl- or triarylborane, followed by reaction of the lithium alkynyltrialkylborate **85** with iodine.[351] R′ may be primary or secondary alkyl as well as aryl, so the reaction has a broader scope than the older reaction **0-102.**[352] R may be alkyl, aryl, or hydrogen, though in the last-mentioned case satisfactory yields are obtained only if lithium acetylide–ethylenediamine is used as the starting compound.[353] When the starting compound is ClC≡CLi, the Cl is also replaced and the product is the symmetrical alkyne RC≡CR.[354] The reaction may be adapted to the preparation of alkenes by treatment of **85** with an electrophile such as propionic acid[355] or tributyltin chloride.[356] The reaction with Bu_3SnCl stereoselectively produces the *Z* alkene.



$$85 \xrightarrow{R''COOH} \mathrm{R{-}\underset{H}{C}{=}\overset{\oplus}{C}{-}\overset{R'}{\underset{\ominus}{B}}R'_2 \longrightarrow R{-}\underset{H}{C}{=}\overset{R'}{C}{-}BR'_2 \xrightarrow{R''COOH} R{-}\underset{H}{C}{=}\underset{H}{C}{-}R'}$$

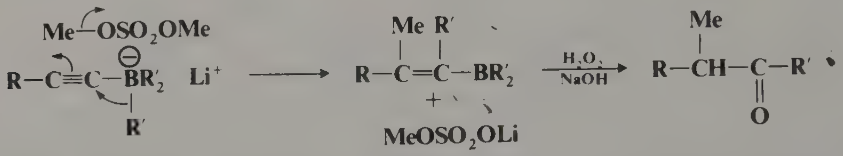
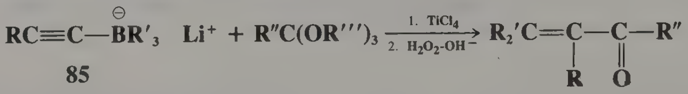
Treatment of **85** with an electrophile such as methyl sulfate, allyl bromide, or triethyloxonium borofluoride, followed by oxidation of the resulting vinylborane gives a ketone (illustrated for methyl sulfate):[357]



The reaction of **85** with ortho esters in the presence of $TiCl_4$, followed by oxidation with H_2O_2 + OH^- gives α,β-unsaturated aldehydes or ketones,[358]



$$RC{\equiv}C{-}\overset{\ominus}{B}R'_3\ \ Li^+ + R''C(OR''')_3 \xrightarrow[2.\ H_2O_2\text{-}OH^-]{1.\ TiCl_4} R_2'C{=}\underset{R}{C}{-}\underset{O}{\overset{\|}{C}}{-}R''$$

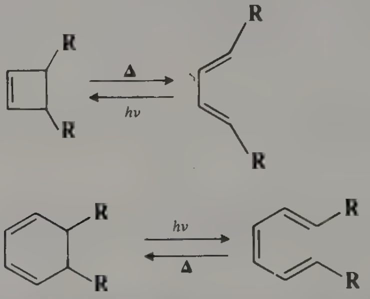
85

while reaction of **85** in THF with CO_2 (under pressure), followed by acetic acid, yields α,β-unsaturated acids R′CH=CRCOOH.[358a]

Non-1,2 Rearrangements

A. Electrocyclic Rearrangements

8-31 Electrocyclic Rearrangements of Cyclobutenes and 1,3-Cyclohexadienes



Cyclobutenes and 1,3-dienes can be interconverted by treatment with uv light or with heat. The thermal reaction is generally not reversible (though exceptions[359] are known), and many cyclobutenes have been converted to 1,3-dienes by heating at temperatures between 100 and 200°C. The photochemical conversion can in principle be carried out in either direction, but most often 1,3-dienes are converted to cyclobutenes rather than the reverse, because the dienes are stronger absorbers of light at the wavelengths used.[360] In a similar reaction, 1,3-cyclohexadienes interconvert with 1,3,5-trienes, but in this case the ring-closing process is generally favored thermally and the ring-opening process photochemically, though exceptions are known in both directions.[361]

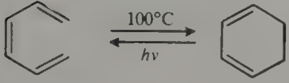
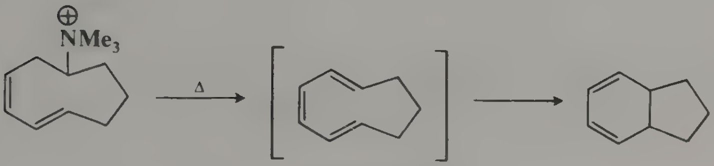
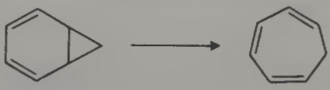
Ref. 362





Not isolated

An interesting example of a 1,3-cyclohexadiene-1,3,5-triene interconversion is the reaction of norcaradienes to give cycloheptatrienes.[363] Norcaradienes give this reaction so readily (because they are *cis*-1,2-divinylcyclopropanes, see p. 1022) that they cannot generally be isolated, though some exceptions are known[364] (see also p. 771).



Norcaradiene

These reactions, called *electrocyclic rearrangements*,[365] take place by pericyclic mechanisms. The evidence for this comes from stereochemical studies, which show a remarkable stereospecificity whose direction depends on whether the reaction is induced by heat or light. For example, it was found for the thermal reaction that *cis*-3,4-dimethylcyclobutene gave only *cis,trans*-2,4-hexadiene, while the trans isomer gave only the trans–trans diene:[366]

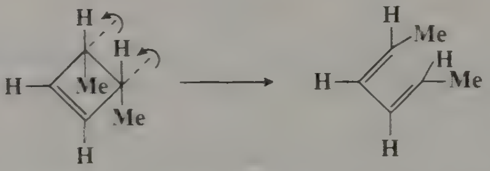
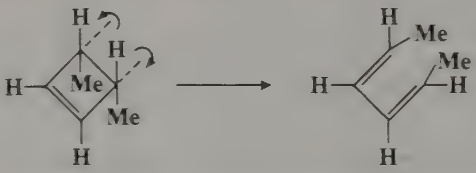
This is evidence for a four-membered cyclic transition state and arises from conrotatory motion about the C-3–C-4 bond. It is called conrotatory because both movements are clockwise (or both counterclockwise). Because both rotate in the same direction, the cis isomer gives the cis–trans diene:[367]



The other possibility (*disrotatory* motion) would have one moving clockwise while the other moves counterclockwise: the cis isomer would have given the cis–cis diene (shown) or the trans–trans diene:



If the motion had been disrotatory, this would still have been evidence for a cyclic mechanism. If the mechanism were a diradical or some other kind of noncyclic process, it is likely that no stereospecificity of either kind would have been observed. The reverse reaction is also conrotatory. In contrast, the photochemical cyclobutene-1,3-diene interconversion is *disrotatory* in either direction. On the other hand, the cyclohexadiene-1,3,5-triene interconversion shows precisely the opposite behavior. The thermal process is *disrotatory*, while the photochemical process is *conrotatory* (in either direction). These startling results are a consequence of the symmetry rules mentioned in Chapter 15 (p. 751).[368] As in the case of cycloaddition reactions, we will use the frontier-orbital and Möbius–Hückel approaches.[369]

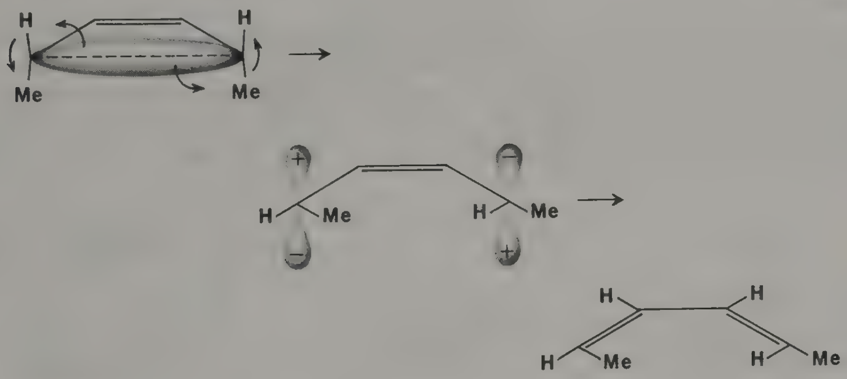
[367] This picture is from Woodward and Hoffmann, *J. Am. Chem. Soc.* **87**, 395 (1965), who coined the terms, *conrotatory* and *disrotatory*.

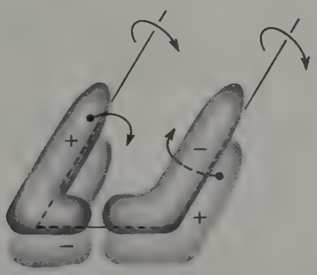
The Frontier-Orbital Method[370]

As applied to these reactions, the frontier-orbital method may be expressed: *A σ bond will open in such a way that the resulting p orbitals will have the symmetry of the highest occupied π orbital of the product.* In the case of cyclobutenes, the HOMO of the product in the thermal reaction is the χ_2 orbital (Figure 1). Therefore, in a thermal process, the cyclobutene must open so that on one side the positive lobe lies above the plane, and on the other side below it. Thus the substituents are forced into conrotatory motion:



On the other hand, in the photochemical process, the HOMO of the product is now the χ_3 orbital (Figure 1), and in order for the *p* orbitals to achieve this symmetry (the two plus lobes on the same side of the plane), the substituents are forced into disrotatory motion.

We may also look at this reaction from the opposite direction (ring closing). For this direction the rule is that *those lobes of orbitals that overlap (in the* HOMO) *must be of the same sign.* For thermal cyclization of butadienes, this requires conrotatory motion:



---

[369] For the correlation diagram method, see Jones, "Physical and Mechanistic Organic Chemistry," 2nd ed., pp. 352–359, Cambridge University Press, Cambridge, 1984; Yates, "Hückel Molecular Orbital Theory," pp. 250–263, Academic Press, New York, 1978; Chapter 15, Ref. 675.

[370] See Chapter 15, Ref. 676.

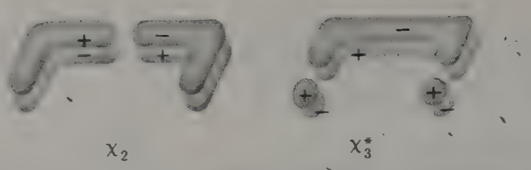

Figure 1 Symmetries of the χ_2 and χ_3* orbitals of a conjugated diene.

In the photochemical process the HOMO is the χ_3 orbital, so that disrotatory motion is required for lobes of the same sign to overlap.

The Möbius–Hückel Method[371]

As we saw on p. 753, in this method we choose a basis set of *p* orbitals and look for sign inversions in the transition state. Figure 2 shows a basis set for a 1,3-diene. It is seen that disrotatory ring closing (Figure 2*a*) results in overlap of plus lobes only, while in conrotatory closing (Figure 2*b*) there is one overlap of a plus with a minus lobe. In the first case we have zero sign inversions, while in the second there is one sign inversion. With zero (or an even number of) sign inversions,

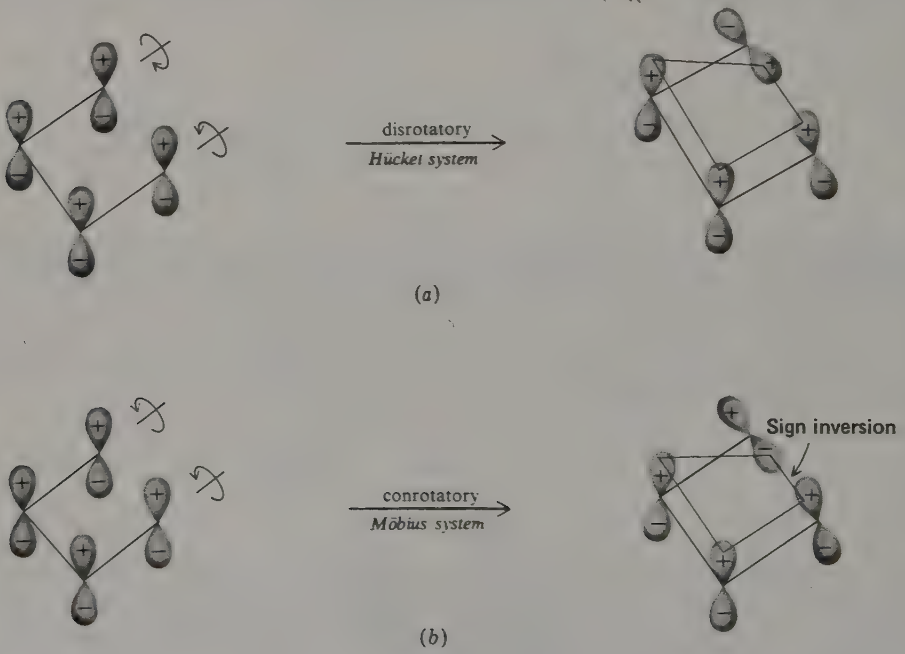

Figure 2 The 1,3-diene-cyclobutene interconversion. The orbitals shown are *not* molecular orbitals, but a basis set of *p* atomic orbitals. (a) Disrotatory ring closure gives zero sign inversions. (b) Conrotatory ring closure gives one sign inversion. We could have chosen to show any other basis set (for example, another basis set would have two plus lobes above the plane and two below, etc.) This would change the number of sign inversions, but the disrotatory mode would still have an even number of sign inversions, and the conrotatory mode an odd number, whichever basis set was chosen.

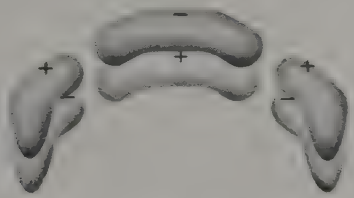
---

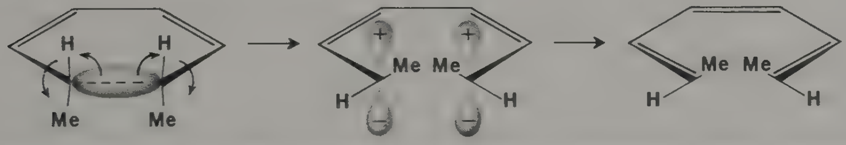
[371] See Chapter 15, Ref. 677.

the disrotatory transition state is a Hückel system, and so is allowed thermally only if the total number of electrons is $4n + 2$ (p. 754). Since the total here is 4, the disrotatory process is not allowed. On the other hand, the conrotatory process, with one sign inversion, is a Möbius system, which is thermally allowed if the total number is $4n$. The conrotatory process is therefore allowed thermally. For the photochemical reactions the rules are reversed: A reaction with $4n$ electrons requires a Hückel system, so that only the disrotatory process is allowed.

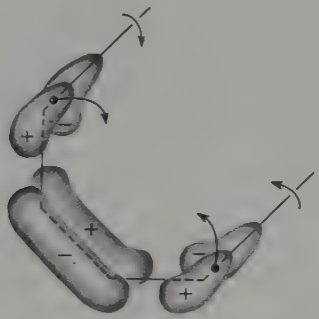
Both the frontier-orbital and the Möbius–Hückel methods can also be applied to the cyclohexadiene–1,3,5-triene reaction; in either case the predicted result is that for the thermal process, only the disrotatory pathway is allowed, and for the photochemical process, only the conrotatory. For example, for a 1,3,5-triene, the symmetry of the HOMO is



In the thermal cleavage of cyclohexadienes, then, the positive lobes must lie on the same side of the plane, requiring disrotatory motion:



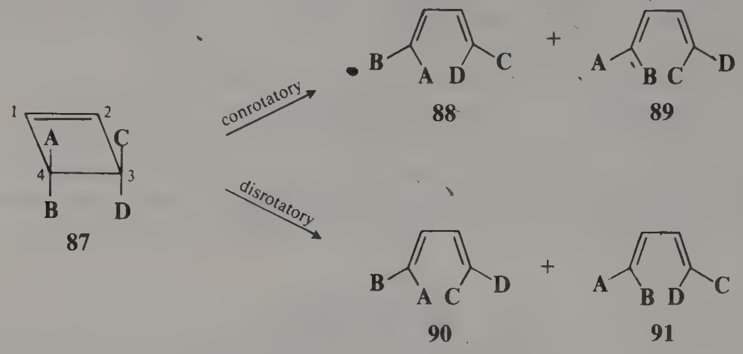
Disrotatory motion is also necessary for the reverse reaction, in order that the orbitals which overlap may be of the same sign:



All these directions are reversed for photochemical processes, because in each case a higher orbital, with inverted symmetry, is occupied.

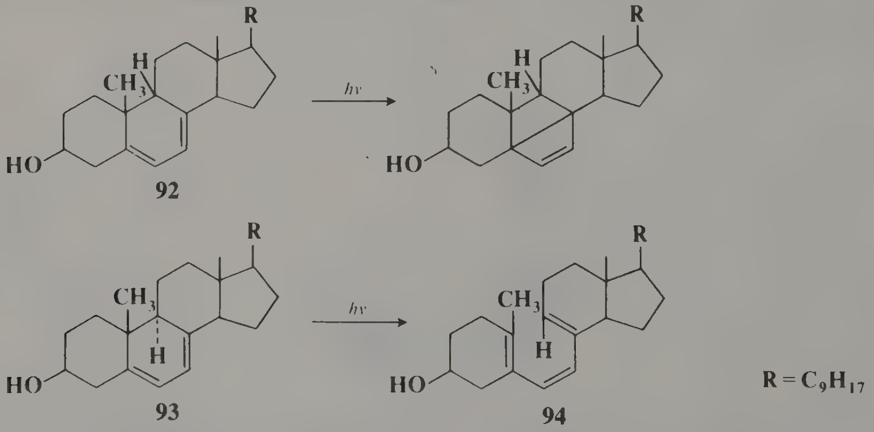
In the Möbius–Hückel approach, diagrams similar to Figure 2 can be drawn for this case. Here too, the disrotatory pathway is a Hückel system and the conrotatory pathway a Möbius system, but since six electrons are now involved, the thermal reaction follows the Hückel pathway and the photochemical reaction follows the Möbius pathway.

In the most general case, there are four possible products that can arise from a given cyclobutene or cyclohexadiene—two from the conrotatory and two from the disrotatory pathway. For example, conrotatory ring opening of **87** gives either **88** or **89,** while disrotatory opening gives either **90** or



91. The orbital-symmetry rules tell us when a given reaction will operate by the conrotatory and when by the disrotatory mode, but they do not say which of the two possible conrotatory or disrotatory pathways will be followed. It is often possible, however, to make such predictions on steric grounds. For example, in the opening of **87** by the disrotatory pathway, **90** arises when groups A and C swing in toward each other (clockwise motion around C-4, counterclockwise around C-3), while **91** is formed when groups B and D swing in and A and C swing out (clockwise motion around C-3, counterclockwise around C-4). We therefore predict that when A and C are larger than B and D, the predominant or exclusive product will be **91,** rather than **90.** Predictions of this kind have largely been borne out.[372]

Cyclohexadienes are of course 1,3-dienes, and in certain cases it is possible to convert them to cyclobutenes instead of to 1,3,5-trienes.[373] An interesting example is found in the pyrocalciferols. Photolysis of the syn isomer **92** (or of the other syn isomer, not shown) leads to the corresponding



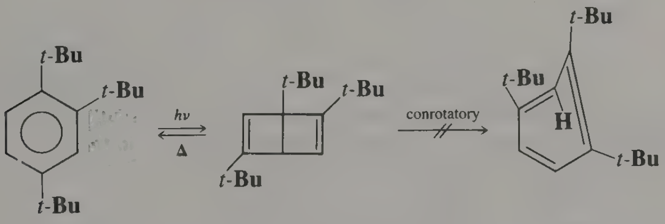
---

[372] For example, see Baldwin and Krueger, *J. Am. Chem. Soc.* **91,** 6444 (1969); Spangler and Hennis, *J. Chem. Soc., Chem. Commun.* 24 (1972). See also Dauben and Michno, *J. Am. Chem. Soc.* **103,** 2284 (1981). For a contrary example, see Dolbier, Koroniak, Burton, Bailey, Shaw, and Hansen, *J. Am. Chem. Soc.* **106,** 1871 (1984).

[373] For a discussion of the factors favoring either direction, see Dauben, Kellogg, Seeman, Vietmeyer, and Wendschuh, *Pure Appl. Chem.* **33,** 197–215 (1973).

cyclobutene,[374] while photolysis of the anti isomers (one of them is **93**) gives the ring-opened 1,3,5-triene **94.** This difference in behavior is at first sight remarkable, but is easily explained by the orbital-symmetry rules. Photochemical ring opening to a 1,3,5-triene must be conrotatory. If **92** were to proceed by this pathway, the product would be the triene **94,** but this compound would have to contain a *trans*-cyclohexene ring (either the methyl group or the hydrogen would have to be directed inside the ring). On the other hand, photochemical conversion to a cyclobutene must be disrotatory, but if **93** were to give this reaction, the product would have to have a trans-fused ring junction. Compounds with such ring junctions are known (p. 114) but are very strained. Stable *trans*-cyclohexenes are unknown (p. 137). Thus, **92** and **93** give the products they do owing to a combination of orbital-symmetry rules and steric influences. Note that **86** (p. 1003) can be opened thermally, though high temperatures are required. The orbital-symmetry rules require concerted thermal ring opening in this system to be conrotatory, but this is impossible here for similar reasons. It is possible that a diradical mechanism is operating, though it has been suggested that a concerted disrotatory pathway is allowed in this case.[375] A concerted mechanism has also been suggested in a case where a butadiene is thermally converted to a cyclobutene in a disrotatory manner.[376]

The 1,3-diene-cyclobutene interconversion can even be applied to benzene rings. For example,[377] photolysis of 1,2,4-tri-*t*-butylbenzene (**95**) gives 1,2,5-tri-*t*-butyl[2.2.0]hexadiene (**96,** a Dewar benzene).[378] The reaction owes its success to the fact that once **96** is formed, it cannot, under the conditions used, revert to **95** by either a thermal or a photochemical route. The orbital-symmetry rules prohibit thermal conversion of **96** to **95** by a pericyclic mechanism, because thermal conversion of a cyclobutene to a 1,3-diene must be conrotatory, and conrotatory reaction of **96** would result in a 1,3,5-cyclohexatriene containing one trans double bond (**97**), which is of course too strained to exist. **96** cannot revert to **95** by a photochemical pathway either, because light of the frequency used to excite **95** would not be absorbed by **96.** This is thus another example of a molecule that owes its stability to the orbital-symmetry rules (see p. 767). Pyrolysis of **96** does give **95,** probably



95 **96** **97**

---

[374] Dauben and Fonken, *J. Am. Chem. Soc.* **81,** 4060 (1959). This was the first reported example of the conversion of a 1,3-diene to a cyclobutene.

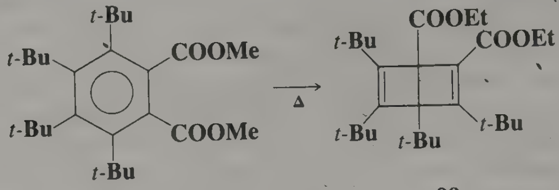
[376] Steiner and Michl, Ref. 359.

[377] Unsubstituted Dewar benzene has been obtained, along with other photoproducts, by photolysis of benzene: Ward and Wishnok, *J. Am. Chem. Soc.* **90,** 1085 (1968); Bryce-Smith, Gilbert, and Robinson, *Angew. Chem. Int. Ed. Engl.* **10,** 745 (1971) [*Angew. Chem.* **83,** 803]. For other examples, see Arnett and Bollinger, *Tetrahedron Lett.* 3803 (1964); Camaggi, Gozzo, and Cevidalli, *Chem. Commun.* 313 (1966); Haller, *J. Am. Chem. Soc.* **88,** 2070 (1966), *J. Chem. Phys.* **47,** 1117 (1967); Barlow, Haszeldine, and Hubbard, *Chem. Commun.* 202 (1969); Lemal, Staros, and Austel, *J. Am. Chem. Soc.* **91,** 3373 (1969).

[378] van Tamelen and Pappas, *J. Am. Chem. Soc.* **84,** 3789 (1962); Wilzbach and Kaplan, *J. Am. Chem. Soc.* **87,** 4004 (1965); van Tamelen, Pappas, and Kirk, *J. Am. Chem. Soc.* **93,** 6092 (1971); van Tamelen, *Acc. Chem. Res.* **5,** 186–192 (1972). As mentioned on p. 767 (Ref. 764), Dewar benzenes can be photolyzed further to give prismanes.

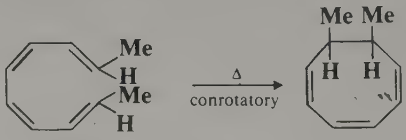
by a diradical mechanism.[379] In the case of **98** and **99**, the Dewar benzene is actually more stable



98 **99**

than the benzene. **98** rearranges to **99** in 90% yield at 120°.[380] In this case thermolysis of the benzene gives the Dewar benzene (rather than the reverse), because of the strain of four adjacent *t*-butyl groups on the ring.

A number of electrocyclic reactions have been carried out with systems of other sizes, e.g., conversion of the 1,3,5,7-octatetraene **100** to the cyclooctatriene **101**.[381] The stereochemistry of



100 **101**

these reactions can be predicted in a similar manner. The results of such predictions can be summarized according to whether the number of electrons involved in the cyclic process is of the form $4n$ or $4n + 2$ (where n is any integer including zero).

	Thermal reaction	Photochemical reaction
$4n$	conrotatory	disrotatory
$4n + 2$	disrotatory	conrotatory

Although the orbital-symmetry rules predict the stereochemical results in almost all cases, it is necessary to recall (p. 755) that they only say what is allowed and what is forbidden, but the fact that a reaction is allowed does not necessarily mean that that reaction takes place, and if an allowed reaction does take place, it does not *necessarily* follow that a concerted pathway is involved, since other pathways of lower energy may be available.[382] Furthermore, a ''forbidden'' reaction might still be made to go, if a method of achieving its high activation energy can be found. This was, in fact, done for the cyclobutene–butadiene interconversion (*cis*-3,4-dichlorocyclobutene gave the forbidden *cis,cis*- and *trans,trans*-1,4-dichloro-1,3-cyclobutadienes, as well as the allowed cis, trans isomer) by the use of ir laser light.[383] This is a thermal reaction. The laser light excites the molecule to a higher vibrational level (p. 203), but not to a higher electronic state.

As is the case for 2 + 2 cycloaddition reactions (**5-48**), certain forbidden electrocyclic reactions can be made to take place by the use of metallic catalysts.[384] An example is the silver ion–catalyzed conversion of tricyclo[$4.2.0.0^{2,5}$]octa-3,7-diene to cyclooctatetraene:[385]

This conversion is very slow thermally (i.e., without the catalyst) because the reaction must take place by a disrotatory pathway, which is disallowed thermally.[386] Cyclobutenes in which carbanionic carbon is generated at a position α to one of the non-double–bonded carbons undergo ring opening to butadienes extremely readily, even at −30°C.[387] The mechanism of this process has not been investigated.

The ring opening of cyclopropyl cations (pp. 304, 966) is an electrocyclic reaction and is governed by the orbital symmetry rules.[388] For this case we may invoke the rule that the σ bond opens in such a way that the resulting *p* orbitals have the symmetry of the highest occupied orbital of the product, in this case, an allylic cation. We may recall that an allylic system has three molecular orbitals (p. 29). For the cation, with only two electrons, the highest occupied orbital is the one of lowest energy (**A**). Thus, the cyclopropyl cation must undergo a disrotatory ring opening in order to maintain the symmetry. (Note that, in contrast, ring opening of the cyclopropyl *anion* must be conrotatory, since in this case it is the next orbital of the allylic system which is the highest occupied, and this has the opposite symmetry.[389]) However, it is very difficult to generate a free cyclopropyl cation (p. 304), and it is likely that in most cases, cleavage of the σ bond is concerted with departure of the leaving group in the original cyclopropyl substrate.[390] This of course means that the σ bond provides anchimeric assistance to the removal of the leaving group (an S_N2-type process), and we would expect that such assistance should come from the back side. This has an important effect on the direction of ring opening. The orbital-symmetry rules require that the ring opening be disrotatory, but as we have seen, there are two disrotatory pathways and the rules do not tell us which is preferred. But the fact that the σ orbital provides assistance from the back side means that the two substituents which are trans to the leaving group must move *outward*, not inward.[391] Thus, the disrotatory pathway that is followed is the one shown in **B**, not the one shown

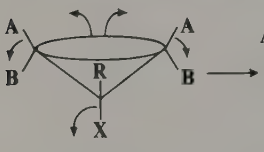
[388] For discussions, see DePuy, *Acc. Chem. Res.* **1**, 33–41 (1968); Schöllkopf, *Angew. Chem. Int. Ed. Engl.* **7**, 588–598 (1968) [*Angew. Chem.* **80**, 603–613].

[389] For evidence that this is so, see Newcomb and Ford, *J. Am. Chem. Soc.* **96**, 2968 (1974); Boche, Buckl, Martens, Schneider, and Wagner, *Chem. Ber.* **112**, 2961 (1979); Coates and Last, *J. Am. Chem. Soc.* **105**, 7322 (1983). For a review of the analogous ring opening of epoxides, see Huisgen, *Angew. Chem. Int. Ed. Engl.* **16**, 572–585 (1977) [*Angew. Chem.* **89**, 589–602].

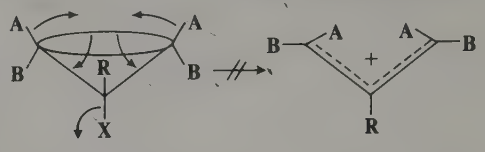
[390] There is evidence that cyclopropylic cations are intermediates in geometrically constrained bicyclic and tricyclic systems where the cyclopropyl ring is locked in in such a way that the ring-opening process is impossible or at least minimized: Olah, Liang, Ledlie, and Costopoulos, *J. Am. Chem. Soc.* **99**, 4196 (1977), and references cited therein.

[391] This statement was first proposed by DePuy, Schnack, Hausser, and Wiedemann, *J. Am. Chem. Soc.* **87**, 4006 (1965).

in **C**, because the former puts the electrons of the σ bond on the side opposite that of the leaving

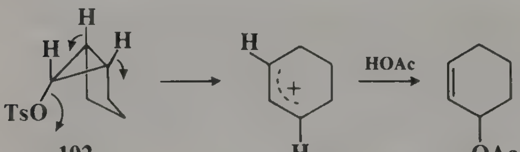


B

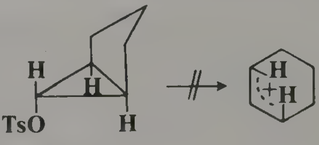


C

group.[392] Strong confirmation of this picture[393] comes from acetolysis of *endo*- (**102**) and *exo*-bicyclo[3,1,0]-hexyl-6-tosylate (**103**). The groups trans to the tosylate must move outward. For **102** this means that the two hydrogens can go outside the framework of the six-membered ring,



102



103

but for **103** they are forced to go inside. Consequently, it is not surprising that the rate ratio for solvolysis of **102**/**103** was found to be greater than 2.5 × 10^6 and that at 150°C **103** did not solvolyze at all.[394] This evidence is kinetic. Unlike the cases of the cyclobutene-1,3-diene and cyclohexadiene-1,3,5-triene interconversions, the direct product here is a cation, which is not stable but reacts with a nucleophile and loses some of its steric integrity in the process, so that much of the evidence has been of the kinetic type rather than from studies of product stereochemistry. However, it has been shown by investigations in super acids, where it is possible to keep the cations intact and to study their structures by nmr, that in all cases studied the cation that is predicted by these rules is in fact formed.[395]

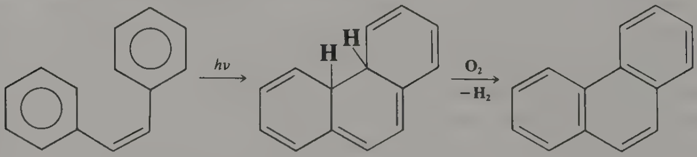
8-32 Conversion of Stilbenes to Phenanthrenes



Stilbenes can be converted to phenanthrenes by irradiation with uv light[396] in the presence of an oxidizing agent such as dissolved molecular oxygen, $FeCl_3$, tetracyanoethylene,[397] or iodine. The reaction is a photochemically allowed conrotatory[398] conversion of a 1,3,5-hexatriene to a cyclohexadiene, followed by removal of two hydrogen atoms by the oxidizing agent. The intermediate dihydrophenanthrene has been isolated in one case.[399] The use of substrates containing hetero atoms (e.g., PhN=NPh) allows the formation of heterocyclic ring systems. The actual reacting species must be the *cis*-stilbene, but *trans*-stilbenes can often be used, because they are isomerized to the cis isomers under the reaction conditions. The reaction can be extended to the preparation of many fused aromatic systems, e.g.,[400]

---

[392] It has been suggested that the pathway shown in **C** is possible in certain cases: Hausser and Grubber, *J. Org. Chem.* **37,** 2648 (1972); Hausser and Uchic, *J. Org. Chem.* **37,** 4087 (1972).

[393] There is much other evidence. For example, see Jefford and Medary, *Tetrahedron Lett.* 2069 (1966); Jefford and Wojnarowski, *Tetrahedron Lett.* 199 (1968); Jefford and Hill, *Tetrahedron Lett.* 1957 (1969); Schleyer, Van Dine, Schöllkopf, and Paust, *J. Am. Chem. Soc.* **88,** 2868 (1966); Sliwinski, Su, and Schleyer, *J. Am. Chem. Soc.* **94,** 133 (1972); Sandler, *J. Org. though not all such systems give the reaction.[401]

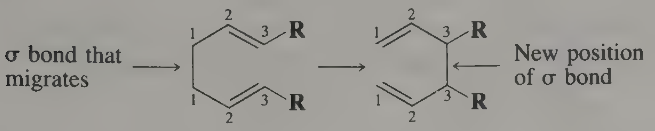
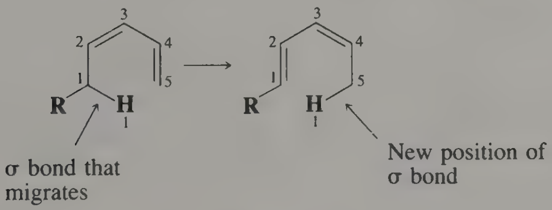
B. Sigmatropic Rearrangements. A sigmatropic rearrangement is defined[402] as migration, in an uncatalyzed intramolecular process, of a σ bond, adjacent to one or more π systems, to a new position in a molecule, with the π systems becoming reorganized in the process. Examples are



Reaction **8-36**
A [3,3] sigmatropic rearrangement



Reaction **8-33**
A [1,5] sigmatropic rearrangement

The *order* of a sigmatropic rearrangement is expressed by two numbers set in brackets: $[i,j]$. These numbers can be determined by counting the atoms over which each end of the σ bond has moved. Each of the original termini is given the number 1. Thus in the first example above, each terminus of the σ bond has migrated from C-1 to C-3, so the order is [3,3]. In the second example the carbon terminus has moved from C-1 to C-5, but the hydrogen terminus has not moved at all, so the order is [1,5].

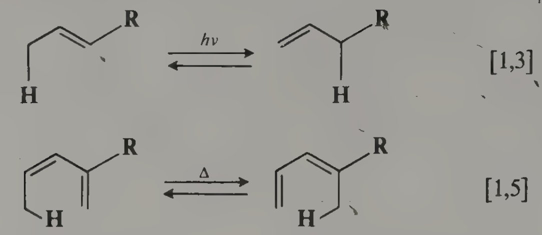
8-33 [1,*j*] Sigmatropic Migrations of Hydrogen



Many examples of thermal or photochemical rearrangements in which a hydrogen atom migrates from one end of a system of π bonds to the other have been reported,[403] though the reaction is subject to geometrical conditions. Pericyclic mechanisms are involved, and the hydrogen must, in the transition state, be in contact with both ends of the chain at the same time. This means that for [1,5] and longer rearrangements, the molecule must be able to adopt the cisoid conformation. Furthermore, there are two geometrical pathways by which any sigmatropic rearrangement can take place, which we illustrate for the case of a [1,5] sigmatropic rearrangement,[404] starting with a

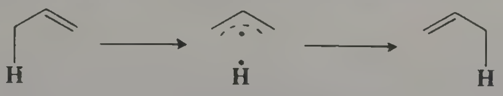
Rev.* **76,** 187–217 (1976); DeWolfe, in Bamford and Tipper, Ref. 365, pp. 474–480; Woodward and Hoffmann, Ref. 402, pp. 114–140; Hansen and Schmid, *Chimia* **24,** 89–99 (1970); Roth, *Chimia* **20,** 229–236 (1966).

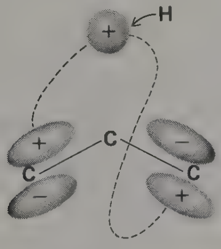
[404] Note that a [1,5] sigmatropic rearrangement of hydrogen is also an internal ene synthesis (**5-16**).

substrate of the form **104,** where the migration origin is an asymmetric carbon atom and U ≠ V. In one of the two pathways, the hydrogen moves along the top or bottom face of the π system. This is called *suprafacial migration.* In the other pathway, the hydrogen moves *across* the π system, from top to bottom, or vice versa. This is *antarafacial* migration. Altogether, a single isomer like **104** can give four products. In a suprafacial migration, H can move across the top of the π system (as drawn above) to give the *R,Z* isomer, or it can rotate 180° and move across the bottom of the π system to give the *S,E* isomer.[405] The antarafacial migration can similarly lead to two diastereomers, in this case the *S,Z* and *R,E* isomers.

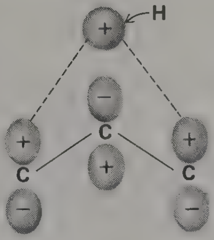
In any given sigmatropic rearrangement, only one of the two pathways is allowed by the orbital-symmetry rules; the other is forbidden. To analyze this situation we first use a modified frontier orbital approach.[406] We will imagine that in the transition state the migrating H atom breaks away from the rest of the system, which we may treat as if it were a free radical. Note that this is not what actually takes place; we merely imagine it in order to be able to analyze the process. In a [1,3] sigmatropic rearrangement the imaginary transition state consists of a hydrogen atom and an allyl radical. The latter species (p. 29) has three π orbitals, but the only one that concerns us here is the HOMO which, in a thermal rearrangement is **D.** The electron of the hydrogen atom is of course in a 1*s* orbital, which has only one lobe. The rule governing sigmatropic migration of hydrogen is that *the H must move from a plus to a plus or from a minus to a minus lobe, of the highest occupied molecular orbital; it cannot move to a lobe of opposite sign.*[407] Obviously, the only way this can happen in a thermal [1,3] sigmatropic rearrangement is if the migration is antarafacial. Consequently, the rule predicts that antarafacial thermal [1,3] sigmatropic rearrangements are allowed, but the suprafacial pathway is forbidden. However, in a photochemical reaction, promotion of an electron means that **E** is now the HOMO; the suprafacial pathway is now allowed and the antarafacial pathway forbidden.



Imaginary transition state for a [1,3] sigmatropic rearrangement



D



E

---

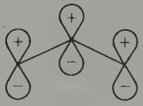
[405] Since we are using the arbitrary designations U, V, Y, and Z, we have been arbitrary in which isomer to call *R,Z* and which to call *S,E*.

[406] See Woodward and Hoffmann, Ref. 402, pp. 114–140.

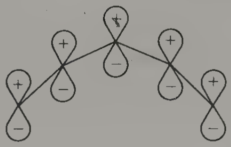
[407] This follows from the principle that bonds are formed only by overlap of orbitals of the same sign. Since this is a concerted reaction, the hydrogen orbital in the transition state must overlap simultaneously with one lobe from the migration origin and one from the terminus. It is obvious that both of these lobes must have the same sign.

A similar analysis of [1,5] sigmatropic rearrangements shows that in this case the thermal reaction must be suprafacial and the photochemical process antarafacial. For the general case, with odd-numbered j, we may say that $[1,j]$ suprafacial migrations are allowed thermally when j is of the form $4n + 1$, and photochemically when j has the form $4n - 1$; the opposite is true for antarafacial migrations.

As expected, the Möbius–Hückel method leads to the same predictions. Here we look at the basis set of orbitals shown in **F** and **G** for [1,3] and [1,5] rearrangements, respectively. A [1,3] shift involves four electrons, so an allowed thermal pericyclic reaction must be a Möbius system (p. 1007) with one or an odd number of sign inversions. As can be seen in **F**, only an antarafacial migration can achieve this. A [1,5] shift, with six electrons, is allowed thermally only when it is a Hückel system with zero or an even number of sign inversions; hence it requires a suprafacial migration.

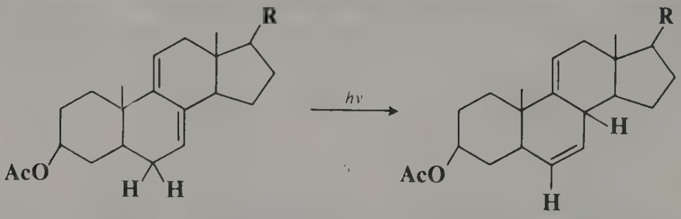


F

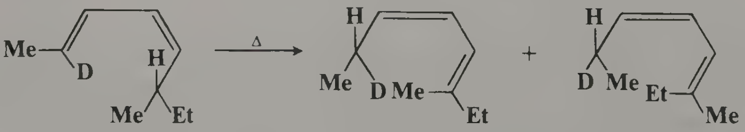


G

The actual reported results bear out this analysis. Thus a thermal [1,3] migration is allowed to take place only antarafacially, but such a transition state would be extremely strained, and thermal [1,3] sigmatropic migrations of hydrogen are unknown. On the other hand, the photochemical pathway allows suprafacial [1,3] shifts, and a few such reactions are known, an example being[408]



The situation is reversed for [1,5] hydrogen shifts. In this case the thermal rearrangements, being suprafacial, are quite common, while photochemical rearrangements are rare.[409] Examples of the thermal reaction are



Ref. 410

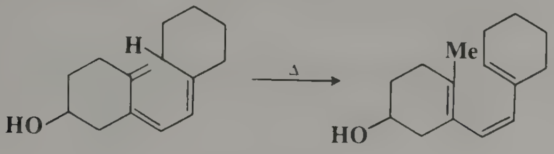
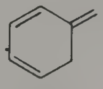
[411] McLean and Haynes, *Tetrahedron* **21,** 2329 (1965). For a review of such rearrangements, see Klärner, *Top. Stereochem.* **15,** 1–42 (1984).

Note that the first example bears out the stereochemical prediction made earlier. Only the two isomers shown were formed. In the second example, migration can continue around the ring. Migrations of this kind are called *circumambulatory rearrangements*.[412]

With respect to [1,7] hydrogen shifts, the orbital symmetry rules predict that the thermal reaction must be antarafacial. Unlike the case of [1,3] shifts, the transition state is not too greatly strained, and such rearrangements have been reported, e.g.,[413]



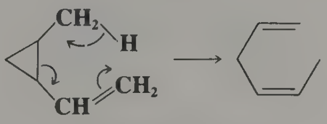


105

Photochemical [1,7] shifts are suprafacial and, not surprisingly, many of these have been observed.[414]

The orbital symmetry rules also help us to explain, as on pp. 767 and 1009, the unexpected stability of certain compounds. Thus, **105** could, by a thermal [1,3] sigmatropic rearrangement, easily convert to toluene, which of course is far more stable because it has an aromatic sextet. Yet **105** has been prepared and is stable at dry ice temperature and in dilute solutions.[415]

Analogs of sigmatropic rearrangements in which a cyclopropane ring replaces one of the double bonds are also known, e.g.,[416]



a homodienyl [1,5] shift

The reverse reaction has also been reported.[417] 2-Vinylcycloalkanols[418] undergo an analogous reaction, as do cyclopropyl ketones (see p. 1029 for this reaction).

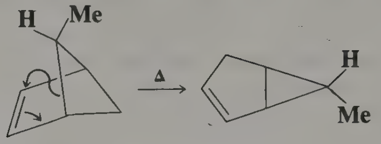
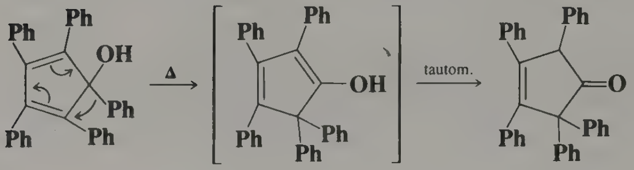
8-34 [1,*j*] Sigmatropic Migrations of Carbon

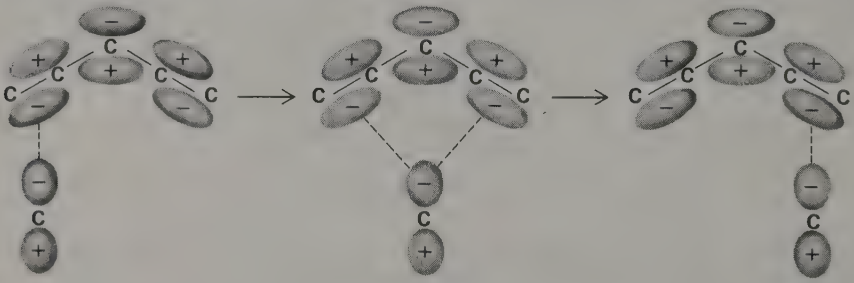


[1,3] migration of alkyl[419]



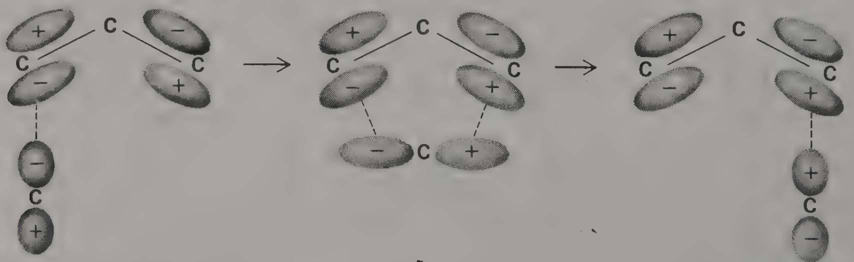
[1,5] migration of phenyl[420]

Sigmatropic migrations of alkyl or aryl groups[421] are less common than the corresponding hydrogen migrations.[422] When they do take place, there is an important difference. Unlike a hydrogen atom, whose electron is in a 1*s* orbital that has only one lobe, a carbon free radical has its odd electron in a *p* orbital that has *two lobes of opposite sign*. Therefore, if we draw the imaginary transition states for this case (see p. 1015), we see that in a thermal suprafacial [1,5] process (**H**), symmetry can be conserved only if the migrating carbon moves in such a way that the lobe which was originally attached to the π system remains attached to the π system. This can happen only if



H

configuration is *retained within the migrating group*. On the other hand, a thermal suprafacial [1,3] migration (**I**) *can* take place if the migrating carbon switches lobes. If the migrating carbon was



I

---

[419] Roth and Friedrich, *Tetrahedron Lett.* 2607 (1969).

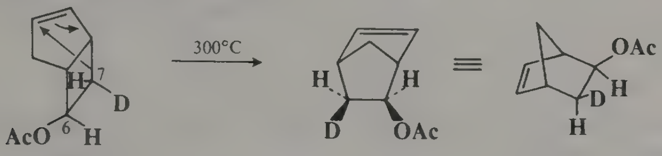
[420] Youssef and Ogliaruso, *J. Org. Chem.* **37,** 2601 (1972).

[421] For reviews, see Mironov, Fedorovich, and Akhrem, Ref. 403; Spangler, Ref. 403.

[422] It has been shown that methyl and phenyl have lower migratory aptitudes than hydrogen in thermal sigmatropic rearrangements: Shen, McEwen, and Wolf, *Tetrahedron Lett.* 827 (1969); Miller, Greisinger, and Boyer, *J. Am. Chem. Soc.* **91,** 1578 (1969).

originally bonded by its minus lobe, it must now use its plus lobe to form the new C—C bond. Thus, configuration in the migrating group will be *inverted*. From these considerations we predict that suprafacial [1,*j*] sigmatropic rearrangements in which carbon is the migrating group are always allowed, both thermally and photochemically, but that thermal [1,3] migrations will proceed with inversion and thermal [1,5] migrations with retention of configuration within the migrating group. More generally, we may say that suprafacial [1,*j*] migrations of carbon in systems where $j = 4n - 1$ proceed with inversion thermally and retention photochemically, while systems where $j = 4n + 1$ show the opposite behavior. Where antarafacial migrations take place, all these predictions are of course reversed.

The first laboratory test of these predictions was the pyrolysis of deuterated *endo*-bicyclo[3.2.0]-hept-2-en-6-yl acetate (**106**), which gave the *exo*-deuterio-*exo*-norbornyl acetate **107**.[423] Thus, as predicted by the orbital symmetry rules, this thermal suprafacial [1,3] sigmatropic reaction took place with complete inversion at C-7. Similar results have been obtained in a number of other cases.[424] However, because rotation of the C-7 carbon is required to be clockwise, the pathway leading to inversion can be blocked by the introduction into **106** of an endo methyl group at C-7, in which case the reaction takes place with predominant retention.[425] It has been suggested that an orbital-symmetry-forbidden concerted reaction takes place in these cases.[426] Photochemical suprafacial [1,3] migrations of carbon have been shown to proceed with retention, as predicted.[427]



106 **107**

Thermal suprafacial [1,5] migrations of carbon have been found to take place with retention,[428] but also with inversion.[429,430] A diradical mechanism has been suggested for the latter case.[429]

Simple nucleophilic, electrophilic, and free-radical 1,2 shifts may also be regarded as sigmatropic rearrangements (in this case, [1,2] rearrangements). We have already (p. 942) applied similar principles to such rearrangements to show that nucleophilic 1,2 shifts are allowed, but the other two types are forbidden unless the migrating group has some means of delocalizing the extra electron or electron pair.

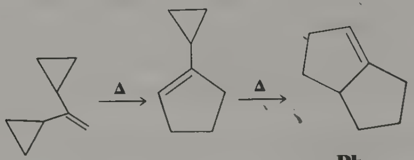
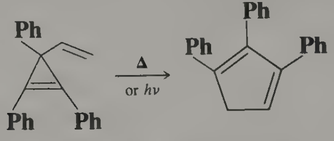
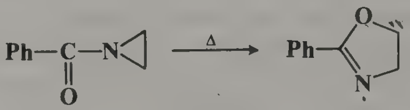
The thermal expansion of a vinylcyclopropane to a cyclopentene ring[431] is a special case of a [1,3] sigmatropic migration of carbon, though it can also be considered an internal $[_{\pi}2 + {}_{\sigma}2]$ cycloaddition reaction (see **5-48**). The reaction has been carried out on many vinylcyclopropanes bearing various substituents in the ring or on the vinyl group and has been extended to 1,1-dicyclopropylethene[432] and (both thermally[433] and photochemically[434]) to vinylcyclopropenes. Various heterocyclic analogs are also known, e.g.,[435]







Vinylcyclobutenes can be similarly converted to cyclohexenes,[436] but larger ring compounds do not generally give the reaction.[437] Though high temperatures (as high as 500°C) are normally required for the thermal reaction, the lithium salts of 2-vinylcyclopropanols rearrange at 25°C.[438] Salts of 2-vinylcyclobutanols behave analogously.[439]

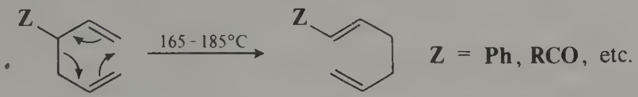
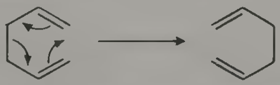
The mechanisms of these ring expansions are not certain. Both concerted[440] and diradical[441] pathways have been proposed, and it is possible that both pathways operate, in different systems.

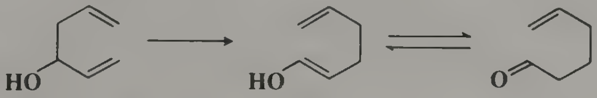
8-36 The Cope Rearrangement



When 1,5-dienes are heated, they isomerize, in a [3,3] sigmatropic rearrangement known as the *Cope rearrangement* (not to be confused with the Cope elimination reaction, **7-8**).[442] When the diene is symmetrical about the 3,4 bond, we have the unusual situation where a reaction gives a product identical with the starting material:[443]



Therefore, a Cope rearrangement can be detected only when the diene is not symmetrical about this bond. Any 1,5-diene gives the rearrangement; for example, 3-methyl-1,5-hexadiene heated to 300°C gives 1,5-heptadiene.[444] However, the reaction takes place more easily (lower temperature required) when there is a group on the 3- or 4-carbon with which the new double bond can conjugate. The reaction is obviously reversible and produces an equilibrium mixture of the two 1,5-dienes, which is richer in the thermodynamically more stable isomer. However, the reaction cannot be reversed for 3-hydroxy-1,5-dienes, because the product tautomerizes to the ketone or aldehyde:



This is called the *oxy-Cope rearrangement*.[445] The oxy-Cope rearrangement is greatly accelerated (by factors of 10^{10} to 10^{17}) if the alkoxide is used rather than the alcohol.[446] In this case the direct product is the enolate ion, which is hydrolyzed to the ketone.

---

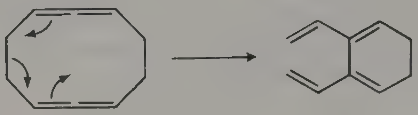
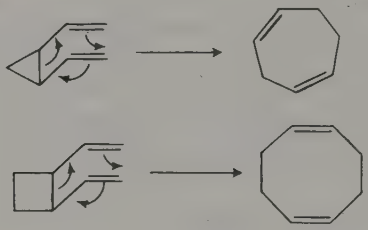
The 1,5-diene system may be inside a ring or part of an allenic system (this example illustrates both of these situations):[447]



but the reaction does not take place when one of the double bonds is part of an aromatic system, e.g., 4-phenyl-1-butene.[448] When the two double bonds are in vinyl groups attached to adjacent ring positions, the product is a ring four carbons larger. This has been applied to divinylcyclopropanes and cyclobutanes:[449]



Indeed, *cis*-1,2-divinylcyclopropanes give this rearrangement so rapidly that they generally cannot be isolated at room temperature,[450] though exceptions are known.[451] When heated, 1,5-diynes are converted to 3,4-dimethylenecyclobutenes.[452] A rate-determining Cope rearrangement is followed

by a very rapid electrocyclic (**8-31**) reaction. The interconversion of 1,3,5-trienes and cyclohexadienes (in **8-31**) is very similar to the Cope rearrangement, though in **8-31**, the 3,4 bond goes from a double bond to a single bond rather than from a single bond to no bond.

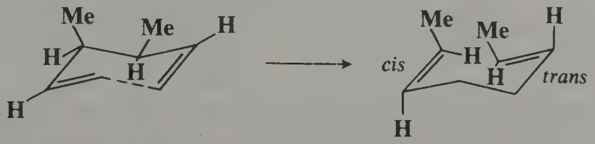
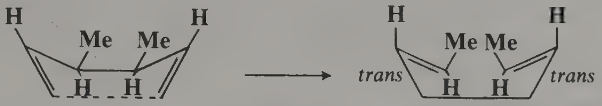
[452] For reviews of Cope rearrangements involving triple bonds, see Viola, Collins, and Filipp, *Tetrahedron* **37,** 3765–3811 (1981); Théron, Verny, and Vessière, in Patai, "The Chemistry of the Carbon–Carbon Triple Bond," pt. 1, pp. 381–445, Wiley, New York, 1978, pp. 428–430; Huntsman, *Intra-Sci. Chem. Rep.* **6,** 151–159 (1972).

Like 2 + 2 cycloadditions (p. 766), Cope rearrangements of simple 1,5-dienes can be catalyzed by certain transition-metal compounds. For example, the addition of $PdCl_2(PhCN)_2$ causes the reaction to take place at room temperature.[453]

As we have indicated with our arrows, the mechanism of the uncatalyzed Cope rearrangement is a simple six-centered pericyclic process. Since the mechanism is so simple, it has been possible to study some rather subtle points, among them the question of whether the six-membered transition state is in the boat or the chair form. For the case of 3,4-dimethyl-1,5-hexadiene it was demonstrated conclusively that the transition state is in the chair form. This was shown by the stereospecific nature of the reaction: The meso isomer gave the cis–trans product, while the *dl* compound gave the trans–trans diene.[454] If the transition state is in the chair form (taking the meso isomer, for example), one methyl must be "axial" and the other "equatorial" and the product must be the cis–trans olefin:



There are two possible boat forms for the transition state of the meso isomer. One of these leads to a trans–trans product:



and the other to a cis–cis olefin. For the *dl* pair the predictions are just the opposite: There is just one boat form, and it leads to the cis–trans olefin, while one chair form ("diaxial" methyls) leads to the cis–cis product and the other ("diequatorial" methyls) predicts the trans–trans product. Thus the nature of the products obtained demonstrates that the transition state is a chair and not a boat.[455] However, 3,4-dimethyl-1,5-hexadiene is free to assume either the chair or boat (it prefers the chair), but other compounds are not so free. Thus 1,2-divinylcyclopropane (p. 1022) can react *only* in the boat form, demonstrating that such reactions are not impossible.[456]

Not all Cope rearrangements proceed by the cyclic six-centered mechanism. Thus *cis*-1,2-divinylcyclobutane (p. 1022) rearranges smoothly to 1,5-cyclooctadiene, since the geometry is favorable. The trans isomer also gives this product, but the main product is 4-vinylcyclohexene (resulting from **8-35**). This reaction can be rationalized as proceeding by a diradical mechanism,[457] though it is possible that at least part of the cyclooctadiene produced comes from a prior epimerization of the *trans*- to the *cis*-divinylcyclobutane followed by Cope rearrangement of the latter.[458]

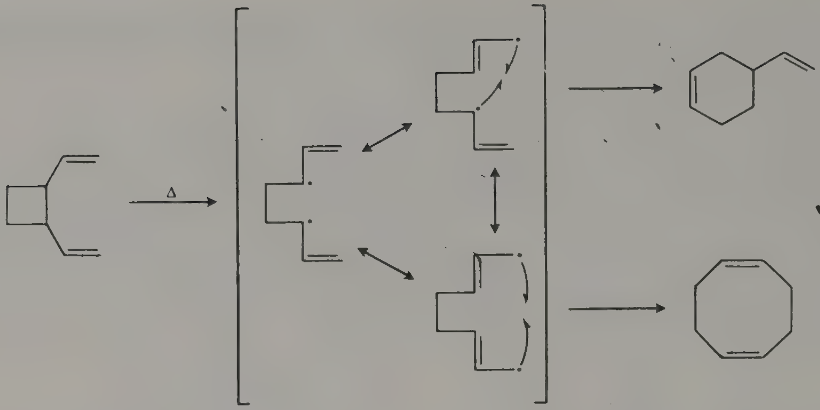
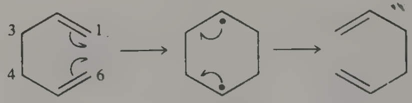
Soc.* **87,** 2620 (1965); Dolbier and Mancini, *Tetrahedron Lett.* 2141 (1975); Berson et al., Ref. 440; Kessler and Ott, *J. Am. Chem. Soc.* **98,** 5014 (1976). For a discussion of diradical mechanisms in Cope rearrangements, see Berson, in Mayo-RGES, Ref. 1, pp. 358–372.

[458] See, for example, Berson and Dervan, *J. Am. Chem. Soc.* **94,** 8949 (1972); Baldwin and Gilbert, *J. Am. Chem. Soc.* **98,** 8283 (1976). For a similar result in the 1,2-divinylcyclopropane series, see Baldwin and Ullenius, Ref. 451.



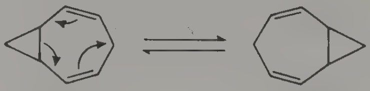
It has been suggested that another type of diradical two-step mechanism may be preferred by some substrates.[459] In this pathway, the 1,6 bond is formed before the 3,4 bond breaks:



108

so that a diradical intermediate (**108**) is involved.[460]

It was pointed out earlier that a Cope rearrangement of 1,5-hexadiene gives 1,5-hexadiene. This is a *degenerate Cope rearrangement* (p. 945). Another molecule that undergoes it is bicyclo[5.1.0]octadiene (**109**).[461] At room temperature the nmr spectrum of this compound is in accord



109 **109**

with the structure shown on the left. At 180°C it is converted by a Cope reaction to a compound equivalent to itself. The interesting thing is that at 180°C the nmr spectrum shows that what exists is an equilibrium mixture of the two structures. That is, at this temperature the molecule rapidly (faster than 10^3 times per second) changes back and forth between the two structures. This is called *valence tautomerism* and is quite distinct from resonance, even though only electrons shift.[462] The positions of the nuclei are not the same in the two structures. Molecules like **109** that exhibit valence tautomerism (in this case, at 180°C) are said to have *fluxional* structures. It may be recalled that *cis*-1,2-divinylcyclopropane does not exist at room temperature because it rapidly rearranges to 1,4-cycloheptadiene (p. 1022), but in **109** the *cis*-divinylcyclopropane structure is frozen into the molecule in both structures. Several other compounds in which this situation holds are also known. Of these, *bullvalene* (**110**) is especially interesting. The Cope rearrangement shown changes the position of the cyclopropane ring from 4,5,10 to 1,7,8. But the molecule could also have undergone rearrangements to put this ring at 1,2,8 or 1,2,7. Any of these could then undergo several Cope rearrangements. In all, there are 10!/3, or more than 1.2 million tautomeric forms, and the cyclopropane ring can be at any three carbons that are adjacent. Since each of these tautomers is equivalent to all the others, this has been called an infinitely degenerate Cope rearrangement. Bullvalene has been synthesized and its proton nmr spectrum determined.[463] At −25°C there are two peaks with an area ratio of 6:4. This is in accord with a single nontautomeric structure. The six are the vinyl protons and the four are the allylic ones. But at 100°C the compound shows only one nmr peak, indicating that we have here a truly unique situation where the compound rapidly interchanges its structure among 1.2 million equivalent forms.[464] The ^{13}C nmr spectrum of bullvalene also shows only one peak at 100°C.[465]

[463] Schröder, *Angew. Chem. Int. Ed. Engl.* **2,** 481 (1963) [*Angew. Chem.* **75,** 772], *Chem. Ber.* **97,** 3140 (1964); Merényi, Oth, and Schröder, *Chem. Ber.* **97,** 3150 (1964). See also Doering et al., Ref. 467. For a review of bullvalenes, see Schröder and Oth, *Angew. Chem. Int. Ed. Engl.* **6,** 414–423 (1967) [*Angew. Chem.* **79,** 458–467].

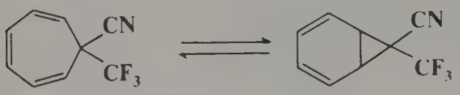
[464] A number of azabullvalenes (**110** containing heterocyclic nitrogen) have been synthesized. They also have fluxional structures when heated, though with fewer tautomeric forms than bullvalene itself: Paquette and Barton, *J. Am. Chem. Soc.* **89,** 5480 (1967); Paquette, Barton, and Whipple, *J. Am. Chem. Soc.* **89,** 5481 (1967); Wegener, *Tetrahedron Lett.* 4985 (1967); Paquette, Malpass, Krow, and Barton, *J. Am. Chem. Soc.* **91,** 5296 (1969).

[465] Oth, Müllen, Gilles, and Schröder, *Helv. Chim. Acta* **57,** 1415 (1974); Nakanishi and Yamamoto, *Tetrahedron Lett.* 1803 (1974); Günther and Ulmen, *Tetrahedron* **30,** 3781 (1974).

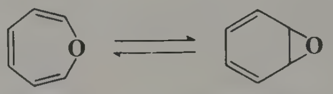
[466] McKennis, Brener, Ward, and Pettit, *J. Am. Chem. Soc.* **93,** 4957 (1971); Paquette, Davis, and James, *Tetrahedron Lett.* 1615 (1974).

there are only two equivalent tautomers.[467] However, nmr spectra indicate that even at room temperature a rapid interchange of both tautomers is present, though by about $-100°C$ this has slowed to the point where the spectrum is in accord with a single structure. In the case of *semibullvalene* (**113**) (barbaralane in which the CH_2 has been removed), not only is there a rapid interchange at room temperature, but even at $-110°C$.[468] **113** has the lowest energy barrier of any known compound capable of undergoing the Cope rearrangement.[469]

The molecules taking part in a valence tautomerization need not be equivalent. Thus, nmr spectra indicate that a true valence tautomerization exists at room temperature between the cycloheptatriene **114** and the norcaradiene **115**.[470] In this case one isomer (**115**) has the *cis*-1,2-divinylcyclopropane structure, while the other does not. In an analogous interconversion, benzene oxide and oxepin exist in a tautomeric equilibrium at room temperature.[471]

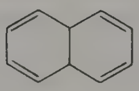


114 **115**

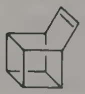


Oxepin Benzene oxide

Bullvalene and hypostrophene are members of a group of compounds all of whose formulas can be expressed by the symbol $(CH)_{10}$.[472] Many other members of this group are known, including **116** to **120** and the [10]annulenes (p. 55). All these compounds represent positions of minimum energy on the $(CH)_{10}$ energy surface, and many of them have been interconverted by electrocyclic or Cope rearrangements. Similar groups of $(CH)_n$ compounds exist for other even-numbered values of n.[472] For example, there are 20 possible $(CH)_8$ compounds,[473] including semibullvalene (**113**),



116



basketene

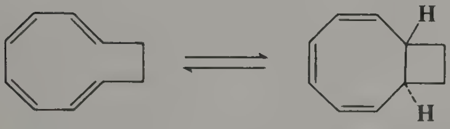
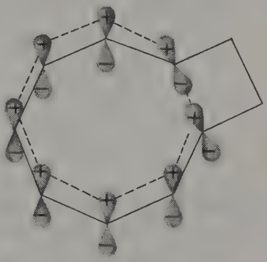
Two **(CH)$_6$** compounds

An interesting example of a valence tautomerization was reported for the molecules (*E*,*Z*,*Z*,*E*)-1,3,5,7-cyclodecatetraene (**126**) and *trans*-bicyclo[6.2.0]deca-2,4,6-triene (**127**), which rapidly interconvert at temperatures above 50°C[476] (an electrocyclic reaction, **8-31**). The transition state for this interconversion (**J**) consists of eight electrons connected in a Möbius array, i.e., with one sign inversion. Since the number of electrons is of the form 4*n*, the Möbius is the only allowed pathway for a thermal reaction (p. 754).

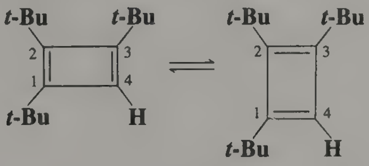


126 **127**



J

Another interesting example of a valence tautomerism is the case of 1,2,3-tri-*t*-butylcyclobutadiene (p. 51). There are two isomers, both rectangular, and ^{13}C nmr spectra show that they exist



in a dynamic equilibrium, even at −185°C.[477]

---

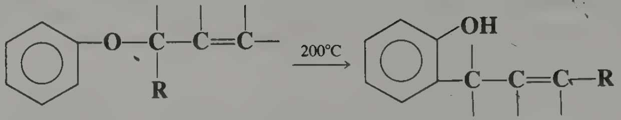
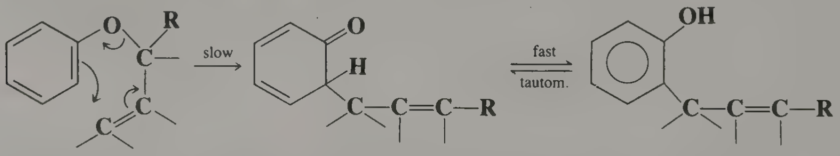
8-37 The Claisen Rearrangement



Allyl aryl ethers, when heated, rearrange to *o*-allylphenols in a reaction called the *Claisen rearrangement*.[478] If both ortho positions are filled, the allyl group migrates to the para position (this is often called the *para-Claisen rearrangement*). Sometimes some para product is obtained even if one or both ortho positions are free,[479] though in general, it may be said that when one or both ortho positions are open, the product is the *o*-allylphenol and that when both ortho positions are blocked, the product is the para compound. There is no reaction when the para and both ortho positions are filled. Migration to the meta position has not been observed. In the ortho migration the allyl group always undergoes an allylic shift. That is, as shown above, a substituent α to the oxygen is now γ to the ring (and vice versa). On the other hand, in the para migration there is never an allylic shift: the allyl group is found exactly as it was in the original ether. Propargyl groups (i.e., groups with a triple bond in the appropriate position) do not generally give the reaction.

The mechanism is a concerted pericyclic [3,3] sigmatropic rearrangement[480] and accounts for all these facts. For the ortho rearrangement:



Evidence is the lack of a catalyst, the fact that the reaction is first order in the ether, the absence of crossover products when mixtures are heated, and the presence of the allylic shift, which is required by this mechanism. The allylic shift for the ortho rearrangement (and the absence of one for the para) has been demonstrated by ^{14}C labeling, even when no substituents are present. Studies of the transition-state geometry have shown that, like the Cope rearrangement, the Claisen rearrangement usually prefers a chairlike transition state.[481] When the ortho positions have no hydrogen, a second [3,3] sigmatropic migration (a Cope reaction) follows:

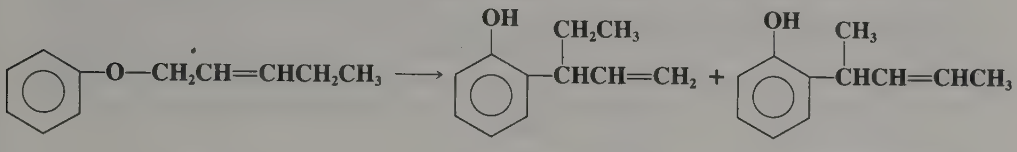
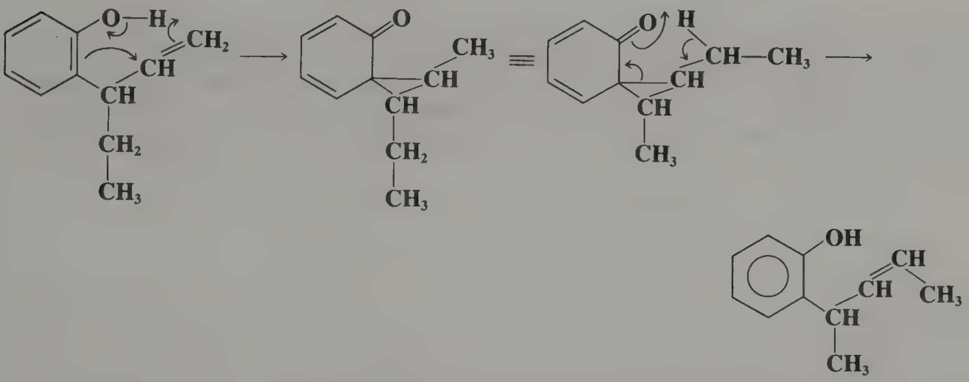
and the group is restored to its original structure. Intermediates of structure **128** have been trapped by means of a Diels–Alder reaction.[482]

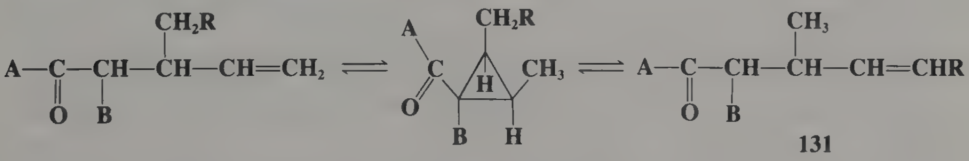
Ethers with an alkyl group in the γ position (ArO—C—C=C—R systems) sometimes give abnormal products, with the β-carbon becoming attached to the ring:[483]



It has been established that these abnormal products do not arise directly from the starting ether but are formed by a further rearrangement of the normal product:[484]



This rearrangement, which has been called an *enolene rearrangement*, a *homodienyl* [1,5] *sigmatropic hydrogen shift* (see p. 1017), and a [1,5] *homosigmatropic rearrangement*, involves a shift of three electron pairs over *seven* atoms. It has been found that this "abnormal" Claisen rearrangement is general and can interconvert the enol forms of systems of the types **129** and **131** through the cyclopropane intermediate **130**.[485]



129 **130** **131**

A = H, R, Ar, Or, etc.
B = H, R, Ar, COR, COAr, COOR, etc.

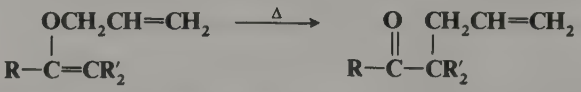
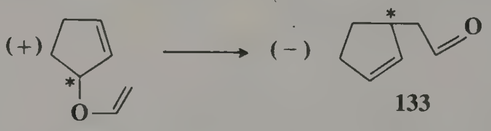
Since the Claisen rearrangement mechanism does not involve ions, it should not be greatly dependent on the presence or absence of substituent groups on the ring. This is the case. Electron-donating groups increase the rate and electron-withdrawing groups decrease it, but the effect is small, with the *p*-amino compound reacting only about 10 to 20 times faster than the *p*-nitro compound.[486] However, solvent effects are greater: rates varied over a 300-fold range when the reaction was run in 17 different solvents.[487] An especially good solvent is trifluoroacetic acid, in which the reaction can be carried out at room temperature.[488] Most Claisen rearrangements are performed without a catalyst, but $AlCl_3$ or BF_3 is sometimes used.[489] In this case it may become a Friedel–Crafts reaction, with the mechanism no longer cyclic,[490] and ortho, meta, and para products may be obtained.

Allyl ethers of enols (allyl vinyl ethers) also undergo the Claisen rearrangement; in fact, it was discovered with these compounds first:[491]



$$\begin{array}{c} OCH_2CH{=}CH_2 \\ | \\ R{-}C{=}CR'_2 \end{array} \xrightarrow{\Delta} \begin{array}{c} O \quad CH_2CH{=}CH_2 \\ \| \quad | \\ R{-}C{-}CR'_2 \end{array}$$

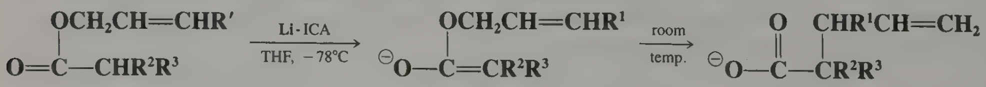
In these cases of course the final tautomerization does not take place even when R′ = H, since there is no aromaticity to restore, and ketones are more stable than enols. The mechanism is similar to that with allyl aryl ethers.[492] One experiment that demonstrated this was the conversion of optically active **132** to **133**, which was still optically active.[493] This is another example of asymmetric induction (p. 103):



132

133

It is possible to treat ketones with allyl alcohol and an acid catalyst to give γ,δ-unsaturated ketones directly, presumably by initial formation of the vinyl ethers, and then Claisen rearrangement.[494] In an analogous procedure, the enolates of allylic esters [formed by treatment of the esters with lithium isopropylcyclohexylamide (ICA)] rearrange to γ,δ-unsaturated acids.[495]



$$\begin{array}{c} OCH_2CH{=}CHR' \\ | \\ O{=}C{-}CHR^2R^3 \end{array} \xrightarrow[\text{THF, }-78^\circ\text{C}]{\text{Li-ICA}} \begin{array}{c} OCH_2CH{=}CHR^1 \\ | \\ {}^{\ominus}O{-}C{=}CR^2R^3 \end{array} \xrightarrow[\text{temp.}]{\text{room}} \begin{array}{c} O \quad CHR^1CH{=}CH_2 \\ \| \quad | \\ {}^{\ominus}O{-}C{-}CR^2R^3 \end{array}$$

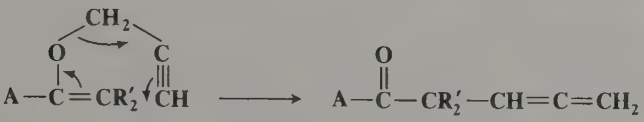
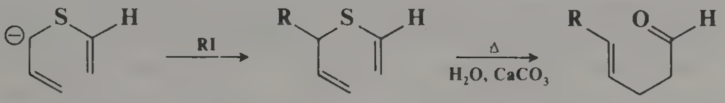
Diallylic ethers give the Claisen rearrangement when heated with tris(triphenylphosphine)ruthenium(II) dichloride. The latter presumably catalyzes the rearrangement of the diallylic ether to an allyl vinyl ether, which undergoes the actual Claisen rearrangement.[496]

A number of expected analogs of the Claisen rearrangement are known,[497] e.g., rearrangement of $ArNHCH_2CH{=}CH_2$,[498] of N-allyl enamines $R_2C{=}CRNRCR_2CR{=}CR_2$,[499] and of $RC(OCH_2CH{=}CH_2){=}NR$.[500] The rearrangement of $R^1CH{=}\overset{+}{N}R^2CHR^3CH_2CH{=}CH_2$ to $R_3CH{=}\overset{+}{N}R^2CHR^1CH_2CH{=}CH_2$ has been called the *aza-Cope rearrangement*.[501] Propargyl vinyl compounds give allenic aldehydes, ketones, esters, or amides:[502]



A = H, R, OR, NR₂

The conversion of allyl aryl thioethers $ArSCH_2CH{=}CH_2$ to *o*-allylthiophenols (the thio-Claisen rearrangement) is not feasible, because the latter are not stable[503] but react to give bicyclic compounds.[504] However, many allyl vinyl sulfides do give the rearrangement,[505] and this has been used in a synthesis of γ,δ-unsaturated aldehydes.[506]



Allyl vinyl sulfones $H_2C{=}CRCH_2{-}SO_2{-}CH{=}CH_2$ rearrange, when heated in the presence of ethanol and pyridine, to unsaturated sulfonate salts $CH_2{=}CRCH_2CH_2CH_2SO_3^-$, produced by reaction of the reagents with the unstable sulfene intermediates $CH_2{=}CRCH_2CH_2CH{=}SO_2$.[507]

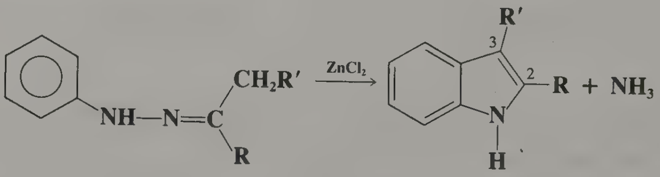
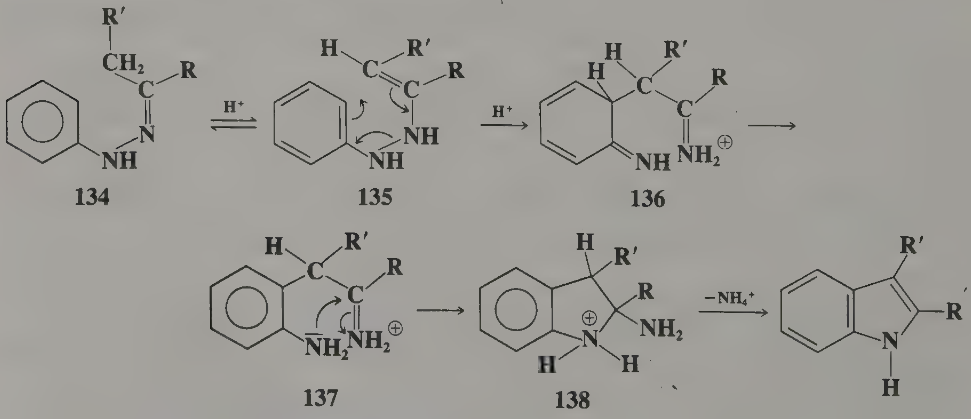
8-38 The Fischer Indole Synthesis



When arylhydrazones of aldehydes or ketones are treated with a catalyst, elimination of ammonia takes place and an indole is formed, in a reaction called the *Fischer indole synthesis*.[509] Zinc chloride is the catalyst most frequently employed, but dozens of others, including other metal halides, proton and Lewis acids, and certain transition-metals have also been used. Arylhydrazones are easily prepared by the treatment of aldehydes or ketones with phenylhydrazine (**6-2**) or by aliphatic diazonium coupling (**2-7**). However, it is not necessary to isolate the arylhydrazone. It can be treated with a mixture of the aldehyde or ketone and the catalyst: this is now common practice. In order to obtain an indole, the aldehyde or ketone must be of the form $RCOCH_2R'$ (R = alkyl, aryl, or hydrogen).

At first glance the reaction does not seem to be a rearrangement. However, the key step of the mechanism is a [3,3] sigmatropic rearrangement:[510]



---

[508] Makisumi, *J. Org. Chem.* **30,** 1989 (1965).

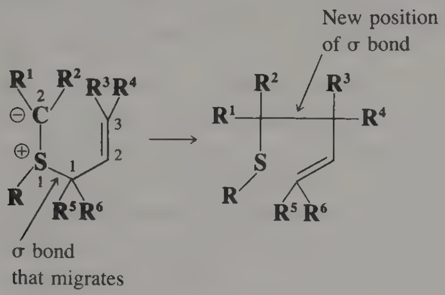
[509] For a monograph, see Robinson, "The Fischer Indole Synthesis," Wiley, New York, 1983. For reviews, see Grandberg and Sorokin, *Russ. Chem. Rev.* **43,** 115–128 (1974); Shine, "Aromatic Rearrangements," Ref. 478, pp. 190–207; Sundberg, "The Chemistry of Indoles," pp. 142–163, Academic Press, New York, 1970; Robinson, *Chem. Rev.* **69,** 227–250 (1969), **63,** 373–401 (1963). For reviews of some abnormal Fischer indole syntheses, see Ishii, *Acc. Chem. Res.* **14,** 275–283 (1981); Fusco and Sannicolo, *Tetrahedron* **36,** 161–170 (1980).

[510] This mechanism was proposed by Robinson and Robinson, *J. Chem. Soc.* **113,** 639 (1918).

There is much evidence for this mechanism, e.g., (1) the isolation of **138**,[511] (2) the detection of **137** by ^{13}C and ^{15}N nmr,[512] (3) the isolation of side products that could only have come from **136**,[513] and (4) ^{15}N labeling experiments that showed that it was the nitrogen farther from the ring that was eliminated as ammonia.[514] The main function of the catalyst seems to be to speed the conversion of **134** to **135**. The reaction can be performed without a catalyst.

OS **III,** 725; **IV,** 884. Also see OS **IV,** 657.

8-39 [2,3] Sigmatropic Rearrangements



Sulfur ylides bearing an allylic group are converted on heating to unsaturated sulfides.[515] This is a concerted [2,3] sigmatropic rearrangement[516] and has also been demonstrated for the analogous cases of nitrogen ylides[517] and the conjugate bases of allylic ethers,[518] as well as certain other

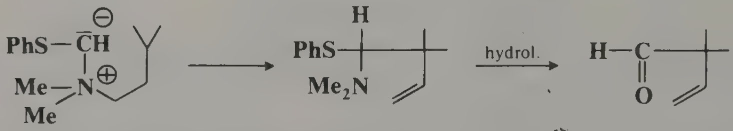
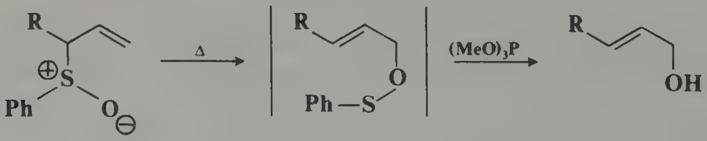
systems.[519] It has even been extended to all-carbon systems.[520]

Since the reactions involve migration of an allylic group from a sulfur, nitrogen, or oxygen atom to an adjacent negatively charged carbon atom, they are special cases of the Stevens or Wittig rearrangements (reactions **8-24**, **8-25**). However, in this case the migrating group *must* be allylic (in reactions **8-24** and **8-25**, other groups may also migrate). Thus, when the migrating group is allylic, there are two possible pathways: (1) the radical-ion or ion-pair mechanisms (**8-24**, **8-25**) and (2) the concerted pericyclic [2,3] sigmatropic rearrangement. These can easily be told apart, since the latter always involves an allylic shift (as in the Claisen rearrangement), while the former pathway does not. Of course, migration of groups other than allylic can take place only by the radical-ion or ion-pair mechanisms, because the orbital symmetry rules forbid a concerted mechanism for 1,2 shifts.

If an OR or SR group is attached to the negative carbon, the reaction becomes a method for the preparation of β,γ-unsaturated aldehydes, because the product is easily hydrolyzed.[521]



Another [2,3] sigmatropic rearrangement converts allylic sulfoxides to allylically rearranged alcohols by treatment with a thiophilic reagent such as trimethyl phosphite.[522] In this case the migration is from sulfur to oxygen. [2,3] oxygen-to-sulfur migrations are also known.[523] The Sommelet–Hauser rearrangement (**3-27**) is also a [2,3] sigmatropic rearrangement.



8-40 The Benzidine Rearrangement

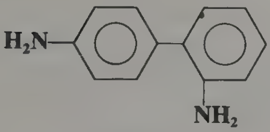
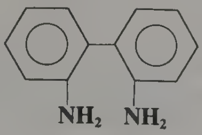
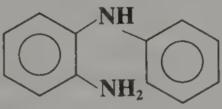
When hydrazobenzene is treated with acids, it rearranges to give about 70% 4,4′-diaminobiphenyl (**139,** benzidine) and about 30% 2,4′-diaminobiphenyl (**140**). This reaction is called the *benzidine rearrangement* and is general for N,N′-diarylhydrazines.[524] Usually, the major product is the 4,4′-diaminobiaryl, but four other products may also be produced. These are the 2,4′-diaminobiaryl (**140**), already referred to, the 2,2′-diaminobiaryl (**141**), and the *o*- and *p*-arylaminoanilines (**142** and **143**), called *semidines*. **141** and the **143** compounds are formed less often and in smaller amounts than the other two side products. Usually, the 4,4′-diaminobiaryl predominates, except when one or both of the para positions of the diarylhydrazine are occupied. However, the 4,4′-diamine may still be produced, even if the para positions are occupied. If SO_3H, COOH, or Cl (but not R, Ar, or NR_2) is present in the para position, it may be ejected. With dinaphthylhydrazines, the major products are not the 4,4′-diaminobinaphthyls, but the 2,2′ isomers. Another side reaction is disproportionation to $ArNH_2$ and ArN=NAr. For example, *p,p′*-$PhC_6H_4NHNHC_6H_4Ph$ gives 88% disproportionation products at 25°C.[525]



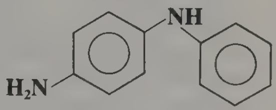
140



141



142



143

The mechanism has been exhaustively studied and several mechanisms have been proposed. At one time it was believed that NHAr broke away from ArNHNHAr and then became attached to the para position to give the semidine (**143**), which then went on to product. The fact that semidines could be isolated lent this argument support, as did the fact that this would be analogous to the rearrangements considered in Chapter 11 (**1-34** to **1-38**). However, this theory was killed when it was discovered that semidines could not be converted to benzidines under the reaction conditions. Cleavage into two independent pieces (either ions or free radicals) has been ruled out by many types of crossover experiments, which always showed that the two rings of the starting material are in the product; that is, ArNHNHAr′ gives no molecules (of any of the five products) containing two Ar groups or two Ar′ groups, and mixtures of ArNHNHAr and Ar′NHNHAr′ give no molecules containing both Ar and Ar′. An important discovery was the fact that, although the reaction is always first order in substrate, it may be either first[526] or second[527] order in $[H^+]$. With some substrates the reaction is entirely first order in $[H^+]$, while with others it is entirely second order in $[H^+]$, regardless of the acidity. With still other substrates, the reaction is first order in $[H^+]$ at low acidities and second order at higher acidities. With the latter substrates fractional orders can often be observed,[528] because at intermediate acidities, both processes take place simultaneously. These kinetic results seem to indicate that the actual reacting species can be either the monoprotonated substrate $\mathrm{ArNH\overset{\oplus}{N}H_2Ar}$ or the diprotonated $\mathrm{Ar\overset{\oplus}{N}H_2\overset{\oplus}{N}H_2Ar}$.

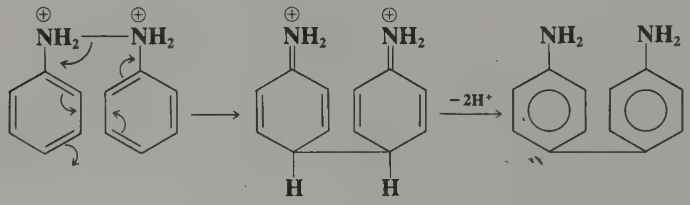
[527] Hammond and Shine, *J. Am. Chem. Soc.* **72,** 220 (1950); Banthorpe and Cooper, *J. Chem. Soc. B* 618 (1968); Banthorpe, Cooper, and O'Sullivan, *J. Chem. Soc. B* 2054 (1971).

[528] Carlin and Odioso, *J. Am. Chem. Soc.* **76,** 100 (1954); Banthorpe, Ingold, and Roy, *J. Chem. Soc. B* 64 (1968); Banthorpe, Ingold, and O'Sullivan, *J. Chem. Soc. B* 624 (1968).

Most of the proposed mechanisms[529] attempted to show how all five products could be produced by variations of a single process. An important breakthrough was the discovery that the two main products, the normal **139** and **140**, are formed in entirely different ways, as shown by isotope-effect studies.[530] When the reaction was run with hydrazobenzene labeled with ^{15}N at both nitrogen atoms, the isotope effect was 1.022 for formation of **139**, but 1.063 for formation of **140**. This showed that the N—N bond is broken in the rate-determining step in both cases, but the steps themselves are obviously different. When the reaction was run with hydrazobenzene labeled with ^{14}C at a para position, there was an isotope effect of 1.028 for formation of **139**, but essentially no isotope effect (1.001) for formation of **140**. This can only mean that for **139** formation of the new C—C bond *and* breaking of the N—N bond both take place in the rate-determining step; in other words, the mechanism is concerted. The following [5.5] sigmatropic rearrangement accounts for this:[531]



144

The diion **144** was obtained as a stable species in super-acid solution at −78°C by treatment of hydrazobenzene with FSO_3H-SO_2 (SO_2ClF).[532] Though the mechanism shown begins with the diprotonated substrate, it is possible that the monoprotonated substrate can also behave the same way. There is evidence that even in the diprotonated pathway, protonation may take place during the transition state rather than before.[533]

140 is formed by a completely different mechanism, although the details are not known. There is rate-determining breaking of the N—N bond, but the C—C bond is not formed during this step. There is evidence that formation of the *p*-semidine (**143**) is intramolecular and concerted.[534] Under certain conditions, benzidine rearrangements have been found to go through radical cations.[535]

C. Other Cyclic Rearrangements

8-41 Metathesis of Olefins

$$CH_3CH{=}CHCH_2CH_3 \xrightarrow[WCl_6\text{-}EtOH]{EtAlCl_2} CH_3CH{=}CHCH_3 + CH_3CH_2CH{=}CHCH_2CH_3$$

When olefins are treated with certain catalysts (most often tungsten or molybdenum complexes), they are converted to other olefins in a reaction in which the alkylidene groups ($R^1R^2C=$) have become interchanged by a process schematically illustrated by the equation:

---

[529] For example, see the "polar-transition-state" mechanism: Banthorpe, Hughes, and Ingold, *J. Chem. Soc.* 2864 (1964), and the "π-complex mechanism:" Dewar, in Mayo-MR, Ref. 1, vol. 1, pp. 323–344.

[530] Shine, Zmuda, Park, Kwart, Horgan, Collins, and Maxwell, *J. Am. Chem. Soc.* **103,** 955 (1981); Shine, Zmuda, Park, Kwart, Horgan, and Brechbiel, *J. Am. Chem. Soc.* **104,** 2501 (1982).

[531] This step was also part of the "polar-transition-state" mechanism; see Ref. 529.

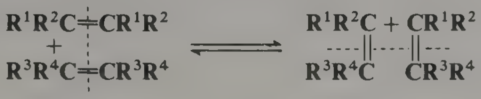
[533] Bunton and Rubin, *J. Am. Chem. Soc.* **98,** 4236 (1976).

[534] Heesing and Schinke, *Chem. Ber.* **110,** 3319 (1977); Shine, Zmuda, Kwart, Horgan, and Brechbiel, *J. Am. Chem. Soc.* **104,** 5181 (1982).

[535] See for example, Nojima, Ando, and Tokura, *J. Chem. Soc., Perkin Trans. 1* 1504 (1976).



The reaction is called *metathesis* of olefins.[536] In the example shown above, 2-pentene (either cis, trans, or a cis–trans mixture) is converted to a mixture of about 50% 2-pentene, 25% 2-butene, and 25% 3-hexene. The reaction is an equilibrium and the same mixture can be obtained by starting with equimolar quantities of 2-butene and 3-hexene.[537] In general, the reaction can be applied to a single unsymmetrical olefin, giving a mixture of itself and two other olefins, or to a mixture of two olefins, in which case the number of different molecules in the product depends on the symmetry of the reactants. As in the case above, a mixture of $R^1R^2C=CR^1R^2$ and $R^3R^4C=CR^3R^4$ gives rise to only one new olefin ($R^1R^2C=CR^3R^4$), while in the most general case, a mixture of $R^1R^2C=CR^3R^4$ and $R^5R^6C=CR^7R^8$ gives a mixture of ten olefins: the original two plus eight new ones. With simple alkenes the proportions of products are generally statistical,[538] which limits the synthetic utility of the reaction since the yield of any one product is low. However, in some cases one alkene may be more or less thermodynamically stable than the rest, so that the proportions are not statistical. Furthermore, it may be possible to shift the equilibrium. For example, 2-methyl-1-butene gives rise to ethylene and 3,4-dimethyl-3-hexene. By allowing the gaseous ethylene to escape, the yield of 3,4-dimethyl-3-hexene can be raised to 95%.[539] In another synthetic application, mixtures of two alkenyl tosylates $RCH=CH(CH_2)_nOTs$ ($n = 7$, 8, or 9) were converted to ditosylates $TsO(CH_2)_nCH=CH(CH_2)_nOTs$.[540] As expected for an equilibrium process, both cis and trans alkenes are produced, with the more stable trans isomers usually predominating. However, if the reaction is stopped before equilibrium is reached, there is some stereospecificity. Cis and trans alkenes produce a high proportion of cis and trans products, respectively.[541]

Many catalysts, both homogeneous[542] and heterogeneous,[543] have been used for this reaction. Some of the former[544] are WCl_6-EtOH-$EtAlCl_2$,[538] $MoCl_2(NO)_2(Ph_3P)_2$-$EtAlCl_2$,[545] WCl_6-BuLi,[546] and WCl_6-$LiAlH_4$,[547] while among the latter are oxides of Mo, W, and Re deposited on alumina or silica gel,[548] as well as certain polymer-supported catalysts.[549] In general, the former group are more useful for synthetic purposes. By choice of the proper catalyst, the reaction has been applied to terminal and internal alkenes, straight chain or branched. The effect of substitution on the ease of reaction is $CH_2= > RCH_2CH= > R_2CHCH= > R_2C=$.[550] Dienes may react intermolecularly or intramolecularly,[551] e.g.,

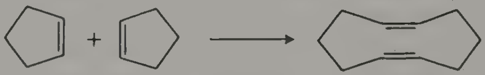
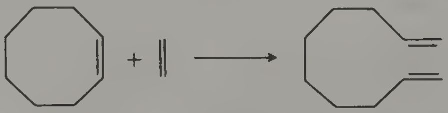
Cyclic olefins give dimeric dienes,[552] e.g..



However, the products can then react with additional monomers and with each other, so that polymers are generally produced, and the cyclic dienes are obtained only in low yield. The reaction between a cyclic and a linear olefin can give a ring-opened diene:[553]



Olefins containing functional groups[554] do not give the reaction with most of the common catalysts, but some success has been reported with WCl_6-$SnMe_4$[555] and with certain other catalysts.

The reaction has also been applied to internal triple bonds:[556]

$$2RC{\equiv}CR' \rightleftharpoons RC{\equiv}CR + R'C{\equiv}CR'$$

but it has not been successful for terminal triple bonds.[557]

The most likely mechanism is a chain mechanism, involving the intervention of a metal-carbene

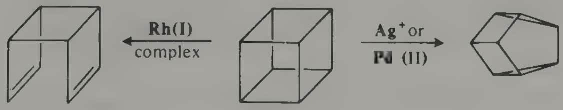
8-42 Metal-Ion-Catalyzed σ-Bond Rearrangements



147 Cubane Cuneane

Many highly strained cage molecules undergo rearrangement when treated with metallic ions such as Ag^+, Rh(I), or Pd(II).[559] The bond rearrangements observed can be formally classified into two main types: (1) 2 + 2 ring openings of cyclobutanes and (2) conversion of a bicyclo[3.3.0] system to a bicyclopropyl system. The molecule cubane supplies an example of each type (see above). Treatment with Rh(I) complexes converts cubane to tricyclo[4.2.0.0^{2,5}]octa-3,7-diene (**147**),[560] an example of type 1, while Ag^+ or Pd(II) causes the second type of reaction, producing cuneane.[561]

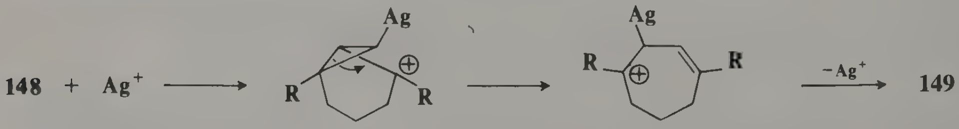
150 is the 9,10-dicarbomethoxy derivative of *snoutane* (pentacyclo[3.3.2.$0^{2,4}$.$0^{3,7}$.$0^{6,8}$]decane).

The mechanisms of these reactions are not completely understood, although relief of strain undoubtedly supplies the driving force. The reactions are thermally forbidden by the orbital-symmetry rules, and the role of the catalyst is to provide low-energy pathways so that the reactions can take place. The type 1 reactions are the reverse of the catalyzed 2 + 2 ring closures discussed at **5-48**. The following mechanism, in which Ag⁺ attacks one of the edge bonds, has been suggested for the conversion of **148** to **149**.[565]



Simpler bicyclobutanes can also be converted to dienes, but in this case the products usually result from cleavage of the central bond and one of the edge bonds.[566] For example, treatment of **151** with $AgBF_4$,[567] $(C_6F_5Cu)_4$,[568] or $[(\pi\text{-allyl})PdCl]_2$[569] gives a mixture of **152** and **153** resulting

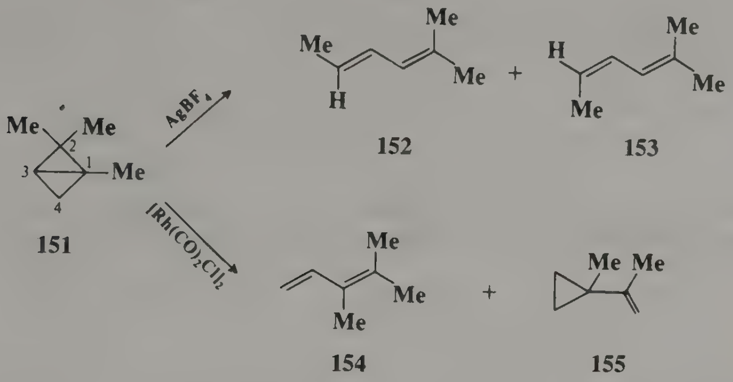
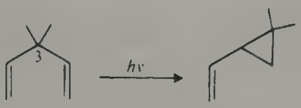
from a formal cleavage of the $C_1—C_3$ and $C_1—C_2$ bonds (note that a hydride shift has taken place). The use of $[Rh(CO)_2Cl]_2$,[570] $[Ru(CO)_3Cl_2]_2$,[570] or $Pd(PhCN)_2Cl_2$[569] cleaves **151** in a different way,



giving **154** and **155**. Although **154** could formally have arisen from a 2 + 2 ring opening with the $C_1—C_3$ bond intact, isotopic labeling has shown that this is not the case, at least for the rhodium complex. It was the $C_1—C_3$ and $C_2—C_3$ bonds that cleaved in this case.[570]

8-43 The Di-π-methane and Related Rearrangements



1,4-Dienes carrying alkyl or aryl substituents on C-3[571] can be photochemically rearranged to vinylcyclopropanes in a reaction called the *di-π-methane rearrangement*.[572] An interesting example is conversion of 1-methylene-4,4-dimethyl-2,5-cyclohexadiene to 2-methylene-6,6-dimethylbicyclo[3.1.0]-3-hexene.[573] For most[574] 1,4-dienes it is only the singlet excited states that give the reaction; triplet states generally take other pathways. For unsymmetrical dienes, the reaction is

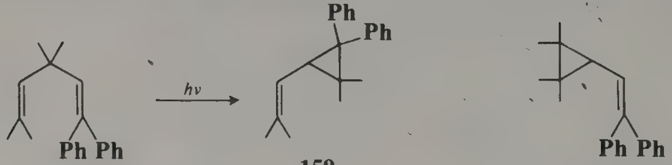
[574] However, some substrates, generally rigid bicyclic molecules, (e.g., barrelene, p. 1027, which is converted to semibullvalene) give the di-π-methane rearrangement only from triplet states.

regioselective. For example, **158** gave **159**, not **160**:[575]

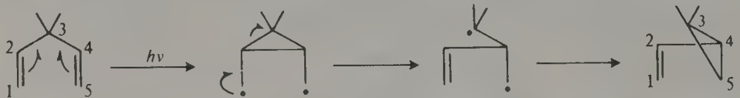


158

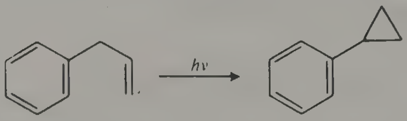
159

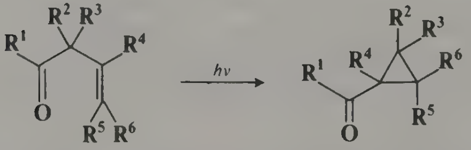
160
Not formed

The mechanism may be described by the diradical pathway given[576] (the C-3 substituents act to stabilize the radical), though the species shown are not necessarily intermediates, but may be transition states. It has been shown, for the case of certain substituted substrates, that configuration is retained at C-1 and C-5 and inverted at C-3.[577]



The reaction has been extended to allylbenzenes[578] (in this case C-3 substituents are not required), to β,γ-unsaturated ketones[579] (the latter reaction, which is called the *oxa-di-π-methane rearrangement*, occurs only from the triplet state[580]), and to triple-bond systems.[581]





When photolyzed, 2,5-cyclohexadienones can undergo a number of different reactions, one of which is formally the same as the di-π-methane rearrangement.[582] In this reaction, photolysis of the substrate **161** gives a bicyclo[3.1.0]hex-2-enone **166**.[583] Though the reaction is formally the same (note the conversion of **156** to **157** above), the mechanism is different from that of the di-π-methane rearrangement, because irradiation of a ketone can cause an $n \rightarrow \pi^*$ transition, which is of course not possible for a diene lacking a carbonyl group. The mechanism[583] in this case has

164 Triplet

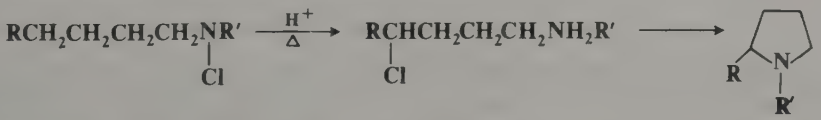
165

166

been formulated as proceeding through the excited triplet states **163** and **164**. In step 1, the molecule undergoes an $n \rightarrow \pi^*$ excitation to the singlet species **162,** which crosses to the triplet **163**. Step 3 is a rearrangement from one excited state to another. Step 4 is a $\pi^* \rightarrow n$ electron demotion (an intersystem crossing from $T_1 \rightarrow S_0$, see p. 210). The conversion of **165** to **166** actually consists of two 1,2 alkyl migrations (a one-step process would be a 1,3 migration of alkyl to a carbocation center, see p. 953): The old C_6—C_5 bond becomes the new C_6—C_4 bond and the old C_6—C_1 bond becomes the new C_6—C_5 bond.[584] This double-migration process is called the *slither mechanism,* as opposed to the single 1,3 migration, which in this case would be the *pivot mechanism.*

2,4-Cyclohexadienones also undergo photochemical rearrangements, but the products are different, generally involving ring opening.[585]

8-44 The Hofmann–Löffler and Related Reactions



$$\underset{\textstyle\text{Cl}}{\text{RCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{N}\text{R}'} \xrightarrow[\Delta]{\text{H}^+} \text{R}\underset{\textstyle\text{Cl}}{\text{C}}\text{HCH}_2\text{CH}_2\text{CH}_2\text{NH}_2\text{R}' \longrightarrow$$

A common feature of the reactions in this section[586] is that they serve to introduce functionality at a position remote from functional groups already present. As such, they have proved very useful in synthesizing many compounds, especially in the steroid field (see also **9-2** and **9-16**). When N-haloamines in which one alkyl group has a hydrogen in the 4 or 5 position are heated with sulfuric acid, pyrrolidines or piperidines are formed, in a reaction known as the *Hofman–Löffler reaction* (also called the *Hofmann–Löffler–Freytag reaction*).[587] R′ is normally alkyl, but the reaction has been extended to R′ = H by use of concentrated sulfuric acid solution and ferrous salts.[588] The first step of the reaction is a rearrangement, with the halogen migrating from the nitrogen to the 4 or 5 position of the alkyl group. It is possible to isolate the resulting haloamine salt, but usually this is not done, and the second step, the ring closure (**0-45**), takes place. Though the reaction is most often induced by heat, this is not necessary, and irradiation and chemical initiators (e.g., peroxides) have been used instead. The mechanism is of a free-radical type, with the main step involving an internal hydrogen abstraction.[589]

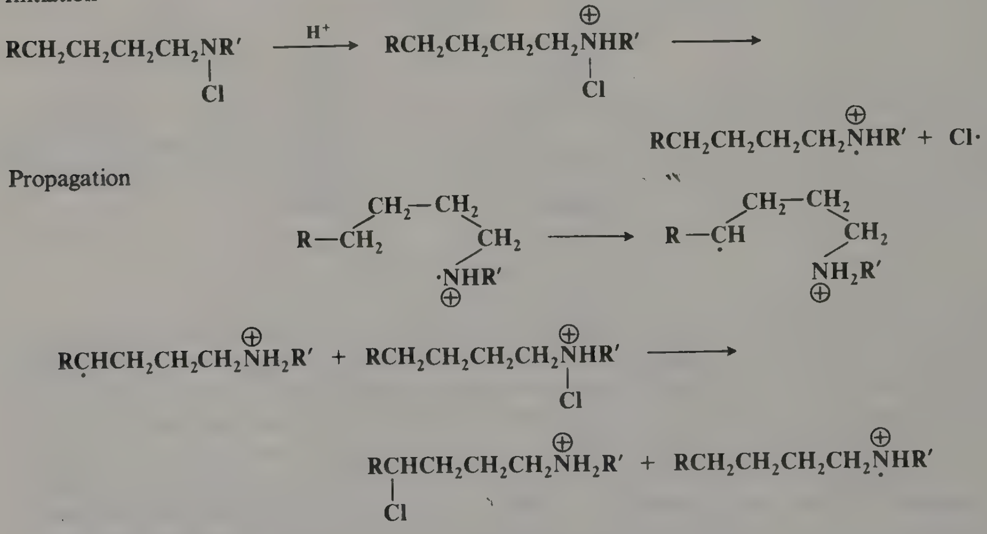
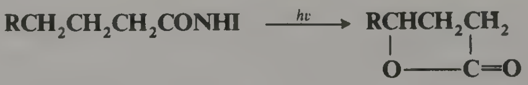
Initiation



Propagation

etc.

A similar reaction has been carried out on N-halo amides, which give γ-lactones:[590]



Another related reaction is the *Barton Reaction*,[591] by which a methyl group in the δ position to an OH group can be oxidized to a CHO group. The alcohol is first converted to the nitrite ester. Photolysis of the nitrite results in conversion of the nitrite group to the OH group and nitrosation of the methyl group. Hydrolysis of the oxime tautomer gives the aldehyde, e.g.,[592]

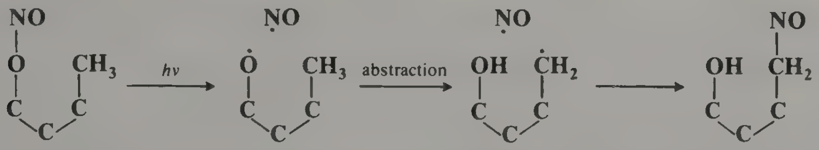
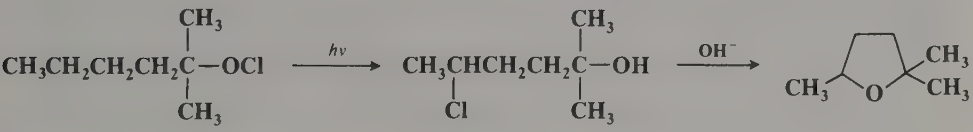
This reaction takes place only when the methyl group is in a favorable steric position. The mechanism is similar to that of the Hofmann–Löffler reaction.[593]



This is one of the few known methods for effecting substitution at an angular methyl group. Not only CH_3 groups but also alkyl groups of the form RCH_2 and R_2CH can give the Barton reaction if the geometry of the system is favorable. An RCH_2 group is converted to the oxime R(C=NOH)[594] (which is hydrolyzable to a ketone) or to a nitroso dimer, while an R_2CH group gives a nitroso compound $R_2C(NO)$. With very few exceptions, the only carbons that become nitrosated are those in the position δ to the original OH group, indicating that a six-membered transition state is necessary for the hydrogen abstraction.[595]

Another reaction with a similar mechanism is the photolytic conversion of tertiary hypohalites



to δ-chloro alcohols, which can then be cyclized to tetrahydrofurans.[596]

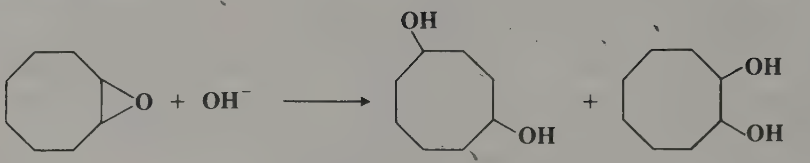
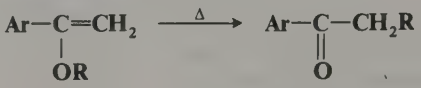
D. Noncyclic Rearrangements

8-45 Hydride Shifts



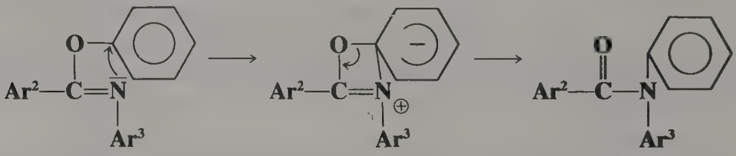
The above is a typical example of a transannular hydride shift. The 1,2-glycol is formed by a normal epoxide hydrolysis reaction (**0-8**). For a discussion of 1,3 and longer hydride shifts, see p. 953.

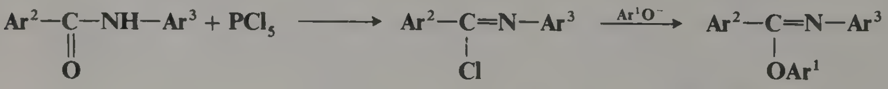
8-46 The Chapman Rearrangement



$$\mathrm{Ar{-}\underset{\displaystyle OR}{\underset{|}{C}}{=}CH_2} \xrightarrow{\Delta} \mathrm{Ar{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}CH_2R}$$

In the *Chapman rearrangement*, N,N-diaryl amides are formed when aryl imino esters are heated.[597] Best yields are obtained in refluxing tetraethylene glycol dimethyl ether (tetraglyme),[598] though the reaction can also be carried out without any solvent at all. Many groups may be present in the rings, e.g., alkyl, halo, OR, CN, COOR, etc. Aryl migrates best when it contains electron-withdrawing groups. On the other hand, electron-withdrawing groups in Ar^2 or Ar^3 decrease the reactivity. The products can be hydrolyzed to diarylamines, and this is a method for preparing these compounds. The mechanism probably involves an intramolecular[599] aromatic nucleophilic substitution, resulting in a 1,3 oxygen-to-nitrogen shift. Imino esters can be prepared from N-aryl amides by reaction with PCl_5, followed by treatment of the resulting imino chloride with an aroxide ion.[600] Imino esters with any or all of the three groups being alkyl also rearrange, but they require catalysis by H_2SO_4 or a trace of methyl iodide or methyl sulfate.[601] The mechanism is different, involving an intermolecular process.[602] This is also true for derivatives for formamide (Ar^2 = H).





$$\mathrm{Ar^2{-}\underset{\displaystyle O}{\underset{\|}{C}}{-}NH{-}Ar^3} + \mathrm{PCl_5} \longrightarrow \mathrm{Ar^2{-}\underset{\displaystyle Cl}{\underset{|}{C}}{=}N{-}Ar^3} \xrightarrow{\mathrm{Ar^1O^-}} \mathrm{Ar^2{-}\underset{\displaystyle OAr^1}{\underset{|}{C}}{=}N{-}Ar^3}$$

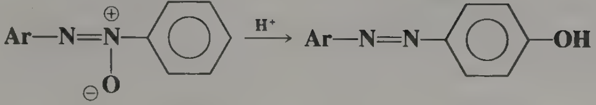
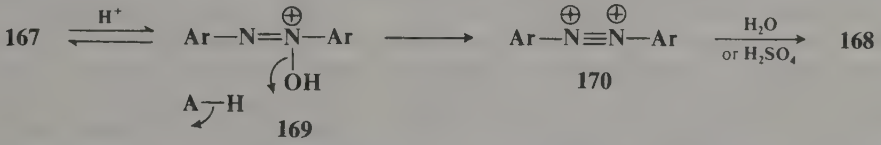
8-47 The Wallach Rearrangement



167 **168**

The conversion of azoxy compounds, on acid treatment, to *p*-hydroxy azo compounds (or sometimes the *o*-hydroxy isomers[603]) is called the *Wallach rearrangement.*[604] When both para positions are occupied, the *o*-hydroxy product may be obtained, but ipso substitution at one of the para positions is also possible.[605] Although the mechanism[606] is not completely settled, the following facts are known: (1) The para rearrangement is intermolecular.[607] (2) When the reaction was carried out with an azoxy compound in which the N—O nitrogen was labeled with ^{15}N, *both* nitrogens of the product carried the label equally,[608] demonstrating that the oxygen did not have a preference for migration to either the near or the far ring. This shows that there is a symmetrical intermediate. (3) Kinetic studies show that two protons are normally required for the reaction.[609] The following mechanism,[610] involving the symmetrical intermediate **170,** has been proposed to explain the facts.[611]



It has proved possible to obtain **169** and **170** as stable acids in super-acid solutions.[532] Another mechanism, involving an intermediate with only one positive charge, has been proposed for certain substrates at low acidities.[612]

When other nucleophiles are used, it may be possible to obtain *o*- or *p*-substituted azo compounds as products. For example, azoxybenzene reacts with aryl sufonyl chlorides $ArSO_2Cl$ to give *o*- and *p*-arenesulfonyloxaazobenzenes $PhN{=}NC_6H_4OSO_2Ar$.[613]

A photochemical Wallach rearrangement[614] is also known: The product is the *o*-hydroxy azo compound, the OH group is found in the farther ring, and the rearrangement is intramolecular.[615]

[603] For example, see Dolenko and Buncel, *Can. J. Chem.* **52,** 623 (1974); Yamamoto, Nishigaki, Umezu, and Matsuura, *Tetrahedron* **36,** 3177 (1980).

19

OXIDATIONS AND REDUCTIONS

First we must examine what we mean when we speak of oxidation and reduction. Inorganic chemists define oxidation in two ways: loss of electrons and increase in oxidation number. In organic chemistry, these definitions, while still technically correct, are not easy to apply. While electrons are directly transferred in some organic oxidations and reductions, the mechanisms of most of these reactions do not involve a direct electron transfer. As for oxidation number, while this is easy to apply in some cases, e.g., the oxidation number of carbon in CH_4 is -4, in most cases attempts to apply the concept lead to fractional values or to apparent absurdities. Thus carbon in propane has an oxidation number of -2.67 and in butane of -2.5, though organic chemists seldom think of these two compounds as being in different oxidation states. An improvement could be made by assigning different oxidation states to different carbon atoms in a molecule, depending on what is bonded to them (e.g., the two carbons in acetic acid are obviously in different oxidation states), but for this a whole set of arbitrary assumptions would be required, since the oxidation number of an atom in a molecule is assigned on the basis of the oxidation numbers of the atoms attached to it. There would seem to be little gained by such a procedure. What organic chemists have done—though more by custom than by any formal agreement—is to set up a series of functional groups, in a qualitative way, arranged in order of increasing oxidation state, and then to define oxidation as *the conversion of a functional group in a molecule from one category to a higher one*. Reduction is the opposite. For the simple functional groups this series is shown in Table 1.[1] It should be noted that this classification applies only to a single carbon atom or to two adjacent carbon atoms. Thus 1,3-dichloropropane is in the same oxidation state as chloromethane, but 1,2-dichloropropane is in a higher one. Obviously, such distinctions are somewhat arbitrary, and if we attempt to carry them too far, we shall find ourselves painted into a corner. Nevertheless the basic idea will serve us well. It should be noted that conversion of any compound to another in the same category is not an oxidation or a reduction. Most oxidations in organic chemistry involve a gain of oxygen and/or a loss of hydrogen. The reverse is true for reductions.

Of course, there is no oxidation without a concurrent reduction. However, we classify reactions as oxidations or reductions depending on whether the *organic compound* is oxidized or reduced. In some cases both the oxidant and reductant are organic, and we will consider those reactions separately.

MECHANISMS

It must be noted tht our definition of oxidation has nothing to do with mechanism. Thus the conversion of bromomethane to methanol with KOH (**0-1**) and to methane with $LiAlH_4$ (**0-77**) have the same S_N2 mechanisms, but one is a reduction (according to our definition) and the other is not. It is impractical to consider the mechanisms of oxidation and reduction reactions in broad

---

TABLE 1 Categories of simple functional groups arranged according to oxidation state

Oxidation is the conversion of a functional group in a molecule to a higher category; reduction is conversion to a lower one. Conversions within a category are neither oxidations nor reductions. The numbers given at the bottom are only approximations

categories in this chapter as we have done for the reactions considered in Chapters 10 to 18.[2] The main reason is that the mechanisms are too diverse, and this in turn is because the bond changes are too different. For example, in Chapter 15, all the reactions involved the bond change $C{=}C \rightarrow W{-}C{-}C{-}Y$ and a relatively few mechanisms covered all the reactions. But for oxidations and reductions the bond changes are far more diverse. Another reason is that the mechanism of a given oxidation or reduction reaction can vary greatly with the oxidizing or reducing agent employed. Very often the mechanism has been studied intensively for only one or a few of many possible agents.

Though we therefore do not cover oxidation and reduction mechanisms in the same way as we have covered other mechanisms, it is still possible to list a few broad mechanistic categories. In doing this, we follow the scheme of Wiberg.[3]

1. *Direct electron transfer.*[4] We have already met a few reactions in which the reduction is actually a direct gain of electrons or the oxidation a direct loss of them. An example is the Birch reduction (**5-11**), where sodium directly transfers an electron to an aromatic ring. An example from this chapter is found in the bimolecular reduction of ketones (**9-63**), where again it is a metal that supplies the electrons. This kind of mechanism is found largely in three types of reaction:[5] (a) the oxidation or reduction of a free radical (oxidation to a positive or reduction to a negative ion), (b) the oxidation of a negative ion or the reduction of a positive ion to a comparatively stable free radical, and (c) electrolytic oxidations or reductions (an example is the Kolbe reaction, **4-38**). An important example of (b) is oxidation of amines and phenolate ions:

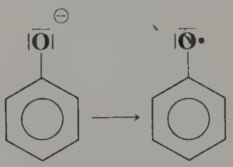
B, C, and D [Trahanovsky (ed.)], 1973, 1978, 1982; Waters, "Mechanisms of Oxidation of Organic Compounds," Wiley, New York, 1964; Stewart, "Oxidation Mechanisms," W. A. Benjamin, New York, 1964. For a review, see Wiberg, *Surv. Prog. Chem.* **1,** 211–248 (1963).

[3] Wiberg, *Surv. Prog. Chem.* **1,** 211–248 (1963).

[4] For a review of direct electron-transfer mechanisms, see Eberson, *Adv. Phys. Org. Chem.* **18,** 79–185 (1982). For a review of multistage electron-transfer mechanisms, see Deuchert and Hünig, *Angew. Chem. Int. Ed. Engl.* **17,** 875–886 (1978) [*Angew. Chem.* **90,** 927–938].



These reactions occur easily because of the relative stability of the radicals involved.[6]

2. *Hydride transfer.*[7] In some reactions a hydride ion is transferred to or from the substrate. The reduction of epoxides with $LiAlH_4$ is an example (**0-81**). Another is the Cannizzaro reaction (**9-70**). Reactions in which a carbocation abstracts a hydride ion belong in this category:[8]

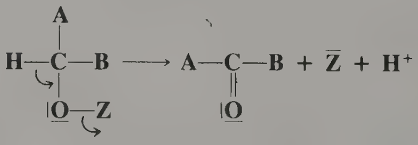
$$\mathbf{R^+ + R'H \longrightarrow RH + R'^+}$$

3. *Hydrogen-atom transfer.* Many oxidation and reduction reactions are free-radical substitutions and involve the transfer of a hydrogen atom. For example, one of the two main propagation steps of reaction **4-1** involves abstraction of hydrogen:

$$\mathbf{RH + Cl\bullet \longrightarrow R\bullet + HCl}$$

This is the case for many of the reactions of Chapter 14.

4. *Formation of ester intermediates.* A number of oxidations involve the formation of an ester intermediate (usually of an inorganic acid), and then the cleavage of this intermediate:



$$\mathrm{H{-}\underset{\underset{O{-}Z}{|}}{\overset{\overset{A}{|}}{C}}{-}B \longrightarrow A{-}\underset{\underset{O}{\|}}{C}{-}B + \overline{Z} + H^+}$$

Z is usually CrO_3H, MnO_3 or a similar inorganic acid moiety. One example of this mechanism was seen in **4-6**, where A was an alkyl or aryl group, B was OH, and Z was CrO_3H. Another is the oxidation of a secondary alcohol to a ketone (**9-3**), where A and B are alkyl or aryl groups and Z is also CrO_3H. In the lead tetraacetate oxidation of glycols (**9-7**) the mechanism also follows this pattern, but the positive leaving group is carbon instead of hydrogen. It should be noted that the cleavage shown is an example of an E2 elimination.

5. *Displacement mechanisms.* In these reactions the organic substrate uses its electrons to cause displacement on an electrophilic oxidizing agent. One example is the addition of bromine to an olefin (**5-27**).

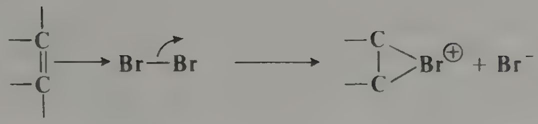
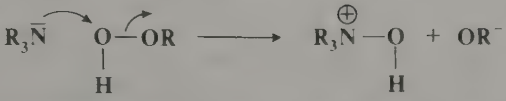
[7] For reviews, see Deno, Peterson, and Saines, *Chem. Rev.* **60,** 7–14 (1960); Kursanov and Parnes, *Russ. Chem. Rev.* **30,** 598–602 (1961).

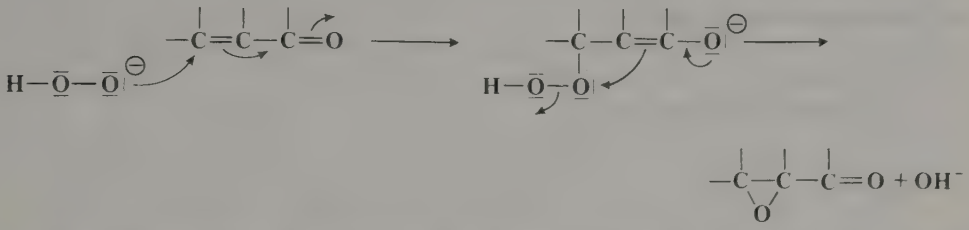
[8] For a review of these reactions, see Nenitzescu, in Olah and Schleyer, "Carbonium Ions," vol. 2, pp. 463–520, Interscience, New York, 1970.



An example from this chapter is found in **9-29**:



6. *Addition–elimination mechanisms.* In the reaction between α,β-unsaturated ketones and alkaline peroxide (**5-37**), the oxidizing agent adds to the substrate and then part of it is lost:



In this case the oxygen of the oxidizing agent was in oxidation state -1 and the OH^- departed with its oxygen in the -2 state, so it was reduced and the substrate oxidized. There are several reactions that follow this pattern of addition of an oxidizing agent and the loss of part of the agent, usually in a different oxidation state. Another example is the oxidation of ketones with SeO_2 (**9-16**). This reaction is also an example of category 4, since it involves formation and E2 cleavage of an ester. This example shows that these six categories are not mutually exclusive.

REACTIONS

In this chapter, the reactions are classified by the type of bond change occurring to the organic substrate, in conformity with our practice in the other chapters.[9] This means that there is no discussion in any one place of the use of a particular oxidizing or reducing agent, e.g., acid dichromate or $LiAlH_4$ (except for a discussion of selectivity of reducing agents, p. 1093). Some oxidizing or reducing agents are fairly specific in their action, attacking only one or a few types of substrate. Others, like acid dichromate, permanganate, $LiAlH_4$, and catalytic hydrogenation, are much more versatile.[10]

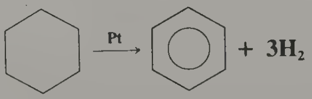
When an oxidation or a reduction could be considered in a previous chapter, this was done. For example, the catalytic hydrogenation of olefins is a reduction, but it is also an addition to the C=C bond and was treated in Chapter 15. In this chapter are discussed only those reactions that do not fit into the nine categories of Chapters 10 to 18. An exception to this rule was made for reactions that involve elimination of hydrogen (**9-1** to **9-6**) which were not treated in Chapter 17 because the mechanisms generally differ from those in that chapter.

Oxidations[11]

The reactions in this section are classified into groups depending on the type of bond change involved. These groups are: (A) eliminations of hydrogen, (B) reactions involving cleavage of carbon–carbon bonds, (C) reactions involving replacement of hydrogen by oxygen, (D) reactions in which oxygen is added to the substrate, and (E) oxidative coupling.

A. Eliminations of Hydrogen

9-1 Aromatization of Six-Membered Rings
Hexahydro-terelimination



Six-membered alicyclic rings can be aromatized in a number of ways.[12] Aromatization is accomplished most easily if there are already one or two double bonds in the ring or if the ring is fused to an aromatic ring. The reaction can also be applied to heterocyclic five- and six-membered rings. Many groups may be present on the ring without interference, and even *gem*-dialkyl substitution does not always prevent the reaction: In such cases one alkyl group often migrates or is eliminated. However, more drastic conditions are usually required for this. In some cases OH and COOH groups are lost from the ring. Cyclic ketones are converted to phenols. Seven-membered and larger rings are often isomerized to six-membered aromatic rings, though this is not the case for partially hydrogenated azulene systems (which are frequently found in nature); these are converted to azulenes.

A. Benjamin, New York, 1972; Refs. 9 and 11.

[11] For books on oxidation reactions, see Chinn, "Selection of Oxidants in Synthesis," Marcel Dekker, New York, 1971; Augustine and Trecker, "Oxidation," 2 vols., Marcel Dekker, New York, 1969, 1971; Ref. 2.

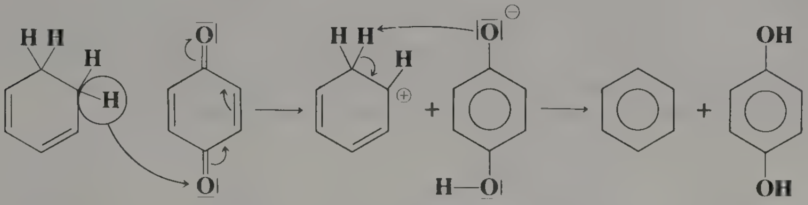
[12] For reviews, see Fu and Harvey, *Chem. Rev.* **78,** 317–361 (1978); Valenta, in Bentley and Kirby, "Elucidation of Chemical Structures by Physical and Chemical Methods" (vol. 4 of Weissberger, "Techniques of Chemistry"), 2d ed., pt. 2, pp. 1–76, Wiley, New York, 1973; House, Ref. 10, pp. 34–44.

There are three types of reagents most frequently used to effect aromatization.

1. Hydrogenation catalysts,[13] such as platinum, palladium, nickel, etc. In this case the reaction is the reverse of double-bond hydrogenation (**5-10** and **5-12**), and presumably the mechanism is also the reverse, though not much is known.[14] The substrate is heated with the catalyst at about 300 to 350°C. The reactions can often be carried out under milder conditions if a hydrogen acceptor, such as maleic acid, cyclohexene, or benzene, is present to remove hydrogen as it is formed. The acceptor is reduced to the saturated compound. It has been reported that dehydrogenation of 1-methylcyclohexene-1-^{13}C over an alumina catalyst gave toluene with the label partially scrambled throughout the aromatic ring.[15]

2. The elements sulfur and selenium, which combine with the hydrogen evolved to give, respectively, H_2S and H_2Se. Little is known about this mechanism either.[16]

3. Quinones,[17] which become reduced to the corresponding hydroquinones. Two important quinones often used for aromatizations are chloranil (2,3,5,6-tetrachloro-1,4-benzoquinone) and DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone).[18] The latter is more reactive and may be used in cases where the substrate is difficult to dehydrogenate. It is likely that the mechanism involves a transfer of hydride to the quinone oxygen, followed by the transfer of a proton to the phenolate ion:[19]



Other reagents that have been used are atmospheric oxygen, MnO_2,[20] SeO_2, various strong bases,[21] Ph_3COH in CF_3COOH,[22] and activated charcoal.[23] The last-mentioned reagent also dehydrogenates cyclopentanes to cyclopentadienes. In some instances the hydrogen is not released as H_2 or transferred to an external oxidizing agent but instead serves to reduce another molecule of substrate. This is a disproportionation reaction and may be illustrated by the conversion of cyclohexene to cyclohexane and benzene.

Aromatization reactions have been particularly important in the proof of structure of many cyclic natural products, especially steroids and terpenes. Diels–Alder adducts (which must contain at least one double bond) are also frequently aromatized.[24]

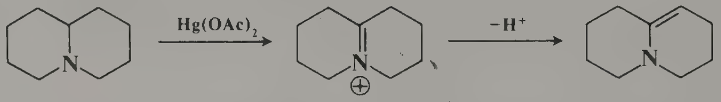
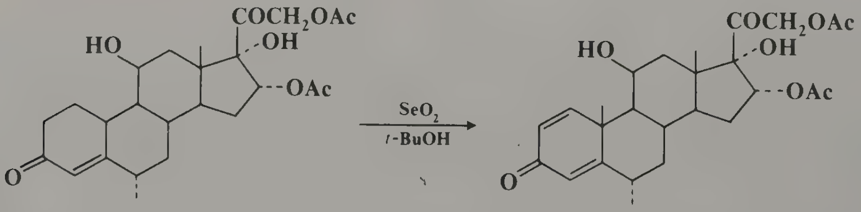
9-2 Dehydrogenations Yielding Carbon–Carbon Bonds
Dihydro-elimination



1

Dehydrogenation of an aliphatic compound to give a double bond in a specific location is not usually a feasible process, though industrially mixtures of olefins are obtained in this way from mixtures of alkanes (generally by heating with chromia–alumina catalysts). There are, however, some notable exceptions, and it is not surprising that these generally involve cases where the new double bond can be in conjugation with a double bond or with an unshared pair of electrons already present. One example is the synthesis developed by Leonard and co-workers,[25] in which tertiary amines give enamines when treated with mercuric acetate[26] (see the example above). In this case the initial product is the iminium ion **1** which loses a proton to give the enamine. In another example, the oxidizing agent SeO_2 can in certain cases convert a carbonyl compound to an α,β-unsaturated carbonyl compound by removing H_2[27] (though this reagent more often gives **9-16**). This reaction has been most often applied in the steroid series, an example being[28]



Similarly, SeO_2 has been used to dehydrogenate 1,4-diketones[29] ($RCOCH_2CH_2COR \rightarrow RCOCH{=}CHCOR$) and 1,2-diarylalkanes ($ArCH_2CH_2Ar \rightarrow ArCH{=}CHAr$). These conversions can also be carried out by certain quinones, most notably DDQ (see **9-1**).[18] Simple aldehydes and ketones have been dehydrogenated (e.g., cyclopentanone → cyclopentenone) by $PdCl_2$,[30] by $FeCl_3$,[31] by benzeneseleninic anhydride[32] (this reagent also dehydrogenates lactones in a similar manner), and by oxygen in the presence of a group VIII metal such as Pd(II) and a cocatalyst such as Cu(II) or a quinone.[33]

In an indirect method of achieving this conversion, the silyl enol ether of a simple ketone is treated with DDQ[34] or with triphenylmethyl cation[35] (for another indirect method, see **7-13**). Dialkyl sulfoxides are dehydrogenated and, at the same time, reduced to sulfides ($RSO_2CH_2CH_2R' \rightarrow RSCH{=}CHR'$) by treatment with Me_3SiI and a sterically hindered amine base.[36]

An entirely different approach to specific dehydrogenation has been reported by R. Breslow[37] and by J. E. Baldwin.[38] By means of this approach it was possible, for example to convert 3α-cholestanol (**2**) to 5α-cholest-14-en-3α-ol (**3**), thus *introducing a double bond at a specific site remote from any functional group.*[39] This was accompanied by conversion of **2** to the ester **4,** followed by irradiation of **4,** which gave 55% **6,** which was then hydrolyzed to **3.** The radiation

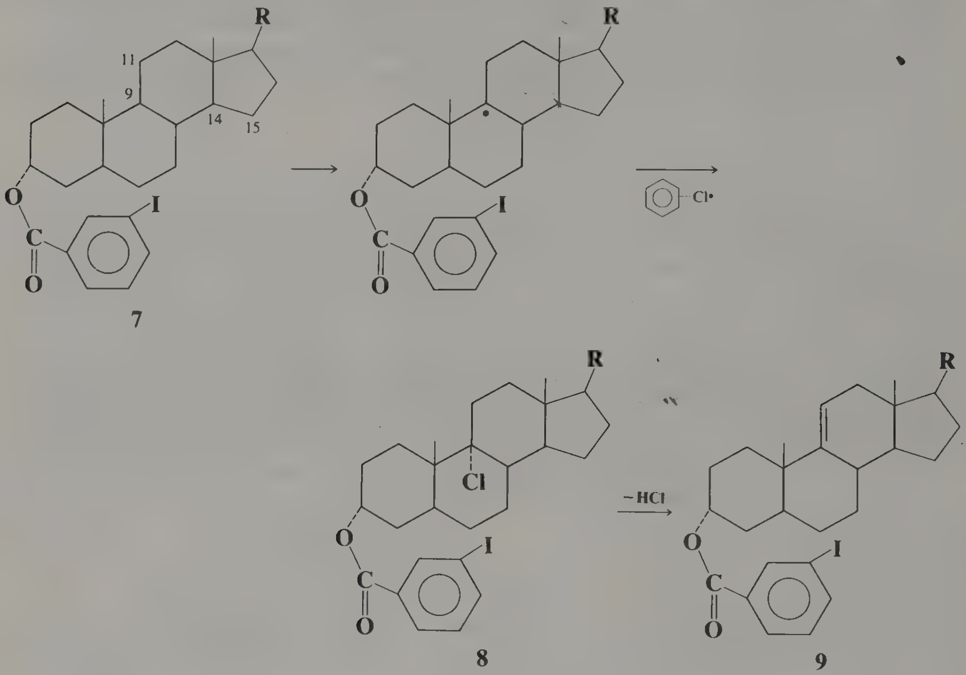
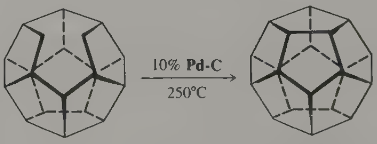
[39] For another method of introducing a remote double bond, see Čeković and Cvetković, *Tetrahedron Lett.* **23,** 3791 (1982). See also Bégué, *J. Org. Chem.* **47,** 4268 (1982).

excites the benzophenone portion of **4** (p. 216), which then abstracts hydrogen from the 14 position to give the diradical **5** which undergoes another internal abstraction to give **6**. In other cases, diradicals like **5** may close to a macrocyclic lactone (**9-16**). In an alternate approach,[40] a 9(11) double bond was introduced into a steroid nucleus by reaction of the *m*-iodo ester **7** with $PhICl_2$



and uv light, which results in hydrogen being abstracted regioselectively from the 9 position, resulting in chlorination at that position. Dehydrohalogenation of **8** gives the 9(11)-unsaturated steroid **9**. In contrast, use of the para isomer of results in chlorination at the 14 position and loss of HCl gives the 14-unsaturated steroid. These reactions are among the very few ways to introduce functionality at a specific site remote from any functional group (see also **9-16**).

A different kind of dehydrogenation was used in the final step of Paquette's synthesis of dodecahedrane:[41]



dodecahedrane

9-3 Oxidation or Dehydrogenation of Alcohols to Aldehydes and Ketones

***C,O*-Dihydro-elimination**

$$\mathrm{RCH_2OH} \xrightarrow[\text{chromite}]{\text{copper}} \mathrm{RCHO}$$

$$\mathrm{RCHOHR'} \xrightarrow[\mathrm{H_2SO_4}]{\mathrm{K_2Cr_2O_7}} \mathrm{RCOR'}$$

Primary alcohols can be converted to aldehydes and secondary alcohols to ketones in four main ways:[42]

1. *With strong oxidizing agents.*[43] Secondary alcohols are easily oxidized to ketones by acid dichromate[44] at room temperature or slightly above. Though this is the most common reagent, many other strong oxidizing agents (e.g., $KMnO_4$, Br_2, MnO_2, ruthenium tetroxide,[45] etc.) have also been employed. A solution of chromic acid and sulfuric acid in water is known as the *Jones reagent.*[46] When secondary alcohols are dissolved in acetone,[47] titration with the Jones reagent oxidizes them to ketones rapidly and in high yield without disturbing any double or triple bonds that may be present (see **9-10**) and without epimerizing an adjacent chiral center.[48] The Jones reagent also oxidizes primary allylic alcohols to the corresponding aldehydes.[49] Three other Cr(VI) reagents commonly used[50] are dipyridine Cr(VI) oxide (Collins's reagent),[51] pyridinium chlorochromate (Corey's reagent),[52] and pyridinium dichromate.[53] MnO_2 is also a fairly specific reagent for OH groups and is often used to oxidize allylic alcohols to α,β-unsaturated aldehydes or ketones. For acid-sensitive compounds either CrO_3 in HMPT[54] or a CrO_3-pyridine complex[55] can be used. Sodium hypochlorite in acetic acid is useful for oxidizing larger amounts of secondary alcohols.[56] The oxidizing agent can be supported on a polymer.[57] Both chromic acid[58] and permanganate[59] have been used in this way (see p. 373). Phase transfer catalysis has also been used with permanganate[60] and chromic acid.[61] Phase transfer catalysis is particularly useful because the oxidizing agents are insoluble in most organic solvents, while the substrates are generally insoluble in water (see p. 320). Ultrasound has been used for $KMnO_4$ oxidations.[62]

Most of these oxidizing agents have also been used to convert primary alcohols to aldehydes, but precautions must be taken so that the aldehyde is not further oxidized to the acid (**9-22**).[63] One way to halt oxidation is by distillation of the aldehyde as it is formed. The following are among the oxidizing agents that have been used to convert at least some primary alcohols to aldehydes:[64] dimethyl sulfoxide (see **9-20**), Collins's reagent, Corey's reagent, pyridinium dichromate, ceric ammonium nitrate (CAN),[65] $Na_2Cr_2O_7$ in water,[66] Ag_2CO_3-on-celite,[67] hot HNO_3 in aqueous glyme,[68] N-methylmorpholine-N-oxide and a Ru complex,[69] O_2-pyridine-CuCl,[70] $Pb(OAc)_4$-pyridine,[71] and benzoyl peroxide-$NiBr_2$.[72] Most of these reagents also oxidize secondary alcohols to ketones. Reagents that can be used specifically to oxidize a secondary OH group in the presence of a primary OH group[73] are Cl_2-pyridine,[74] $(Bu_3Sn)_2O$-Br_2,[75] $NaBrO_3$-CAN,[76] and NaOCl in HOAc,[77] while $RuCl_2(PPh_3)_3$-benzene[78] and Br_2-$Ni(OBz)_2$[79] oxidize primary OH groups in the presence of a secondary OH group.

2. *By catalytic dehydrogenation.*[80] For the conversion of primary alcohols to aldehydes, dehydrogenation catalysts have the advantage over strong oxidizing agents that further oxidation to the acid is prevented. Copper chromite is the agent most often used, but other catalysts, e.g., silver and copper, have also been employed. Many ketones have also been prepared in this manner. Catalytic dehydrogenation is more often used industrially than as a laboratory method. However, a convenient laboratory procedure using copper oxide has been reported.[81]

3. *The Oppenauer oxidation.* When a ketone in the presence of base is used as the oxidizing agent (it is reduced to a secondary alcohol), the reaction is known as the *Oppenauer oxidation.*[82]

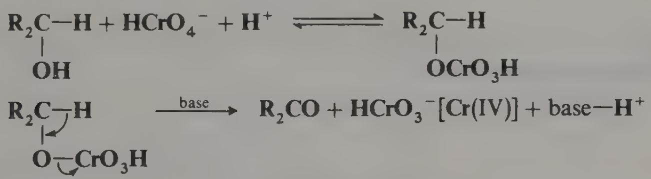
This is the reverse of the Meerwein–Pondorf–Verley reaction (**6-26**), and the mechanism is also the reverse. The ketones most commonly used are acetone, butanone, and cyclohexanone. The most common base is aluminum *t*-butoxide.[83] The chief advantage of the method is its high selectivity. Although the method is most often used for the preparation of ketones, it has also been used for aldehydes.

4. *With* N-*bromosuccinimide or related compounds.* These compounds are chemoselective oxidizing agents and often oxidize OH groups without disturbing other oxidizable groups.[84] N-Bromosuccinimide does not oxidize aliphatic primary alcohols, but N-chlorosuccinimide does. With these reagents it is often possible to oxidize only one of several OH groups that may be present in a molecule. The combination of N-iodosuccinimide and $Bu_4N^+ I^-$ oxidize primary (to aldehydes) and secondary alcohols in high yields.[85]

Primary and secondary alcohols can also be oxidized, indirectly, through their esters (see **9-20**). In some cases, isolation of the ester is not required and the alcohol can then be oxidized to the aldehyde or ketone in one step. Alkoxide ions can be oxidized to aldehydes or ketones in good yield by photooxidation with O_2[86] (singlet O_2 is the oxidizing agent here; see **4-8, 5-38**).

The mechanism of oxidation with acid dichromate has been intensively studied.[87] The currently accepted mechanism is essentially that proposed by Westheimer.[88] The first two steps constitute an example of category 4 (p. 1050).



$$\underset{OH}{R_2C{-}H} + HCrO_4^- + H^+ \rightleftharpoons \underset{OCrO_3H}{R_2C{-}H}$$

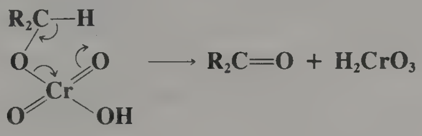
$$\underset{O{-}CrO_3H}{R_2C{-}H} \xrightarrow{\text{base}} R_2CO + HCrO_3^-[Cr(IV)] + \text{base}{-}H^+$$

$$R_2CHOH + Cr(IV) \longrightarrow R_2\dot{C}OH + Cr(III)$$

$$R_2\dot{C}OH + Cr(VI) \longrightarrow R_2CO + Cr(V)$$

$$R_2CHOH + Cr(V) \longrightarrow R_2CO + Cr(III)$$

The base in the second step may be water, though it is also possible[89] that in some cases no external base is involved and that the proton is transferred directly to one of the CrO_3H oxygens, in which



$$\longrightarrow R_2C{=}O + H_2CrO_3$$

case the Cr(IV) species produced would be H_2CrO_3. Part of the evidence for this mechanism was the isotope effect of about 6 found on use of MeCDOHMe, showing that the α-hydrogen is removed in the rate-determining step.[90] Note that, as in **4-6,** the substrate is oxidized by three different oxidation states of chromium.[91]

With other oxidizing agents, mechanisms are less clear.[92] It seems certain that some oxidizing agents operate by a hydride-shift mechanism,[93] e.g., dehydrogenation with triphenylmethyl cation[94] and the Oppenauer oxidation, and some by a free-radical mechanism, e.g., oxidation with $S_2O_8^{2-}$ [95] and with VO_2^+.[96] A summary of many proposed mechanisms is given by Littler.[97]

Secondary alkyl ethers can be oxidized to ketones by bromine (e.g., $Me_2CHOCHMe_2 + Br_2 \rightarrow Me_2CO$).[98] Primary alkyl ethers give carboxylic acids (**9-22**) with bromine, but can be cleaved to aldehydes with 1-chlorobenzotriazole.[99] Acetals can be oxidized to esters with peracetic acid[100] or with ozone.[101]

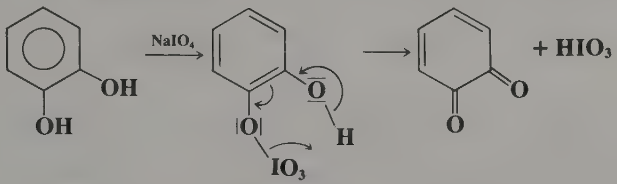
Ortho and para diols are easily oxidized to *ortho*- and *para*-quinones, respectively.[102] Either or both OH groups can be replaced by NH_2 groups to give the same products, though for the preparation of *ortho*-quinones only OH groups are normally satisfactory. The reaction has been successfully carried out with other groups para to OH or NH_2: halogen, OR, Me, *t*-Bu, and even H, though with the last yields are poor. Many oxidizing agents have been used: acid dichromate, silver oxide, lead tetraacetate, HIO_4, and atmospheric oxygen, to name a few. A particularly effective reagent for rings with only one OH or NH_2 group is $(KSO_3)_2N—O\bullet$ (dipotassium nitrosodisulfonate; Fremy's salt), which is a stable free radical.[103] Phenols, even some whose para positions are unoccupied, can be oxidized to *ortho*-quinones with diphenylseleninic anhydride.[104]

Less is known about the mechanism than is the case for **9-3,** but, as in that case, it seems to vary with the oxidizing agent. For oxidation of catechol with $NaIO_4$, it was found that the reaction conducted in $H_2{}^{18}O$ gave unlabeled quinone,[105] so that the following mechanism, which is an example of category 4 (p. 1050), was proposed:



However, for autoxidations (i.e., with atmospheric oxygen) a free-radical mechanism is known to operate.[106]

9-5 Dehydrogenation of Amines
1/1/*N*,2/2/*C*-Tetrahydro-bielimination

$$RCH_2NH_2 \xrightarrow[2.\ H_2O]{1.\ IF_5} RCN$$

Primary amines at a primary carbon can be dehydrogenated to nitriles. The reaction has been carried out in a variety of ways: by treatment with IF_5,[107] lead tetraacetate,[108] nickel peroxide,[109] silver(II) picolinate,[110] $CuCl$-O_2-pyridine,[111] N-bromosuccinimide and triethylamine,[112] or Cl_2-$NaHCO_3$ followed by CsF.[113] Secondary amines can sometimes be dehydrogenated to imines.[114]

A reaction that involves dehydrogenation to an imine which then reacts further is the reaction of primary or secondary amines with palladium black.[115] The imine initially formed by the dehydrogenation reacts with another molecule of the same or a different amine to give an aminal, which loses NH_3 or RNH_2 to give a secondary or tertiary amine. An example is the reaction between N-methylbenzylamine and N-methylbutylamine, which produces 95% N-methyl-N-butylbenzylamine.

Another method for the conversion of primary to secondary amines ($2RNH_2 \rightarrow R_2NH$) involves treatment with a catalytic amount of sodium hydride.[116] This reaction also involves an imine intermediate.

9-6 Oxidation of Hydrazines, Hydrazones, and Hydroxylamines
1/*N*,2/*N*-Dihydro-elimination

$$Ar{-}NH{-}NH{-}Ar \xrightarrow{NaOBr} Ar{-}N{=}N{-}Ar$$

N,N′-Diarylhydrazines (hydrazo compounds) are oxidized to azo compounds by several oxidizing agents, including NaOBr, HgO,[117] $K_3Fe(CN)_6$ under phase transfer conditions,[118] benzeneseleninic anhydride,[119] MnO_2 (this reagent yields cis azobenzenes),[120] $CuCl_2$, and air and NaOH.[121] The reaction is also applicable to N,N′-dialkyl- and N,N′-diacylhydrazines. Hydrazines (both alkyl and aryl) substituted on only one side also give azo compounds,[122] but these are unstable and decompose to nitrogen and the hydrocarbon:

$$Ar{-}NH{-}NH_2 \longrightarrow [Ar{-}N{=}NH] \longrightarrow ArH + N_2$$

When hydrazones are oxidized with HgO, Ag_2O, or certain other oxidizing agents, diazo compounds are obtained (see also **7-28**):

$$R_2C{=}N{-}NH_2 \xrightarrow{HgO} R_2C{=}\overset{\oplus}{N}{=}\overset{\ominus}{N}$$

Hydrazones of the form $ArCH{=}NNH_2$ react with HgO in solvents such as diglyme or ethanol to give nitriles ArCN.[123] Aromatic hydroxylamines are easily oxidized to nitroso compounds, most commonly by acid dichromate.[124]

$$Ar{-}NH{-}OH \xrightarrow{CrO_3} Ar{-}N{=}O$$

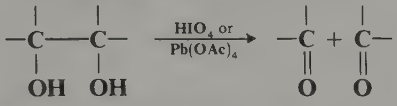
B. Oxidations Involving Cleavage of Carbon–Carbon Bonds[125]

9-7 Oxidative Cleavage of Glycols and Related Compounds

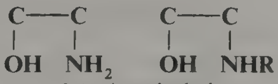


$$-\underset{OH}{\overset{|}{\underset{|}{C}}}-\underset{OH}{\overset{|}{\underset{|}{C}}}- \xrightarrow[Pb(OAc)_4]{HIO_4\text{ or}} -\underset{O}{\overset{|}{\underset{\|}{C}}} + \underset{O}{\overset{|}{\underset{\|}{C}}}-$$

1,2-Glycols are easily cleaved under mild conditions and in good yield with periodic acid or lead tetraacetate.[126] The products are 2 moles of aldehyde, or 2 moles of ketone, or 1 mole of each, depending on the groups attached to the two carbons. The yields are so good that olefins are often converted to glycols (**5-36**) and then cleaved with HIO_4 or $Pb(OAc)_4$ rather than being cleaved directly with ozone (**9-9**) or dichromate or permanganate (**9-10**). A number of other oxidizing agents also give the same products, among them activated MnO_2,[127] thallium(III) salts,[128] pyridinium chlorochromate,[129] and O_2 catalyzed by Co(III) salts.[130] Permanganate, dichromate, N-iodosuccinimide,[131] N-bromosuccinimide-triphenylbismuth,[132] iodine triacetate,[133] and several other oxidizing agents also cleave glycols, giving carboxylic acids rather than aldehydes, but these reagents are seldom used synthetically.

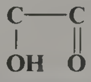
The two reagents (periodic acid and lead tetraacetate) are complementary, since periodic acid is best used in water and lead tetraacetate in organic solvents. When three or more OH groups are located on adjacent carbons, then the middle one (or ones) is converted to formic acid.

Similar cleavage is undergone by other compounds that contain oxygens or nitrogens on adjacent carbons:



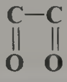
$$\underset{OH}{\underset{|}{C}}-\underset{NH_2}{\underset{|}{C}} \qquad \underset{OH}{\underset{|}{C}}-\underset{NHR}{\underset{|}{C}}$$

β-Amino alcohols



$$\underset{OH}{\underset{|}{C}}-\underset{O}{\underset{\|}{C}}$$

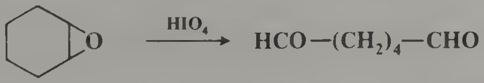
α-Hydroxy aldehydes and ketones



$$\underset{O}{\underset{\|}{C}}-\underset{O}{\underset{\|}{C}}$$

α-Diketones
α-Keto aldehydes
Glyoxal

α-Diketones and α-hydroxy ketones are also cleaved by alkaline H_2O_2.[134] HIO_4 has been used to cleave epoxides to aldehydes,[135] e.g.,



α-Hydroxy acids and α-keto acids are not cleaved by HIO_4 but are cleaved by $Pb(OAc)_4$, alkaline H_2O_2, and other reagents. These are oxidative decarboxylations. α-Hydroxy acids give aldehydes or ketones, and α-keto acids give acids:

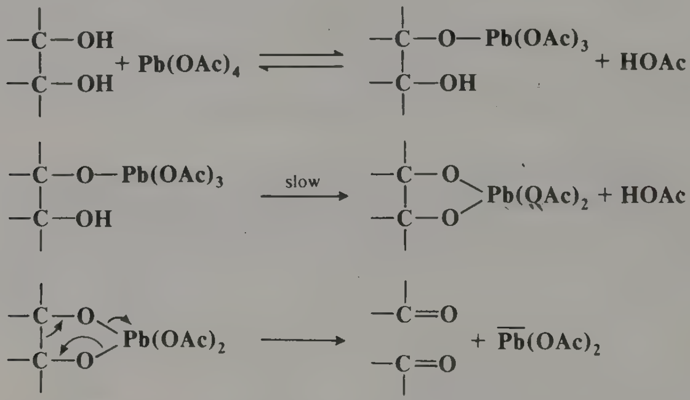
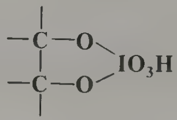
The mechanism of glycol oxidation with $Pb(OAc)_4$ was proposed by Criegee:[136]



This mechanism is supported by these facts: (1) the kinetics are second order (first order in each reactant); (2) added acetic acid retards the reaction (drives the equilibrium to the left); and (3) cis glycols react much more rapidly than trans glycols.[137] For periodic acid the mechanism is similar, with the intermediate[138]



However, the cyclic-intermediate mechanism cannot account for all glycol oxidations, since some glycols that cannot form such an ester (e.g., **10**) are nevertheless cleaved by lead tetraacetate

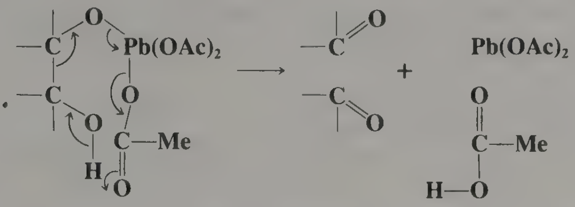
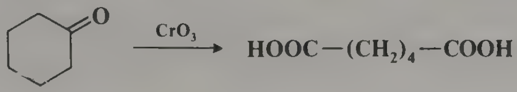
(though other glycols that cannot form cyclic esters are *not* cleaved, by either reagent[139]). To account for cases like **10**, a cyclic transition state has been proposed:[137]



OS **IV,** 124.

9-8 Oxidative Cleavage of Ketones, Aldehydes, and Alcohols



Oxidative cleavage of open-chain ketones or alcohols[140] is seldom a useful preparative procedure, not because these compounds do not undergo oxidation (they do, with the exception of diaryl ketones) but because the result is generally a hopeless mixture. However, the reaction is quite useful for cyclic ketones and the corresponding secondary alcohols, the dicarboxylic acid being prepared in good yield. The formation of adipic acid from cyclohexanone (shown above) is an important industrial procedure. Acid dichromate and permanganate are the most common oxidizing agents, though autoxidation (oxidation with atmospheric oxygen) in alkaline solution[141] and potassium superoxide under phase transfer conditions[142] have also been used. The last-mentioned reagent has also been used to cleave open-chain ketones to give carboxylic acid products in good yield.[142]

The mechanism for the cleavage of ketones by strong oxidizing agents is probably through the enol form.[143] The process may be illustrated for chromic acid:

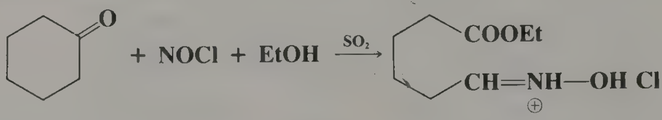
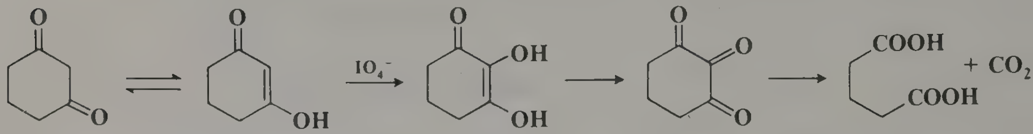
The formation of the chromium ester from the enol is similar to the bromination of ketones (**2-4**). A similar mechanism was demonstrated for nitric acid.[144] However, in some cases, the ketone is attacked directly, and not through the enol.[145]

Cyclic ketones can also be cleaved by treatment with NOCl and an alcohol in liquid SO_2 to give an ω-oximinocarboxylic ester, e.g.,[146]



Cyclic 1,3-diketones, which exist mainly in the monoenolic form, can be cleaved with sodium periodate with loss of one carbon, e.g.,[147]



The species actually undergoing the cleavage is the triketone, so this is an example of **9-7**.

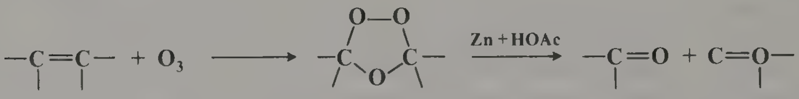
9-9 Ozonolysis



11

When compounds containing double bonds are treated with ozone, usually at low temperatures, they are converted to compounds called ozonides (**11**) that can be isolated but, because some of them are explosive, are more often decomposed with zinc and acetic acid or catalytic hydrogenation to give 2 moles of aldehyde, or 2 moles of ketone, or 1 mole of each, depending on the groups attached to the olefin.[148] The decomposition of **11** has also been carried out with many other reducing agents, among them trimethyl phosphite,[149] thiourea,[150] and dimethyl sulfide.[151] However, ozonides can also be *oxidized* with oxygen, peracids, or H_2O_2 to give ketones and/or carboxylic acids or *reduced* with $LiAlH_4$, $NaBH_4$, BH_3, or catalytic hydrogenation with excess H_2 to give 2 moles of alcohol.[152] Ozonides can also be treated with ammonia, hydrogen, and a catalyst to give the corresponding amines,[153] or with an alcohol and anhydrous HCl to give the corresponding carboxylic esters.[154] Ozonolysis is therefore an important synthetic reaction. In the past it was also very valuable for location of the double bonds in unknown compounds, though with the advent of instrumental methods of structure determination, this usage has declined.

A wide variety of olefins undergo ozonolysis, including cyclic ones, where cleavage gives rise to one bifunctional product. Olefins in which the double bond is connected to electron-donating groups react many times faster than those in which it is connected to electron-withdrawing groups.[155] The reaction has often been carried out on compounds containing more than one double bond; generally the bonds are all cleaved. In some cases, especially when bulky groups are present, conversion of the substrate to an epoxide (**5-37**) becomes an important side reaction and can be the main reaction.[156] Ozonolysis of triple bonds[157] is less common and the reaction proceeds less easily, since ozone is an electrophilic agent[158] and therefore prefers double to triple bonds (p. 671). Compounds that contain triple bonds generally give carboxylic acids, though sometimes ozone oxidizes them to α-diketones. Aromatic compounds are also attacked less readily than olefins, but they have often been cleaved. Aromatic compounds behave as if the double bonds in the Kekulé structures were really there. Thus benzene gives 3 moles of glyoxal (HCOCHO), and *o*-xylene gives a glyoxal/MeCOCHO/MeCOCOMe ratio of 3:2:1, which shows that in this case cleavage is statistical. With polycyclic aromatic compounds the site of attack depends on the structure of the molecule and on the solvent.[159]

Although a large amount of work has been done on the mechanism of ozonization (formation of **11**), not all the details are known. The basic mechanism was formulated by Criegee.[160] The first step of the Criegee mechanism is a 1,3 dipolar addition (**5-46**) of ozone to substrate to give the "initial" or "primary" ozonide **12**.[161] This species is highly unstable and cleaves to an aldehyde or ketone (**13**) and an intermediate which Criegee showed as a zwitterion (**14**) but which may be a biradical (**15**). The intermediate (which we will represent as **14**) may then undergo various reactions, three of which lead to normal products. One of these is a recombination with **13**, the

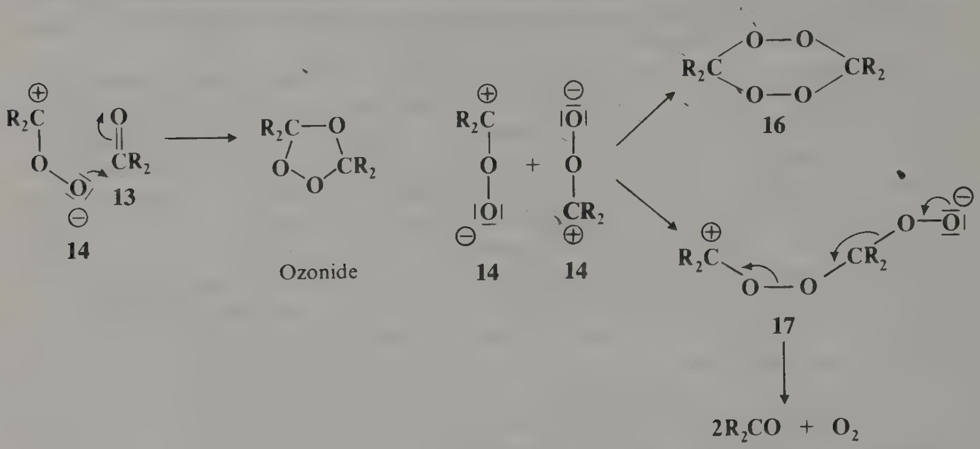
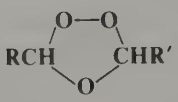
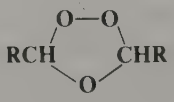
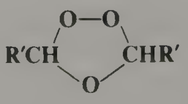
second a dimerization to the bisperoxide **16,** and the third a kind of dimerization to **17.**[162] If the



first path is taken (this is normally possible only if **13** is an aldehyde; most ketones are not reactive enough[163]), hydrolysis of the ozonide gives the normal products. If **16** is formed, hydrolysis of it gives one of the products, and of course **13,** which then does not undergo further reaction, is the other. **17,** if formed, can decompose directly, as shown, to give the normal products and oxygen. In protic solvents, **14** is converted to a hydroperoxide, and these have been isolated, for example,  $Me_2\underset{\displaystyle OOH}{\underset{|}{C}}—OMe$ from $Me_2C{=}CMe_2$ in methanol. Further evidence for the mechanism is that **16** can be isolated in some cases, e.g., from $Me_2C{=}CMe_2$. But perhaps the most impressive evidence comes from the detection of cross products. In the Criegee mechanism, the two parts of the original olefin break apart and then recombine to form the ozonide. In the case of an unsymmetrical olefin RCH=CHR′ there should be three ozonides:







since there are two different aldehydes **13** and two different species **14,** and these can recombine in the three ways shown. Actually *six* ozonides, corresponding to the cis and trans forms of these three, were isolated and characterized for methyl oleate.[164] Similar results have been reported for smaller olefins, e.g., 2-pentene, 2-hexene, 4-nonene, and even 2-methyl-2-pentene.[165] The last-mentioned case is especially interesting, since it is quite plausible that this unsymmetrical olefin would cleave in only one way, so that only one ozonide (in cis and trans versions) would be found; but this is not so, and three were found for this case too. However, terminal olefins give little or no cross ozonide formation.[166] In general, the less alkylated end of the olefin tends to go to **13** and the other to **14**. Still other evidence for the Criegee mechanism is: (1) When $Me_2C{=}CMe_2$ was ozonized in the presence of HCHO, the ozonide **18** could be isolated;[167] (2) **14** prepared in an

---

[162] Fliszár, Gravel, and Cavalieri, *Can. J. Chem.* **44,** 67, 1013 (1966); Fliszár and Chylińska, *Can. J. Chem.* **45,** 29 (1967), **46,** 783 (1968).

[163] It follows that tetrasubstituted alkenes do not normally give ozonides. However, they do give the normal cleavage products (ketones) by the other pathways.

[164] Riezebos, Grimmelikhuysen, and van Dorp, *Recl. Trav. Chim. Pays-Bas* **82,** 1234 (1963); Privett and Nickell, *J. Am. Oil Chem. Soc.* **41,** 72 (1964).

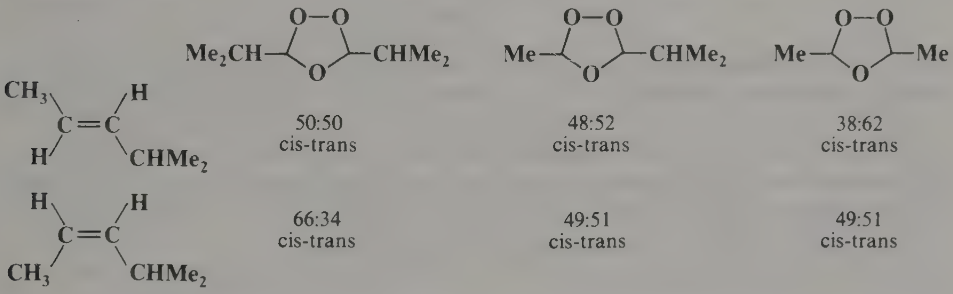
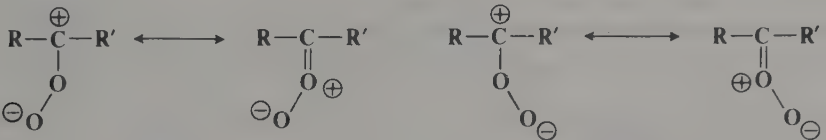
18

entirely different manner (photooxidation of diazo compounds), reacted with aldehydes to give ozonides;[168] and (3) cis and trans olefins generally give the same ozonide, which would be expected if they cleave first.[169] However, this was not true for $Me_3CCH{=}CHCMe_3$, where the cis olefin gave the cis ozonide (chiefly), and the trans gave the trans.[170] The latter result is not compatible with the Criegee mechanism. Also incompatible with the Criegee mechanism was the finding that the cis/trans ratios of symmetrical (cross) ozonides obtained from *cis*- and *trans*-4-methyl-2-pentene were not the same.[171]



If the Criegee mechanism operated as shown above, the cis/trans ratio for each of the two cross ozonides would have to be identical for the cis and trans olefins, since in this mechanism they are completely cleaved.

The above stereochemical results have been explained[172] on the basis of the Criegee mechanism with the following refinements: (1) The formation of **12** is stereospecific, as expected from a 1,3 dipolar cycloaddition. (2) Once they are formed, **14** and **13** remain attracted to each other, much like an ion pair. (3) **14** exists in syn and anti forms, which are produced in different amounts and



syn-**14** *anti*-**14**

---

[167] Even ketones can react with **14** to form ozonides, provided they are present in large excess: Criegee and Korber, *Chem. Ber.* **104,** 1812 (1971).

[168] Murray and Suzui, *J. Am. Chem. Soc.* **95,** 3343 (1973); Higley and Murray, *J. Am. Chem. Soc.* **96,** 3330 (1974).

[169] See, for example, Murray and Williams, *J. Org. Chem.* **34,** 1896 (1969).

[170] Schröder, *Chem. Ber.* **95,** 733 (1962); Kolsaker, *Acta Chem. Scand., Ser. B* **32,** 557 (1978).

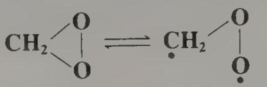
[171] Murray, Youssefyeh, and Story, *J. Am. Chem. Soc.* **88,** 3143, 3655 (1966); Story, Murray, and Youssefyeh, *J. Am. Chem. Soc.* **88,** 3144 (1966). Also see Greenwood, *J. Am. Chem. Soc.* **88,** 3146 (1966); Choe, Srinivasan, and Kuczkowski, *J. Am. Chem. Soc.* **105,** 4703 (1983).

[172] Bauld, Thompson, Hudson, and Bailey, *J. Am. Chem. Soc.* **90,** 1822 (1968); Lattimer, Kuczkowski, and Gillies, *J. Am. Chem. Soc.* **96,** 348 (1974); Bailey and Ferrell, *J. Am. Chem. Soc.* **100,** 899 (1978).

can hold their shapes, at least for a time. This is plausible if we remember that a C=O canonical form contributes to the structure of **14**. (4) The combination of **14** and **13** is also a 1,3 dipolar cycloaddition, so configuration is retained in this step too.[173]

Evidence that the basic Criegee mechanism operates even in these cases comes from ^{18}O labeling experiments, making use of the fact, mentioned above, that mixed ozonides (e.g., **18**) can be isolated when an external aldehyde is added. Both the normal and modified Criegee mechanisms predict that if ^{18}O-labeled aldehyde is added to the ozonolysis mixture, the label will appear in the ether oxygen (see the reaction between **14** and **13**), and this is what is found.[174] There is evidence that the anti-**14** couples much more readily than the syn-**14**.[175]

The ozonolysis of ethylene in the liquid phase (without a solvent) was shown to take place by the Criegee mechanism.[176] This reaction has been used to study the structure of the intermediate **14** or **15**. The compound dioxirane (**19**) was identified in the reaction mixture[177] at low temperatures



19 **15(R = H)**

and is probably in equilibrium with the biradical **15**(R = H). It had previously been proposed, on the basis of valence-bond calculations, that the ground state of the intermediate is in fact **15** and that **19** is more stable.[178]

Ozonolysis in the gas phase is not generally carried out in the laboratory. However, the reaction is important because it takes place in the upper atmosphere and contributes to air pollution. There is much evidence that the Criegee mechanism operates in the gas phase too, though the products are more complex because of other reactions that also take place.[179]

9-10 Oxidative Cleavage of Double Bonds and Aromatic Rings

$$R_2C{=}CHR \xrightarrow{CrO_3} R_2C{=}O + RCOOH$$

Double bonds can be cleaved by many oxidizing agents,[180] the most common of which are neutral or acid permanganate and acid dichromate. The products are generally 2 moles of ketone, 2 moles of carboxylic acid, or 1 mole of each, depending on what groups are attached to the olefin. With ordinary solutions of permanganate or dichromate yields are generally low, and the reaction is seldom a useful synthetic method; but high yields can be obtained by oxidizing with $KMnO_4$ dissolved in benzene containing the crown ether dicyclohexano-18-crown-6 (see p. 77).[181] The crown ether coordinates with K^+, permitting the $KMnO_4$ to dissolve in benzene. Another reagent frequently used for synthetic purposes is the *Lemieux–von Rudloff reagent:* HIO_4 containing a trace of MnO_4^-.[182] The MnO_4^- is the actual oxidizing agent, being reduced to the manganate stage, and the purpose of the HIO_4 is to reoxidize the manganate back to MnO_4^-. Another reagent that behaves similarly is $NaIO_4$-ruthenium tetroxide.[183] The *Barbier–Wieland procedure* for decreasing the length of a chain by one carbon involves oxidative cleavage by acid dichromate ($NaIO_4$-ruthenium tetroxide has also been used), but this is cleavage of a 1,1-diphenyl olefin, which generally gives good yields:

---

[173] For isotope-effect evidence that this step is concerted in some cases, see Choe and Kuczkowski, *J. Am. Chem. Soc.* **105,** 4839 (1983). However, there is evidence that it may not always be concerted: see for example, Murray and Su, *J. Org. Chem.* **48,** 817 (1983).

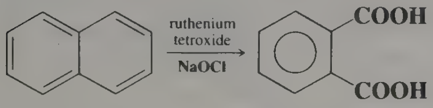
$$\mathrm{RCH_2COOH} \underset{(0\text{-}25)}{\xrightarrow[\mathrm{H^+}]{\mathrm{EtOH}}} \mathrm{RCH_2COOEt} \xrightarrow[(6\text{-}32)]{\mathrm{PhMgBr}}$$

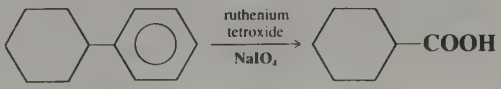
$$\mathrm{RCH_2}\underset{\mathrm{OH}}{\underset{|}{\mathrm{C}}}\mathrm{Ph_2} \xrightarrow[(7\text{-}1)]{\Delta} \mathrm{RCH{=}CPh_2} \xrightarrow[\mathrm{NaIO_4\text{-}RuO_4}]{\mathrm{CrO_3} \text{ or}} \mathrm{RCOOH} + \mathrm{Ph_2CO}$$

With certain reagents, the oxidation of double bonds can be stopped at the aldehyde stage, and in these cases the products are the same as in the ozonolysis procedure. Among these reagents are chromyl trichloroacetate[184] and $NaIO_4$-OsO_4.[185]

The mechanism of oxidation probably involves in most cases the initial formation of a glycol (**5-36**) or cyclic ester,[186] and then further oxidation as in **9-7.**[187] In line with the electrophilic attack on the olefin, triple bonds are more resistant to oxidation than double bonds.

Aromatic rings can be cleaved with strong enough oxidizing agents. An important laboratory reagent for this purpose is ruthenium tetroxide along with a cooxidant such as $NaIO_4$ or NaOCl (household bleach may be used).[188] Examples[189] are the oxidation of naphthalene to phthalic acid[190]





and, even more remarkably, of cyclohexylbenzene to cyclohexanecarboxylic acid[191] (note the contrast with **9-11**). The latter conversion was also accomplished with ozone.[192] Another reagent that oxidizes aromatic rings is air catalyzed by V_2O_5. The oxidations of naphthalene to phthalic anhydride and of benzene to maleic anhydride (p. 711) by this reagent are important industrial procedures.[193] *o*-Diamines have been oxidized with nickel peroxide, with lead tetraacetate,[194] and with O_2 catalyzed by CuCl:[195]

[186] See for example, Lee and Spitzer, *J. Org. Chem.* **41,** 3644 (1976); Lee, Chang, and Helliwell, *J. Org. Chem.* **41,** 3644, 3646 (1976).

[187] There is evidence that oxidation with Cr(VI) in aqueous acetic acid involves an epoxide intermediate: Awasthy and Roček, *J. Am. Chem. Soc.* **91,** 991 (1969); Roček and Drozd, *J. Am. Chem. Soc.* **92,** 6668 (1970). See also Erickson and Clark, *Tetrahedron Lett.* 3997 (1969).

[188] Ruthenium tetroxide is an expensive reagent, but the cost may be greatly reduced by the use of an inexpensive cooxidant such as NaOCl, the function of which is to oxidize RuO_2 back to ruthenium tetroxide.

[189] For other examples, see Piatak, Herbst, Wicha, and Caspi, *J. Org. Chem.* **34,** 116 (1969); Wolfe, Hasan, and Campbell, *Chem. Commun.* 1420 (1970); Ayres and Hossain, *Chem Commun.* 428 (1972).

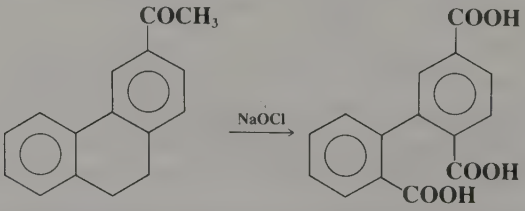
9-11 Oxidation of Aromatic Side Chains

$$ArR \xrightarrow{KMnO_4} ArCOOH$$

Alkyl chains on aromatic rings can be oxidized to COOH groups by many oxidizing agents, including permanganate, nitric acid, and acid dichromate.[198] The method is most often applied to the methyl group, though longer side chains can also be cleaved. However, tertiary alkyl groups are resistant to oxidation, and when they *are* oxidized, ring cleavage usually occurs too.[199] It is usually difficult to oxidize an R group on a fused aromatic system without cleaving the ring or oxidizing it to a quinone (**9-19**). However, this has been done (e.g., 2-methylnaphthalene was converted to 2-naphthoic acid) with aqueous $Na_2Cr_2O_7$.[200] Functional groups may be present anywhere on the side chain and, if in the α-position, greatly increase the ease of oxidation. However, an exception is an α-phenyl group. In such cases the reaction stops at the diaryl ketone stage. Molecules containing aryl groups on different carbons cleave so that each ring gets one carbon atom, e.g.,



It is possible to oxidize only one alkyl group of a ring that contains more than one. The order of reactivity[201] toward most reagents is $CH_2Ar > CHR_2 > CH_2R > CH_3$.[202] Groups on the ring susceptible to oxidation (OH, NHR, NH_2, etc.) must be protected. The oxidation can be performed with oxygen, in which case it is autoxidation, and the mechanism is like that in **4-8**, with a hydroperoxide intermediate. With this procedure it is possible to isolate ketones from $ArCH_2R$, and this is often done.[203]

[195] Kajimoto, Takahashi, and Tsuji, *J. Org. Chem.* **41,** 1389 (1976).

[196] Tsuji and Takayanagi, *Tetrahedron* **34,** 641 (1978). See also Pandell, *J. Org. Chem.* **41,** 3992 (1976); Rogić, Demmin, and Hammond, *J. Am. Chem. Soc.* **98,** 7441 (1976).

[197] McKillop, Oldenziel, Swann, Taylor, and Robey, *J. Am. Chem. Soc.* **95,** 1296 (1973).

[198] For many examples, see Lee, Ref. 10, pp. 43–64.

[199] Brandenberger, Maas, and Dvoretzky, *J. Am. Chem. Soc.* **83,** 2146 (1961).

[200] Friedman, Fishel, and Shechter, *J. Org. Chem.* **30,** 1453 (1965).

[201] Oxidation with Co(III) is an exception. The methyl group is oxidized in preference to the other alkyl groups: Onopchenko, Schulz, and Seekircher, *J. Org. Chem.* **37,** 1414 (1972).

[202] For example, see Foster and Hickinbottom, *J. Chem. Soc.* 680 (1960); Ferguson and Wims, *J. Org. Chem.* **25,** 668 (1960).

[203] For a review, see Pines and Stalick, Ref. 21, pp. 508–543.

The mechanism has been studied for the closely related reaction: $Ar_2CH_2 + CrO_3 \rightarrow Ar_2C{=}O$.[204] A deuterium isotope effect of 6.4 was found, indicating that the rate-determining step is either $Ar_2CH_2 \rightarrow Ar_2CH\cdot$ or $Ar_2CH_2 \rightarrow Ar_2CH^+$. Either way this explains why tertiary groups are not converted to COOH and why the reactivity order is $CHR_2 > CH_2R > CH_3$, as mentioned above. Both free radicals and carbocations exhibit this order of stability (Chapter 5). The two possibilities are examples of categories 2 and 3 (p. 1050). Just how the radical or the cation goes on to the product is not known. $\mathrm{Ar{-}\overset{|}{\underset{|}{C}}{-}OH}$ may be an intermediate, in which case the further reaction would be like that in **9-3.**

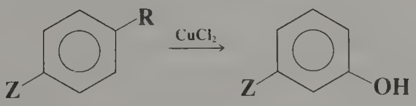
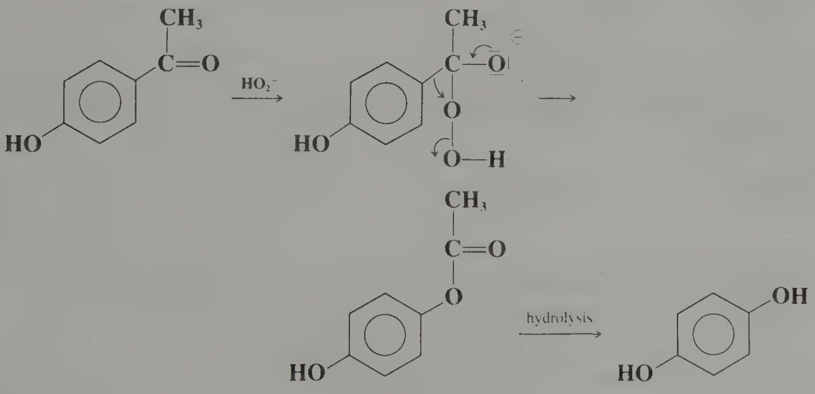
9-12 Oxidative Cleavage of Alkyl Groups from Rings



It is possible to replace an alkyl group on a ring by an OH group. When the alkyl group is one oxidizable to COOH (**9-11**), cupric salts are oxidizing agents, and the OH group is found in a position ortho to that occupied by the alkyl group.[205] What happens here is initial oxidation to COOH, and then an example of **3-20.**[206] This reaction is used industrially to convert toluene to phenol.

In another kind of reaction, an aromatic aldehyde ArCHO or ketone ArCOR′ is converted to a phenol ArOH on treatment with alkaline H_2O_2,[207] but there must be an OH or NH_2 group in the ortho or para position. This is called the *Dakin reaction*.[208] The mechanism may be similar to that of the Baeyer–Villiger reaction (**8-22**):[209]



20

The intermediate **20** has been isolated.[210]

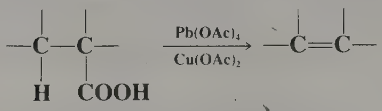
9-13 Oxidative Decarboxylation

$$\mathrm{RCOOH} \xrightarrow{\mathrm{Pb(OAc)_4}} \mathrm{ROAc}$$

Acetoxy-de-carboxy-substitution



Hydro-carboxy-elimination

Carboxylic acids can be decarboxylated[211] with lead tetraacetate to give a variety of products, among them the ester ROAc (formed by replacement of COOH by an acetoxy group), the alkane RH (see **2-39**), and, if a β-hydrogen is present, the alkene formed by elimination of H and COOH, as well as numerous other products arising from rearrangements, internal cyclizations,[212] and reactions with solvent molecules. When R is tertiary, the chief product is usually the alkene, which is often obtained in good yield. High yields of alkenes can also be obtained when R is primary or secondary, in this case by the use of $Cu(OAc)_2$-$Pb(OAc)_4$ instead of $Pb(OAc)_4$.[213] In the absence of $Cu(OAc)_2$, primary acids give mostly alkanes (though yields are generally low) and secondary acids may give esters or alkenes. Esters have been obtained in good yields from some secondary acids, from β,γ-unsaturated acids, and from acids in which R is a benzylic group. γ-Keto acids give good yields of α,β-unsaturated ketones.[214] Other oxidizing agents, including Co(III), Ag(II), Mn(III), and Ce(IV), have also been used to effect oxidative decarboxylation.[215]

The mechanism with lead tetraacetate is generally accepted to be of the free-radical type.[216] First there is an interchange of ester groups:

$$\mathrm{Pb(OAc)_4 + RCOOH \longrightarrow \underset{\textbf{21}}{Pb(OAc)_3OCOR} \quad or \quad \underset{\textbf{22}}{Pb(OAc)_2(OCOR)_2}}$$

There follows a free-radical chain mechanism (shown for **21** though **22** and other lead esters may behave similarly)

$$\text{Initiation} \qquad \underset{\textbf{21}}{\mathrm{Pb(OAc)_3OCOR}} \longrightarrow \mathrm{\dot{P}b(OAc)_3 + R\cdot + CO_2}$$

$$\text{Propagation} \qquad \mathrm{R\cdot + Pb(OAc)_3OCOR \longrightarrow R^+ + \dot{P}b(OAc)_2OCOR + OAc^-}$$

$$\mathrm{\dot{P}b(OAc)_2OCOR \longrightarrow Pb(OAc)_2 + R\cdot + CO_2}$$

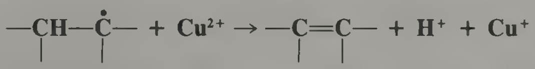
[215] For references, see Trahanovsky, Cramer, and Brixius, *J. Am. Chem. Soc.* **96,** 1077 (1974); Kochi, "Organometallic Mechanisms and Catalysis," pp. 99–106, Academic Press, New York, 1978. See also Dessau and Heiba, *J. Org. Chem.* **40,** 3647 (1975); Fristad, Fry, and Klang, *J. Org. Chem.* **48,** 3575 (1983); Barton, Crich, and Motherwell, *J. Chem. Soc., Chem. Commun.* 242 (1984).

[216] Kochi, *J. Am. Chem. Soc.* **87,** 1811, 3609 (1965); Starnes, *J. Am. Chem. Soc.* **86,** 5603 (1964); Davies and Waring, *Chem. Commun.* 263 (1965); Kochi, Bacha, and Bethea, *J. Am. Chem. Soc.* **89,** 6538 (1967); Cantello, Mellor, and Scholes, *J. Chem. Soc., Perkin Trans. 2* 348 (1974); Beckwith, Cross, and Gream, *Aust. J. Chem.* **27,** 1673, 1693 (1974).

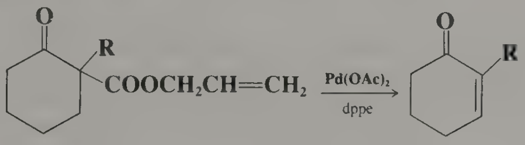
Products can then be formed either from R• or R^+. Primary R• abstract H from solvent molecules to give RH. R^+ can lose H^+ to give an alkene, react with HOAc to give the ester, react with solvent molecules or with another functional group in the same molecule, or rearrange, thus accounting for the large number of possible products. R• can also dimerize to give R—R. The effect of Cu^{2+} ions[217] is to oxidize the radicals to alkenes, thus producing good yields of alkenes



$$-\underset{|}{C}H-\underset{|}{\dot{C}}- + Cu^{2+} \rightarrow -\underset{|}{C}=\underset{|}{C}- + H^+ + Cu^+$$

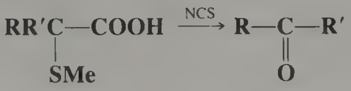
from primary and secondary substrates. Cu^{2+} has no effect on tertiary radicals, because these are efficiently oxidized to alkenes by lead tetraacetate.

Certain allylic β-keto esters (e.g., **23**) can be decarbalkoxylated, with removal of H and COOR, to give α,β-unsaturated ketones, by treatment with palladium(II) acetate and 1,2-bis(diphenylphosphino)ethane (dppe).[218]



23

In another type of oxidative decarboxylation, α-methylthio carboxylic acids can be decarboxylated to the corresponding ketones with N-chlorosuccinimide (NCS) in an alcohol solvent containing $NaHCO_3$:[219]

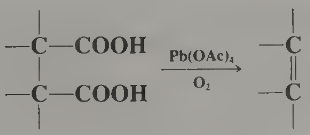


$$RR'\underset{\substack{|\\ SMe}}{C}-COOH \xrightarrow{NCS} R-\underset{\substack{\|\\ O}}{C}-R'$$

In still another type, arylacetic acids can be oxidized to aldehydes with one less carbon ($ArCH_2COOH \rightarrow ArCHO$) by tetrabutylammonium periodate.[220] Simple aliphatic carboxylic acids were converted to nitriles with one less carbon ($RCH_2COOH \rightarrow RC\equiv N$) by treatment with trifluoroacetic anhydride and $NaNO_2$ in F_3CCOOH.[221]

See also **4-39.**

9-14 Bisdecarboxylation
Dicarboxy-elimination



$$\begin{array}{l} -\overset{|}{C}-COOH \\ -\underset{|}{\overset{|}{C}}-COOH \end{array} \xrightarrow[O_2]{Pb(OAc)_4} \begin{array}{l} -\overset{|}{C} \\ \;\;\| \\ -\underset{|}{C} \end{array}$$

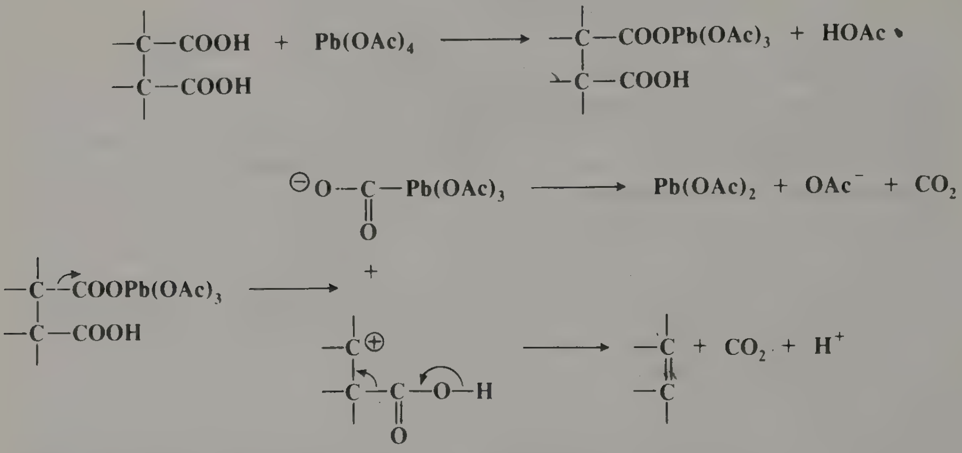
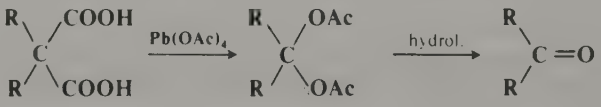
[221] Smushkevich, Usorov, and Suvorov, *J. Org. Chem. USSR* **11,** 653 (1975).

Compounds containing carboxyl groups on adjacent carbons (succinic acid derivatives) can be bisdecarboxylated with lead tetraacetate in the presence of O_2.[211] The reaction is of wide scope. The elimination is stereoselective, but not stereospecific (both *meso*- and *dl*-2,3-diphenylsuccinic acid gave *trans*-stilbene);[222] a concerted mechanism is thus unlikely (see Chapter 15). The following mechanism is not inconsistent with the data:



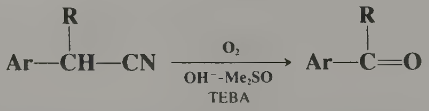
though a free-radical mechanism seems to hold in some cases.

Compounds containing geminal carboxyl groups (disubstituted malonic acid derivatives) can also be bisdecarboxylated with lead tetraacetate, *gem*-diacetates (acylals) being produced, which are easily hydrolyzable to ketones:[223]



Bisdecarboxylation of succinic acid derivatives to give alkenes has also been carried out by treatment of the corresponding anhydrides with nickel, iron, or rhodium complexes,[224] by decomposition of the corresponding bis peresters,[225] and electrolytically.[226]

9-15 Oxidative Decyanation
Oxo-de-hydro,cyano-bisubstitution



$$\mathrm{Ar{-}\overset{R}{\overset{|}{C}}H{-}CN} \xrightarrow[\text{OH}^-\text{-Me}_2\text{SO}\ \ \text{TEBA}]{O_2} \mathrm{Ar{-}\overset{R}{\overset{|}{C}}{=}O}$$

α-Substituted aryl nitriles having a sufficiently acidic α-hydrogen can be converted to ketones by oxidation with air under phase transfer conditions. The nitrile is added to NaOH in benzene or

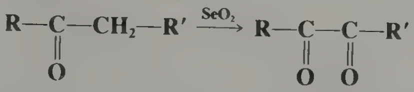
Me_2SO containing a catalytic amount of triethylbenzylammonium chloride (TEBA).[227] This reaction could not be applied to aliphatic nitriles, but an indirect method for achieving this conversion is given in **9-58.** α,α-Dialkylamino nitriles can be converted to ketones [$R_2C(NMe_2)CN \rightarrow R_2C{=}O$] by hydrolysis with $CuSO_4$ in aqueous methanol.[228]

C. Reactions Involving Replacement of Hydrogen by Oxygen

9-16 Oxidation of Methylene to Carbonyl

Oxo-de-dihydro-bisubstitution[229]



$$R-\underset{\underset{O}{\|}}{C}-CH_2-R' \xrightarrow{SeO_2} R-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-R'$$

Methyl or methylene groups α to a carbonyl can be oxidized with selenium dioxide to give, respectively, α-keto aldehydes and α-diketones.[230] The reaction can also be carried out α to an aromatic ring or to a double bond, though in the latter case, hydroxylation (see **4-4**) is the more common result. Although SeO_2 is the reagent most often used, the reaction has also been carried out with N_2O_3 and other oxidizing agents.[231] Substrates most easily oxidized contain two aryl groups on CH_2, and these substrates can be oxidized with many oxidizing agents (see **9-11**). Monoaryl alkanes have been oxidized to alkyl aryl ketones with several oxidizing agents, including CrO_3-acetic acid,[232] ceric ammonium nitrate,[233] benzeneseleninic anhydride PhSe(O)OSe(O)Ph,[234] a silver ion-persulfate couple,[235] and DDQ,[236] as well as with SeO_2. With these substrates the oxidation sometimes takes place on the β-carbon (e.g., $PhCH_2CH_3 \rightarrow PhCH_2CHO$). It has been shown for the case where chromyl chloride is the oxidizing agent that there is initial α oxidation followed by rearrangement.[237] Alkenes of the form $C{=}C{-}CH_2$ have been oxidized to α,β-unsaturated ketones by sodium dichromate in HOAc-Ac_2O, by *t*-butyl chromate in CCl_4-HOAc-Ac_2O,[238] by aqueous Na_2O_2 (α,β-unsaturated alkenes),[239] by *t*-BuOOH and $Cr(CO)_6$,[239a] by CrO_3-pyridine complex,[240] and by mercuric salts.[241] CrO_3-pyridine has also been used to convert alkynes of the form $C{\equiv}C{-}CH_2$ to α-keto acetylenes.[242] Two mechanisms have been suggested for the reaction with SeO_2. One of these involves a selenate ester of the enol:[243]

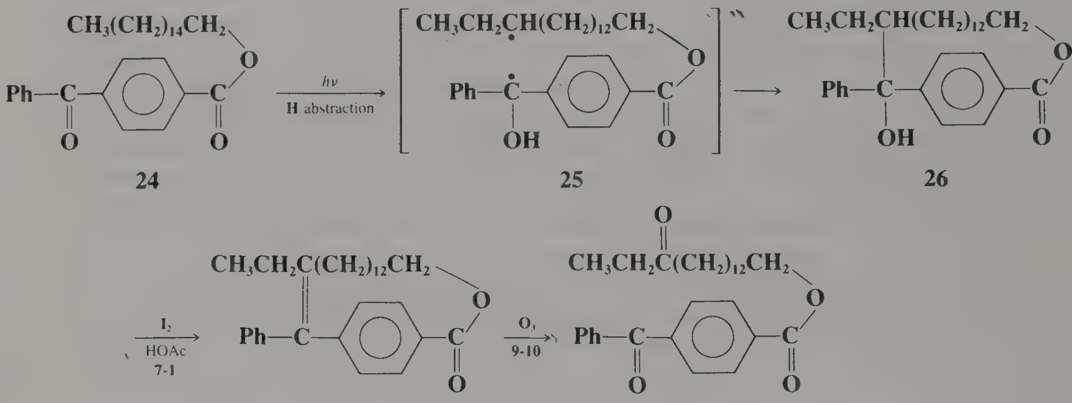
In the other proposed mechanism,[244] the principal intermediate is a β-ketoseleninic acid $—\overset{\overset{O}{\|}}{C}CH\overset{\overset{O}{\|}}{Se}OH$, and a selenate ester is not involved.

It has proved possible to convert CH_2 to C=O groups, even if they are not near any functional groups, indirectly, by the remote oxidation method of Breslow[37] (see **9-2**).[245] In a typical example,



24 **25** **26** **27** **28**

the keto ester **24** was irradiated to give the hydroxy lactone **26,** which was dehydrated to **27.** Ozonolysis of **27** gave the diketo ester **28,** in which the C-14 CH_2 group of **24** has been oxidized to a C=O group.[246] The reaction was not completely regioselective: **28** comprised about 60% of the product, with the remainder consisting of other compounds in which the keto group was located at C-12, C-15, and other positions along the carbon chain. When longer chains were used (C_{18}, C_{20}), the reaction was less regioselective, the maximum percentage of any single product being about 20%. The method has also been applied in the steroid series, with greater regioselectivity.[247] Greater regioselectivity was also achieved with flexible chains, when the aromatic portion was connected to the chain at two positions.[248] In the method so far described, the reaction takes place because one portion of a molecule (the benzophenone moiety) abstracts hydrogen from another portion of the same molecule, i.e., the two portions are connected by a series of covalent bonds. However, the reaction can also be carried out where the two reacting centers are actually in different molecules, providing the two molecules are held together by hydrogen bonding. For example, one of the CH_2 groups of *n*-hexadecanol hemisuccinate $CH_3(CH_2)_{14}CH_2OCOCH_2CH_2COOH$ was oxidized to a C═O group by applying the above procedure to a mixture of it and benzophenone-4-carboxylic acid *p*-$PhCOC_6H_4COOH$ in CCl_4.[249]

9-17 Oxidation of Arylmethanes

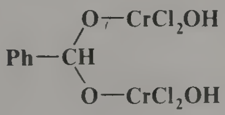
$$\mathbf{ArCH_3 \xrightarrow{CrO_2Cl_2} ArCHO}$$

Methyl groups on an aromatic ring can be oxidized to the aldehyde stage by several oxidizing agents. The reaction is a special case of **9-16.** When the reagent is chromyl chloride (CrO_2Cl_2), the reaction is called the *Étard reaction*[250] and the yields are high.[251] Another oxidizing agent is a mixture of CrO_3 and Ac_2O. In this case the reaction stops at the aldehyde stage because the initial product is $ArCH(OAc)_2$ (an acylal), which is resistant to further oxidation. Hydrolysis of the acylal gives the aldehyde.

Among other oxidizing agents that have been used to accomplish the conversion of $ArCH_3$ to ArCHO are ceric ammonium nitrate,[252] benzeneseleninic anhydride,[234] ceric trifluoroacetate,[253] and silver(II) oxide.[254] Oxidation of $ArCH_3$ to carboxylic acids is considered at **9-11.**

Conversion of $ArCH_3$ to ArCHO can also be achieved indirectly by bromination to give $ArCHBr_2$ (**4-1**), followed by hydrolysis (**0-2**).

The mechanism of the Étard reaction is not completely known.[255] An insoluble complex is formed on addition of the reagents, which is hydrolyzed to the aldehyde. The complex is probably a kind of acylal, but what the structure is is not fully settled, though many proposals have been made as to its structure and as to how it is hydrolyzed. It is known that $ArCH_2Cl$ is not an intermediate (see **9-20**), since it reacts only very slowly with chromyl chloride. Magnetic susceptibility measurements[256] indicate that the complex from toluene is **29,** a structure first proposed by Étard.



29

According to this proposal the reaction stops after only two hydrogens have been replaced because of the insolubility of **29.** There is disagreement on how **29** is formed, assuming that the complex has this structure. Both an ionic[257] and a free-radical[258] process have been proposed:

---

[249] Breslow and Scholl, *J. Am. Chem. Soc.* **93,** 2331 (1971). See also Breslow and Heyer, *Tetrahedron Lett.* **24,** 5039 (1983).

[250] The name Étard reaction is often applied to any oxidation with chromyl chloride, e.g., oxidation of glycols (**9–7**), olefins (**9–10**), etc.

[251] For a review, see Hartford and Darrin, *Chem. Rev.* **58,** 1–61 (1958), pp. 25–53.

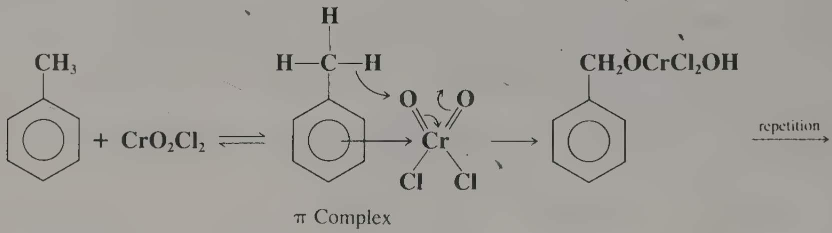
Ionic process:



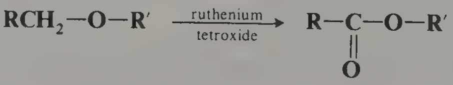
Free-radical process:

$$\mathrm{ArCH_3 + Cl_2CrO_2 \longrightarrow ArCH_2\cdot + HO\dot{C}rOCl_2}$$
$$\mathrm{ArCH_2\cdot + HO\dot{C}rOCl_2 \longrightarrow ArCH_2OCrCl_2OH \xrightarrow{\text{repetition}}}$$

An entirely different structure for the complex was proposed by Nenitzescu and co-workers.[259] On the basis of esr studies they proposed that the complex is $PhCH_2OCrCl_2OCrOCl_2OH$, which is isomeric with **29.** However, this view has been challenged by Wiberg and Eisenthal,[258] who interpret the esr result as being in accord with **29.** Still another proposal is that the complex is composed of benzaldehyde coordinated with reduced chromyl chloride.[260]

OS **II,** 441; **III,** 641; **IV,** 31, 713.

9-18 Oxidation of Ethers to Esters and Related Reactions



$$\mathrm{RCH_2{-}O{-}R' \xrightarrow[\text{tetroxide}]{\text{ruthenium}} R{-}\underset{\underset{\displaystyle O}{\|}}{C}{-}O{-}R'}$$

Ethers in which at least one group is primary alkyl can be oxidized to the corresponding esters in high yields with ruthenium tetroxide.[261] Cyclic ethers give lactones. The reaction, which is a special case of **9-16,** has also been accomplished with CrO_3 in sulfuric acid,[262] with benzyltriethylammonium permanganate,[263] and with trichloroisocyanuric acid (**30**) in the presence of an excess of water.[264] In a similar reaction, lactams (e.g., **31**) can be converted to cyclic imides by oxidation with a

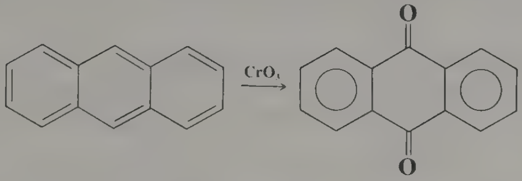
hydroperoxide or peracid and an Mn(II) or Mn(III) salt.[265] Certain tertiary amines containing a methyl group can be oxidized[266] to formamides ($R_2NCH_3 \rightarrow R_2NCHO$) by MnO_2,[267] CrO_3-pyridine,[268] O_2 and platinum,[269] or other oxidizing agents, but the reaction is not general. Primary benzylic amines $ArCH_2NH_2$ can be converted to $ArCONH_2$ by an indirect method.[270]

9-19 Oxidation of Aromatic Hydrocarbons to Quinones



Condensed aromatic systems (including naphthalenes) can be directly oxidized to quinones by various oxidizing agents.[271] Yields are generally not high, though good yields have been reported with ceric ammonium sulfate.[272] Benzene cannot be so oxidized by strong oxidizing agents but can be electrolytically oxidized to benzoquinone.

OS **IV,** 698, 757. Also see OS **II,** 554.

9-20 Oxidation of Primary Halides and Esters of Primary Alcohols to Aldehydes
Oxo-de-hydro,halo-bisubstitution

$$RCH_2Cl \xrightarrow{(CH_3)_2SO} RCHO$$

Primary alkyl halides (chlorides, bromides, and iodides) can be oxidized to aldehydes easily and in good yields with dimethyl sulfoxide.[273] Tosyl esters of primary alcohols can be similarly converted to aldehydes,[274] and epoxides[275] give α-hydroxy ketones or aldehydes.[276] The reaction with tosyl esters is an indirect way of oxidizing primary alcohols to aldehydes (**9-3**). This type of oxidation can also be carried out without isolation of an intermediate ester: The alcohol is treated with dimethyl sulfoxide, dicyclohexylcarbodiimide (DCC),[277] and anhydrous phosphoric acid.[278] In this way a primary alcohol can be converted to the aldehyde with no carboxylic acid being produced.[279]

[275] Epoxides can be converted to α-halo ketones by treatment with bromodimethylsulfonium bromide: Olah, Vankar, and Arvanaghi, *Tetrahedron Lett.* 3653 (1979).

[276] Cohen and Tsuji, *J. Org. Chem.* **26,** 1681 (1961); Tsuji, *Tetrahedron Lett.* 2413 (1966); Santosusso and Swern, *Tetrahedron Lett.* 4261 (1968), *J. Org. Chem.* **40,** 2764 (1975).

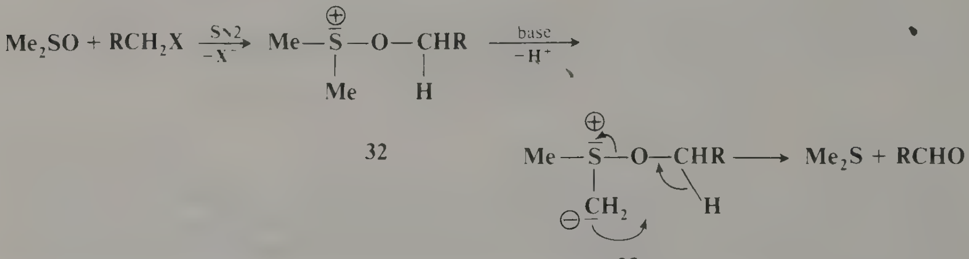
[277] The DCC is converted to dicyclohexylurea, which in some cases is difficult to separate from the product. One way to avoid this problem is to use a carbodiimide linked to an insoluble polymer: Weinshenker and Shen, *Tetrahedron Lett.* 3285 (1972).

[278] Pfitzner and Moffatt, *J. Am. Chem. Soc.* **87,** 5661, 5670 (1965); Fenselau and Moffatt, *J. Am. Chem. Soc.* **88,** 1762 (1966); Albright and Goldman, *J. Org. Chem.* **30,** 1107 (1965).

[279] For a review, see Moffatt, in Augustine and Trecker, Ref. 11, vol. 2, pp. 1–64.

Similar oxidation of alcohols has been carried out with dimethyl sulfoxide and other reagents[280] in place of DCC: acetic anhydride,[281] SO_3-pyridine-triethylamine,[282] trifluoroacetic anhydride,[283] chlorosulfonyl isocyanate,[284] oxalyl chloride,[285] molybdenum peroxide,[286] tosyl chloride,[287] chlorine,[288] bromine,[289] $AgBF_4$ and Et_3N,[290] $(CF_3SO_2)_2O$,[291] KI and $NaHCO_3$,[292] and methanesulfonic anhydride,[287] among others.

The mechanism of these dimethyl sulfoxide oxidations is probably as follows:[293]



32

33

though in some cases the base abstracts a proton directly from the carbon being oxidized, in which case the ylide **33** is not an intermediate. Alkoxysulfonium salts **32** have been isolated.[294] This mechanism predicts that secondary compounds should be oxidizable to ketones, and this is the case. In a related procedure for the oxidation of alcohols, the intermediate **32**[295] is formed without the use of dimethyl sulfoxide by treating the substrate with a complex generated from chlorine or N-chlorosuccinimide and dimethyl sulfide.[296]

Another way to oxidize primary alkyl halides to aldehydes is by the use of hexamethylenetetramine followed by water. However, this reaction, called the *Sommelet reaction*,[297] is limited to benzylic halides. The reaction is seldom useful when the R in RCH_2Cl is alkyl. The first part of the reaction is conversion to the amine $ArCH_2NH_2$ (**0-46**), which can be isolated. Reaction of the amine with excess hexamethylenetetramine gives the aldehyde. It is this last step which is the actual Sommelet reaction, though the entire process can be conducted without isolation of intermediates. Once the amine is formed, it is converted to an imine ($ArCH_2N{=}CH_2$) with formaldehyde liberated from the reagent. The key step then follows: transfer of hydrogen from another mole of the arylamine to the imine:

---

[295] It has been suggested that in the DCC reaction, **32** is not involved, but the ylide **33** is formed directly from a precursor containing DCC and dimethyl sulfoxide: Torssell, Ref. 294; Moffatt, *J. Org. Chem.* **36,** 1909 (1971).

[296] Vilsmaier and Sprügel, *Liebigs Ann. Chem.* **747,** 151 (1971); Corey and Kim, *J. Am. Chem. Soc.* **94,** 7586 (1972), *J. Org. Chem.* **38,** 1233 (1973); McCormick, *Tetrahedron Lett.* 1701 (1974); Crosby, Weinshenker, and Uh, *J. Am. Chem. Soc.* **97,** 2232 (1975).

[297] For a review, see Angyal, *Org. React.* **8,** 197 (1954).

$$ArCH_2N{=}CH_2 + ArCH_2NH_2 \longrightarrow ArCH_2NHCH_3 + ArCH{=}NH$$

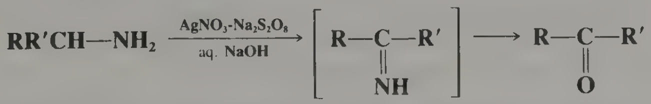
This last imine is then hydrolyzed by water to the aldehyde. Alternatively, the benzylamine may transfer hydrogen directly to hexamethylenetetramine. Primary amines (including alkyl RCH_2NH_2) can also be oxidized to imines (and hence hydrolyzed to aldehydes or ketones) by benzophenone and uv light.[298]

Other reagents that convert benzylic halides to aldehydes are 2-nitropropane-NaOEt in EtOH,[299] mercury(I) nitrate followed by ethanolic alkali,[300] and pyridine followed by *p*-nitrosodimethylaniline and then water. The latter procedure is called the *Kröhnke reaction*. Primary halides in general have been oxidized to aldehydes by trimethylamine oxide $Me_3\overset{\oplus}{N}-\overset{\ominus}{O}$,[301] 4-dimethylaminopyridine-N-oxide,[302] and by K_2CrO_4 in HMPT in the presence of a crown ether.[303] The first of these procedures has also been applied to primary tosylates.[301]

OS **II,** 336; **III,** 811; **IV,** 690, 918, 932; **V,** 242, 668, 825, 852, 872. Also see OS **V,** 689; **56,** 99.

9-21 Oxidation of Amines to Aldehydes, Ketones, or Dihalides

Oxo-de-hydro,amino-bisubstitution (overall transformation)



$$RR'CH{-}NH_2 \xrightarrow[\text{aq. NaOH}]{AgNO_3\text{-}Na_2S_2O_8} \left[\begin{array}{c} R{-}\underset{\underset{NH}{\|}}{C}{-}R' \end{array}\right] \longrightarrow R{-}\underset{\underset{O}{\|}}{C}{-}R'$$

Primary aliphatic amines can be oxidized to aldehydes or ketones by reaction with Ag(II) prepared in situ by treatment of silver nitrate with sodium persulfate.[304] The reaction consists of dehydrogenation to the imine (**9-5**), followed by hydrolysis. Other reagents that have been used are nitrosobenzene[305] (for benzylamines), 3,5-di-*t*-butyl-1,2-benzoquinone,[306] *p*-nitrobenzenesulfonyl peroxide,[307] diphenylseleninic anhydride,[308] 4-formyl-1-methylpyridinium benzenesulfonate,[309] $PdCl_2$ or $AuCl_3$,[310] and aqueous NaOCl with phase-transfer catalysts.[311] Benzylic amine salts $PhCHRNR_2'H^+\ Cl^-$ (R,R' = H or alkyl) give benzaldehydes or aryl ketones when heated in Me_2SO.[312] Several indirect methods for achieving the conversion $RR'CH{-}NH_2 \rightarrow RR'C{=}O$ (R' = alkyl, aryl, or H) have been reported.[313]

Chem.* **46,** 1937 (1981).

Primary, secondary, and tertiary aliphatic amines have been cleaved to give aldehydes, ketones, or carboxylic acids with aqueous bromine[314] and with neutral permanganate.[315] The other product of this reaction is the amine with one less alkyl group. A similar reaction has been performed on α-amino ketones, with mercuric acetate, to give 1,2-dicarbonyl compounds.[316]

In a different type of procedure, primary amines at a primary carbon can be converted to *gem*-dihalides[$RCH_2NH_2 \rightarrow RCHX_2$ (X = Br or Cl)] by treatment with an alkyl nitrite and the anhydrous copper(I) halide.[317]

9-22 Oxidation of Primary Alcohols to Carboxylic Acids

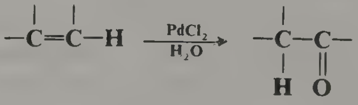
Oxo-de-dihydro-bisubstitution

$$RCH_2OH \xrightarrow{CrO_3} RCOOH$$

Primary alcohols can be oxidized to carboxylic acids by many strong oxidizing agents including chromic acid, permanganate, and nitric acid. The reaction may be looked on as a combination of **9-3** and **4-6.** When acid conditions are used, a considerable amount of ester RCOOR is often isolated, though this is probably not formed by a combination of the acid with unreacted alcohol, but by a combination of intermediate aldehyde with unreacted alcohol to give an acetal or hemiacetal, which is oxidized to the ester.[318] Aldehydes RCHO can be directly converted to carboxylic esters RCOOR′ by treatment with O_3 in the presence of an alcohol.[319] Lactones can be prepared by oxidizing diols in which at least one OH is primary.[320] Primary alkyl ethers can be selectively cleaved to carboxylic acids by aqueous Br_2 ($RCH_2OR' \rightarrow RCOOH$).[98]

OS **I,** 138, 168; **IV,** 499, 677; **V,** 580. Also see OS **III,** 745.

9-23 Oxidation of Olefins to Aldehydes and Ketones



$$-\overset{|}{C}=\overset{|}{C}-H \xrightarrow[H_2O]{PdCl_2} -\underset{H}{\overset{|}{\underset{|}{C}}}-\underset{O}{\underset{\|}{C}}-$$

Monosubstituted and 1,2-disubstituted olefins can be oxidized to aldehydes and ketones by palladium chloride and similar salts of noble metals.[321] 1,1-Disubstituted olefins generally give poor results. The reaction is used industrially to prepare acetaldehyde from ethylene (the *Wacker process*), but it is also suitable for laboratory preparations. The palladium chloride is reduced to palladium.

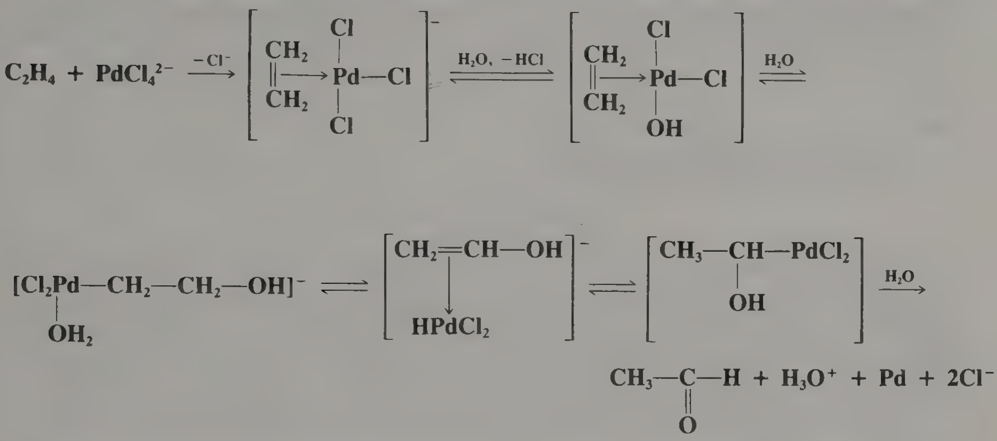
Because the reagent is expensive, the reaction is usually carried out with a cooxidant, most often $CuCl_2$, whose function is to reoxidize the Pd to Pd(II). The $CuCl_2$ is reduced to Cu(I), which itself is reoxidized to Cu(II) by air, so that atmospheric oxygen is the only oxidizing agent actually used up. Many other cooxidants have been tried, among them O_3, Fe^{3+}, and PbO_2. The principal product is an aldehyde only from ethylene: With other olefins Markovnikov's rule is followed, and ketones are formed predominantly. The generally accepted mechanism involves π complexes of palladium.[322]



This mechanism accounts for the fact, established by deuterium labeling, that the four hydrogens of the acetaldehyde all come from the original ethylene and none from the solvent.

Similar reactions have been carried out with other oxidizing agents. An example involving migration of an alkyl group instead of hydrogen is oxidation of $Me_2C{=}CMe_2$ with peroxytrifluoroacetic acid-boron trifluoride to give Me_3COMe (pinacolone).[323] This reaction consists of epoxidation (**5-37**) followed by pinacol rearrangement of the epoxide (**8-2**). Other reagents used have been chromyl chloride[324] (e.g., $Me_3CCH_2CMe{=}CH_2 \rightarrow Me_3CCH_2CHMeCHO$), $Pb(OAc)_4$-F_3CCOOH[325] (e.g., $PhCH{=}CH_2 \rightarrow PhCH_2CHO$), thallium(III) nitrate-methanol[326] (e.g., cyclohexene → cyclopentanecarboxaldehyde), Cl_2 or Br_2 and $AgNO_3$,[327] disiamylborane followed by pyridinium chlorochromate,[328] H_2O_2 and a Pd catalyst,[329] O_2 and a catalyst,[330] CrO_3-H_2SO_4-Hg(II) salts,[331] $HgSO_4$-H_2O,[332] and $Hg(OAc)_2$ followed by $PdCl_2$.[333]

Alkenes have also been converted to more-highly-oxidized products. Examples are: (1) treatment with $KMnO_4$ in aqueous acetone containing acetic acid gives α-hydroxy ketones.[334] (2) 1,2-Disubstituted and trisubstituted alkenes give α-chloro ketones when oxidized with chromyl chloride in acetone: $RCH{=}CR'R'' \rightarrow RCOCClR'R''$.[335] (3) $KMnO_4$ in acetic anhydride oxidizes large-ring cycloalkenes to 1,2-diketones.[336]

Enol ethers are oxidized to esters ($RCH{=}CHOR' \rightarrow RCH_2COOR'$) with pyridinium chlorochromate.[337] Carboxylic acids can be prepared from terminal alkynes ($RC{\equiv}CH \rightarrow RCH_2COOH$) by conversion of the alkyne to its thiophenyl ether $RC{\equiv}CSPh$ and treatment of this with $HgSO_4$ in $HOAc\text{-}H_2SO_4$.[338]

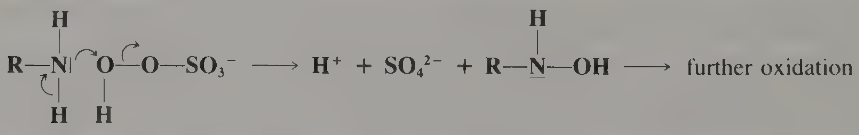
OS **51,** 4.

9-24 Oxidation of Amines to Nitroso Compounds

***N*-Oxo-de-dihydro-bisubstitution**

$$ArNH_2 \xrightarrow{H_2SO_5} Ar{-}N{=}O$$

Primary aromatic amines can be oxidized[339] to nitroso compounds. Most often the conversion is accomplished by Caro's acid (H_2SO_5) or with H_2O_2 in HOAc.[340] Hydroxylamines, which are probably intermediates in most cases, can sometimes be isolated, but under the reaction conditions they are generally oxidized to the nitroso compounds. Primary aliphatic amines can be oxidized in this manner, but the nitroso compound is stable only if there is no α-hydrogen. If there is an α-hydrogen, the compound tautomerizes to the oxime.[341] The mechanism with H_2SO_5 has been postulated to be an example of category 5 (p. 1050).[342]



$$R{-}\underset{H}{\overset{H}{N}}{-}\underset{H}{O}{-}O{-}SO_3^- \longrightarrow H^+ + SO_4^{2-} + R{-}\overset{H}{N}{-}OH \longrightarrow \text{further oxidation}$$

Secondary amines are oxidized to hydroxylamines (which are resistant to further oxidation) by benzoyl peroxide and Na_2HPO_4.[343]

OS **III,** 334.

9-25 Oxidation of Primary Amines, Oximes, or Nitroso Compounds to Nitro Compounds

$$R_3CNH_2 \xrightarrow{KMnO_4} R_3CNO_2$$

$$R_2C{=}NOH \xrightarrow{F_3CCOOOH} R_2CHNO_2$$

[343] Biloski and Ganem, *Synthesis* 537 (1983).

Primary amines at a tertiary carbon can be oxidized to nitro compounds in excellent yields with $KMnO_4$.[344] This type of nitro compound is not easily prepared in other ways. Primary, secondary, and tertiary alkyl primary amines can be oxidized to the corresponding nitro compounds in good yields with dry ozone.[345] Primary and secondary alkylamines and primary aromatic amines[346] can be oxidized to nitro compounds with various peracids, including peracetic, peroxytrifluoroacetic, and *m*-chloroperbenzoic acids. Primary aromatic amines have also been oxidized to nitro compounds with *t*-butyl hydroperoxide in the presence of certain molybdenum and vanadium compounds,[347] and with sodium perborate.[348] Oximes can be oxidized to nitro compounds with peroxytrifluoroacetic acid, among other ways.[344] Aromatic nitroso compounds are easily oxidized to nitro compounds by many oxidizing agents.[349]

OS **III,** 334; **V,** 367, 845; **52,** 77.

9-26 Oxidation of Mercaptans and Other Sulfur Compounds to Sulfonic Acids

$$\mathbf{RSH} \xrightarrow{HNO_3} \mathbf{RSO_3H}$$

Mercaptans, sulfoxides, sulfones, disulfides,[350] and other sulfur compounds can be oxidized to sulfonic acids with many oxidizing agents, though for synthetic purposes the reaction is most important for mercaptans.[351] Among oxidizing agents used are boiling nitric acid and barium permanganate. Autoxidation (oxidation by atmospheric oxygen) can be accomplished in basic solution.[352] Aliphatic mercaptans can be oxidized to sulfinic acids with *m*-chloroperbenzoic acid in CH_2Cl_2.[353] Mercaptans can also be oxidized to disulfides (**9-36**).

OS **II,** 471; **III,** 226. Also see OS **V,** 1070.

9-27 Oxidation of Mercaptans and Other Sulfur Compounds to Sulfonyl Halides

$$\mathbf{RSH + Cl_2} \xrightarrow{H_2O} \mathbf{RSO_2Cl}$$

Oxidation of mercaptans with chlorine and water gives sulfonyl chlorides directly.[354] Among other sulfur compounds that give the same reaction are sulfides, disulfides, thiocyanates, thioacetates RSCOMe, Bunte salts (see **0-41**), and isothiuronium salts (see **0-37**). The method has also been used for the preparation of sulfonyl bromides, fluorides, and iodides. R may be primary or secondary alkyl or aryl, but not tertiary alkyl.

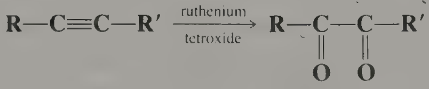
D. Reactions in Which Oxygen is Added to the Substrate

9-28 The Oxidation of Alkynes to α-Diketones

Dioxo-biaddition



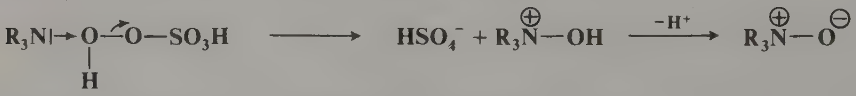
$$R-C\equiv C-R' \xrightarrow[\text{tetroxide}]{\text{ruthenium}} R-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-R'$$

Internal alkynes have been oxidized[354a] to α-diketones by several oxidizing agents, including ruthenium tetroxide,[355] neutral $KMnO_4$,[356] SeO_2 with a small amount of H_2SO_4,[357] N-bromosuccinimide in anhydrous dimethyl sulfoxide,[358] iodosylbenzene and a ruthenium complex catalyst,[359] and thallium(III) nitrate.[197] Ozone generally oxidizes triple-bond compounds to carboxylic acids (**9-9**), but α-diketones are sometimes obtained instead. SeO_2 with a small amount of H_2SO_4 oxidizes arylacetylenes to α-keto acids ($ArC\equiv CH \rightarrow ArCOCOOH$).[357]

9-29 Oxidation of Tertiary Amines to Amine Oxides

$$R_3N \xrightarrow{H_2O_2} R_3\overset{\oplus}{N}-\overset{\ominus}{O}$$

Tertiary amines can be converted to amine oxides by oxidation. Hydrogen peroxide is often used, but peracids are also important reagents for this purpose. Pyridine and its derivatives are oxidized only by peracids.[360] In the attack by hydrogen peroxide there is first formed a trialkylammonium peroxide, a hydrogen-bonded complex represented as $R_3N{\cdot}H_2O_2$, which can be isolated.[361] The decomposition of this complex probably involves an attack by the OH^+ moiety of the H_2O_2. Oxidation with Caro's acid has been shown to proceed in this manner:[362]

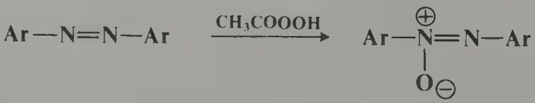


$$R_3N| \rightarrow \underset{\underset{H}{|}}{O}-O-SO_3H \longrightarrow HSO_4^- + R_3\overset{\oplus}{N}-OH \xrightarrow{-H^+} R_3\overset{\oplus}{N}-O^{\ominus}$$

This mechanism is the same as that of **9-24**; the products differ only because tertiary amine oxides cannot be further oxidized. The mechanism with other peracids is probably the same. The reaction has also been carried out with hydroperoxides in the presence of V or Mn complexes.[363]

OS **IV**, 612, 704, 828; **50**, 56; **58**, 43.

9-30 Oxidation of Azobenzenes to Azoxybenzenes



$$Ar-N=N-Ar \xrightarrow{CH_3COOOH} Ar-\underset{\underset{O^{\ominus}}{|}}{\overset{\oplus}{N}}=N-Ar$$

[354a] For a review of oxidations of triple bonds, see Simándi, in Patai and Rappoport, "The Chemistry of Functional Groups, Supplement C," pt. 1, pp. 513–570, 1982.

[360] For a review, see Katritzky and Lagowski, "Chemistry of the Heterocyclic N-Oxides," pp. 21–72, 539–542, Academic Press, New York, 1971.

[361] Oswald and Guertin, *J. Org. Chem.* **28,** 651 (1963).

[362] Ogata and Tabushi, *Bull. Chem. Soc. Jpn.* **31,** 969 (1958).

[363] Kuhnen, *Chem. Ber.* **99,** 3384 (1966); Sheng and Zajacek, *J. Org. Chem.* **33,** 588 (1968).

Azo compounds can be oxidized to azoxy compounds by peracids[364] or by hydroperoxides and molybdenum complexes.[365] The mechanism is probably the same as that of **9-29.**[366]

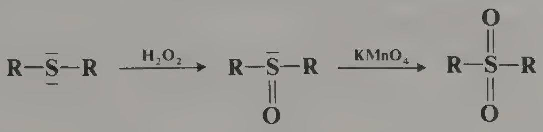
9-31 Oxidation of Isonitriles to Isocyanates

$$\mathrm{R{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{\bar{C}}} \xrightarrow[\mathrm{Me_2SO}]{\mathrm{Cl_2}} \mathrm{R{-}N{=}C{=}O}$$

Isonitriles have been oxidized to isocyanates with HgO and with O_3, as well as with a halogen and dimethyl sulfoxide (or pyridine N-oxide).[366a] In the latter case the oxidizing agent is the halogen, which converts the isonitrile to $R{-}N{=}CCl_2$ which is hydrolyzed to the isocyanate.[367] Isonitriles can also be oxidized by nitrile oxides, which are thus reduced to nitriles:[368] $\mathrm{Ar{-}C{\equiv}\overset{\oplus}{N}{-}\bar{\underline{O}}|^{\ominus}} + \mathrm{R{-}\overset{\oplus}{N}{\equiv}\bar{C}^{\ominus}} \rightarrow \mathrm{Ar{-}C{\equiv}N} + \mathrm{R{-}N{=}C{=}O}$. Cyanide ion has been oxidized to cyanate ion with many oxidizing agents. When isonitriles are oxidized by thallium(III) nitrate in the presence of methanol, carbamates are formed, by reaction of the initially formed isocyanate with the methanol (**6-8**).[369]

Isonitriles can be converted to isothiocyanates (RNC → RNCS) by treatment with a disulfide such as PhCOSSCOPh and thallium(I) acetate or lead(II) acetate.[370]

9-32 Oxidation of Sulfides to Sulfoxides and Sulfones



$$\mathrm{R{-}\underline{\bar{S}}{-}R} \xrightarrow{\mathrm{H_2O_2}} \mathrm{R{-}\underset{\overset{\|}{O}}{\bar{S}}{-}R} \xrightarrow{\mathrm{KMnO_4}} \mathrm{R{-}\overset{\overset{O}{\|}}{\underset{\overset{\|}{O}}{S}}{-}R}$$

Sulfides can be oxidized to sulfoxides by 1 mole of 30% H_2O_2 or by many other oxidizing agents,[371] including $NaIO_4$,[372] *t*-BuOCl,[373] acyl nitrites,[374] sodium perborate,[348] and peracids.[375] Sulfoxides can be further oxidized to sulfones by another mole of H_2O_2, $KMnO_4$, sodium perborate, potassium hydrogen persulfate $KHSO_5$,[376] or a number of other agents. If enough oxidizing agent is present, sulfides can be directly converted to sulfones without isolation of the sulfoxides. These reactions give high yields, and many functional groups do not interfere.[377] Selenides R_2Se can be oxidized to selenoxides and selenones.[378]

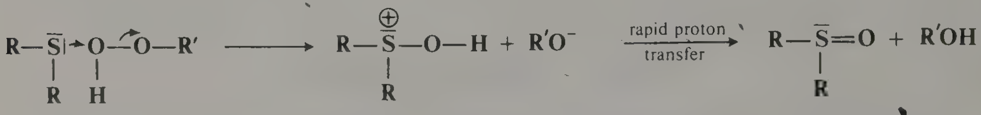
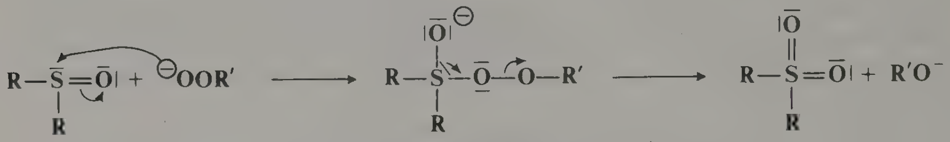
When the oxidizing agent is a peroxide, the mechanism[379] of oxidation to the sulfoxide is similar to that of **9-29.**[380]



$$\mathrm{R{-}\underset{R}{\underset{|}{\bar{S}}}{-}\underset{H}{\underset{|}{O}}{-}O{-}R'} \longrightarrow \mathrm{R{-}\overset{\oplus}{\underset{R}{\underset{|}{\bar{S}}}}{-}O{-}H + R'O^-} \xrightarrow[\text{transfer}]{\text{rapid proton}} \mathrm{R{-}\underset{R}{\underset{|}{\bar{S}}}{=}O + R'OH}$$

The second oxidation, which is normally slower than the first[381] (which is why sulfoxides are so easily isolable), has the same mechanism in neutral or acid solution, but in basic solution it has been shown that the conjugate base of the peroxy compound ($R'OO^-$) also attacks the SO group as a nucleophile:[382]

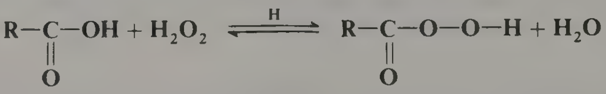


$$\mathrm{R{-}\underset{R}{\underset{|}{\bar{S}}}{=}\bar{O}| + {}^{\ominus}OOR'} \longrightarrow \mathrm{R{-}\overset{|\bar{O}|^{\ominus}}{\overset{|}{\underset{R}{\underset{|}{S}}}}{-}\bar{O}{-}O{-}R'} \longrightarrow \mathrm{R{-}\overset{|\bar{O}}{\overset{\|}{\underset{R}{\underset{|}{S}}}}{=}\bar{O}| + R'O^-}$$

OS **V,** 791; **50,** 31, 33; **57,** 53. Also see OS **V,** 723; **59,** 58.

9-33 Oxidation of Carboxylic Acids to Peroxy Acids

Peroxy-de-hydroxy-substitution

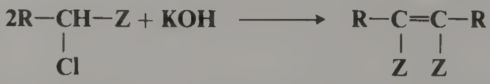


$$\mathrm{R{-}\underset{O}{\underset{\|}{C}}{-}OH + H_2O_2} \overset{H}{\rightleftharpoons} \mathrm{R{-}\underset{O}{\underset{\|}{C}}{-}O{-}O{-}H + H_2O}$$

The oxidation of carboxylic acids with H_2O_2 and an acid catalyst is the best general method for the preparation of peroxy acids.[383] The most common catalyst for aliphatic R is concentrated sulfuric acid. The reaction is an equilibrium and is driven to the right by removal of water or by the use of excess reagents. For aromatic R the best catalyst is methanesulfonic acid, which is also used as the solvent.

E. Oxidative Coupling

9-34 Coupling Involving Carbanions



$$\mathrm{2R{-}\underset{Cl}{\underset{|}{CH}}{-}Z + KOH} \longrightarrow \mathrm{R{-}\underset{Z}{\underset{|}{C}}{=}\underset{Z}{\underset{|}{C}}{-}R}$$

---

[379] For a discussion of the mechanism with various other agents, see Srinivasan, Chellamani, and Kuthalingam, *J. Org. Chem.* **47,** 428 (1982).

[380] Modena and Todesco, *J. Chem. Soc.* 4920 (1962), and references cited therein. For a review, see Barnard, Bateman, and Cunneen, in Kharasch, "Organic Sulfur Compounds," vol. 1, pp. 229–247, Pergamon, New York, 1961.

[381] There are some reagents that oxidize sulfones in preference to sulfoxides, e.g., $NaMnO_4$: see Henbest and Khan, *Chem. Commun.* 1036 (1968).

[382] Curci and Modena, *Tetrahedron Lett.* 1749 (1963), *Tetrahedron* **22,** 1227 (1966); Curci, DiFuria, and Modena, *J. Chem. Soc., Perkin Trans. 2* 603 (1978). See also Ogata and Suyama, *Chem. Ind. (London)* 707 (1971), *J. Chem. Soc., Perkin Trans. 2* 755 (1973); Oae and Takata, *Tetrahedron Lett.* **21,** 3213 (1980); Akasaka and Ando, *J. Chem. Soc., Chem. Commun.* 1203 (1983).

[383] For a review of the preparation of peroxy acids, see Swern, in Swern, "Organic Peroxides," vol. 1, pp. 313–516, Interscience, New York, 1970.

Alkyl halides with an electron-withdrawing group on the halogen-bearing carbon can be dimerized to olefins by treatment with bases. Z may be nitro, aryl, etc. Although carbene intermediates have sometimes been suggested, it is likely that in most cases the mechanism[384] involves nucleophilic substitution followed by elimination[385] (illustrated for benzyl chloride):

$$\mathrm{PhCH_2Cl} \xrightarrow{\text{base}} \mathrm{Ph\overset{\ominus}{\bar{C}}HCl} \xrightarrow[\mathrm{S_N}]{\mathrm{PhCH_2Cl}} \mathrm{PhCHClCH_2Ph} \xrightarrow{-\mathrm{HCl}} \mathrm{PhCH{=}CHPh}$$

α,α-Dibromotoluenes $ArCHBr_2$ give tolanes $ArC{\equiv}CAr$, by debromination of the intermediates $ArCBr{=}CBrAr$.[386] In a related reaction, diarylmethane dihalides Ar_2CX_2 have been dimerized to tetraaryl alkenes $Ar_2C{=}CAr_2$ with sodium selenide,[387] with copper,[388] and with iron pentacarbonyl.[389] Aryl diazomethanes $ArCHN_2$ are oxidized to $ArCH{=}CHAr$ by ceric ammonium nitrate.[390]

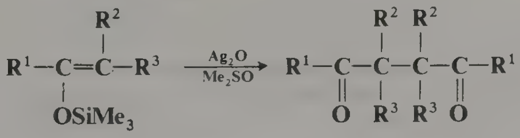
A somewhat different type of coupling is observed when salts of β-keto esters, arylacetonitriles $ArCH_2CN$, and other compounds of the form ZCH_2Z' are treated with an oxidizing agent such as iodine,[391] PbO_2,[392] Ag_2O,[393] Cu(II) salts,[394] or a Cu-amine-O_2 system,[395] e.g.,

$$\mathrm{Ar_2CH_2} \xrightarrow[\text{liq. NH}_3]{\mathrm{NaNH_2}} \mathrm{Ar\overset{\ominus}{\bar{C}}H} + \mathrm{I_2} \longrightarrow \mathrm{Ar_2CH{-}CHAr_2}$$

In this case the product is a substituted alkane rather than an alkene. This reaction has been used to close rings.[396] The reaction with I_2 has been applied to enolates of monoesters to give succinic esters.[397]

OS **II,** 273; **IV,** 372, 869, 914. Also see OS **I,** 46; **IV,** 877.

9-35 Dimerization of Silyl Enol Ethers or of Lithium Enolates



$$\mathrm{R^1{-}C(OSiMe_3){=}C(R^2){-}R^3} \xrightarrow[\mathrm{Me_2SO}]{\mathrm{Ag_2O}} \mathrm{R^1{-}C({=}O){-}C(R^2)(R^3){-}C(R^2)(R^3){-}C({=}O){-}R^1}$$

34

Silyl enol ethers can be dimerized to symmetrical 1,4-diketones by treatment with Ag_2O in dimethyl sulfoxide or certain other polar aprotic solvents.[398] The reaction has been performed with R^2, R^3 = hydrogen or alkyl, though best yields are obtained when $R^2 = R^3 = H$. In certain cases, unsymmetrical 1,4-diketones have been prepared by using a mixture of two silyl enol ethers. If R^1 = OR (in which case the substrate is a ketene silyl acetal), dimerization with $TiCl_4$ leads to a dialkyl succinate (**34,** R^1 = OR).[399]

[395] de Jongh, de Jonge, and Mijs, *J. Org. Chem.* **36,** 3160 (1971).

[396] Chung and Dunn, *J. Org. Chem.* **48,** 1125 (1983).

[397] Brocksom, Petragnani, Rodrigues, and Teixeira, *Synthesis* 396 (1975).

[398] Ito, Konoike, and Saegusa, *J. Am. Chem. Soc.* **97,** 649 (1975).

In a similar reaction, lithium enolates RC(Li)=CH_2 were dimerized to 1,4-diketones $RCOCH_2CH_2COR$ with $CuCl_2$, $FeCl_3$, or copper(II) triflate, in a nonprotic solvent.[400]

9-36 Oxidation of Mercaptans to Disulfides

$$2RSH \xrightarrow{H_2O_2} RSSR$$

Mercaptans are easily oxidized to disulfides.[401] Hydrogen peroxide is the most common reagent, but many oxidizing agents give the reaction, among them thallium(III) acetate,[402] Me_2SO-I_2,[403] Br_2 under phase transfer conditions,[404] NO,[405] and NO_2.[405] However, strong oxidizing agents may give **9-26.** Even the oxygen in the air oxidizes mercaptans on standing, if a small amount of base is present. The reaction is reversible (see **9-62**), and the interconversion between cysteine and cystine is an important one in biochemistry.

The mechanism has been studied for several oxidizing agents and varies with the agent.[406] For oxygen it is[407]

$$\begin{array}{rcl} RSH + B^- & \rightleftharpoons & RS^- + BH \\ RS^- + O_2 & \longrightarrow & RS\cdot + \dot{O}_2{}^- \\ RS^- + \dot{O}_2{}^- & \longrightarrow & RS\cdot + O_2{}^{2-} \\ 2RS\cdot & \longrightarrow & RSSR \\ O_2{}^{2-} + BH & \longrightarrow & OH^- + B^- + O_2 \end{array}$$

With respect to the sulfur, this mechanism is similar to that of **4-15,** involving as it does loss of a proton, oxidation to a free radical, and radical coupling.

Unsymmetrical disulfides can be prepared[408] by treatment of a mercaptan RSH with diethyl azodicarboxylate EtOOCN=NCOOEt to give an adduct, to which another mercaptan R′SH is then added, producing the disulfide RSSR′.[409]

OS **III,** 86, 116.

9-37 Oxidation of Amines to Azo or Azoxy Compounds

$$ArNH_2 \xrightarrow{MnO_2} Ar{-}N{=}N{-}Ar$$

Primary aromatic amines have been oxidized to azo compounds by a variety of oxidizing agents, among them MnO_2, lead tetraacetate, O_2 and a base, barium permanganate,[410] and sodium perborate in acetic acid. *t*-Butyl hydroperoxide has been used to oxidize certain primary amines to azoxy compounds.[411]

Reductions: Selectivity[411a]

It is often necessary to reduce one group in a molecule without affecting another reducible group. It is usually possible to find a reducing agent that will chemoselectively do this. The most common broad-spectrum reducing agents are the metal hydrides[412] and hydrogen (with a catalyst).[413] Many different metal–hydride systems and hydrogenation catalysts have been investigated in order to find conditions under which a given group will be reduced without reducing another group in the same molecule. Tables 2, 3, and 4 list the reactivity of various functional groups toward catalytic hydrogenation, $LiAlH_4$, and BH_3, respectively.[414,415] Table 5 shows which groups can be reduced by catalytic hydrogenation and various metal hydrides.[416] Of course, the tables cannot be exact,

[414] Table 2 is from House, Ref. 10, p. 9.

[415] Tables 3 and 4 are from Brown, Ref. 412, pp. 213 and 232, respectively.

[416] The first ten columns are from Brown and Krishnamurthy, Ref. 412, p. 604. The columns on $(i\text{-}Bu)_2AlH$ and $NaAlEt_2H_2$ are from Stinson, *Chem. Eng. News* **58,** No. 44, 19 (Nov. 3, 1980). The column on $LiBEt_3H$ is from Brown, Kim, and Krishnamurthy, *J. Org. Chem.* **45,** 1 (1980). For a similar table that shows additional reducing agents, see Hajós, Ref. 10, pp. 16–17. For tables showing which agents reduce a wide variety of functional groups, see Hudlický, Ref. 411a, pp. 177–200.

TABLE 3 The ease of reduction of various functional groups with $LiAlH_4$ in ether[415]

However, $LiAlH_4$ is a very powerful reagent, and much less chemoselectivity is possible here than with most of the other metal hydrides

Reaction	Substrate	Product	
6-26	RCHO	RCH_2OH	Easiest
6-26	RCOR	RCHOHR	
9-46	RCOCl	RCH_2OH	
9-43	Lactone	Diol	
0-81		RCH_2CHOHR	
9-43	RCOOR′	RCH_2OH + R′OH	
9-39	RCOOH	RCH_2OH	
9-39	$RCOO^-$	RCH_2OH	
9-40	$RCONR'_2$	$RCH_2NR'_2$	
6-28	RC≡N	RCH_2NH_2	
9-48	RNO_2	RNH_2	
9-68	$ArNO_2$	ArN═NAr	Most difficult
5-10	RCH═CHR		Inert

because the nature of R and the reaction conditions obviously affect reactivity. Nevertheless, the tables do give a fairly good indication of which reagents reduce which groups.[417] $LiAlH_4$ is a very powerful and unselective reagent.[418] Consequently, other metal hydrides are generally used when chemoselectivity is required. As mentioned on p. 813, a number of less reactive (and more selective) reagents have been prepared by replacing some of the hydrogens of $LiAlH_4$ with alkoxy groups (by treatment of $LiAlH_4$ with ROH).[419] Most of the metal hydrides are nucleophilic reagents and

TABLE 4 The ease of reduction of various functional groups with borane[415]

It is evident that this reagent and $LiAlH_4$ (Table 3) complement each other

Reaction	Substrate	Product

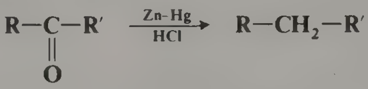
attack the carbon atom of a carbon–hetero single or multiple bond. However, BH_3[424] and AlH_3[425] are electrophiles (Lewis acids) and attack the hetero atom. This accounts for the different patterns of selectivity shown in the tables.

The reactions in this section are grouped into classifications based on bond charges, similar to those used for the oxidation reactions. These sections are: (A) reactions involving replacement of oxygen by hydrogen, (B) reactions in which an oxygen is removed from the substrate, (C) reduction with cleavage, and (D) reductive coupling.

A. Reactions Involving Replacement of Oxygen by Hydrogen In reactions **9-38** to **9-42**, a C=O is reduced to a CH_2 group.

9-38 Reduction of Carbonyl to Methylene in Aldehydes and Ketones

Dihydro-de-oxo-bisubstitution[426]



$$R-\underset{\underset{O}{\|}}{C}-R' \xrightarrow[HCl]{Zn-Hg} R-CH_2-R'$$

There are various ways of reducing the C=O group of aldehydes and ketones to CH_2.[427] The two most important methods are the *Clemmensen reduction* and the *Wolff–Kishner reduction* (in the Russian literature this is called the *Kizhner reaction*). The Clemmensen reduction consists of heating the aldehyde or ketone with zinc amalgam and aqueous HCl.[428] Ketones are reduced more often than aldehydes. In the Wolff–Kishner reduction,[429] the aldehyde or ketone is heated with hydrazine hydrate and a base (usually NaOH or KOH). The *Huang–Minlon modification*[430] of the Wolff–Kishner reaction, in which the reaction is carried out in refluxing diethylene glycol, has completely replaced the original procedure. The reaction can also be carried out under more moderate conditions (room temperature) in dimethyl sulfoxide with potassium *t*-butoxide as base.[431] The Wolff–Kishner reaction can also be applied to the semicarbazones of aldehydes or ketones. The Clemmensen reduction is usually easier to perform, but it fails for acid-sensitive and high-molecular-weight substrates. For these cases the Wolff–Kishner reduction is quite useful. For high-molecular-weight substrates, a modified Clemmensen reduction, using activated zinc and gaseous HCl in an organic solvent such as ether or acetic anhydride, has proved successful.[432] The Clemmensen and Wolff–Kishner reactions are complementary, since the former uses acidic and the latter basic conditions.

Both methods are fairly specific for aldehydes and ketones and can be carried out with many

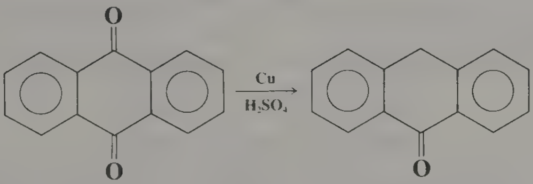
other functional groups present. However, certain types of aldehydes and ketones do not give normal reduction products. Under Clemmensen conditions,[433] α-hydroxy ketones give either ketones (hydrogenolysis of the OH, **0-79**) or olefins, and 1,3-diones usually undergo rearrangement, e.g., $MeCOCH_2COMe \rightarrow MeCOCHMe_2$.[434] A similar rearrangement is observed on Clemmensen reduction of unsaturated cyclic ketones.[435] Neither method is suitable for α,β-unsaturated ketones. These give pyrazolines[436] under Wolff–Kishner conditions, while under Clemmensen conditions both groups of these molecules may be reduced or if only one group is reduced, it is the C=C bond.[437] Sterically hindered ketones are resistant to both the Clemmensen and Huang–Minlon procedures but can be reduced by vigorous treatment with anhydrous hydrazine.[438] In the Clemmensen reduction, pinacols (**9-63**) are often side products.

Other reagents have also been used to reduce the C=O of aldehydes and ketones to CH_2. Among these are catalytic hydrogenation at 180 to 250°C[439] and, for aryl ketones (ArCOR and ArCOAr), $LiAlH_4$-$AlCl_3$,[440] $LiAlH_4$-P_2I_4,[441] Li-NH_3,[442] cyclohexene or limonene (as H_2 donors) and Pd-C-$FeCl_3$,[443] Raney nickel (which contains adsorbed hydrogen),[444] or trialkylsilanes in F_3CCOOH.[445] Most of these reagents also reduce aryl aldehydes ArCHO to methylbenzenes $ArCH_3$.[446] Aliphatic aldehydes RCHO can be reduced to RCH_3 with the sandwich compound titanocene dichloride $(C_5H_5)_2TiCl_2$.[447] One carbonyl group of 1,2-diketones can be selectively reduced by H_2S with an amine catalyst[448] or by HI in refluxing acetic acid.[449] One carbonyl group of quinones can be reduced with copper and sulfuric acid or with tin and HCl:[450]



An indirect method of accomplishing the reaction is reduction of tosylhydrazones ($R_2C=N-NHTs$) to R_2CH_2 with $NaBH_4$, BH_3, catecholborane, bis(benzyloxy)borane, $NaBH_3CN$, or bis(triphenylphosphine)copper(I) tetrahydroborate.[451] The reduction of α,β-unsaturated tosylhydrazones with $NaBH_3CN$, with $NaBH_4$-HOAc, or with catecholborane proceeds with migration of the double bond to the position formerly occupied by the carbonyl carbon, even if this removes the double bond from conjugation with an aromatic ring.[452] e.g.,

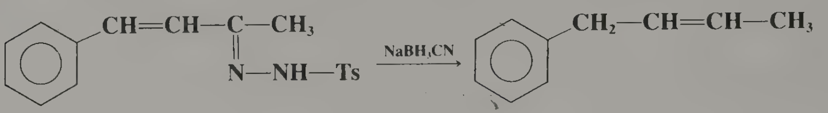
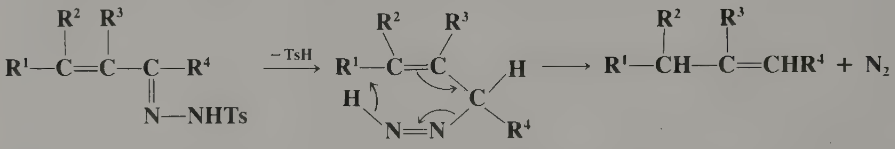
[450] Meyer, *Org. Synth.* **I,** 60; Macleod and Allen, *Org Synth.* **II,** 62.



A cyclic mechanism is apparently involved:



Conjugated acetylenic ketones give allenes.[453] Another indirect method is conversion of the aldehyde or ketone to a dithioacetal or ketal, and desulfurization of this (**4-37**). In still another indirect method, the ketone is converted to an enol triflate $-\overset{|}{C}=\overset{|}{C}-OTf$, which is reduced with H_2 and a platinum-oxide catalyst.[454]

The first step in the mechanism[455] of the Wolff–Kishner reaction consists of formation of the hydrazone (**6-20**).

$$R_2C{=}O \rightarrow R_2C{=}N{-}NH_2$$

It is this species that undergoes reduction in the presence of base, most probably in the following manner:

$$R_2C{=}N{-}NH_2 \overset{OH^-}{\rightleftharpoons} R_2CH{-}N{=}NH + OH^- \longrightarrow R_2CH{-}N{=}N^{\ominus} + H_2O$$

$$R_2CH{-}N{=}N^{\ominus} \xrightarrow{-N_2} R_2\overline{C}H^{\ominus} \xrightarrow{H_2O} R_2CH_2 + OH^-$$

Not much is known about the mechanism of the Clemmensen reduction, though a complex mechanism has been proposed.[456] One thing reasonably certain is that the corresponding alcohol is not an intermediate, since alcohols prepared in other ways fail to give the reaction. Note that the alcohol is not an intermediate in the Wolff–Kishner reduction either.

9-39 Reduction of Carboxylic Acids to Alcohols

$$\mathrm{RCOOH} \xrightarrow{\mathrm{LiAlH_4}} \mathrm{RCH_2OH}$$

Carboxylic acids are easily reduced to primary alcohols by $LiAlH_4$.[457] The reaction does not stop at the aldehyde stage (but see **0-85**). The conditions are particularly mild, the reduction proceeding quite well at room temperature. Other hydrides have also been used, but not $NaBH_4$ (see Table 5).[458] Catalytic hydrogenation is also generally ineffective. Borane is particularly good for carboxyl groups (Table 4) and permits selective reduction of them in the presence of many other groups (though the reaction with double bonds takes place at about the same rate).[459] Aluminum hydride reduces COOH groups without affecting carbon–halogen bonds in the same molecule.

OS **III,** 60.

9-40 Reduction of Amides to Amines

$$\mathrm{RCONH_2} \xrightarrow{\mathrm{LiAlH_4}} \mathrm{RCH_2NH_2}$$

Amides can be reduced[460] to amines with $LiAlH_4$ or by catalytic hydrogenation, though high temperatures and pressures are usually required for the latter. Even with $LiAlH_4$ the reaction is more difficult than the reduction of most other functional groups, and other groups often can be reduced without disturbing an amide function. $NaBH_4$ by itself does not reduce amides, though it does so in the presence of certain other reagents.[461] Substituted amides can be similarly reduced:

$$\mathrm{RCONHR'} \longrightarrow \mathrm{RCH_2NHR'}$$
$$\mathrm{RCONR'_2} \longrightarrow \mathrm{RCH_2NR'_2}$$

Borane is a good reducing agent for all three types of amides.[462] Another method for the reduction of mono- and disubstituted amides in high yields consists of treatment with triethyloxonium fluoroborate $Et_3O^+\ BF_4^-$ to give the imino ether fluoroborate $RC(OEt){=}NR_2^+\ BF_4^-$, followed by reduction of this with $NaBH_4$ in ethanol.[463] Still another reagent that reduces disubstituted amides to amines is trichlorosilane.[464]

With some $RCONR_2'$, $LiAlH_4$ causes cleavage, and the aldehyde (**0-86**) or alcohol is obtained. Lithium triethylborohydride produces the alcohol with most N,N-disubstituted amides, though not with unsubstituted or N-substituted amides.[465] Thioamides can be reduced with hydrogen and Raney nickel.[466] Lactams are reduced to cyclic amines in high yields with $LiAlH_4$, though cleavage sometimes occurs here too. Imides are generally reduced on both sides, though it is sometimes possible to stop with just one. Both cyclic and acyclic imides have been reduced in this manner, though with acyclic imides cleavage is often obtained, e.g.,[467]

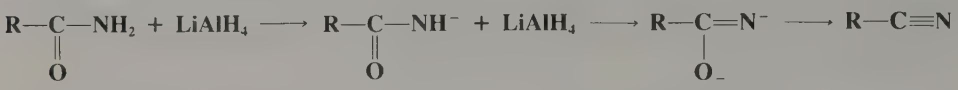
$$\mathbf{PhN(COMe)_2 \longrightarrow PhNHEt}$$

Nitriles have been isolated as intermediates in the treatment of unsubstituted amides with $LiAlH_4$.[468] The following mechanism has been proposed for the conversion of the amide to the nitrile:[468]



$$R{-}C(=O){-}NH_2 + LiAlH_4 \longrightarrow R{-}C(=O){-}NH^- + LiAlH_4 \longrightarrow R{-}C(O^-){=}N^- \longrightarrow R{-}C{\equiv}N$$

OS **IV,** 339, 354, 564; **54,** 88; **61,** 24.

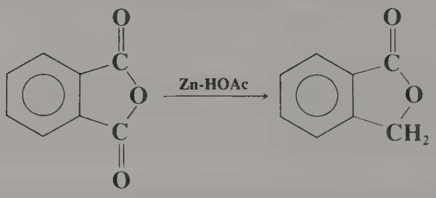
9-41 Reduction of Carboxylic Esters to Ethers

$$\mathbf{RCOOR'} \xrightarrow[\text{LiAlH}_4]{\text{BF}_3\text{-etherate}} \mathbf{RCH_2OR'}$$

Carboxylic esters and lactones have been reduced to ethers, though the more usual course is the obtention of 2 moles of alcohol (**9-43**). Reduction to ethers has been accomplished with a reagent prepared from BF_3-etherate and either $LiAlH_4$, $LiBH_4$, or $NaBH_4$,[469] with trichlorosilane and uv light,[470] and with catalytic hydrogenation. The reaction with the BF_3 reagent apparently succeeds with secondary R′, but not with primary R′, which give **9-43.** Lactones give cyclic ethers.[471] Thiono esters RCSOR′ can be reduced to ethers RCH_2OR' with Raney nickel (**4-37**).[472] Since the thiono esters can be prepared from carboxylic esters (**6-11**), this provides an indirect method for the conversion of carboxylic esters to ethers. Thiol esters RCOSR′ have been reduced to sulfides RCH_2SR'.[473]

See also **9-44, 0-82.**

9-42 Reduction of Cyclic Anhydrides to Lactones



---

Chem.* **39,** 2470 (1974); Baldwin and Haut, *J. Org. Chem.* **40,** 3885 (1975). See also Kraus, Frazier, Roth, Taschner, and Neuenschwander, *J. Org. Chem.* **46,** 2417 (1981).

[471] See, for example, Pettit, Kasturi, Green, and Knight, *J. Org. Chem.* **26,** 4773 (1961); Edward and Ferland, *Chem. Ind. (London)* 975 (1964).

[472] Baxter and Bradshaw, *J. Org. Chem.* **46,** 831 (1981).

[473] Eliel and Daignault, *J. Org. Chem.* **29,** 1630 (1964); Bublitz, *J. Org. Chem.* **32,** 1630 (1967).

Cyclic anhydrides can give lactones if reduced with Zn-HOAc, hydrogen and platinum or $RuCl_2(Ph_3P)_3$,[474] $NaBH_4$,[475] or even $LiAlH_4$, although with the last-mentioned reagent diols are the more usual product (**9-45**). With some reagents the reaction can be accomplished regioselectively, i.e., only a specific one of the two C=O groups of an unsymmetrical anhydride is reduced.[476] Open-chain anhydrides either are not reduced at all (e.g., with $NaBH_4$) or give 2 moles of alcohol.

There are no *Organic Syntheses* references, but see OS **II,** 526, for a related reaction.

9-43 Reduction of Carboxylic Esters to Alcohols

Dihydro,hydroxy-de-oxo,alkoxy-tersubstitution

$$RCOOR' \xrightarrow{LiAlH_4} RCH_2OH + R'OH$$

$LiAlH_4$ reduces carboxylic esters to give 2 moles of alcohol.[477] The reaction is of wide scope and has been used to reduce many esters. Where the interest is in obtaining R'OH, this is a method of ''hydrolyzing'' esters. Lactones yield diols. $LiBH_4$ also gives the reaction,[478] as do i-Bu_2AlH, lithium triethylborohydride, BH_3-SMe_2 in refluxing THF,[479] and triethoxysilane $HSi(OEt)_3$.[480] $NaBH_4$ reduces phenolic esters, especially those containing electron-withdrawing groups,[481] but its reaction with other esters is usually so slow that such reactions are seldom feasible (though exceptions are known[482]), and it is generally possible to reduce an aldehyde or ketone without reducing an ester function in the same molecule. However, $NaBH_4$ reduces esters in the presence of certain compounds (see Table 5).[483] With the reagent $NaBH(OMe)_3$ it is possible to reduce a secondary ester function $R_2CHCOOR'$ in the presence of a tertiary ester function R_3CCOOR'.[484] Esters can also be reduced to alcohols by hydrogenation over copper chromite catalysts,[485] though high pressures and temperatures are required.[486] Ester functions generally survive low-pressure catalytic hydrogenations. Before the discovery of $LiAlH_4$, the most common way of carrying out the reaction was with sodium in ethanol, a method known as the *Bouveault–Blanc procedure*. This procedure is still sometimes used where selectivity is necessary. See also **9-41, 9-44,** and **0-82.**

OS **II,** 154, 325, 372, 468; **III,** 671; **IV,** 834; **53,** 70.

9-44 Reduction of Carboxylic Acids and Esters to Alkanes

Trihydro-de-oxo,alkoxy-tersubstitution, etc.

$$RCOOR' \xrightarrow{(C_5H_5)_2TiCl_2} RCH_3 + R'OH$$

The reagent titanocene dichloride reduces esters in a different manner from that of **0-82, 9-41,** or **9-43.** The products are the alkane RCH_3 and the alcohol R'OH.[447] The mechanism probably involves an alkene intermediate. Aromatic acids can be reduced to methylbenzenes by a procedure involving refluxing first with trichlorosilane in MeCN, then with tripropylamine added, and finally with KOH and MeOH (after removal of the MeCN).[487] The following sequence has been suggested:[487]

[486] See also Grey, Pez, Wallo, and Corsi, *J. Chem. Soc., Chem. Commun.* 783 (1980).

$$\mathrm{ArCOOH} \xrightarrow{\mathrm{SiHCl_3}} \mathrm{(ArCO)_2O} \xrightarrow[\mathrm{R_3N}]{\mathrm{SiHCl_3}} \mathrm{ArCH_2SiCl_3} \xrightarrow[\mathrm{MeOH}]{\mathrm{KOH}} \mathrm{ArCH_3}$$

Esters of aromatic acids are not reduced by this procedure, so that an aromatic COOH group can be reduced in the presence of a COOR′ group.[488] However, it is also possible to reduce aromatic ester groups, by a variation of the trichlorosilane procedure.[489] *o*- and *p*-hydroxybenzoic acids and their esters have been reduced to cresols $HOC_6H_4CH_3$ with sodium bis(2-methoxyethoxy)aluminum hydride $NaAlH_2(OC_2H_4OMe)_2$[490]

Carboxylic acids can also be converted to alkanes, indirectly,[491] by reduction of the corresponding tosylhydrazides $RCONHNH_2$ with $LiAlH_4$ or borane.[492]

OS **56,** 83.

9-45 Reduction of Anhydrides to Alcohols

$$\mathrm{RCOOCOR} \xrightarrow{\mathrm{LiAlH_4}} \mathrm{2RCH_2OH}$$

$LiAlH_4$ usually reduces open-chain anhydrides to give 2 moles of alcohol. With cyclic anhydrides the reaction with $LiAlH_4$ can be controlled to give either diols or lactones[493] (see **9-42**).

OS **57,** 53.

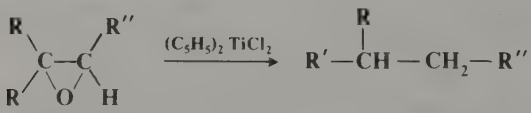
9-46 Reduction of Acyl Halides to Alcohols

$$\mathrm{RCOCl} \xrightarrow{\mathrm{LiAlH_4}} \mathrm{RCH_2OH}$$

Acyl halides are reduced[494] to alcohols by $LiAlH_4$ or $NaBH_4$, as well as by other metal hydrides (Table 5), but not by borane. The reaction may be regarded as a combination of **9-38** and **0-77.**

OS **IV,** 271.

9-47 Complete Reduction of Epoxides



Though the usual product of epoxide reductions is the alcohol (**0-81**), 1,2-epoxides are reduced all the way to the alkane by titanocene dichloride[447] and Et_3SiH-BH_3.[495]

9-48 Reduction of Nitro Compounds to Amines

$$RNO_2 \xrightarrow[HCl]{Zn} RNH_2$$

Both aliphatic[496] and aromatic nitro compounds can be reduced to amines, though the reaction has been applied much more often to aromatic nitro compounds, owing to their greater availability. Many reducing agents have been used to reduce aromatic nitro compounds, among them Zn, Sn, or Fe (or sometimes other metals) and acid, catalytic hydrogenation,[497] AlH_3-$AlCl_3$, hydrazine and a catalyst,[498] dodecacarbonyltriiron[$Fe_3(CO)_{12}$]-methanol,[499] $TiCl_3$,[500] hot liquid paraffin,[501] formic acid and Pd-C,[502] and sulfides such as NaHS, $(NH_4)_2S$, or polysulfides. The reaction with sulfides or polysulfides is called the *Zinin reduction.*[503] The reagent sodium dihydro(trithio)borate $NaBH_2S_3$ reduces aromatic nitro compounds to amines,[504] but aliphatic nitro compounds give other products (see **9-59**). In contrast, $LiAlH_4$ reduces aliphatic nitro compounds to amines, but with aromatic nitro compounds the products with this reagent are azo compounds (**9-68**). Most metal hydrides, including $NaBH_4$ and BH_3, do not reduce nitro groups at all, though aromatic nitro compounds have been reduced to amines with $NaBH_4$ and various catalysts, such as $NiCl_2(PPh_3)_2$ or $CoCl_2$.[505] Treatment of aromatic nitro compounds with $NaBH_4$ alone has resulted in reduction of the *ring* to a cyclohexane ring with the nitro group still intact[506] or in cleavage of the nitro group from the ring.[507] With $(NH_4)_2S$ or other sulfides or polysulfides it is often possible to reduce just one of two or three nitro groups on an aromatic ring or on two different rings in one molecule.[508] The nitro groups of N-nitro compounds can also be reduced to amino groups, e.g., nitrourea $NH_2CONHNO_2$ gives semicarbazide $NH_2CONHNH_2$.

With some reducing agents, especially with aromatic nitro compounds, the reduction can be stopped at an intermediate stage, and hydroxylamines (**9-50**), hydrazobenzenes (**9-69**), azobenzenes (**9-68**), and azoxybenzenes (**9-67**) can be obtained in this manner. However, nitroso compounds, which are often postulated as intermediates, are too reactive to be isolated, if indeed they are intermediates (see however, **9-49**). Reduction by metals in mineral acids cannot be stopped, but always produces the amine. The mechanisms of these reductions have been very little studied, though it is usually presumed that, at least with some reducing agents, nitroso compounds and hydroxylamines are intermediates. Both of these types of compounds give amines when exposed to most of these reducing agents (**9-51**), and hydroxylamines can be isolated (**9-50**). With metals and acid the following path has been suggested:[509]

9-49 Reduction of Nitro Compounds to Nitroso Compounds

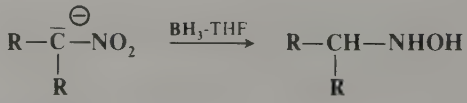
$$\mathrm{ArNO_2} \xrightarrow[\mathrm{H_2O}]{h\nu,\ \mathrm{CN^-}} \mathrm{ArNO}$$

Certain aromatic nitroso compounds can be obtained in good yields by irradiation of the corresponding nitro compounds in 0.1 *M* aqueous KCN with uv light.[510] When nitro compounds are treated with most other reducing agents, nitroso compounds are either not formed or react further under the reaction conditions and cannot be isolated.

9-50 Reduction of Nitro Compounds to Hydroxylamines

$$\mathrm{ArNO_2} \xrightarrow[\mathrm{H_2O}]{\mathrm{Zn}} \mathrm{ArNHOH}$$

When aromatic nitro compounds are reduced with zinc and water under neutral conditions,[511] hydroxylamines are formed. Borane in THF reduces *aliphatic* nitro compounds (in the form of their salts) to hydroxylamines:[512]



$$\mathrm{R{-}\overset{\ominus}{\bar{C}}(R){-}NO_2} \xrightarrow{\mathrm{BH_3\text{-}THF}} \mathrm{R{-}CH(R){-}NHOH}$$

OS **I,** 445; **III,** 668; **IV,** 148; **52,** 77.

9-51 Reduction of Nitroso Compounds and Hydroxylamines to Amines

$$\mathrm{RNO} \xrightarrow[\mathrm{HCl}]{\mathrm{Zn}} \mathrm{RNH_2}$$

N-Dihydro-de-oxo-bisubstitution

$$\mathrm{RNHOH} \xrightarrow[\mathrm{HCl}]{\mathrm{Zn}} \mathrm{RNH_2}$$

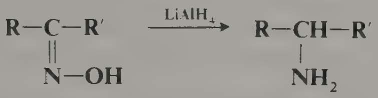
N-Hydro-de-hydroxylation or *N*-Dehydroxylation

Nitroso compounds and hydroxylamines can be reduced to amines by the same reagents that reduce nitro compounds (**9-48**). N-Nitroso compounds are similarly reduced to hydrazines:[513]

$$\mathrm{R_2N{-}NO} \longrightarrow \mathrm{R_2N{-}NH_2}$$

OS **I,** 511; **II,** 33, 202, 211, 418; **III,** 91; **IV,** 247.

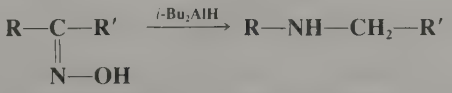
9-52 Reduction of Oximes to Primary Amines or Aziridines



$$\underset{\substack{\|\\ \mathrm{N{-}OH}}}{\mathrm{R{-}C{-}R'}} \xrightarrow{\mathrm{LiAlH_4}} \underset{\substack{|\\ \mathrm{NH_2}}}{\mathrm{R{-}CH{-}R'}}$$

Both aldoximes and ketoximes can be reduced to primary amines with $\mathrm{LiAlH_4}$. The reaction is slower than with ketones, so that, for example, PhCOCH=NOH gave 34% PhCHOHCH=NOH.[514] Other reducing agents that give this reduction are zinc and acetic acid, sodium ethoxide, $\mathrm{BH_3}$ at 105 to 110°C,[515] bis(2-methoxyethoxy)aluminum hydride,[516] sodium dihydro(trithio)borate,[517] and sodium and an alcohol.[518] Catalytic hydrogenation is also effective.[519]

When the reducing agent is diisobutylaluminum hydride, the product is a secondary amine, arising from a rearrangement:[520]



$$\underset{\substack{\|\\ \mathrm{N{-}OH}}}{\mathrm{R{-}C{-}R'}} \xrightarrow{i\text{-}\mathrm{Bu_2AlH}} \mathrm{R{-}NH{-}CH_2{-}R'}$$

With certain oximes (e.g., those of the type $\mathrm{ArCH_2CR{=}NOH}$), treatment with $\mathrm{LiAlH_4}$ gives aziridines,[521] e.g.,

[520] Sasatani, Miyazaki, Maruoka, and Yamamoto, *Tetrahedron Lett.* **24,** 4711 (1983). See also Rerick, Trottier, Daignault, and DeFoe, *Tetrahedron Lett.* 629 (1963); Petrarca and Emery, *Tetrahedron Lett.* 635 (1963); Graham and Williams, *Tetrahedron* **21,** 3263 (1965).

[521] For a review, see Kotera and Kitahonoki, *Org. Prep. Proced.* **1,** 305–324 (1969). For examples, see Shandala, Solomon, and Waight, *J. Chem. Soc.* 892 (1965); Kitahonoki, Kotera, Matsukawa, Miyazaki, Okada, Takahashi, and Takano, *Tetrahedron Lett.* 1059 (1965); Kitahonoki, Takano, Matsuura, and Kotera, *Tetrahedron* **25,** 335 (1969); Landor, Sonola, and Tatchell, *J. Chem. Soc., Perkin Trans. 1* 1294 (1974); Ferrero, Rouillard, Decouzon, and Azzaro, *Tetrahedron Lett.* 131 (1974); Diab, Laurent, and Mison, *Tetrahedron Lett.* 1605 (1974).

Hydrazones, arylhydrazones, and semicarbazones can also be reduced to amines with various reducing agents, including Zn-HCl and H_2 and Raney nickel.

Oximes can also be reduced to hydroxylamines (**6-27**).

OS **II,** 318; **III,** 513; **V,** 32, 83, 373, 376.

9-53 Reduction of Miscellaneous Nitrogen Compounds

$$\mathrm{R{-}N{=}C{=}O \xrightarrow{LiAlH_4} R{-}NH{-}CH_3}$$

$$\mathrm{R{-}N{=}C{=}S \xrightarrow{LiAlH_4} R{-}NH{-}CH_3}$$

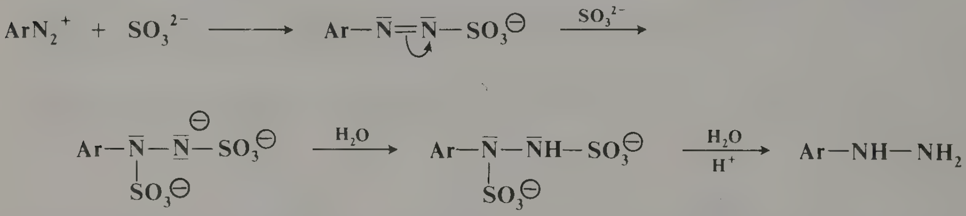
$$\mathrm{R{-}N_3 \xrightarrow{LiAlH_4} RNH_2}$$

$$\mathrm{Ar{-}N{=}N{-}Ar \xrightarrow[catalyst]{H_2} Ar{-}NH{-}NH{-}Ar}$$

$$\mathrm{ArN_2^+\ Cl^- \xrightarrow{Na_2SO_3} ArNHNH_2}$$

$$\mathrm{R_2N{-}NO \xrightarrow[Ni]{H_2} R_2NH}$$

Isocyanates and isothiocyanates are reduced to methylamines, and azides to primary amines[522] on treatment with $LiAlH_4$. Sulfonyl azides RSO_2N_3 have been reduced to sulfonamides RSO_2NH_2 by irradiation in isopropyl alcohol[523] and with NaH.[524] $LiAlH_4$ does not usually reduce azo compounds[525] (indeed these are the products from $LiAlH_4$ reduction of nitro compounds, **9-68**), but these can be reduced to hydrazo compounds by catalytic hydrogenation or with diimide[526] (see **5-10**). Diazonium salts are reduced to hydrazines by sodium sulfite. This reaction probably has a nucleophilic mechanism.[527]



$$\mathrm{ArN_2^+ + SO_3^{2-} \longrightarrow Ar{-}\bar{N}{=}\bar{N}{-}SO_3^{\ominus} \xrightarrow{SO_3^{2-}}}$$

$$\mathrm{Ar{-}\underset{SO_3^{\ominus}}{\bar{N}}{-}\overset{\ominus}{\bar{N}}{-}SO_3^{\ominus} \xrightarrow{H_2O} Ar{-}\underset{SO_3^{\ominus}}{\bar{N}}{-}\bar{N}H{-}SO_3^{\ominus} \xrightarrow[H^+]{H_2O} Ar{-}NH{-}NH_2}$$

The initial product is a salt of hydrazinesulfonic acid, which is converted to the hydrazine by acid treatment. Diazonium salts can also be reduced to arenes (**4-23**). N-Nitrosoamines can be denitrosated to secondary amines by a number of reducing agents, including H_2 and a catalyst,[528] and $NaBH_4$-$TiCl_4$,[529] as well as by hydrolysis.[530]

A cyano group can be reduced to a methyl group by treatment with a terpene such as limonene

9-54 Reduction of Sulfonyl Halides and Sulfonic Acids to Mercaptans and Sulfides

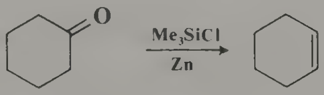
$$RSO_2Cl \xrightarrow{LiAlH_4} RSH$$

Mercaptans can be prepared by the reduction of sulfonyl halides[533] with $LiAlH_4$. Usually, the reaction is carried out on aromatic sulfonyl chlorides. Zinc and acetic acid, and HI, also give the reduction. Sulfonic acids have been reduced to mercaptans with a mixture of triphenylphosphine and I_2.[534] Disulfides RSSR can also be produced.[535] For the reduction of sulfonyl chlorides to sulfinic acids, see **0-121.**

OS **I,** 504; **IV,** 695; **V,** 843.

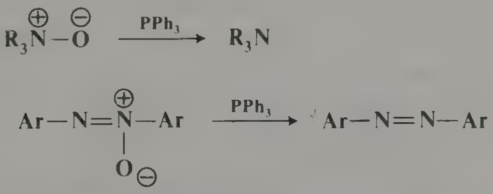
B. Reactions in Which an Oxygen Is Removed from the Substrate

9-55 Reduction of Cyclic Ketones to Cycloalkenes



Cyclic ketones can be directly reduced to cycloalkenes by treatment with chlorotrimethylsilane and zinc.[536] Halogen and ester groups are not affected. Yields are best for six-membered rings. There are many indirect methods for achieving this conversion, among them formation and decomposition of the tosylhydrazone (**7-11**).

9-56 Reduction of Amine Oxides and Azoxy Compounds



$$R_3\overset{\oplus}{N}-\overset{\ominus}{O} \xrightarrow{PPh_3} R_3N$$

$$Ar-N=\underset{\displaystyle O^{\ominus}}{\overset{\oplus}{N}}-Ar \xrightarrow{PPh_3} Ar-N=N-Ar$$

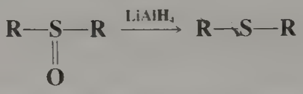
[536] Motherwell, *J. Chem. Soc., Chem. Commun.* 935 (1973).

Amine oxides[537] and azoxy compounds (both alkyl and aryl)[538] can be reduced practically quantitatively with triphenylphosphine.[539] Other reducing agents, e.g., $LiAlH_4$, H_2-Ni, PCl_3, CS_2,[539a] and sulfur have also been used. Nitrile oxides[540] $R{-}C{\equiv}\overset{\oplus}{N}{-}\overset{\ominus}{O}$ can be reduced to nitriles with trialkylphosphines,[541] and isocyanates RNCO to isonitriles RNC with Cl_3SiH-Et_3N.[542]

OS **IV**, 166.

9-57 Reduction of Sulfoxides and Sulfones



$$R-\underset{\underset{O}{\|}}{S}-R \xrightarrow{LiAlH_4} R-S-R$$

Sulfoxides can be reduced to sulfides, by $LiAlH_4$ or other reagents,[543] among them HI, Bu_3SnH,[544] $TiCl_2$,[545] $MeSiCl_3$-NaI,[546] PCl_3,[547] H_2-Pd-C,[548] acetyl chloride,[549] Ph_3P,[550] *t*-BuBr,[551] and tris(dimethylamino)phosphine-I_2.[552] Sulfones, however, are usually stable to reducing agents, though they have been reduced to sulfides with diisobutylaluminum hydride $(i\text{-}Bu)_2AlH$.[553] A less general reagent is $LiAlH_4$, which reduces some sulfones to sulfides, but not others.[554] Both sulfoxides and sulfones can be reduced by heating with sulfur (which is oxidized to SO_2), though the reaction with sulfoxides proceeds at a lower temperature. It has been shown by using substrate labeled with ^{35}S that sulfoxides simply give up the oxygen to the sulfur, but that the reaction with sulfones is more complex, since about 75% of the original radioactivity of the sulfone is lost.[555] This indicates that most of the sulfur in the sulfide product comes in this case from the *reagent*. There is no direct general method for the reduction of sulfones to sulfoxides, but an indirect method has been reported.[556] Selenoxides can be reduced to selenides with a number of reagents.[557]

9-58 Reduction of Hydroperoxides

$$R-O-O-H \xrightarrow{LiAlH_4} ROH$$

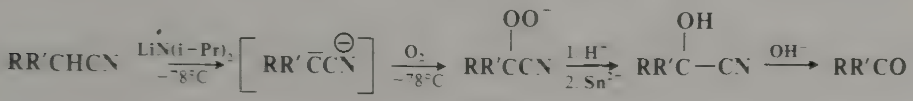
[557] See for example, Sakaki and Oae, *Chem. Lett.* 1003 (1977); Still, Hasan, and Turnbull, *Can. J. Chem.* **56,** 1423 (1978); Denis and Krief, *J. Chem. Soc., Chem. Commun.* 544 (1980).

Hydroperoxides can be reduced to alcohols with $LiAlH_4$ or Ph_3P[558] or by catalytic hydrogenation. This functional group is very susceptible to catalytic hydrogenation, as shown by the fact that a double bond may be present in the same molecule without being reduced.[559]

The reaction is an important step in a method for the oxidative decyanation of nitriles containing an α-hydrogen.[560] The nitrile is first converted to the α-hydroperoxy nitrile by treatment with base



$$RR'CHCN \xrightarrow[-78^\circ C]{LiN(i\text{-}Pr)_2} \left[RR'\bar{C}CN^{\ominus}\right] \xrightarrow[-78^\circ C]{O_2} RR'\overset{OO^-}{\overset{|}{C}}CN \xrightarrow[2.\ Sn^{2+}]{1.\ H^+} RR'\overset{OH}{\overset{|}{C}}-CN \xrightarrow{OH^-} RR'CO$$

at −78°C followed by O_2. The hydroperoxy nitrile is then reduced to the cyanohydrin, which is cleaved (the reverse of **6-49**) to the corresponding ketone. The method is not successful for the preparation of aldehydes (R′ = H).

9-59 Reduction of Aliphatic Nitro Compounds to Oximes or Nitriles

$$RCH_2NO_2 \xrightarrow[HOAc]{Zn} RCH{=}NOH$$

Nitro compounds that contain an α-hydrogen can be reduced to oximes with zinc dust in HOAc[561] or with other reagents, among them Co-Cu(II) salts in alkanediamines,[562] $CrCl_2$,[563] and (for α-nitro sulfones) $NaNO_2$.[564]

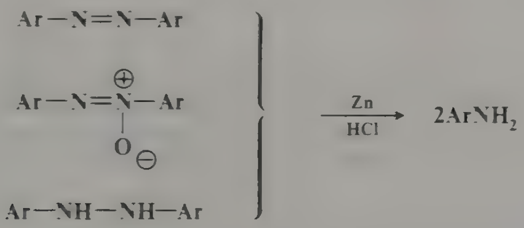
Primary aliphatic nitro compounds can be reduced to nitriles with sodium dihydro(trithio)borate.[565] Secondary compounds give mostly ketones (e.g., nitrocyclohexane → 45% cyclohexanone, 30% cyclohexanone oxime, and 19% N-cyclohexylhydroxylamine). Tertiary aliphatic nitro compounds do not react with this reagent. See also **9-48**.

$$RCH_2NO_2 \xrightarrow{NaBH_2S_3} RC{\equiv}N$$

OS IV, 932.

C. Reduction with Cleavage

9-60 Reduction of Azo, Azoxy, and Hydrazo Compounds to Amines



$$\left.\begin{array}{c} Ar-N{=}N-Ar \\ Ar-N{=}\overset{\oplus}{\underset{O^{\ominus}}{N}}-Ar \\ Ar-NH-NH-Ar \end{array}\right\} \xrightarrow[HCl]{Zn} 2ArNH_2$$

---

Azo, azoxy, and hydrazo compounds can all be reduced to amines.[565] Metals (notably zinc) and acids, and $Na_2S_2O_4$, are frequently used as reducing agents. Borane reduces azo compounds to amines, though it does not reduce nitro compounds.[566] $LiAlH_4$ does not reduce hydrazo compounds or azo compounds, though with the latter, hydrazo compounds are sometimes isolated. With azoxy compounds, $LiAlH_4$ gives only azo compounds (**9-56**).

OS **I,** 49; **II,** 35, 39; **III,** 360. Also see OS **II,** 290.

9-61 Reduction of Peroxides

$$\mathbf{R{-}O{-}O{-}R \xrightarrow{LiAlH_4} 2ROH}$$

Peroxides are cleaved to 2 moles of alcohol by $LiAlH_4$ or by catalytic hydrogenation. Peroxides can be reduced to ethers with $P(OEt)_3$.[567]

$$\mathbf{ROOR + P(OEt)_3 \longrightarrow ROR + OP(OEt)_3}$$

In a similar reaction, disulfides RSSR′ can be converted to sulfides RSR′ by treatment with tris(diethylamino)phosphine $(Et_2N)_3P$.[568]

OS **58,** 138.

9-62 Reduction of Disulfides to Mercaptans

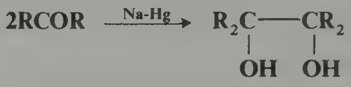
$$\mathbf{RSSR \xrightarrow[H^+]{Zn} 2RSH}$$

Disulfides can be reduced to mercaptans by mild reducing agents,[569] such as zinc and dilute acid or Ph_3P and H_2O.[570] The reaction can also be accomplished simply by heating with alkali.[571] $LiAlH_4$ has also been used.

OS **II,** 580. Also see OS **IV,** 295.

D. Reductive Coupling

9-63 Bimolecular Reduction of Aldehydes and Ketones to Pinacols



$$\mathbf{2RCOR \xrightarrow{Na\text{-}Hg} \underset{OH}{R_2C}{-}\underset{OH}{CR_2}}$$

Pinacols can be synthesized by reduction of aldehydes and ketones with active metals such as sodium, magnesium, or aluminum.[572] Aromatic ketones give better yields than aliphatic ones. The use of a $Mg\text{-}MgI_2$ mixture has been called the *Gomberg-Bachmann pinacol synthesis*. As with a number of other reactions involving sodium, there is a direct electron transfer here, converting the ketone or aldehyde to a ketyl, which dimerizes.

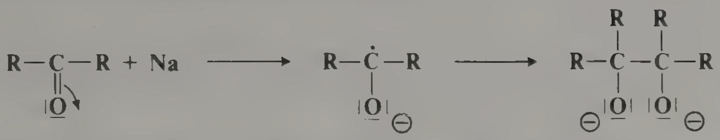
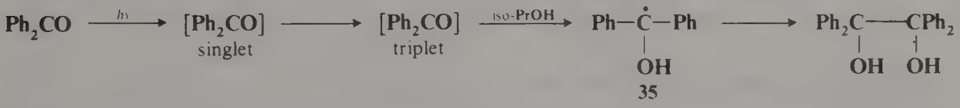
[572] For a convenient method, see Schreibmann, *Tetrahedron Lett.* 4271 (1970).



Other reagents have been used, including SmI_2,[573] Ce-I_2,[574] and a reagent prepared from $TiCl_4$ and Mg amalgam.[575] Unsymmetrical coupling between a ketone R^1COR^2 and another ketone R^3COZ, where Z = CN, COOH, COOEt, or pyridyl, has been achieved with $TiCl_3$ in aqueous solution.[576] This reaction can also be accomplished with an α,β-unsaturated aldehyde R′CH=CH—CHO instead of R^1COR^2.[577]

The dimerization of ketones to pinacols can also be accomplished photochemically; indeed, this is one of the most common photochemical reactions.[578] The substrate, which is usually a diaryl or aryl alkyl ketone (though a few aromatic aldehydes and dialkyl ketones have been dimerized), is irradiated with uv light in the presence of a hydrogen donor such as isopropyl alcohol, toluene, or an amine.[579] In the case of benzophenone, irradiated in the presence of isopropyl alcohol, the ketone molecule initially undergoes $n \rightarrow \pi^*$ excitation, and the singlet species thus formed crosses to the T_1 state with a very high efficiency. The T_1 species abstracts hydrogen from the alcohol (p. 216)



and then dimerizes. The iso-PrO• radical, which is formed by this process, donates H• to another molecule of ground-state benzophenone, producing acetone and another molecule of **35**. This

$$\text{iso-PrO}\cdot + Ph_2CO \longrightarrow Me_2CO + \underset{\textbf{35}}{Ph_2COH}$$

mechanism[580] predicts that the quantum yield for the disappearance of benzoquinone should be 2, since each quantum of light results in the conversion of 2 moles of benzophenone to **35.** Under favorable experimental conditions the observed quantum yield does approach 2. Benzophenone abstracts hydrogen with very high efficiency. Other aromatic ketones are dimerized with lower quantum yields, and some (e.g., *p*-aminobenzophenone, *o*-methylacetophenone) cannot be dimerized at all in isopropyl alcohol (though *p*-aminobenzophenone, for example, can be dimerized in cyclohexane[581]). The reaction has also been carried out electrochemically.[582]

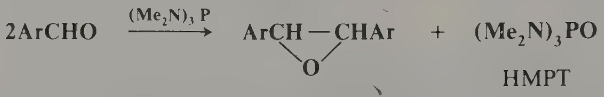
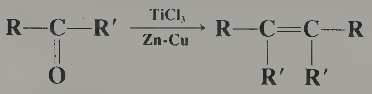
9-64 Bimolecular Reduction of Aldehydes and Ketones to Epoxides



Aromatic aldehydes can be dimerized to epoxides by treatment with hexamethylphosphorus triamide.[583] The reagent[584] is converted to hexamethylphosphoric triamide (HMPT). The reaction can be used for the preparation of mixed epoxides by the use of a mixture of two aldehydes in which the less reactive aldehyde predominates. Epoxides have also been prepared by treatment of aromatic aldehydes or ketones with the anions $(Me_2N)_2\overset{\ominus}{P}{=}O$ and $(EtO)_2\overset{\ominus}{P}{=}O$ (derived, respectively, by treatment with an alkali metal of HMPT or triethyl phosphite).[585]

OS **V,** 358.

9-65 Bimolecular Reduction of Aldehydes or Ketones to Alkenes



$$R{-}\underset{\underset{O}{\|}}{C}{-}R' \xrightarrow[\text{Zn-Cu}]{TiCl_3} R{-}\underset{\underset{R'}{|}}{C}{=}\underset{\underset{R'}{|}}{C}{-}R$$

Aldehydes and ketones, both aromatic and aliphatic (including cyclic ketones), can be converted in high yields to dimeric alkenes[586] by treatment with $TiCl_3$ and a zinc–copper couple.[587] The reaction has also been accomplished with Mg and a $TiCl_3$–THF complex,[588] with $TiCl_4$ and Zn,[589] with $TiCl_3$-$LiAlH_4$,[590] with $TiCl_3$ and K or Li,[591] and with certain compounds prepared from WCl_6 and either lithium, lithium iodide, $LiAlH_4$, or an alkyllithium[592] (see **7-21**). The reaction has been used to convert dialdehydes and diketones to cycloalkenes.[593] Rings of 3 to 16 and 22 members have been closed in this way, e.g.,[594]

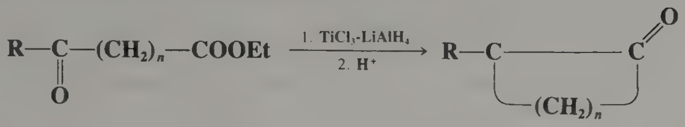
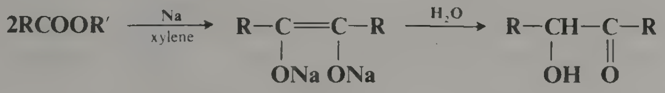
The same reaction on a keto ester gives a cycloalkanone.[595]



Unsymmetrical alkenes can be prepared from a mixture of two ketones, if one is in excess.[596] The mechanism consists of initial coupling of two radical species to give a 1,2-dioxygen compound (a titanium pinacolate), which is then deoxygenated.[597]

OS **60,** 113.

9-66 The Acyloin Condensation



$$2\mathrm{RCOOR'} \xrightarrow[\text{xylene}]{\mathrm{Na}} \underset{\mathrm{ONa}\ \ \mathrm{ONa}}{\mathrm{R{-}C{=}C{-}R}} \xrightarrow{\mathrm{H_2O}} \underset{\mathrm{OH}\ \ \ \mathrm{O}}{\mathrm{R{-}CH{-}\overset{}{C}{-}R}}$$

36

When carboxylic esters are heated with sodium in refluxing ether or benzene, a bimolecular reduction takes place,and the product is an α-hydroxy ketone (called an acyloin).[598] The reaction, called the *acyloin condensation,* is quite successful when R is alkyl. Acyloins with long chains have been prepared in this way, for example, R = $C_{17}H_{35}$, but for high-molecular-weight esters, toluene or xylene is used as the solvent. The acyloin condensation has been used with great success, in boiling xylene, to prepare cyclic acyloins from diesters.[599] The yields are 50 to 60% for the preparation of 6- and 7-membered rings, 30 to 40% for 8- and 9-membered,[600] and 60 to 95% for rings of 10 to 20 members. Even larger rings have been closed in this manner. This is one of the best ways of closing rings of 10 members or more. The reaction has been used to close 4-membered rings,[601] though this is generally not successful. Small traces of oxygen greatly reduce the yields; hence the reaction must be conducted in an extremely pure nitrogen atmosphere. The presence of double or triple bonds does not interfere.[602] Even a benzene ring may be present, and many paracyclophane derivatives (**37**) with n = 9 or more have been synthesized in this manner.[603]

[600] Yields of nine-membered ring products can be increased by adding a homologous diester, e.g., dimethyl tridecanedioate: Finley and Sasaki, *J. Am. Chem. Soc.* **88,** 4267 (1966).

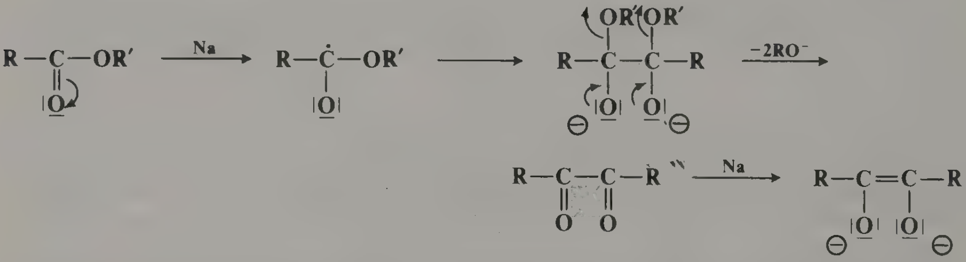
[601] Cope and Herrick, *J. Am. Chem. Soc.* **72,** 983 (1950); Bloomfield and Irelan, *J. Org. Chem.* **31,** 2017 (1966).

[602] Cram and Gaston, *J. Am. Chem. Soc.* **82,** 6386 (1960).

[603] For a review, see Cram, *Rec. Chem. Prog.* **20,** 71 (1959).

Yields in the acyloin condensation can be improved by running the reaction in the presence of chlorotrimethylsilane Me_3SiCl, in which case the dianion **36** is converted to the bis silyl enol ether **38,** which can be isolated and subsequently hydrolyzed to the acyloin with aqueous acid.[604] This is now the standard way to conduct the acyloin condensation. Among other things, this method inhibits the Dieckmann condensation[605] (**0-111**), which otherwise competes with the acyloin condensation when a five-, six-, or seven-membered ring can be closed (note that the ring formed by a Dieckmann condensation is always one carbon atom smaller than that formed by an acyloin condensation of the same substrate). The Me_3SiCl method is especially good for the closing of four-membered rings.[606]

The mechanism is not known with certainty, but it is usually presumed that the diketone RCOCOR is an intermediate,[607] since small amounts of it are usually isolated as side products, and when it is resistant to reduction (e.g., *t*-Bu—CO—CO—*t*-Bu), it is the major product. A possible sequence (analogous to that of **9-63**) is



In order to account for the ready formation of large rings, which means that the two ends of the chain must approach each other even though this is conformationally unfavorable for long chains, it may be postulated that the two ends become attached to nearby sites on the surface of the sodium.

The acyloin condensation was used in an ingenious manner to prepare the first reported catenane (see p. 80). The catenane (**41**) was prepared by a statistical synthesis (p. 81) in the following manner: An acyloin condensation was performed on the diethyl ester of the C_{34} dicarboxylic acid (tetratriacontandioic acid) to give the cyclic acyloin **39.** This was reduced by a Clemmensen reduction with DCl in D_2O instead of HCl in H_2O, thus producing a C_{34} cycloalkane containing deuterium (**40**):[608]

[604] Schräpler and Rühlmann, *Chem. Ber.* **97,** 1383 (1964). For a review of the Me_3SiCl method, see Rühlmann, *Synthesis* 236–253 (1971).

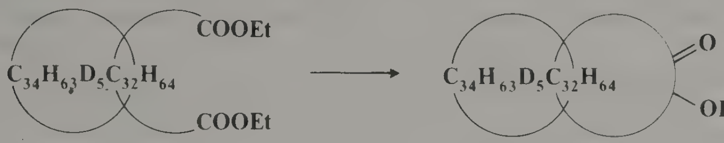
[605] Bloomfield, *Tetrahedron Lett.* 591 (1968).

[606] Bloomfield, *Tetrahedron Lett.* 587 (1968); Gream and Worthley, *Tetrahedron Lett.* 3319 (1968); Wynberg, Reiffers, and Strating, *Recl. Trav. Chim. Pays-Bas* **89,** 982 (1970); Bloomfield, Martin, and Nelke, *J. Chem. Soc., Chem. Commun.* 96 (1972). See also Delbaere and Whitham, *J. Chem. Soc., Perkin Trans. 1* 879 (1974).

[607] Another mechanism, involving addition of the ketyl to another molecule of ester (rather than a dimerization of two ketyl radicals), in which a diketone is not an intermediate, has been proposed: Bloomfield, Owsley, Ainsworth, and Robertson, *J. Org. Chem.* **40,** 393 (1975).

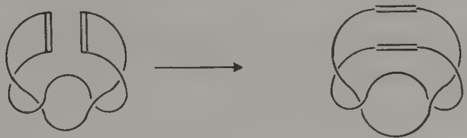
[608] This work was done by Wasserman, *J. Am. Chem. Soc.* **82,** 4433 (1960). For other statistical syntheses, see Agam and Zilkha, *J. Am. Chem. Soc.* **98,** 5214 (1976); Schill, Schweickert, Fritz, and Vetter, *Angew. Chem. Int. Ed. Engl.* **22,** 889 (1983) [*Angew. Chem.* **95,** 909].

40 contained about five atoms of deuterium per molecule. The reaction was then repeated, this time *in a* 1 : 1 *mixture of xylene and* **40** *as solvent.* It was hoped that in some of the molecules of ester would be threaded through **40** before they closed:



41

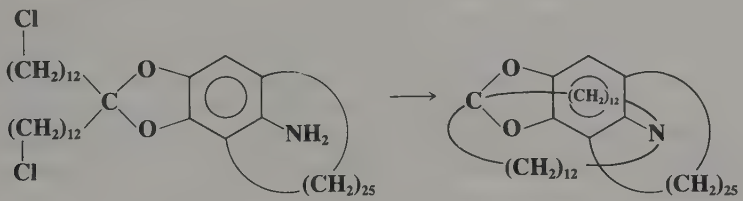
The first thing that was done with the product was to remove by chromatography the **40** that had been used as the solvent. The remaining material still contained deuterium, as determined by ir spectra, even with all the **40** gone. This was strong evidence that the material consisted not only of **39,** but also of **41.** As further evidence, the mixture was oxidized to open up the acyloin rings (reaction **9-7**). From the oxidation product was isolated the C_{34} diacid (as expected) *containing no deuterium,* and **40,** containing deuterium. The total yield of **41** and **39** was 5 to 20%, but the percentage of **41** in this mixture was only about 1 to 2%.[608] This synthesis of a catenane produced only a small yield and relied on chance, on the probability that a diester molecule would be threaded through **40** before it closed. Another statistical synthesis makes use of the olefin metathesis reaction (**8-41**).[609] When this is applied to large-ring dienes, some of the molecules become twisted (**42**)



42 **43**

before the reaction takes place. When such a molecule reacts, the product is the catenane **43.** Mass spectral evidence shows that some catenanes are indeed formed.

A catenane has also been prepared by a *directed* synthesis.[610] The key step here was formation of a tertiary amine by **0-45.**



44 **45**

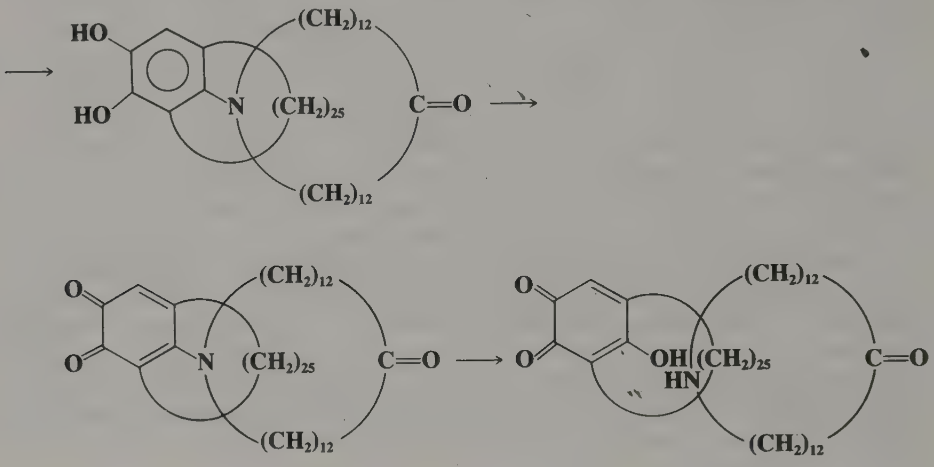
---

[609] Wolovsky, *J. Am. Chem. Soc.* **92,** 2132 (1970); Ben-Efraim, Batich, and Wasserman, *J. Am. Chem. Soc.* **92,** 2133 (1970).

Ber.* **98,** 2906 (1965), **99,** 2689 (1966), **100,** 2021 (1967); Logemann, Rissler, Schill, and Fritz, *Chem. Ber.* **114,** 2245 (1981). For the preparation of [3]catenanes by a similar approach, see Schill and Zürcher, *Chem. Ber.* **110,** 2046 (1977); Schill, Rissler, Fritz, and Vetter, *Angew. Chem. Int. Ed. Engl.* **20,** 187 (1981) [*Angew. Chem.* **93,** 197]. See also Dietrich-Bucheker, Sauvage, and Kintzinger, *Tetrahedron Lett.* **24,** 5095 (1983); Dietrich-Bucheker, Sauvage, and Kern, *J. Am. Chem. Soc.* **106,** 3043 (1984).

Sterically, one of the halide groups of **44** is above the plane, and the other below it, so that ring closure must occur *through* the 28-membered ring. After **45** was formed, the acetal was cleaved (**0-7**). It was then necessary to cleave the remaining bond holding the two rings together, i.e., the C—N bond. This was done by oxidation to the *ortho*-quinone (**9-4**), which converted the amine function to an enamine, which was hydrolyzable (**6-2**) with acid to give the catenane (**46**):

45



46

The original large ring (of **44**) was closed by a Thorpe–Ziegler reaction (**6-48**) after an attempted acyloin condensation proved unsuccessful.

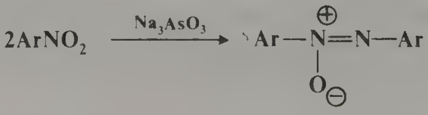
9-67 Reduction of Nitro to Azoxy Compounds



$$2ArNO_2 \xrightarrow{Na_3AsO_3} Ar-\overset{\oplus}{\underset{\underset{O^{\ominus}}{|}}{N}}=N-Ar$$

Azoxy compounds can be obtained from nitro compounds with certain reducing agents, notably sodium arsenite, sodium ethoxide, NaTeH,[611] lead,[612] $NaBH_4$-$CoCl_2$,[613] and glucose.[614] The most probable mechanism with most reagents is that one molecule of nitro compound is reduced to a nitroso compound and another to a hydroxylamine (**9-50**), and these combine (**2-53**). The combination step is rapid compared to the reduction process.[615] Nitroso compounds can be reduced to azoxy compounds with triethyl phosphite or triphenylphosphine[616] or with an alkaline aqueous solution of an alcohol.[617]

9-68 Reduction of Nitro to Azo Compounds

$$2ArNO_2 \xrightarrow{LiAlH_4} Ar{-}N{=}N{-}Ar$$

Nitro compounds can be reduced to azo compounds with various reducing agents, of which $LiAlH_4$ and zinc and alkali are the most common.[618] With many of these reagents, slight differences in conditions may lead either to the azo or azoxy (reaction **9-67**) compound. Analogously to **9-67,** this reaction may be looked on as a combination of $ArN{=}O$ and $ArNH_2$ (**2-52**). However, when the reducing agent was $HOCH_2CH_2ONa$[619] or $NaBH_4$,[620] it was shown that azoxy compounds were intermediates. Nitroso compounds can be reduced to azo compounds with $LiAlH_4$.

OS **III,** 103.

9-69 Reduction of Nitro to Hydrazo Compounds

$$2ArNO_2 \xrightarrow[NaOH]{Zn} Ar{-}NH{-}NH{-}Ar$$

Nitro compounds can be reduced to hydrazo compounds with zinc and sodium hydroxide, or electrolytically, or with $LiAlH_4$ mixed with a metal chloride such as $TiCl_4$ or VCl_3.[621] The reduction has also been accomplished with hydrazine hydrate and Raney nickel.[622]

Reactions in Which an Organic Substrate is Both Oxidized and Reduced

Some reactions that belong in this category have been considered in earlier chapters. Among these are the Tollens' condensation (**6-46**), the benzil–benzilic acid rearrangement (**8-7**), and the Wallach rearrangement (**8-47**).

9-70 The Cannizzaro Reaction

$$2ArCHO \xrightarrow{NaOH} ArCH_2OH + ArCOO^-$$

Aromatic aldehydes, and aliphatic ones with no α-hydrogen, give the *Cannizzaro reaction* when treated with NaOH or other strong bases.[623] In this reaction one molecule of aldehyde oxidizes another to the acid and is itself reduced to the primary alcohol. Aldehydes with an α-hydrogen do not give the reaction, because when these compounds are treated with base the aldol condensation (**6-40**) is much faster.[624] Normally, the best yield of acid or alcohol is 50% each, but this can be altered in certain cases. When the aldehyde contains a hydroxide group in the ring, excess base oxidizes the alcohol formed and the acid can be prepared in high yield (the OH^- is reduced to H_2). On the other hand, high yields of alcohol can be obtained from almost any aldehyde by running the reaction in the presence of formaldehyde. In this case the formaldehyde reduces the aldehyde to alcohol and is itself oxidized to formic acid. In such a case, where the oxidant aldehyde differs from the reductant aldehyde, the reaction is called the *crossed Cannizzaro reaction*. The Tollens' condensation (**6-46**) includes a crossed Cannizzaro reaction as its last step. α-Keto aldehydes give internal Cannizzaro reactions:

---

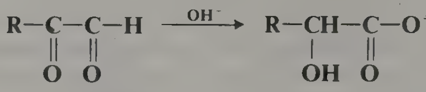
[623] For a review, see Geissman, *Org. React.* **2,** 94–113 (1944).

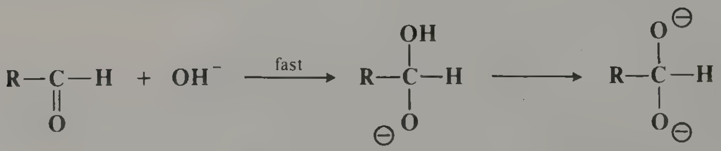
[624] An exception is cyclopropanecarboxaldehyde: van der Maeden, Steinberg, and de Boer, *Recl. Trav. Chim. Pays-Bas* **91,** 221 (1972).



$$R{-}\underset{\|}{\overset{}{C}}{-}\underset{\|}{C}{-}H \xrightarrow{OH^-} R{-}CH(OH){-}C(=O){-}O^-$$

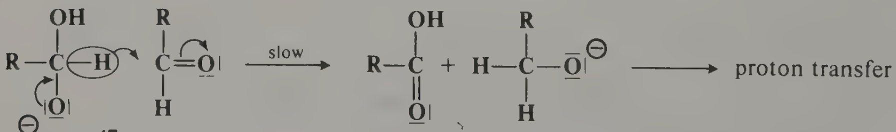
This product is also obtained on alkaline hydrolysis of compounds of the formula $RCOCHX_2$. Similar reactions have been performed on α-keto acetals[625] and γ-keto aldehydes.

The mechanism[626] of the Cannizzaro reaction[627] involves a hydride shift (an example of mechanism type 2, p. 1050). First OH^- adds to the C=O to give **47**, which may lose a proton in the basic solution to give the diion **48**.

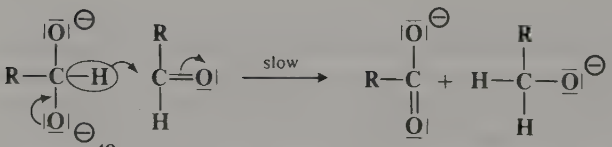


47 **48**

The strong electron-donating character of O^- greatly facilitates the ability of the aldehydic hydrogen to leave with its electron pair. Of course, this effect is even stronger in **48**. When the hydride does leave, it attacks another molecule of aldehyde. The hydride may come from **47** or **48**:



47



48

If the hydride ion comes from **47**, the final step is a rapid proton transfer. In the other case, the acid salt is formed directly, and the alkoxide ion acquires a proton from the solvent. Evidence for this mechanism is: (1) The reaction may be first order in base and second order in substrate (thus going through **47**) or, at higher base concentrations, second order in each (going through **48**); and

[625] Thompson, *J. Org. Chem.* **32,** 3947 (1967).

[626] For evidence that an SET pathway may intervene, see Ashby, Coleman, and Gamasa, *Tetrahedron Lett.* **24,** 851 (1983).

[627] See for example, Swain, Powell, Sheppard, and Morgan, *J. Am. Chem. Soc.* **101,** 3576 (1979).

(2) when the reaction was run in D_2O, the recovered alcohol contained no α-deuterium,[628] indicating that the hydrogen comes from another mole of aldehyde and not from the medium.[629]

OS **I,** 276; **II,** 590; **III,** 538; **IV,** 110.

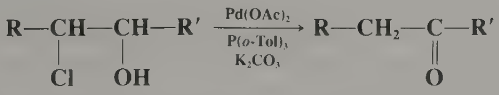
9-71 The Tishchenko Reaction

$$2\text{RCHO} \xrightarrow{\text{Al(OEt)}_3} \text{RCOOCH}_2\text{R}$$

When aldehydes, with or without α-hydrogen, are treated with aluminum ethoxide, one molecule is oxidized and another reduced, as in **9-70,** but here they are found as the ester. The process is called the *Tishchenko reaction.* Crossed Tishchenko reactions are also possible. With more strongly basic alkoxides, such as magnesium or sodium alkoxides, aldehydes with an α-hydrogen give the aldol condensation. Like **9-70,** this reaction has a mechanism that involves hydride transfer.[630] The Tishchenko reaction can also be catalyzed by ruthenium complexes,[631] by lithium tungsten dioxide $LiWO_2$,[632] by boric acid,[633] and, for aromatic aldehydes, by disodium tetracarbonylferrate $Na_2Fe(CO)_4$.[634]

OS **I,** 104.

9-72 Conversion of Halohydrins to Ketones



$$\underset{\text{Cl}}{\underset{|}{\text{R—CH}}}\text{—}\underset{\text{OH}}{\underset{|}{\text{CH}}}\text{—R}' \xrightarrow[\text{P}(o\text{-Tol})_3,\ \text{K}_2\text{CO}_3]{\text{Pd(OAc)}_2} \text{R—CH}_2\text{—}\underset{\text{O}}{\underset{\|}{\text{C}}}\text{—R}'$$

Halohydrins are converted to ketones by treatment with palladium acetate and tri-*o*-tolylphosphine in the presence of K_2CO_3.[635] One carbon atom of the substrate is oxidized; the other reduced.

9-73 The Willgerodt Reaction

$$\text{ArCOCH}_3 \xrightarrow{(\text{NH}_4)_2\text{S}_x} \text{ArCH}_2\text{CONH}_2 + \text{ArCH}_2\text{COO}^- \ \text{NH}_4^+$$

In the *Willgerodt reaction* a straight- or branched-chain aryl alkyl ketone is converted to the amide and/or the ammonium salt of the acid by heating with ammonium polysulfide.[636] The carbonyl group of the product is always at the end of the chain. Thus $ArCOCH_2CH_3$ gives the amide and the salt of $ArCH_2CH_2COOH$, and $ArCOCH_2CH_2CH_3$ gives derivatives of $ArCH_2CH_2CH_2COOH$. However, yields sharply decrease with increasing length of chain. The reaction has also been carried out on vinyl and ethynyl aromatic compounds and on aliphatic ketones, but yields are usually lower in these cases. The use of sulfur and a dry primary or secondary amine (or ammonia) as the reagent is called the *Kindler modification* of the Willgerodt reaction.[637] The product in this case is $Ar(CH_2)_nCSNR_2$, which can be hydrolyzed to the acid.[638] Particularly good results are obtained with morpholine as the amine. For volatile amines the HCl salts can be used instead, with NaOAc in DMF at 100°C.[639]

[629] When the reaction was run at 100°C in MeOH-H_2O, isotopic exchange was observed (the product from PhCDO had lost some of its deuterium): Swain, Powell, Lynch, Alpha, and Dunlap, *J. Am. Chem. Soc.* **101,** 3584 (1979). Side reactions were postulated to account for the loss of deuterium. See however, Chung, *J. Chem. Soc., Chem. Commun.* 480 (1982).

[630] See, for example, Zakharkin and Sorokina, *J. Gen. Chem. USSR* **37,** 525 (1967); Saegusa, Ueshima, and Kitagawa, *Bull. Chem. Soc. Jpn.* **42,** 248 (1969); Ogata, Kawasaki, and Kishi, *Tetrahedron* **23,** 825 (1967); Ogata and Kishi, *Tetrahedron* **25,** 929 (1969).

[631] Ito, Horino, Koshiro, and Yamamoto, *Bull. Chem. Soc. Jpn.* **55,** 504 (1982).

[632] Villacorta and San Filippo, *J. Org. Chem.* **48,** 1151 (1983).

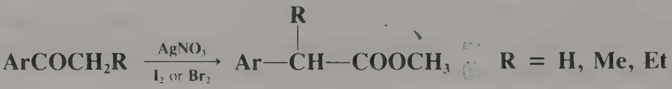
[633] Stapp, *J. Org. Chem.* **38,** 1433 (1973).

[634] Yamashita, Watanabe, Mitsudo, and Takegami, *Bull. Chem. Soc. Jpn.* **49,** 3597 (1976).

[635] Tsuji, Nagashima, and Sato, *Tetrahedron Lett.* **23,** 3085 (1982). For a different reagent, see Momose and Yamada, *Tetrahedron Lett.* **24,** 2669 (1983).

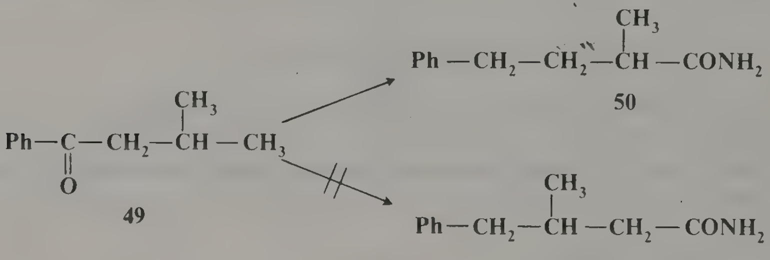
[636] For reviews, see Brown, *Synthesis* 358–375 (1975); Wegler, Kühle, and Schäfer, *Newer Methods Prep. Org. Chem.* **3,** 1–51 (1964).

Alkyl aryl ketones can be converted to arylacetic acid derivatives in an entirely different manner. The reaction consists of treatment of the substrate with silver nitrate and I_2 or Br_2,[640] or with thallium nitrate, MeOH, and trimethyl orthoformate adsorbed on K-10, an acidic clay.[641]



$$ArCOCH_2R \xrightarrow[I_2 \text{ or } Br_2]{AgNO_3} Ar{-}\overset{\displaystyle R}{\overset{|}{C}H}{-}COOCH_3 \qquad R = H, Me, Et$$

The mechanism of the Willgerodt reaction is not completely known, but some conceivable mechanisms can be excluded. Thus, one might suppose that the alkyl group becomes completely detached from the ring and then attacks it with its other end. However, this possibility is ruled out by experiments such as the following: When isobutyl phenyl ketone (**49**) is subjected to the Willgerodt reaction, the product is **50**, not **51**, which would arise if the end carbon of the ketone became bonded to the ring in the product:[642]



49 **50** **51**

This also excludes a cyclic-intermediate mechanism similar to that of the Claisen rearrangement (**8-37**). Another important fact is that the reaction is successful for singly branched side chains, such as **49**, but not for doubly branched side chains, as in $PhCOCMe_3$.[642] Still another piece of evidence is that compounds oxygenated along the chain give the same products; thus $PhCOCH_2CH_3$, $PhCH_2COMe$, and $PhCH_2CH_2CHO$ all give $PhCH_2CH_2CONH_2$.[643] All these facts point to a mechanism consisting of consecutive oxidations and reductions along the chain. Just what form these take is not certain, though a number of theories have been proposed. Initial reduction to the hydrocarbon may be ruled out, since alkylbenzenes do not give the reaction. In certain cases imines[644] or enamines[645] have been isolated from primary and secondary amines, respectively, and these have been shown to give the normal products, leading to the suggestion that they may be reaction intermediates.

Appendix A
THE LITERATURE OF ORGANIC CHEMISTRY

All discoveries made in the laboratory must be published somewhere if the information is to be made generally available. A new experimental result that is not published might as well not have been obtained, insofar as it benefits the entire chemical world. The total body of chemical knowledge (called *the literature*) is located on the combined shelves of all the chemical libraries in the world. Anyone who wishes to learn whether the answer to any chemical question is known and, if so, what the answer is, has only to turn to the contents of these shelves. Indeed the very expressions "is known," "has been done," etc., really mean "has been published." To the uninitiated, the contents of the shelves may appear formidably large, but fortunately the process of extracting information from the literature of organic chemistry is usually not difficult. In this appendix we shall examine the literature of organic chemistry, confining our attention chiefly to the results of laboratory work, rather than those of industrial organic chemistry.[1] The literature can be divided into two broad categories: *primary sources* and *secondary sources.* A primary source publishes the original results of laboratory investigations. Books, indexes, and other publications which cover material that has previously been published in primary sources are called secondary sources. It is because of the excellence of the secondary sources in organic chemistry (especially *Chemical Abstracts* and Beilstein) that literature searching is comparatively not difficult. The two chief kinds of primary source are journals and patents. There are several types of secondary source.

PRIMARY SOURCES

Journals

For more than a hundred years, nearly all new work in organic chemistry (except for that disclosed in patents) has been published in journals. There are thousands of journals that publish chemical papers, in many countries and in many languages. Some print papers covering all fields of science; some are restricted to chemistry; some to organic chemistry; and there are a few that are still more specialized. Fortunately for the sanity of organic chemists, the vast majority of important papers in "pure" organic chemistry (as opposed to "applied") are published in relatively few journals, perhaps 50 or fewer. Of course, this is still a large number, especially since some are published weekly and some semimonthly, but it is considerably smaller than the total number of journals (perhaps as high as 10,000) that publish chemical articles.

---

[1] For books on the chemical literature, see Mellon, "Chemical Publications," 5th ed., McGraw-Hill, New York, 1982; Wolman, "Chemical Information," Wiley, New York, 1983; Skolnik, "The Literature Matrix of Chemistry," Wiley, New York, 1982; Maizell, "How to Find Chemical Information," Wiley, New York, 1979; Antony, "Guide to Basic Information Sources in Chemistry," Jeffrey Norton Publishers, New York, 1979; Bottle, "Use of the Chemical Literature," Butterworths, London, 1979; Woodburn, "Using the Chemical Literature," Marcel Dekker, New York, 1974; Crane, Patterson, and Marr, "A Guide to the Literature of Chemistry," 2d ed., Wiley, New York, 1957. For a three-part article on the literature of organic chemistry, see Hancock, *J. Chem. Educ.* **45,** 193–199, 260–266, 336–339 (1968).

In addition to ordinary papers, there are two other types of publications in which original work is reported: *notes* and *communications*. A note is a brief paper, usually without a summary (most papers are published with summaries or abstracts prepared by the author). Otherwise, a note is similar to a paper. In recent years, the use of notes has been declining and some journals no longer publish them. Communications (also called *letters*) are also brief and usually without summaries (though some journals now publish summaries along with their communications, a welcome trend). However, communications differ from notes and papers in three respects:

1. They are brief, not because the work is of small scope, but because they are condensed. Usually they include only the most important experimental details or none at all.

2. They are of immediate significance. Journals that publish communications make every effort to have them appear as soon as possible after they are received. Some papers and notes are of great importance, and some are of lesser importance, but all communications are supposed to be of high importance.

3. Communications are preliminary reports, and the material in them may be republished as papers at a later date, in contrast to the material in papers and notes, which cannot be republished.

Although papers (we use the term in its general sense, to cover notes and communications also) are published in many languages, the English-speaking chemist is in a fairly fortunate position. At present well over half of the important papers in organic chemistry are published in English. Not only are American, British, and British Commonwealth journals published almost entirely in English, but so are many others around the world. There are predominantly English-language journals published in Japan, Italy, Czechoslovakia, Sweden, the Netherlands, Israel, and other countries. Most of the articles published in other languages have summaries printed in English also. Furthermore, the second most important language (in terms of the number of organic chemical papers published) is Russian, and most of these papers are available in English translation, though in most cases, six months to a year later. A considerable number of important papers are published in German and French; these are generally not available in translation, so that the organic chemist should have at least a reading knowledge of these languages. An exception is the journal *Angewandte Chemie*, which in 1962 became available in English under the title *Angewandte Chemie International Edition in English*. Of course, a reading knowledge of French and German (especially German) is even more important for the older literature. Before about 1920, more than half of the important chemical papers were in these languages. It must be realized that the original literature is never obsolete. Secondary sources become superseded or outdated, but nineteenth century journals may be found in most chemical libraries and are still consulted. Table 1 presents a list of the more important current journals that publish original papers[2] and communications in organic chemistry.[3] Some of them also publish review articles, book reviews, and other material. Changes in journal title are not infrequent; footnotes to the table indicate some of the more important, but some of the other journals listed have also undergone title changes.

The primary literature has grown so much in recent years that attempts have been made to reduce the volume. One such attempt is the *Journal of Chemical Research*, begun in 1977. The main section of this journal, called the ''Synopses,'' publishes synopses, which are essentially long abstracts, with references. The full texts of most of the papers are published only in microfiche and miniprint versions. For some years, the American Chemical Society journals, including *J. Am. Chem. Soc.* and *J. Org. Chem.*, have provided supplementary material for some of their papers. This material is available from the Distribution Office at the ACS Washington office, either on microfiche or as a photocopy. These practices have not yet succeeded in substantially reducing the total volume of the world's primary chemical literature.

---

[2] In Table 1 notes are counted as papers.

[3] See Mellon and Crane, Patterson, and Marr, Ref. 1, for longer lists of journals, including discontinued ones.

TABLE 1 A list of the more important current journals that publish original papers in organic chemistry, listed in alphabetical order of *Chemical Abstracts* abbreviations, which are indicated in boldface.

Also indicated are the principal languages (E = English, G = German, F = French, R = Russian), the number of issues per year as of 1984 (exclusive of issues devoted entirely to indexes), and whether the journal primarily publishes papers (including in some cases notes) (P) or communications (C)

Patents

In many countries, including the United States, it is possible to patent a new compound or a new method for making a known compound (either laboratory or industrial procedures), as long as the compounds are useful. It comes as a surprise to many to learn that a substantial proportion of the patents granted (on the order of 20 to 30%) are chemical patents. Chemical patents are part of the chemical literature, and both U.S. and foreign patents are regularly abstracted by *Chemical Abstracts*. In addition to learning about the contents of patents from this source, chemists may consult the *Official Gazette* of the U.S. Patent Office, which, published weekly and available in most

[11] Before 1978 this journal was called **Roczniki Chemii**.

[12] *Pure Appl. Chem.* publishes IUPAC reports and lectures given at IUPAC meetings.

[13] Previous to 1980 this journal was called **Recueil** des **Trav**aux **Chim**iques des **Pays-Bas.**

TABLE 2 Journals from Table 1 available in English translation
The numbers are keyed to those of Table 1: The year of first translation is given in parentheses

2. Angewandte Chemie, International Edition in English (1962)
17. Doklady Chemistry (English Translation) (1956)
24. Bulletin of the Academy of Sciences of the USSR, Division of Chemical Science (1952)
55. Journal of General Chemistry of the USSR (1949)
56. Journal of Organic Chemistry USSR (1965)

libraries, lists titles of all patents issued that week. Bound volumes of all U.S. patents are kept in a number of large libraries, including the New York Public Library, which also has an extensive collection of foreign patents. Photocopies of any U.S. patent and most foreign patents can be obtained at low cost from the U.S. Patent Office, Washington, D.C., 20231. In addition, *Chemical Abstracts* lists, in the introduction to the first issue of each volume, instructions for obtaining patents from 28 countries.

Although patents are often very useful to the laboratory chemist, and no literature search is complete that neglects relevant patents, as a rule they are not as reliable as papers. There are two reasons for this:

1. It is in the interest of the inventor to claim as much as possible. Therefore he or she may, for example, actually have carried out a reaction with ethanol and with 1-propanol, but will claim all primary alcohols, and perhaps even secondary and tertiary alcohols, glycols, and phenols. An investigator repeating the reaction on an alcohol that the inventor did not use may find that the reaction gives no yield at all. In general, it is safest to duplicate the *actual examples* given, of which most chemical patents contain one or more.

2. Although legally a patent gives an inventor a monopoly, any alleged infringements must be protected in court, and this may cost a good deal of money. Therefore some patents are written so that certain essential details are concealed or entirely omitted. This practice is not exactly cricket, because a patent is supposed to be a full disclosure, but patent attorneys are generally skilled in the art of writing patents, and procedures given are not always sufficient to duplicate the results.

Fortunately, the above statements do not apply to all chemical patents: many make full disclosures and claim only what was actually done. It must also be pointed out that it is not always possible to duplicate the work reported in *every* paper in a journal. In general, however, the laboratory chemist must be more wary of patents than of papers.

SECONDARY SOURCES

Journal articles and patents contain virtually all of the original work in organic chemistry. However, if this were all—if there were no indexes, abstracts, review articles, and other secondary sources—the literature would be unusable, because it is so vast that no one could hope to find anything in particular. Fortunately, the secondary sources are excellent. There are various kinds and the categories tend to merge. Our classification is somewhat arbitrary.

Listings of Titles

The profusion of original papers is so great that publications that merely list the titles of current papers find much use. Such lists are primarily methods of alerting the chemist to useful papers published in journals that he or she does not normally read. There are two ''title'' publications covering the whole of chemistry. One of these, *Current Contents Physical and Chemical Sciences*,[14] which began in 1967 and appears weekly, contains the contents pages of all issues of about 750 journals in chemistry, physics, mathematics, and allied sciences. Each issue contains an author index, which, however, lists only the first-named author of each paper. The author's address is also given, so that one may write for reprints. The other ''title'' publication is *Chemical Titles*, begun in 1961, which is published by Chemical Abstracts Service and is produced by a computer. This biweekly publication lists, in English, all titles from more than 700 journals, all in the field of chemistry. The most useful aspect of this publication is the way the titles are given. They are listed in alphabetical order of *every word in the title*, except for such words as ''the,'' ''of,'' ''investigation,'' ''synthesis,'' etc. (each issue contains a list of words prevented from indexing). This means that a title containing seven significant words is listed seven times. Furthermore, at each listing are given the words that immediately precede and follow the alphabetically listed word (called the *keyword*). For example, two short portions of the issue of January 9, 1984, are shown in Fig. 1. Note that a paper entitled ''Reactions of Cyclohexenyl Halides with Tributylstannane. Stereoelectronic Effects on SH2 Reactions at Halogen'' is listed under *cyclohexenyl* and under *stereoelectronic*. It is also listed under *hexenyl, halides, butylstannane, stannane*, and *halogen*, making seven listings in all. Certain words (e.g., cyclohexenyl, tributylstannane) are broken into two or more parts so that additional listings may be obtained. The = sign indicates the end of a title. The value of the index is increased by a ''wraparound'' feature. If the keyword ends (or begins) the title, what would otherwise be empty space is filled by as many words from the *beginning* (or the end) of the title as will fit. For example, at the entry under the keyword *steroidal*, in the above example, appears the title ''Preparation and Cleavage Reactions of some Steroidal Epoxides.'' There is room in front of the keyword only for *cleavage reactions of some*. The remainder of the title, *Preparation and* is therefore placed at the end of the line. Where the wraparound feature is used but the entire title still will not fit, the symbol + is given. This type of listing is called a *Keyword-in-Context* (KWIC) index and is obviously highly useful. For example, anyone interested in oxaziridine or any of its derivatives has only to look it up in *Chemical Titles* to find at once all the papers (in that issue) in which this word appears in the title (the Jan. 9, 1984 issue contains three such listings). The code number given at each entry refers to the source. For example, for the title on the stereoelectronic effects, mentioned above, the number is AJCHAS-0036-2123. The symbols have the following meanings: AJCHAS means *Aust. J. Chem.*, 0036 is the volume number (36), and 2123 is the page number. In the second section of each issue (called the Bibliography) the complete titles and the authors are given. Incidentally, this Bibliography duplicates, for the journals that they both cover, the listings in *Current Contents Physical and Chemical Sciences*, since the complete contents of journals are given in order of page number. Each issue of *Chemical Titles* has an author index, covering all authors, not just the first author. Addresses are not given.

Abstracts

Listings of titles are valuable, as far as they go, but they do not tell what is in the paper, beyond the implications carried by the titles. From the earliest days of organic chemistry, abstracts of papers have been widely available, often as sections of journals whose principal interests lay elsewhere.[15] At the present time there are only two publications entirely devoted to abstracts covering

---

[14] Title pages of organic chemistry journals are also carried by *Current Contents Life Sciences*, which is a similar publication covering biochemistry and medicine.

[15] For example, *Chem. Ind.* (*London*) and *Synthesis* publish abstracts of papers that appear in other journals. In the past, journals such as *J. Am. Chem. Soc.*, *J. Chem. Soc.*, and *Ber.* also did so.

Figure 1 Two short portions from the Jan. 9, 1984 issue of *Chemical Titles*

the whole field of chemistry. One of these, *Referativnyi Zhurnal, Khimiya*, which began in 1953, is published in Russian and is chiefly of interest to Russian-speaking chemists. The other is *Chemical Abstracts*. This publication, which appears weekly, prints abstracts in English of virtually every paper containing original work in pure or applied chemistry published anywhere in the world. Approximately 12,000 journals are covered, in many languages. In addition, *CA* publishes abstracts of every patent of chemical interest from 18 countries, including the United States, United Kingdom, Japan, France, and the Soviet Union, as well as many patents from eight additional countries. *CA* lists and indexes but does not abstract review articles and books. The abstracts currently appear in 80 sections, of which sections 21 to 34 are devoted to organic chemistry, under such headings as Alicyclic Compounds, Alkaloids, Physical Organic Chemistry, Heterocyclic Compounds (One Hetero Atom), etc. Each abstract of a paper begins with a heading that gives (1) the abstract number;[16] (2) the title of the paper; (3) the authors names as fully as given in the paper; (4) the authors' address; (5) the abbreviated name of the journal (see Table 1);[17] (6) the year, volume, issue, and page numbers; and (7) the language of the paper. In earlier years *CA* gave the language only if it differed from the language of the journal title. Abstracts of patents begin with the title, inventor and company (if any), patent number, patent class number, date patent issued, country of priority, patent application number, date patent applied for, and number of pages in the patent. The body of the abstract is a concise summary of the information in the paper. For many common journals, e.g., *J. Am. Chem. Soc.*, *J. Org. Chem.*, *J. Chem. Soc.*, the author's summary (if there is one) is used in *CA* as it appears in the original paper, with perhaps some editing and additional information. Each issue of *CA* contains an author index, a patent index, and a keyword index, somewhat similar to the KWIC index of *Chemical Titles* (p. 1127). However, the words in the *CA* keyword index are taken from the titles *and* the texts or contexts of the abstracts. The keywords are not given in exact context, as in *Chemical Titles*, but a few extra words are given for each entry. The patent index lists all patents in order of number. The same compound or method is often patented in several countries. *CA* abstracts only the first patent, but does list the patent numbers of the duplicated patents in the patent index along with all previous patent numbers that correspond to it. Before 1981 there were separate Patent Number Indexes and Patent Concordances (the latter began in 1963).

At the end of each section of *CA* there is a list of cross-references to related papers in other sections.

Chemical Abstracts is, of course, highly useful for "current awareness"; it allows one to read, in one place, abstracts of virtually all new work in chemistry, though its large size puts a limit on the extent of this type of usefulness.[18] *CA* is even more useful as a repository of chemical information, a place for finding out what was done in the past. This value stems from the excellent indexes, which enable the chemist in most cases to ascertain quickly where information is located. From the time of its founding in 1907 until 1961, *CA* published annual indexes. Since 1962 there are two volumes published each year, and a separate index is issued for each volume. For each volume there is an index of subjects, authors, formulas, and patent numbers. Beginning in 1972 the subject index has been issued in two parts, a chemical substance index and a general subject index, which includes all entries that are not the names of single chemical substances. However, the indexes to each volume become essentially superseded as collective indexes are issued. The first collective indexes are ten-year (decennial) indexes, but the volume of information has made five-year indexes necessary since 1956. Collective indexes so far published are shown at the top of p. 1129. Thus a user of the indexes at this time would consult the collective indexes through 1981 and the semiannual indexes thereafter.

Beginning with the eighth collective index period, *CA* has published an *Index Guide*. This publication gives structural formulas and/or alternate names for thousands of compounds, as well as many other cross-references. It is designed to help the user efficiently and rapidly to find *CA* references to subjects of interest in the general subject, formula, and chemical substance indexes. Each collective index contains its own *Index Guide*. A new *Index Guide* is issued every 18 months.

Along with each index (annual, semiannual, or collective) appears an index of ring systems.

---

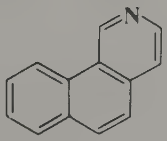
[16] Beginning in 1967. See p. 1129.

[17] These abbreviations are changed from time to time. Therefore the reader may notice inconsistencies.

[18] It is possible to subscribe to *CA Selects*, which provides copies of all abstracts within various narrow fields, such as organofluorine chemistry, organic reaction mechanisms, organic stereochemistry, etc.

Coll. index	Subject	Chemical substance	Author	Formula	Patent number
1	1907–1916		1907–1916		
2	1917–1926		1917–1926		1907–1936
3	1927–1936		1927–1936	1920–1946	
4	1937–1946		1937–1946		1937–1946
5	1947–1956		1947–1956	1947–1956	1947–1956
6	1957–1961		1957–1961	1957–1961	1957–1961
7	1962–1966		1962–1966	1962–1966	1962–1966
8	1967–1971		1967–1971	1967–1971	1967–1971
9	1972–1976	1972–1976	1972–1976	1972–1976	1972–1976
10	1977–1981	1977–1981	1977–1981	1977–1981	1977–1981

This valuable index enables the user to ascertain immediately if any ring system appears in the corresponding subject or chemical substance index and under what names. For example, someone wishing to determine whether any compounds containing this ring system



Benz(*h*)isoquinoline

are reported in the 1977–1981 collective index (even if he or she did not know the name) would locate, under the heading "3-ring systems," the listing **6, 6, 6** (since the compound has three rings of six members each), under which he or she would find the sublisting $C_5N—C_6—C_6$ (since one ring contains five carbons and a nitrogen while the others are all-carbon), under which is listed the name benz(*h*)isoquinoline, as well as the names of 34 other systems $C_5N—C_6—C_6$. A search of the subject index under these names will give all references to these ring systems that have appeared in *CA* from 1977 to 1981.

Before 1967, *CA* used a two-column page, with each column separately numbered. A row of letters from *a* to *h* appeared down the center of the page. These letters are for the guidance of the user. Thus an entry 7337*b* refers to the *b* section of column 7337. In early years superscript numbers, e.g., 4327^5, were used in a similar manner. In very early years these numbers were not printed on the page at all, though they are given in the decennial indexes, so that the user must mentally divide the page into nine parts. Beginning with 1967, abstracts are individually numbered and column numbers are discarded and replaced with page numbers. Therefore, beginning with 1967, index entries give abstract number rather than column number. The abstract numbers are followed by a letter that serves as a check character to prevent miscopying errors in computer handling. To use the *CA* subject, chemical substance, and formula indexes intelligently requires practice, and the student should become familiar with representative volumes of these indexes and with the introductory sections to them, as well as with the *Index Guides*.

In the *CA* formula indexes formulas are listed in order of (1) number of carbon atoms; (2) number of hydrogen atoms; (3) other elements in alphabetic order. Thus, all C_3 compounds are listed before any C_4 compound; all C_5H_7 compounds before any C_5H_8 compound; $C_7H_{11}Br$ before $C_7H_{11}N$; $C_9H_6N_4S$ before C_9H_6O, etc. Deuterium and tritium are represented by D and T and treated alphabetically, e.g., C_2H_5DO after C_2H_5Cl and before C_2H_5F or C_2H_6.

Since 1965, *CA* has assigned a Registry Number to each unique chemical substance. This is a number of the form [766-51-8] that remains invariant, no matter what names are used in the literature. More than 6 million numbers have already been assigned and thousands are added each week. Registry Numbers are primarily for computer use. All numbers so far have been published with the *CA* preferred names in a multivolume "Registry Handbook."

It is possible to use a computer to search *CA*, at least for recent years. All abstracts published since mid-1975 and some between 1967 and mid-1975 are available online in libraries that provide this service. All bibliographic citations, keyword index terms for the weekly *CA* issues, and general subject and chemical substance index entries since 1967 are currently available for retrieval and display. It is likely that this service will be expanded.

Although *CA* and *Referativnyi Zhurnal, Khimya* are currently the only chemical abstracting publications that cover the entire field of chemistry, there were a number of earlier abstracting publications now defunct. The most important of these are *Chemisches Zentralblatt* and *British Abstracts*. These publications are still valuable because they began before *CA* and can therefore supply abstracts for papers that appeared before 1907. Furthermore, even for papers published after 1907, *Zentralblatt* and *British Abstracts* are often more detailed. *Zentralblatt* was published, under various names, from 1830 to 1969.[19] *British Abstracts* was a separate publication from 1926 to 1953, but earlier abstracts from this source are available in the *Journal of the Chemical Society* from 1871 to 1925.

Another publication should also be mentioned here. *Current Abstracts of Chemistry and Index Chemicus*, begun in 1960, and appearing weekly, is largely devoted to printing structural formulas of all *new* compounds appearing in about 110 journals, with monthly formula, subject, author, and journal indexes, which are cumulated semiannually and annually.[20] As with *CA*, the material in this publication is available online via computer.

Beilstein

This publication is so important to organic chemistry that it deserves a section by itself. Beilstein's "Handbuch der organischen Chemie," usually referred to as *Beilstein*, lists all the known organic compounds reported in the literature during its period of coverage. For each compound are given: all names; the molecular formula; the structural formula; all methods of preparation (briefly, e.g., "by refluxing 1-butanol with NaBr and sulfuric acid"); physical constants such as melting point, refractive index, etc.; other physical properties; chemical properties including reactions; occurrence in nature (i.e., which species it was isolated from); biological properties, if any; derivatives with melting points; analytical data, and any other information that has been reported in the literature.[21] Equally important, for every piece of information, a reference is given to the original literature. Furthermore, the data in Beilstein have been critically evaluated. That is, all information is carefully researched and documented, and duplicate and erroneous results are eliminated. Some compounds are discussed in two or three lines and others require several pages. The value of such a work should be obvious.

[19] An "obituary" of *Zentralblatt* by Weiske, which gives its history and statistical data about its abstracts and indexes, was published in the April 1973 issue of *Chem. Ber.* (pp. I–XVI).

[20] For a discussion of this publication, see Garfield and Sim, *Pure Appl. Chem.* **49,** 1803 (1977).

[21] For a discussion of how data are processed for inclusion in Beilstein, see Luckenbach, Ecker, and Sunkel, *Angew. Chem. Int. Ed. Engl.* **20,** 841–849 (1981) [*Angew. Chem.* **93,** 876–885].

For many years a degree of training was required in order to use Beilstein, but the publication of a formula index now makes it fairly easy to use. The first three editions are obsolete. The fourth edition (*vierte Auflage*) covers the literature from its beginnings through 1909. This edition, called *das Hauptwerk*, consists of 27 volumes. The compounds are arranged in order of a system too elaborate to discuss fully here.[22] The compounds are divided into three divisions which are further subdivided into ''systems'':

Division	Volumes	System numbers
I. Acyclic compounds	1–4	1–449
II. Carbocyclic compounds	5–16	450–2359
III. Heterocyclic compounds	17–27	2360–4720

Das Hauptwerk is still the basis of Beilstein and has not been superseded. The later literature is covered by supplements that have been arranged to parallel *das Hauptwerk*. The same system is used, so that the compounds are treated in the same order. The first supplement (*erstes Ergänzungswerk*) covers 1910–1919; the second supplement (*zweites Ergänzungswerk*) covers 1920–1929; the third supplement (*drittes Ergänzungswerk*) covers 1930–1949; and the fourth supplement (*viertes Ergänzungswerk*) covers 1950–1959. Like *das Hauptwerk*, each supplement contains 27 volumes,[23] except that supplements 3 and 4 have been combined beginning with vol. 17, so that for vols. 17 to 27 the combined third and fourth supplement covers the years 1930–1959. Each supplement has been divided into volumes in the same way as *das Hauptwerk*, and, for example, compounds found in vol. 3, system number 199 of *das Hauptwerk* will also be found in vol. 3, system number 199 of each supplement.[24] To make cross-referencing even easier, each supplement gives, for each compound, the page numbers at which the same compound may be found in the earlier books. Thus, on page 545 of vol. 6 of the third supplement, under the listing phenetole are found the symbols (H 140; E I 80; E II 142) indicating that earlier information on phenetole is given on page 140 of vol. 6 of *das Hauptwerk*, on page 80 of the first, and page 142 of the second supplement. Furthermore, each page of the supplements contains, at the top center, the corresponding page numbers of *das Hauptwerk*. Since the same systematic order is followed in all five series, location of a compound in any one series gives its location in the other four. If a compound is found, for example, in vol. 5 of *das Hauptwerk*, one has but to note the page number and scan vol. 5 of each supplement until that number appears in the top center of the page (the same number may cover several pages). Of course, many compounds are found in only one, two, three, or four of the series, since no work may have been published on that compound during the period covered. Although a given volume of Beilstein is complete to the end of the time period specified, volumes in the second, third, and fourth supplements often contain material that goes considerably beyond that period. For example, p. 3962 of vol. 1 of the fourth supplement (1950–1959) contains references to papers published in 1968 and 1971.

---

[22] For descriptions of the Beilstein system and directions for using it, see Sunkel, Hoffmann, and Luckenbach, *J. Chem. Educ.* **58**, 982 (1981); Luckenbach, *CHEMTECH* 612–621 (1979). The Beilstein Institute has also published two English-language guides to the system. One, available free, is ''How to Use Beilstein,'' Beilstein Institute, Frankfurt/Main, 1979. The other is by Weissbach, ''A Manual for the Use of Beilstein's Handbuch der Organischen Chemie,'' Springer-Verlag, New York, 1976. An older work, which many students will find easier to follow, is by Huntress, ''A Brief Introduction to the Use of *Beilstein's Handbuch der Organischen Chemie*,'' 2d ed., Wiley, New York, 1938.

[23] In some cases, to keep the system parallel and to avoid books that are too big or too small, volumes are issued in two or more parts, and, in other cases, two volumes are bound as one.

[24] The fourth supplement (which will eventually cover vols. 1 to 16) is not yet complete as of this writing. The combined third and fourth supplements (vols. 17 to 27) are almost complete.

From *das Hauptwerk* to the fourth supplement, Beilstein is in German, though it is not difficult to read since most of the words are the names of compounds (a Beilstein German–English Dictionary, available free from the publisher, is in many libraries). The fifth supplement, covering 1960–1979, will be in English. Publication of the fifth supplement began in 1984, with the first part of vol. 17.

Volumes 28 and 29 of Beilstein are subject and formula indexes, respectively. The most recent complete edition of these volumes is part of the second supplement and covers not only *das Hauptwerk* but the first two supplements as well. For vol. 1 there is a cumulative subject and a cumulative formula index, which combine *das Hauptwerk* and all four supplements.[25] Similar index volumes, covering all four supplements, have been issued so far for vols. 2–3, 4, 5, 6, 17–18, 19, 20–22, and 23–25. Cumulative indexes for the remaining volumes will be issued as the volumes are completed. For English-speaking chemists (and probably for many German-speaking chemists) the formula indexes are more convenient. Of course, one must still know some German, because most formula listings contain the names of many isomers. If a compound is found only in *das Hauptwerk*, the index listing is merely the volume and page numbers, e.g., **1,** 501. Roman numbers are used to indicate the supplements, for example, **26,** 15, I 5, II 7. Thus the subject and formula indexes lead at once to locations in *das Hauptwerk* and the first two supplements (and, for vols. 1–6 and 17–25, for the third and fourth supplements as well). Locating the compound in the third and fourth supplements is then simple (if that volume has already appeared) by the page-number indication mentioned above. However, the most recent edition of vols. 28 and 29 obviously can contain only compounds that have appeared in the literature before 1930. In order to ascertain if a particular compound not listed in vol. 28 or 29 is listed in the third and/or fourth supplements, one can follow one of two procedures. For compounds that would be found in vols. 1–6 and 17–25 (and any later cumulative index volumes that have appeared), one can consult these index volumes. For compounds belonging elsewhere, each separately bound portion of each volume of the third and fourth supplements has its own subject and formula indexes. If one knows (from an approximate knowledge of the system) in which volume the compound is likely to be found, the searcher can turn to the indexes of that volume or (with a little extra labor) can look in all the indexes. The other procedure is to learn the system—which was done by most organic chemists before the appearance of the original formula index.[22] Even an approximate knowledge of the system often helps. The Beilstein formula indexes are constructed the same way as the *CA* indexes (p. 1129). Upon completion of the fourth supplement, complete cumulative subject and formula indexes will be issued for *das Hauptwerk* and all four supplements.

There is also a fourth division of Beilstein (systems 4721 to 4877) that covers natural products of uncertain structure: rubbers, sugars, etc. These are treated in vols. 30 and 31, which do not go beyond 1935 and which are covered in the collective indexes. These volumes will not be updated. All such compounds are now included in the regular Beilstein volumes.

Compendia and Tables of Information

In addition to Beilstein, there are many other reference works in organic chemistry that are essentially compilations of data. These books are very useful and often save the research worker a great deal of time. In this section we discuss some of the more important of such works.

---

[25] Most page number entries in the combined indexes contain a letter, e.g., $CHBr_2Cl$ 67f, II 33a, III 87d, IV, 81. These letters tell where on the page to find the compound and are useful because the names given in the index are not necessarily those used in the earlier series. The letter "a" means the compound is the first on its page, "b" is the second, etc. No letters are given for the fourth supplement.

1. Some years ago a work was announced that was to be the English equivalent of Beilstein: Elsevier's ''Encyclopedia of Organic Chemistry.'' Three volumes were published, in more than 15 parts: vol. 12, bicyclic compounds; vol. 13, tricyclic compounds; and vol. 14, tetra- and higher-cyclic compounds. These volumes cover many natural products, especially terpenes and steroids. Although the production of the earlier volumes in the series has now been abandoned, these volumes remain valuable.

2. The fifth edition of ''Heilbron's Dictionary of Organic Compounds,'' J. Buckingham, Ed., 7 vols., Chapman and Hall, London, 1982, contains brief listings of more than 150,000 organic compounds, giving names, structural formulas, physical properties, and derivatives, with references.[26] For many entries additional data concerning occurrence, biological activity, and toxicity hazard information are also given. The arrangement is alphabetical. The dictionary contains indexes of names, formulas, hetero atoms, and *CA* Registry Numbers. The first annual supplement was issued in 1983. A similar work, devoted to organometallic compounds, is ''Dictionary of Organometallic Compounds,'' 3 vols., published by Chapman and Hall in 1984.

3. A multivolume compendium of physical data is Landolt-Börnstein's ''Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik, und Technik,'' 6th ed., Springer-Verlag, Berlin, 1950–. This compendium, which is not yet complete, lists a great deal of data, some of which are of interest to organic chemists, e.g., indexes of refraction, heats of combustion, optical rotations, and spectral data. Literature references are given for all data.

4. ''The Handbook of Chemistry and Physics,'' CRC Press, Boca Raton, Florida (called the ''rubber handbook''), which is revised annually (64th ed., 1983–84), is a valuable repository of data quickly found. For organic chemists the most important table is ''Physical Constants of Organic Compounds, which lists names, formulas, color, solubilities, and physical properties of thousands of compounds. However, there are many other useful tables. A similar work is Lange's ''Handbook of Chemistry,'' 12th ed., McGraw-Hill, New York, 1979.

5. A list of most of the known natural compounds, e.g., terpenes, alkaloids, carbohydrates, to which structures have been assigned, along with structural formulas, melting points, optical rotations, and references, is provided in Devon and Scott, ''Handbook of Naturally Occurring Compounds,'' 3 vols., Academic Press, New York, 1972–.

6. Dreisbach, ''Physical Properties of Chemical Compounds,'' Advanced in Chemistry Series nos. 15, 22, 29, American Chemical Society, Washington, D.C., 1955–1961 lists many physical properties of more than 1000 organic compounds.

7. Physical properties of thousands of organometallic compounds, with references, are collected in four large compendia: the ''Dictionary of Organometallic Compounds,'' mentioned under item 2, above; Dub, ''Organometallic Compounds,'' 2d ed., 3 vols. with supplements and index, Springer-Verlag, New York, 1966–1975; Hagihara, Kumada, and Okawara, ''Handbook of Organometallic Compounds,'' W. A. Benjamin, New York, 1968; and Kaufman, ''Handbook of Organometallic Compounds,'' Van Nostrand, Princeton, N.J., 1961.

8. ''The Merck Index of Chemicals and Drugs,'' 10th ed., Merck and Company, Rahway, N.J., 1983, is a good source of information about chemicals of medicinal importance. Many drugs are given three types of name: *chemical name* (which is the name an organic chemist would give it; of course, there may well be more than one); *generic name*, which must be placed on all containers of the drug; and *trade names*, which are different for each company that markets the drug. For example, the generic name for 1-(4-chlorobenzhydryl)-4-methylpiperazine is chlorcyclazine. Among the trade names for this drug, which is an antihistamine, are Trihistan, Perazyl, and Alergicide. The ''Merck Index'' is especially valuable because it gives all known names of all three types for each compound and the names are cross-indexed. A formula index is included. Also given, for each compound, are the structural formula, *CA* preferred name and Registry number, physical properties, medicinal and other uses, toxicity indications, and references to methods of synthesis. The ‘‘Merck Index’’ also includes a lengthy list of organic name reactions, with references, as well as miscellaneous tables.

---

[26] For a review of this work with particular attention to errors, see Smith, *J. Am. Chem. Soc.* **105,** 6198 (1983) [book review].

9. There are two publications that list properties of azeotropic mixtures. Timmermans, ‘‘The Physico-Chemical Constants of Binary Systems in Concentrated Solutions,’’ 4 vols., Interscience, New York, 1959–1960, with supplements beginning 1965, is by far the more comprehensive. The other is ‘‘Azeotropic Data,’’ 2 vols., Advances in Chemistry Series no. 6 and no. 35, American Chemical Society, Washington, D.C., 1952, 1962.

10. Calculated boiling points at many pressures are given for many compounds in Dreisbach, ‘‘Pressure–Volume–Temperature Relationships of Organic Compounds,’’ McGraw-Hill, New York, 1952.

11. Thousands of dipole moments, with references, are collected in McClellan, ‘‘Tables of Experimental Dipole Moments,’’ vol. 1, W. H. Freeman, San Francisco, Calif., 1963; vol. 2, Rahara Enterprises, El Cerrita, Calif., 1974.

12. ‘‘Tables of Interatomic Distances and Configurations in Molecules and Ions,’’ London Chemical Society Special Publication no. 11, 1958, and its supplement, Special Publication no. 18, 1965, include bond distances and angles for hundreds of compounds, along with references.

13. The ‘‘Ring Systems Handbook,’’ published in 1984 by the Chemical Abstracts Service, provides the names and formulas of ring and cage systems that have been published in *CA*. The ring systems are listed under a system essentially the same as that used for the *CA* index of ring systems (p. 1129). Each entry gives the *CA* index name and Registry Number for that ring system. In many cases a *CA* reference is also given. There is a separate Formula Index (for the parent ring systems) and a Ring Name Index. Supplements are issued twice a year. The ‘‘Ring Systems Handbook’’ supersedes earlier publications called ‘‘The Parent Compound Handbook’’ and ‘‘The Ring Index’’.

14. The Sadtler Research Laboratories publish large collections of ir, uv, nmr, and other spectra, in loose-leaf form. Indexes are available.

15. Infrared, uv, nmr, Raman, and mass spectral data, as well as melting-point, boiling-point, solubility, and density data for 21,000 organic compounds are collected in the ‘‘Atlas of Spectral Data and Physical Constants for Organic Compounds,’’ 2d ed., 6 vols., CRC Press, Cleveland, Ohio, 1973, edited by Grasselli and Ritchey. It differs from the Sadtler collection in that the data are given in tabular form (lists of peaks) rather than reproductions of the actual spectra, but this book has the advantage that all the spectral and physical data for a given compound appear on one line. References are given to the Sadtler and other collections of spectra. Volumes 5 and 6 contain indexes of spectral peaks for ir, uv, nmr, ^{13}C nmr, mass, and Raman spectra, as well as formula and physical constant indexes.

16. The ‘‘Aldrich Library of Infrared Spectra,’’ 3d ed., Aldrich Chemical Company, Milwaukee, Wis., 1981, by Pouchert contains more than 12,000 ir spectra so arranged that the user can readily see the change that takes place in a given spectrum when a slight change is made in the structure of a molecule.

17. An extensive list of visible and uv peaks is given in ‘‘Organic Electronic Spectral Data,’’ Interscience, New York. Twenty volumes have appeared so far, covering the literature through 1978.

18. A collection of 500 ^{13}C nmr spectra is found in Johnson and Jankowski, ‘‘Carbon-13 NMR Spectra,’’ Wiley, New York, 1972.

Reviews

A review article is an intensive survey of a rather narrow field; e.g., the titles of some recent reviews are "Preparation, Reactions, and Physical Properties of Organobismuth Compounds,"[27] "Lewis Acid Induced α-Alkylation of Carbonyl Compounds,"[28] and "The Chemistry of the Isoindoles."[29] A good review article is of enormous value, because it is a thorough survey of all the work done in the field under discussion. Review articles are printed in review journals and in certain books. The most important review journals in organic chemistry (though most are not exclusively devoted to organic chemistry) are, with the year of founding, principal languages, and issues per year:

Review journals

Accounts of **Chem**ical **Res**earch (1968)	E	12
Aldrichimica Acta (1968)	E	4
Angewandte **Chem**ie (1888)	G	12
and its English translation: **Angew**andte **Chem**ie, **Int**ernational **Edition** in **Engl**ish (1962)	E	12
Chemical **Rev**iews (1924)	E	6
Chemical **Soc**iety **Rev**iews (1947)[30]	E	4
Heterocycles (1973)	E	12
Natural **Prod**uct **Rep**orts (1984)	E	6
Reviews of **Chem**ical **Intermed**iates (1973)	E	4
Synthesis (1969)	EG	12
Tetrahedron (1958)	EGF	24
Topics in **Curr**ent **Chem**istry (1949)[31]	EG	Irreg.
Uspekhii **Khim**ii (1932)	R	12
and its English translation: **Russian Chemical Reviews** (1960)	E	12

Some of the journals listed in Table 1, notably the *Bull Soc. Chim. Fr.* and *J. Organomet. Chem.* also publish occasional review articles.

There are several open-ended serial publications that are similar in content to the review journals but are published irregularly (seldom more often than once a year) and are hardbound. Some of these publish reviews in all fields of chemistry; some cover only organic chemistry; some specialize further. The coverage is indicated by the titles. Some of the more important such publications, with *CA* abbreviations, are:

---

[27] Freedman and Doak, *Chem. Rev.* **82,** 15–57 (1982).

[28] Reetz, *Angew Chem. Int. Ed. Engl.* **21,** 96–108 (1982) [*Angew. Chem.* **94,** 97–109].

[29] Bonnett and North, *Adv. Heterocycl. Chem.* **29,** 341–399 (1981).

[30] Successor to *Quarterly Reviews* (abbreviated as *Q. Rev., Chem. Soc.*).

[31] Formerly called **Fortschr**itte der **Chem**ischen **Forsch**ung.

Topics in Stereochemistry
Topics in Sulfur Chemistry

There are several publications that provide listings of review articles in organic chemistry. The most important is the *J. Org. Chem.*, which began to list review articles in 1978 (the first list is at *J. Org. Chem.* **43,** 3085). These lists, which appear twice each year, give the titles and reference sources of virtually all review articles in the field of organic chemistry that have appeared in the preceding six months, including those in the review journals and serials mentioned above, as well as those in monographs and treatises of the type mentioned on p. 1138. There is also a listing of new monographs on a single subject. Each list includes a subject index.

Another publication is the "Index of Reviews in Organic Chemistry," compiled by Lewis, Chemical Society, London, a classified listing of review articles. The first volume, published in 1971, lists reviews from about 1960 (in some cases much earlier) to about 1970 in alphabetical order of topic. Thus four reviews are listed under "Knoevenagel condensation," five under "Inclusion compounds," and one under "Vinyl ketones." There is no index. A second volume (1977) covers the literature to 1976. Annual or biannual supplements have appeared beginning in 1980. Still another list of review articles (unclassified, but with author and subject indexes) is found in Kharasch, Wolf, and Harrison, "Index to Reviews, Symposia Volumes, and Monographs in Organic Chemistry," Pergamon, New York. Three volumes have appeared, covering 1940–1960 (published 1962); 1961–1962 (published 1964); and 1963–1964 (published 1966). Classified lists of review articles on organometallic chemistry are found in articles by Smith and Walton[32] and by Bruce.[33] A similar list for heterocyclic chemistry is found in articles by Katritzky and coauthors.[34]

[32] Smith and Walton, *Adv. Organomet. Chem.* **13,** 453–558 (1975).

[33] Bruce, *Adv. Organomet. Chem.* **10,** 273–346 (1972), **11,** 447–471 (1973), **12,** 380–407 (1974).

[34] Katritzky and Jones, *Adv. Heterocycl. Chem.* **25,** 303–391 (1979); Katritzky and Weeds, *Adv. Heterocycl. Chem.* **7,** 225–299 (1966).

Annual Reviews

The review articles discussed in the previous section are each devoted to a narrow topic covering the work done in that area over a period of years. An annual review is a publication that covers a broad area but limits the period covered, usually to 1 or 2 years.

1. The oldest annual review publication still publishing is *Annual Reports on the Progress of Chemistry*, published by the Royal Society of Chemistry (formerly the Chemical Society) which began in 1905, and which covers the whole field of chemistry. Since 1967, it has been divided into sections. Organic chemistry is found in Section B.

2. Because the number of papers in chemistry has become so large, the Royal Society of Chemistry publishes annual-review-type volumes of smaller scope, called *Specialist Periodical Reports*. Among those of interest to organic chemists are ''Aliphatic and Related Natural Product Chemistry'' (vol. 3 covers 1980–1981); ''Photochemistry'' (vol. 13 covers 1980–1981); ''The Alkaloids,'' (vol. 12 covers 1980–1981); ''General and Synthetic Methods,'' (vol. 6 covers 1981).

3. Organic Reaction Mechanisms,'' published by Wiley, New York, is an annual survey that covers the latest developments in the field of mechanisms. The first volume, covering 1965, appeared in 1966.

4. There are two annual reviews devoted to progress in organic synthesis. Theilheimer, ''Synthetic Methods of Organic Chemistry,'' S. Karger Verlag, Basel, is an annual compilation, beginning in 1946, of new methods for the synthesis of organic compounds, arranged according to a system based on bond closings and bond breakings. Equations, brief procedures, yields, and literature references are given. Volume 37 was issued in 1983. Volumes 3 and 4 are available only in German, but all the rest are in English. There is an index to each volume. Cumulative indexes appear in every fifth volume. Beginning with vol. 8, each volume includes a short summary of trends in synthetic organic chemistry. A more recent series is ''Annual Reports in Organic Synthesis,'' Academic Press, New York, which has covered the literature of each year since 1970. Equations are listed with yields and references according to a fairly simple system. A monthly publication, also devoted to new synthetic methods, is *Methods in Organic Synthesis*, which began in 1984. The journal *Synthesis* also publishes similar reports (taken from other journals) in each issue.

5. The *Journal Of Organometallic Chemistry* several times a year publishes annual surveys arranged according to metallic element. For example, vol. 262, published in January 1984, contains annual surveys for 1982 of organic compounds containing B, Sb, Bi, Mn, Tc, Re, Co, Rh, and Ir, as well as the use of transition metals in organic synthesis. These annual reviews formerly appeared in *Organometallic Chemistry Reviews, Section B*, which was a separate journal published from 1968 to 1974. Still earlier (for 1964–1966), these reviews were published in book form.

General Treatises

There are a number of large-scale multivolume treatises that cover the whole field of organic chemistry or large areas of it.

1. ''Rodd's Chemistry of Carbon Compounds,'' edited by Coffey, Elsevier, Amsterdam, is a treatise consisting of five main volumes, each of which contains several parts. Publication began in 1964 and is not yet complete. The organization is not greatly different from most textbooks, but the coverage is much broader and deeper. Supplements to some of the volumes have appeared. An earlier edition, called ''Chemistry of Carbon Compounds,'' edited by Rodd, was published in 10 parts from 1951 to 1962.

2. Houben-Weyl's ''Methoden der organischen Chemie,'' Georg Thieme Verlag, Stuttgart, is a major treatise in German devoted to laboratory methods. The fourth edition, which was begun in 1952 and consists of 16 volumes, most of them in several parts, is edited by E. Muller. Supplementary volumes have begun to appear. The first four volumes contain general laboratory methods, analytical methods, physical methods, and general chemical methods. The later volumes are devoted to the synthesis of specific types of compounds, e.g., hydrocarbons, oxygen compounds, nitrogen compounds, etc.

3. ''Comprehensive Organic Chemistry,'' Pergamon, New York, 1979, is a six-volume treatise on the synthesis and reactions of organic compounds. The first three volumes cover the various functional groups, vol. 4, heterocyclic compounds, and vol. 5, biological compounds such as proteins, carbohydrates, and lipids. Probably the most useful volume is vol. 6, which contains formula, subject, and author indexes, as well as indexes of reactions and reagents. The last two of these not only refer to pages within the treatise, but directly give references to review articles and original papers. For example, on p. 1129, under ''Chromic acid-sulphuric acid (Jones reagent), oxidation, alcohols,'' are listed 13 references to original papers. Two similar treatises, the nine-volume ''Comprehensive Organometallic Chemistry'' (1982) and the eight-volume ''Comprehensive Heterocyclic Chemistry'' (1984) are also published by Pergamon. The indexes to these works also include references.

4. A major treatise devoted to experimental methods of chemistry is ''Techniques of Chemistry,'' edited by Weissberger, Wiley, New York. This publication, which began in 1970, so far consists of 18 volumes, most of them in several parts, covering such topics as electrochemical and spectral methods, kinetic methods, photochromism, and organic solvents. ''Techniques of Chemistry'' is a successor to an earlier series, called ''Techniques of Organic Chemistry,'' which appeared in 14 volumes, some of them in more than one edition, from 1945 to 1969.

5. ''Comprehensive Chemical Kinetics,'' edited by Bamford and Tipper, 1969–, Elsevier, Amsterdam, is a multivolume treatise covering the area of reaction kinetics. Six of these volumes (not all published at the time of writing) deal with the kinetics and mechanisms of organic reactions in a thorough and comprehensive manner.

6. Three multivolume treatises that cover specific areas are Elderfield, ''Heterocyclic Compounds,'' Wiley, New York, 1950–; Manske and Holmes, ''The Alkaloids,'' Academic Press, New York, 1950–; Simonson, Owen, Barton, and Ross, ''The Terpenes,'' Cambridge University Press, London, 1947–1957.

Monographs and Treatises on Specific Areas

Organic chemistry is blessed with a large number of books devoted to a thorough coverage of a specific area. Many of these are essentially very long review articles, differing from ordinary review articles only in size and scope. Some of the books are by a single author, and others have chapters by different authors but all are carefully planned to cover a specific area. Many of these books have been referred to in footnotes in appropriate places in this book. Several companies have published series of monographs of which we shall mention three of the most notable.

1. A series of unrelated monographs covering various areas of organic chemistry is published by Academic Press, New York. More than 40 titles have been published so far. Typical books in the series are Johnson, ''Ylid Chemistry,'' 1966; Ugi, ''Isonitrile Chemistry,'' 1971; Wasserman and Murray, ''Singlet Oxygen,'' 1979; Mayo, ''Rearrangements in Ground and Excited States,'' 1980; Trost and Melvin, ''Sulfur Ylides,'' 1975; Cram, ''Fundamentals of Carbanion Chemistry,'' 1965; Shamma, ''The Isoquinoline Alkaloids,'' 1972; and Rochester, ''Acidity Functions,'' 1970.

2. Wiley-Interscience publishes a series called ''The Chemistry of Functional Groups,'' under the general editorship of Patai. Each volume deals with the preparation, reactions, and physical and chemical properties of compounds containing a given functional group. Volumes covering more than 20 functional groups have appeared so far, including books on alkenes, cyano compounds, amines, carboxylic acids and esters, quinones, etc. Several more are planned.

3. A series of monographs on reaction mechanisms is published by the Elsevier Publishing Company. Among the books so far published in this series are Bunton, ''Nucleophilic Substitution at a Saturated Carbon Atom,'' 1963; Norman and Taylor, ''Electrophilic Substitution in Benzenoid Compounds,'' 1965; Miller, ''Nucleophilic Aromatic Substitution,'' 1968; Shine, ''Aromatic Rearrangements,'' 1967; and Buncel, ''Carbanions,'' 1974.

Textbooks

There are many excellent textbooks in the field of organic chemistry. We restrict ourselves to listing only a few of those published, mostly since 1977. Some of these are first-year texts and some are advanced (advanced texts generally give references; first-year texts do not, though they may give general bibliographies, suggestions for further reading, etc.); some cover the whole field, and others cover reactions, structure, and/or mechanism only. All the books listed here are not only good textbooks but valuable reference books for graduate students and practicing chemists.

Alder, Baker, and Brown, ''Mechanism in Organic Chemistry,'' Wiley-Interscience, New York, 1971.

Carey and Sundberg, ''Advanced Organic Chemistry,'' 2 vols., Plenum, 2d. ed., 1983, 1984.

Carruthers, ''Some Modern Methods of Organic Synthesis,'' 2d ed., Cambridge University Press, London, 1978.

Ege, ''Organic Chemistry,'' D.C. Heath, New York, 1984.

Fessenden and Fessenden, ''Organic Chemistry,'' 2d ed., Willard Grant Press, Boston, 1982.

Harris and Wamser, ''Fundamentals of Organic Reaction Mechanisms,'' Wiley, New York, 1976.

Pine, Hendrickson, Cram, and Hammond, ''Organic Chemistry,'' 4th ed., McGraw-Hill, New York, 1980.

House, ''Modern Synthetic Reactions,'' 2d ed., W. A. Benjamin, New York, 1972.

Ingold, ''Structure and Mechanism in Organic Chemistry,'' 2d ed., Cornell University Press, Ithaca, N.Y., 1969.

Jones, ''Physical and Mechanistic Organic Chemistry,'' 2d ed., Cambridge University Press, London, 1984.

Kemp and Vellaccio, ''Organic Chemistry,'' Worth Publishers, New York, 1980.

Loudon, ''Organic Chemistry,'' Addison-Wesley, Reading, Mass., 1984.

Lowry and Richardson, ''Mechanism and Theory in Organic Chemistry,'' Harper and Row, New York, 1981.

McMurry, ''Organic Chemistry,'' Brooks/Cole, Monterey, Calif., 1984.

Morrison and Boyd, ''Organic Chemistry,'' 4th ed., Allyn and Bacon, Boston, 1982.

Solomons, ''Organic Chemistry,'' 3d ed., Wiley, New York, 1984.

Streitwieser and Heathcock, ''Introductory Organic Chemistry,'' 2d ed., Macmillan, New York, 1981.

Sykes, ''A Guidebook to Mechanism in Organic Chemistry,'' 5th ed., Longmans, New York, 1981.

Weininger and Stermitz, ''Organic Chemistry,'' Academic Press, New York, 1984.

Wingrove and Caret, ''Organic Chemistry,'' Harper and Row, New York, 1981.

Other Books

In this section we mention several books that do not fit conveniently into the previous categories. All but the last have to do with laboratory synthesis.

1. *Organic Syntheses,* published by Wiley, New York is a collection of procedures for the preparation of specific compounds. The thin annual volumes have appeared each year since 1921. The procedures for each 10- (or 9-) year period are collected in cumulative volumes, in this manner:

Annual volumes	Collective volumes
1–9	I
10–19	II
20–29	III
30–39	IV
40–49	V

The advantage of the procedures in *Organic Syntheses,* compared with those found in original journals, is that these procedures are *tested.* Each preparation is carried out first by its author and then by a member of the *Organic Syntheses* editorial board, and only if the yield is essentially duplicated is the procedure published. While it is possible to repeat most procedures given in journals, this is not always the case. All *Organic Syntheses* preparations are noted in Beilstein and in *CA*. In order to locate a given reaction in *Organic Syntheses,* the reader may use the OS references given in the present volume (through OS **61**); the indexes in *Organic Syntheses* itself; Sugasawa and Nakai; ''Reaction Index of Organic Syntheses,'' Wiley, New York, 1967 (through OS **45**); or Shriner and Shriner, ''Organic Syntheses Collective Volumes I, II, III, IV, V Cumulative Indices,'' Wiley, New York, 1976. A similar publication is *Organic Photochemical Syntheses,* also published by Wiley, New York; vol. 1 appeared in 1971.

2. Volume 1 of ''Reagents for Organic Synthesis,'' by Fieser and Fieser, Wiley, New York, 1967, is a 1457-page volume which discusses, in separate sections, some 1120 reagents and catalysts. It tells how each reagent is used in organic synthesis (with references) and, for each, tells which companies sell it, or how to prepare it, or both. The listing is alphabetical. Ten additional volumes have so far been published, which continue the format of vol. 1 and add more recent material.

3. ''Survey of Organic Synthesis,'' by Buehler and Pearson, Wiley, New York, 2 vols., 1970, 1977, discusses hundreds of reactions used to prepare the principal types of organic compounds. The arrangement is by chapters, each covering a functional group, e.g., ketones, acyl halides, amines, etc. Each reaction is thoroughly discussed and brief synthetic procedures are given. There are many references.

4. A similar publication is Sandler and Karo, ''Organic Functional Group Preparations,'' 3 vols., Academic Press, 1968–1972 (part of the series of Academic Press monographs mentioned on p. 1138). This publication covers more functional groups than Buehler and Pearson.

5. "Compendium of Organic Synthetic Methods," Wiley, New York, contains equations describing the preparation of about 4000 monofunctional and difunctional compounds with references. Five volumes have been published so far (1971 and 1974, edited by Harrison and Harrison; 1977, edited by Hegedus and Wade; 1980 and 1984, edited by Wade).

6. Two books that are rich in experimental procedures, both translated from the German, are Weygand and Hilgetag, "Preparative Organic Chemistry," edited by Hilgetag and Martini, Wiley, New York, 1972, and Becker et al., "Organicum," translated by Hazzard, Addison-Wesley, Reading, Mass., 1973. Another valuable book, more devoted to general laboratory technique than to specific procedures, is "Fundamentals of Preparative Organic Chemistry," by Keese, Müller, and Toube, Wiley, New York, 1982.

7. "The Vocabulary of Organic Chemistry," by Orchin, Kaplan, Macomber, Wilson, and Zimmer, Wiley, New York, 1980, presents definitions of more than 1000 terms used in many branches of organic chemistry, including stereochemistry, thermodynamics, wave mechanics, natural products, and fossil fuels. There are also lists of classes of organic compounds, types of mechanism, and name reactions (with mechanisms). The arrangement is topical rather than alphabetical, but there is a good index. An official IUPAC list of definitions, "Glossary of Terms Used in Physical Organic Chemistry," was published in 1983 in *Pure and Applied Chemistry* (**55,** 1281–1371).

LITERATURE SEARCHING

Information about a Specific Compound

Most organic chemists find it necessary, occasionally or frequently, to search the literature for information concerning specific compounds. They may need to know if a compound has ever been prepared and if so, how, and/or they may be seeking a melting point, an ir spectrum, or some other property. The directions for this particular type of literature search are so much more specific than for other searches that we discuss them first. Someone who wants all the information that has ever been published on any compound begins by consulting the formula index to the second supplement of Beilstein (p. 1132), which quickly shows whether the compound is mentioned in the literature through 1929. If it is there, the searcher turns to the pages indicated, where all methods used to prepare the compound are given, as well as all physical properties, with references. If the compound is in a volume of Beilstein of which the third and/or fourth supplement has been published, it may be found there, by the method described on p. 1131. If the compound is not listed in the cumulative formula index (and is thus absent from the literature through 1929), the next step is to ascertain whether it is in the third or fourth supplement, which is done as described on p. 1132. If the compound is in one of the volumes for which a cumulative formula index is already available, much of this labor is unnecessary, since this index will give, in one place, the Beilstein locations in *das Hauptwerk* and all four supplements. At this point the investigator will know (1) all information published through 1959[35] or 1949,[36] or (2) that the compound is not mentioned in the literature through 1959[35] or 1949.[36] In some cases, scrutiny of Beilstein will be sufficient, perhaps if only a boiling point or a refractive index is required. In other cases, especially where specific laboratory directions are needed, the investigator will have to turn to the original papers.

To carry the search past 1949 (or 1959), the chemist next turns to the collective formula indexes of *Chemical Abstracts:* 1947–1956 (if this period was not covered by Beilstein); 1957–1961; 1962–

---

[35] For compounds that would naturally belong to a volume for which the fourth supplement has already been published.

[36] For compounds that would naturally belong to a volume for which the fourth supplement has not been published.

1966; 1967–1971; 1972–1976; 1977–1981; such later collective indexes as have appeared; and the semiannual indexes thereafter. If a given formula index contains only a few references to the compound in question, the pages or abstract numbers will be given directly in the formula index. However, if there are many references, the reader will be directed to see the chemical substance index or (before 1972) the subject index for the same period; and here the number of page or abstract numbers may be very large indeed. Fortunately, numerous subheadings are given, and these often help the user to narrow the search to the more promising entries. Nevertheless, one will undoubtedly turn to many abstracts that do not prove to be helpful. In many cases, the information in the abstracts will be sufficient. If not, the original references must be consulted. In some cases (the index entry is marked by an asterisk or a double asterisk) the compound is not mentioned in the abstract, though it is in the original paper or patent. Incidentally, all entries in the *CA* indexes that refer to patents are prefixed by the letter P. Since 1967, the prefixes B and R have also been used to signify books and reviews, respectively.

By the procedure outlined above, all information regarding a specific compound that has been published up to about a year before the search can be found by a procedure that is always straightforward and that in many cases is rapid (if the compound has been reported only a few times). Equally important, if the compound has not been reported, the investigator will know that, too. It should be pointed out that for common compounds, such as benzene, ether, acetone, etc., trivial mentions in the literature are not indexed (so that they will not be found by this procedure), only significant ones. Thus, if acetone is converted to another compound, an index entry will be found, but not if it is used as a solvent or an eluent in a common procedure.

There are several methods for learning whether a compound is mentioned in the literature after the period covered by the latest semiannual formula index of *CA*. One may consult *Chemical Titles* and the keyword index (p. 1128) at the end of each issue of *CA*. In these cases, of course, it is necessary to know what name might be used for the compound. The name is not necessary for *Current Abstracts of Chemistry and Index Chemicus* (p. 1130); one consults the monthly formula indexes. However, these methods are far from complete. *Current Abstracts of Chemistry and Index Chemicus* lists primarily *new* compounds, those which would not have been found in the earlier search. As for *Chemical Titles*, the compound can be found only if it is mentioned in the title. The keyword indexes in *CA* are more complete, being based on internal subject matter as well as title, but they are by no means exhaustive. Furthermore, all three of these publications lag some distance behind the original journals, though *Chemical Titles* is very close. There is no method for the *complete* location of all references to a compound after the period covered by the latest semiannual formula index of *CA*.

The complete procedure described above may not be necessary in all cases. Often all the information one needs about a compound will be found in one of the handbooks (p. 1133), in the "Dictionary of Organic Compounds" (p. 1133), or in one of the other compendia listed in this chapter, most of which give references to the original literature.

Other Searches[37]

There is no definite procedure for making other literature searches. Any chemist who wishes to learn all that is known about the mechanism of the reaction between aldehydes and HCN, or which compounds of the general formula Ar_3CR have been prepared, or which are the best catalysts for Friedel–Crafts acylation of naphthalene derivatives with anhydrides, or where the group $C(NH_2){=}NH$ absorbs in the ir, is dependent on his or her ingenuity and knowledge of the literature

---

[37] This discussion is necessarily short. For much more extensive discussions, consult the books in Ref. 1.

(though computer searching can often help). If a specific piece of information is needed, it may be possible to find it in one of the compendia mentioned previously. If the topic is more general, the best procedure is often to begin by consulting one or more monographs, treatises, or textbooks that will give general background information and often provide references to review articles and original papers. For example, Olah's treatise on Friedel–Crafts reactions (Ref. 195 in Chapter 11) should certainly be consulted on the Friedel–Crafts topic mentioned above. In many cases this is sufficient, but when a complete search is required, it is necessary to consult the *CA* subject and/or chemical substance indexes, where the ingenuity of the investigator is most required, for now it must be decided which words to look under. If one is interested in the mechanism of the reaction between aldehydes and HCN, one might look under "aldehydes," or "hydrogen cyanide," or even under "acetaldehyde" or "benzaldehyde," etc., but then the search is likely to prove long. A better choice in this case would be "cyanohydrin," since these are the normal products and references there would be fewer. It would be a waste of time to look under "mechanism." In any case, many of the abstracts would not prove helpful. Literature searching of this kind is necessarily a wasteful process. Of course, the searcher would not consult the *CA* annual indexes but only the collective indexes as far as they go and the semiannual indexes thereafter. If it is necessary to search before 1907 (and even before 1920, since *CA* was not very complete from 1907 to about 1920), recourse may be made to *Chemisches Zentralblatt* (p. 1130) and the abstracts in the *Journal of the Chemical Society* (p. 1130).

Science Citation Index

A publication that can greatly facilitate literature searching is the computer-produced *Science Citation Index* (*SCI*), begun in 1961. This publication, which is quite different from any other mentioned in this chapter, gives a list of all papers in a given year that have cited a given paper, patent, or book. Its utility lies in the fact that it enables the user to search *forward* from a given paper or patent, rather than backward, as is usually the case. For example, suppose a chemist is familiar with a paper by Jencks and Gilchrist [*J. Am. Chem. Soc.* **90,** 2622 (1968)] entitled "Nonlinear Structure-Reactivity Correlations. The Reactivity of Nucleophilic Reagents toward Esters." The chemist is easily able to begin a search for earlier papers by using references supplied in this paper and can then go further backward with the aid of references in those papers, etc. But for obvious reasons the paper itself supplies no way to locate *later* papers. *SCI* is designed to make up for this gap. The citation index of *SCI* lists all papers, patents, or books cited in a given year or quarter (by first author only) and then gives a list of papers that have done the citing. The index is published bimonthly and cumulated annually. For example, column 27216 of the 1982 *Citation Index* shows that the Jencks paper mentioned above was cited as a footnote in 18 papers published in 1982 or late 1981. It is reasonable to assume that most of the papers that cited the Jencks paper were on closely related subjects. For each of the 18 papers are listed the first author, journal abbreviation, volume and page numbers, and year. In a similar manner, if one consulted *SCI* for all the years from 1968 on, one would have a complete list of papers that cited that paper. One could obviously broaden the search by then consulting *SCI* (from 1982 on) for papers that cited these 18 papers and so on. Papers, patents, or books listed, for example, in the 1982 *SCI* may go back many years, e.g., papers published by Einstein in 1905 and 1906 are included. The only requirement is that a paper published in 1982 (or late 1981) has mentioned the earlier paper in a footnote. The arrangement of cited papers or books is alphabetical by cited first author and then by cited year. The arrangement of patents is by patent number, regardless of country.

SCI covers about 3300 journals in the physical and biological sciences, as well as in medicine, agriculture, technology, and the behavioral sciences. In addition to the Citation Index, each bimonthly and annual *SCI* also includes three other indexes. One of these, called *Source Index*, is similar to the *CA* author index. It lists the titles, journal abbreviations, volume, issue, page numbers, and year of all papers published by a given author during that two-month period or year. All authors are listed; not just first authors. The second, called the *Corporate Index*, lists all publications that have been published from a given institution during that period, by first author. Thus the *Corporate Index* for 1982 lists 22 papers by 17 different first authors emanating from the Department of Organic Chemistry of the University of Adelaide, Australia. The third index included in *SCI* is the *Permuterm*[38] *Subject Index*. This index alphabetically lists every significant word in the titles of all papers published in that year or quarter, paired with all other significant words in the same title. Thus, for example, a title with seven significant words appears at 42 separate places in the index. Each of the seven words appears six times as the main word, each time paired with a different word as the co-word. The user is then led to the *Source Index*, where the full reference is given. *SCI* is also available online.

The publishers of *SCI* also produce another publication, called *Index to Scientific Reviews*, that appears semiannually (the second issue of each year cumulates the first). This publication, which began in 1974, is very similar to *SCI*, but confines itself to listing citations to review articles. The citations come from about 2500 journals in the same general areas as are covered by *SCI*. The review articles cited appeared in about 150 review journals and books, as well as in those journals that publish occasional review articles. Like *SCI*, the *Index to Scientific Reviews* contains citation, source, corporate, and Permuterm indexes.

How to Locate Journal Articles

Having obtained a reference from Beilstein, *SCI, CA*, a treatise, or some other source, one often needs to consult the original journal (the location of patents is discussed on p. 1125). The first step is to ascertain the full name of the journal, since it is the abbreviation that is generally given. Of course, everyone should be familiar with the abbreviations of the very important journals, such as *J. Org. Chem.*, *Chem. Ber.*, etc., but references are often found to journals whose titles are not at all familiar (e.g., *K. Skogs Lantbruksakad. Tidskr.* or *Nauchn. Tr. Mosk. Lesotekh. Inst.*). In such cases, one consults the *Chemical Abstracts Service Source Index* (*CASSI*), 1979 edition, which contains the names of all of the journals covered by *CA* from 1907 to 1979 (even those no longer published), with the most recent abbreviations in bold print. The journals are listed in alphabetical order of the *abbreviations*, not of the titles. Journal title changes have not been infrequent, and *CASSI* also contains all former names, with cross-references to the current names. Quarterly supplements, cumulated annually, to *CASSI* have appeared since 1980 listing new journals and recent changes in journal titles. It should be pointed out that, while many publications use the *CA* abbreviations, not all do. The student will find that usages vary from country to country, and even from journal to journal within a country. Furthermore, the *CA* abbreviations change from time to time.

Once the complete title is known, the journal can easily be obtained if it is in the library customarily used by the chemist. If not, one must use another library, and the next step is to find out which libraries carry the journal. *CASSI* answers this question too, since it carries a list of some 369 libraries in the United States and other countries, and *for each journal it tells which of these libraries carries it*, and furthermore, if the holdings are incomplete, which volumes of that journal are carried by each library. It may be possible to visit the closest library personally. If not, many of these libraries maintain one or more of the following services: lending, microfilms, photocopying; and a copy of the article may be obtained in one of these ways, photocopying being most common. *CASSI* also includes lists of journal publishers and sales agents, document suppliers, and document depositories. Photocopies of most documents cited in *CA* can be obtained from Chemical Abstracts Service, Customer Services, P.O. Box 3012, Columbus, Ohio, 43210, U.S.A.

[38] Registered trade name.

Appendix B

CLASSIFICATION OF REACTIONS BY TYPE OF COMPOUND SYNTHESIZED

Acetals and Ketals

0-14 Reaction between alkoxides and *gem*-dihalides (Williamson) or α-halo ethers
0-17 Reaction between diazoalkanes and alcohols
0-19 Transetherification
0-80 Reduction of ortho esters
0-85 Reduction of mesylate esters
0-93 Reaction between Grignard reagents and ortho esters
5-4 Addition of alcohols or phenols to triple bonds
6-6 Addition of alcohols to aldehydes or ketones
6-53 Addition of aldehydes to olefins (Prins)
6-58 Trimerization and polymerization of aldehydes

Acetylenes (*see* Alkynes)

Acids (*see* Carboxylic Acids, Sulfonic Acids)

Acylals

5-5 Addition of acids to alkynes
6-57 Acylation of aldehydes or ketones
9-14 Bisdecarboxylation of malonic acids
9-17 Oxidation of arylmethanes with CrO_3 and Ac_2O

Acyl Halides

0-3 Reaction between 1,1,1-trihalides and SO_3
0-75 From carboxylic acids
0-76 Conversion of acid derivatives to acyl halides
4-3 Halogenation of aldehydes
5-1 Addition of hydrogen halides to ketenes
5-21 Free-radical addition of acyl halides to olefins

Acyloins (*see* Hydroxy Aldehydes and Ketones)

Alcohols (*see also* Diols, Hydroxy Esters, etc.)

0-1 Hydrolysis of alkyl halides
0-4 Hydrolysis of inorganic esters
0-5 Diazotization of primary aliphatic amines
0-7 Hydrolysis of enol ethers, acetals, or ortho esters
0-11 Hydrolysis of carboxylic esters
0-13 Decarbonylation of carboxylic acids
0-19 Transetherification
0-25 Transesterification
0-57 Ammonolysis of esters
0-69 Cleavage of ethers with concentrated acids
0-80 Reduction of acetals or ortho esters
0-81 Reduction of epoxides
0-93 Cleavage of acetals or ortho esters with Grignard reagents
0-94 Reaction between organometallic compounds and epoxides
0-99 Alkylation of alcohols
0-117 Hydrolysis of sulfonic esters
1-13 Alkylation of aromatic rings with ethylene oxide
1-24 Hydroxyalkylation of aromatic rings
2-23 Reaction between organometallic reagents and oxygen
4-4 Hydroxylation at an aliphatic carbon
5-2 Hydration of olefins
5-13 Hydroboration–oxidation of alkenes
5-18 Addition of organometallic compounds to unsaturated alcohols

Alcohols (continued)

5-21 Free-radical addition of alcohols to olefins
5-43 Addition of OH and SR to double bonds
6-26 Reduction of aldehydes or ketones
6-30 Additions of Grignard reagents to aldehydes or ketones
6-33 Addition of Grignard reagents to esters or acyl halides
7-2 Alkaline cleavage of ethers
7-42 Reaction of N-substituted amides with certain catalysts
8-1 Rearrangement of alcohols or olefins (Wagner–Meerwein)
8-3 Expansion and contraction of rings (Demyanov)
8-22 Cleavage of methyl ketones with peracids (Baeyer–Villiger)
8-23 Cleavage of hydroperoxides
8-25 Rearrangement of ethers upon treatment with alkyllithiums (Wittig)
8-26 From boranes and CO, or CN^-, or $CHCl_2OMe$; from boranes and bromine
8-27 From boranes, CO, water, and NaOH
8-28 From boranes, CO, and $LiAlH_4$
8-39 [2,3] sigmatropic rearrangements of allylic ethers or allylic sulfoxides
8-44 Photolysis of hypohalites
9-9 Reduction of ozonides
9-39 Reduction of carboxylic acids
9-43 Reduction of esters
9-44 Reduction of carboxylic esters with titanocene dichloride
9-45 Reduction of anhydrides
9-46 Reduction of acyl halides
9-58 Reduction of hydroperoxides
9-61 Reduction of peroxides
9-70 Reaction between aldehydes and base (Cannizzaro)

Aldehydes (*see also* Dicarbonyl Compounds, Unsaturated Carbonyl Compounds, etc.)

0-2 Hydrolysis of *gem*-dihalides
0-4 Hydrolysis of vinyl esters of inorganic acids
0-7 Hydrolysis of enol ethers, acetals, thioacetals, etc.
0-11 Hydrolysis of enol esters
0-84 Reduction of acyl halides
0-85 Reduction of carboxylic acids, esters, or anhydrides
0-86 Reduction of amides
0-97 Alkylation and hydrolysis of imines; alkylation of aldehydes
0-99 Alkylation and hydrolysis of dithianes
0-100 Alkylation and hydrolysis of oxazines and similar compounds
0-101 Reaction of diazo aldehydes with boranes
0-104 Carbonylation of alkyl halides
0-107 Reaction between formates or formamides and organometallic compounds
0-113 Formylation of carboxylic acid salts
0-116 Reaction between formic acid, another acid, and thorium oxide
1-16 Formylation of aromatic rings with formamides and $POCl_3$ (Vilsmeier)
1-17 Formylation of aromatic rings with carbon monoxide and HCl (Gatterman–Koch)
1-18 Formylation of aromatic rings with HCN and HCl (Gatterman)
1-19 Formylation of aromatic rings with chloroform (Reimer–Tiemann)
1-20 Other formylations of aromatic rings
1-43 Reaction between arylcarbinols and diazonium salts (Stiles–Sisti)
2-31 Carbonylation of organometallic compounds
2-39 Decarboxylation of α-keto or glycidic acids
3-27 Rearrangement of aromatic amino sulfides (Sommelet–Hauser)
4-18 Arylation of allylic alcohols
4-30 Reaction of diazonium salts with oximes, followed by hydrolysis
5-3 Hydration of acetylene
5-10 Selective reduction of unsaturated aldehydes
5-13 Oxidation of boranes; hydrolysis of unsaturated boranes
5-17 Michael reaction of ketene thioacetal monoxides, followed by hydrolysis
5-18 Addition of organometallic compounds to unsaturated aldehydes
5-19 Addition of boranes to unsaturated aldehydes

Aldehydes (continued)
5-23 Hydroformylation of olefins (oxo process)
6-2 Hydrolysis of imines, oximes, hydrazones, or other C=N compounds
6-4 Hydrolysis of primary nitro compounds (Nef)
6-29 Reduction of nitriles
6-33 Addition of Grignard reagents to formamides
6-36 Reaction of alkyllithium compounds with oxazines
6-42 Reaction of aldehydes or ketones with boron methides
6-71 Hydrolysis of metalated aldimines
7-1 Dehydration of 1,2-diols
7-2 Pyrolysis of vinyl ethers
7-34 Fragmentation of γ-amino or γ-hydroxy halides
7-35 Fragmentation of 1,3-diols or γ-amino alcohols
7-41 Fragmentation of certain ketoximes
7-46 Pyrolysis of β-hydroxy olefins
7-47 Pyrolysis of allyl ethers
8-2 Rearrangements of diols (pinacol)
8-10 Homologization of aldehydes
8-16 Reaction between α-hydroxy or α-halo amides and NaOBr (Hofmann)
8-23 Cleavage of hydroperoxides
8-28 Treatment of boranes with CO and $LiAl(OMe)_3$
8-44 Photolysis of nitrites, followed by hydrolysis (Barton)
9-3 Oxidation of primary alcohols
9-7 Oxidative cleavage of glycols or related compounds
9-9 Ozonolysis of olefins
9-13 Oxidation of arylacetic acids
9-16 Oxidation of activated methyl groups
9-17 Oxidation of arylmethanes (Étard)
9-20 Oxidation of primary halides or esters of primary alcohols
9-21 Oxidation of amines
9-23 Oxidation of olefins with noble-metal salts

Alicyclic Compounds

0-87 Internal coupling (Wurtz)
0-89 Cyclization of diallylic halides
0-91 Cyclization of 1,3-diols
0-96 Internal malonic ester synthesis
0-101 Cyclization of haloboranes
0-111 Internal condensation of diesters (Dieckmann)
0-116 Ketonic decarboxylation of dicarboxylic acids
1-13 Intramolecular Friedel–Crafts alkylation
1-14 Scholl ring closure
1-15 Intramolecular Friedel–Crafts acylation
1-25 Cyclodehydration of aldehydes and ketones
2-18 Intramolecular insertion of carbenes
3-16 Cyclization of dihalobiphenyls
4-15 Coupling of terminal diynes (cycloalkynes)
4-16 Intramolecular arylation (Pschorr)
4-34 Cyclization of dimagnesio compounds
4-35 Coupling of dienes through borane intermediates
5-5 Cyclization of olefinic acids
5-11 Reduction of aromatic rings
5-15 Cyclization of dienes
5-18 Cyclization of unsaturated Grignard reagents
5-22 Hydrocarboxylation of dienes
5-46 Cycloaddition of allylic anions or cations to olefins
5-47 Addition of olefins to dienes (Diels–Alder)
5-48 Dimerization of olefins
5-49 Addition of carbenes or carbenoids to olefins or alkynes
5-50 Tetramerization of alkynes
5-51 Other cycloaddition reactions
6-30 Ring closure of halo carbonyl compounds
6-40 Internal aldol condensation
6-47 Internal Wittig reactions
6-48 Cyclization of dinitriles (Thorpe–Ziegler)
7-49 Extrusion of N_2 from pyrazolines or pyrazoles
7-50 Extrusion of CO from cyclic ketones
7-51 Extrusion of SO_2 from cyclic sulfones
7-52 Decarboxylation of cyclic peroxides (Story)
8-1 Wagner–Meerwein rearrangements to give cyclic products

Alicyclic Compounds (continued)

8-3	Expansion and contraction of rings (Demyanov)
8-8	Ring contraction of halo ketones (Favorskii)
8-9	Ring contraction of cyclic diazo ketones (Wolff)
8-10	Ring expansion of cyclic ketones
8-26	Treatment of cyclic boranes with CO
8-27	Treatment of cyclic boranes with CO, H_2O, NaOH, and H_2O_2
8-31	Cyclization of conjugated dienes and trienes
8-34	[1,*j*] sigmatropic migrations of carbon
8-35	Ring expansion of vinylcyclopropenes and cyclobutenes
8-36	Ring expansion of vinylcycloalkanes; cyclization of diynes
8-41	Metathesis of dienes
8-42	Metal-ion-catalyzed σ-bond rearrangements
8-43	The di-π-methane rearrangement
9-2	Dehydrogenative ring closing
9-34	Oxidative cyclization
9-55	Reduction of cyclic ketones to cycloalkenes
9-64	Cyclization of diketones or keto esters
9-66	Condensation of diesters (acyloin)

Alkanes (*see also* Alicyclic Compounds)

0-77	Reduction of alkyl halides
0-78	Reduction of tosylates and similar compounds
0-79	Hydrogenolysis of alcohols
0-82	Reductive cleavage of esters
0-83	Reduction of the C—N bond
0-87	Coupling of alkyl halides (Wurtz)
0-88	Coupling of alkyl halides with organometallic reagents
0-90	Reaction between organometallic reagents and alkyl sulfates or sulfonates
0-91	Coupling of alcohols
0-93	Reaction between Grignard reagents and ethers
0-99	Reduction of dithianes
2-16	Alkylation of alkanes
2-18	Insertion of carbenes
2-22	Reaction between organometallic compounds and acids
2-39	Decarboxylation of carboxylic acids
2-40	Cleavage of tertiary alkoxides
2-44	Cleavage of nonenolizable ketones
2-45	Cleavage of ketones with amide ion (Haller–Bauer)
2-46	Cleavage of alkanes
2-47	Decyanation of nitriles
4-14	Coupling of alkanes
4-34	Coupling of Grignard reagents
4-35	Coupling of boranes
4-36	Coupling of other organometallic compounds
4-37	Desulfurization of sulfur compounds
4-38	Decarboxylative dimerization (Kolbe)
4-40	Decarbonylation of aldehydes or acyl halides
5-10	Reduction of olefins and alkynes
5-11	Reduction of aromatic rings
5-12	Reductive cleavage of cyclopropanes
5-15	Addition of alkanes to olefins
6-30	Reaction of ketones with trimethylaluminum
6-33	Reaction of carboxylic acids with trimethylaluminum
9-6	Oxidation of hydrazines
9-13	Oxidative decarboxylation of carboxylic acids
9-38	Reduction of aldehydes or ketones (Wolff–Kishner; Clemmensen)
9-44	Reduction of carboxylic acids or esters
9-47	Reduction of epoxides
9-53	Reduction of cyano to methyl groups

Alkenes (*see also* Alicyclic Compounds, Unsaturated Acids, Unsaturated Alcohols, etc.)

0-70	Reduction of α-keto epoxides
0-77	Reduction of unsaturated halides
0-79	Reduction of allylic alcohols
0-83	Reductive cleavage of enamines
0-87	Coupling of vinyl halides
0-88	Coupling of unsaturated halides with organometallic reagents
0-89	Coupling of allylic halides, tosylates, or acetates
0-90	Coupling of vinyl triflates with organometallic reagents
0-91	Coupling of allylic alcohols with organometallic reagents
0-92	Coupling of allylic esters with organometallic reagents
0-93	Cleavage of allylic, vinylic, or silyl ethers

Alkenes (continued)

0-95	Coupling of vinylic and allylic sulfur and selenium compounds with organometallic compounds
2-2	Migration of double and triple bonds
2-31	Reaction of Grignard reagents or nickel complexes with CO
2-39	Decarboxylation of unsaturated acids
4-17	Arylation of olefins (Meerwein)
4-18	Arylation of olefins by organopalladium compounds
4-29	Vinylation of diazonium salts
4-34	Dimerization of allylic Grignard reagents
4-35	Dimerization of vinylchloroboranes
4-36	Dimerization of vinyl organometallic reagents
4-37	Desulfurization of thiophenes
4-38	Additive dimerization of olefins and carboxylic acids
5-10	Selective reduction of alkynes or allenes
5-11	Reduction of aromatic rings
5-13	Reduction of vinylic boranes
5-15	Dimerization of olefins
5-16	The ene synthesis
5-47	Addition of olefins to dienes (Diels–Alder)
5-49	Addition of carbenes to aromatic rings
5-50	Tetramerization of alkynes
5-51	Dimerization of dienes
5-52	Addition of two alkyl groups to an alkyne
5-54	Reaction of diphenylacetylene with methylsulfinyl carbanion
6-30	Reaction of *gem*-dimetallic compounds with aldehydes or ketones
6-42	Addition to aldehydes or ketones of α-sulfinyl carbanions or of α-lithiosilanes (Peterson); from tosylhydrazone salts
6-44	Reaction between anhydrides and aldehydes
6-47	Reaction between phosphorus ylides and aldehydes or ketones (Wittig)
6-64	Reaction of sulfonyl halides with tertiary amines and diazoalkanes
7-1	Dehydration of alcohols
7-2	Alkaline cleavage of ethers
7-3	Pyrolysis of carboxylic esters
7-4	Pyrolysis of xanthates (Chugaev)
7-5	Cleavage of inorganic esters and sulfonates
7-6	Cleavage of quaternary ammonium hydroxides (Hofmann)
7-7	Cleavage of quaternary ammonium salts
7-8	Cleavage of amine oxides (Cope)
7-9	Cleavage of other amine derivatives
7-10	Cleavage of aliphatic diazonium salts
7-11	Decomposition of tosylhydrazones
7-12	Cleavage of sulfonium compounds
7-13	Cleavage of sulfoxides, selenoxides, and sulfones
7-14	Dehydrohalogenation of alkyl halides
7-15	Reaction of sulfonyl halides with tertiary amines
7-16	Elimination of boranes
7-17	Elimination of HM from organometallic compounds
7-19	Decarbonylation of acyl halides
7-20	Cleavage of Michael adducts
7-21	Deoxygenation of *vic*-diols
7-22	Cleavage of cyclic thionocarbonates
7-23	Deoxidation of epoxides
7-24	Desulfurization of episulfides
7-25	Reaction of α-halo sulfones with bases (Ramberg–Bäcklund)
7-26	Reaction of aziridines with nitrous acid
7-27	Denitration of *vic*-dinitro compounds
7-29	Dehalogenation of *vic*-dihalides
7-31	Elimination of a halo and a hetero group (Boord)
7-32	Cleavage of β-hydroxy sulfides and related compounds
7-33	Fragmentation of γ-branched alcohols or halides
7-34	Fragmentation of γ-amino or γ-hydroxy halides
7-35	Fragmentation of 1,3-diols or γ-amino alcohols
7-36	Decarbonylation of β-hydroxy carboxylic acids and of β-lactones
7-39	Elimination of CO and CO_2 from bridged bicyclic compounds
7-46	Pyrolysis of β-hydroxy olefins
7-47	Pyrolysis of allyl ethers
7-54	Twofold extrusion from certain cyclic molecules

Alkenes (continued)

8-1 Rearrangement of alcohols and olefins (Wagner–Meerwein)
8-3 Expansion and contraction of rings (Demyanov)
8-9 Rearrangement of carbenes or carbenoids
8-29 Reaction between vinylboranes and iodine or NaOMe
8-30 Reaction of lithium alkynyltrialkylborates with electrophiles
8-31 Electrocyclic rearrangements of cyclobutenes and cyclohexadienes
8-33 [1,*j*] sigmatropic migrations of hydrogen
8-34 [1,*j*] sigmatropic migrations of carbon
8-35 Rearrangement of vinylcyclopropanes
8-36 Rearrangement of 1,5-dienes (Cope)
8-41 Metathesis of olefins
8-42 Cyclobutane reversions
8-43 The di-π-methane rearrangement
9-2 Dehydrogenation of diarylalkanes; remote dehydrogenation
9-13 Oxidative decarboxylation of carboxylic acids
9-14 Bisdecarboxylation of succinic acids
9-34 Oxidative coupling of halides
9-38 Reduction of α-hydroxy ketones; of unsaturated tosylhydrazones
9-55 Reduction of cyclic ketones
9-65 Bimolecular reduction of aldehydes or ketones

Alkyl Halides (*see also* Dihalides, Halohydrins, etc.)

0-66 Halide exchange (Finkelstein)
0-67 Reaction between inorganic esters and halide ions
0-68 Reaction between alcohols and hydrogen halides or inorganic acid halides
0-69 Cleavage of ethers with HI or HBr
0-71 Cleavage of esters with LiI
0-73 Conversion of amines to halides
0-74 Cleavage of tertiary amines (von Braun)
0-77 Reduction of dihalides
0-88 Coupling of dihalides with Grignard reagents
1-13 Reaction between aromatic rings and carbon tetrachloride
1-26 Haloalkylation of aromatic rings
2-28 Halogenation of organometallic compounds
2-38 Exchange between halides and organometallic compounds
4-1 Free-radical halogenation
4-2 Allylic halogenation
4-39 Decarboxylative halogenation (Hunsdiecker)
5-1 Addition of hydrogen halides to alkenes or alkynes
5-21 Free-radical addition of alkyl halides to olefins
5-27 Addition of halogens to olefins or alkynes
5-34 Addition of alkyl or aryl halides to olefins
7-42 Reaction of N-substituted amides with PCl_5 (von Braun)

Alkynes (*see also* Alkynyl Halides, Alkynyl Ethers)

0-89 Propargylation of alkyl halides
0-102 Alkylation at an alkynyl carbon
2-2 Triple-bond migration
2-39 Decarboxylation of acetylenic acids
3-1 Reaction between aryl iodides and copper acetylides
4-15 Coupling of alkynes (Eglinton)
4-34 Dimerization of alkynyl organometallic compounds
4-35 Coupling of alkynyl borates
7-1 Dehydration of aryl ketones
7-6 Pyrolysis of bisquaternary ammonium hydroxides
7-13 Cleavage of selenoxides or vinylic sulfides
7-14 Dehydrohalogenation of dihalides or vinyl halides
7-25 Decomposition of thiiren-1,1-dioxides
7-28 Reaction of bistosylhydrazones with metallic oxides
7-29 Dehalogenation of tetrahalides
7-31 Cleavage of enol phosphorinates
8-11 Rearrangement of vinyl halides (Fritsch–Buttenberg–Wiechell)
8-30 From boranes and lithium acetylides
8-41 Metathesis of alkynes
9-34 Oxidation of dihalotoluenes

Alkynyl Halides

2-28 Reaction of acetylide ions with halogens

Alkynyl Ethers

7-14 Reaction between vinylidine dihalides and amide ion

Allenes

0-77 Reduction of propargyl halides
0-89 Alkylation of propargyl halides
0-90 Alkylation of propargyl tosylates
0-92 Reaction between propargyl esters and organometallic reagents
2-2 Rearrangement of alkynes
6-47 Reaction of phosphoranes with ketenes or CO_2
7-14 Dehydrohalogenation of dihalides
7-29 Dehalogenation of tetrahalides or dihaloalkenes
7-46 Pyrolysis of β-hydroxy alkynes
8-3 Contraction of three-membered rings
8-37 Rearrangement of propargyl vinyl compounds
9-38 Reduction of acetylenic ketones

Amidals (*see* Bisamides)

Amides (*see also* Bisamides)

0-12 Cleavage of an alkyl group from N-*t*-butyl amides
0-53 Reaction between secondary amines and chloroform
0-54 Amination of acyl halides
0-55 Amination of anhydrides
0-56 Amination of acids
0-57 Amination of esters
0-58 Amination of amides
0-59 Amination of other acid derivatives
0-60 N-Alkylation of amides
0-105 Carbonylation of alkyl halides
1-6 Amidation of aromatic rings with hydroxamic acids
1-21 Carbamoylation of aromatic rings (Gatterman)
1-23 Amidation of aromatic rings with isocyanates
1-37 Rearrangement of N-halo-N-acyl aromatic amines (Orton)
2-11 Insertion by nitrenes
2-29 Indirectly from aldehydes
2-31 From imines, CO, and a borane
2-41 Reaction between amino acids and anhydrides (Dakin–West)
2-45 Cleavage of ketones with amide ion (Haller–Bauer)
2-47 Decyanation of cyano amides
2-55 Carbonylation of amines
3-6 N-Arylation of amides
4-13 Reaction of aldehydes with ammonia
4-22 Carbamidation of nitrogen heterocycles
5-3 Hydration of ynamines
5-8 Addition of amides to olefins; addition of amines to ketenes
5-21 Free-radical addition of amides to olefins
5-22 Hydrocarboxylation of olefins in the presence of amines
6-5 Partial hydrolysis of nitriles
6-15 Reductive alkylation of amines (Leuckart)
6-27 Reduction of isocyanates
6-37 Addition of Grignard reagents to isocyanates
6-56 Addition of alcohols or other carbocation sources to nitriles (Ritter)
6-67 Addition of water to isonitriles
8-8 Rearrangement of α-halo ketones in the presence of amines (Favorskii)
8-9 Rearrangement of diazo ketones in the presence of amines (Arndt–Eistert)
8-16 Reaction between amides, lead tetraacetate, and acetic acid
8-19 Reaction between ketones and hydrazoic acid (Schmidt)
8-20 Rearrangement of oximes (Beckmann)
8-46 Rearrangement of aryl imidates (Chapman)
9-18 Oxidation of tertiary amines
9-73 Oxidation of aryl ketones with ammonium polysulfide (Willgerodt)

Amidines

0-36 Reaction of N-alkylimino esters with secondary amines
0-57 Amination of imidates
5-8 Addition of amines to ketenimines
6-18 Addition of ammonia or amines to nitriles or nitrilium salts

Aminals

6-14 Addition of amines to aldehydes or ketones

Amine Oxides

9-29 Oxidation of tertiary amines

Amines (*see also* Cyanoamines, Amino Acids, etc.)

0-12 Hydrolysis of amides
0-36 Reduction of N-alkylimino esters
0-38 Cleavage of amines or quaternary ammonium salts
0-45 Alkylation of ammonia or amines
0-46 Reaction between alkyl halides and hexamethylenetetramine (Delépine)
0-47 Reaction of alkyl halides with cyanamide
0-48 From alcohols or ethers
0-49 Transamination
0-50 Alkylation of amines with diazo compounds
0-52 Amination of alkanes
0-60 Hydrolysis of phthalimides (Gabriel); etc.
0-73 Cleavage of aromatic amines or quaternary ammonium salts
0-83 Reduction of quaternary ammonium salts or aziridines
0-93 Cleavage of amine ethers or thioethers with organometallic compounds
0-99 Alkylation of amines
0-117 Hydrolysis of sulfonamides
1-6 Direct amination of aromatic rings
1-27 Aminoalkylation of aromatic rings
1-34 Rearrangement of N-nitroamines
1-35 Rearrangement of N-nitrosoamines (Fischer–Hepp)
1-36 Rearrangement of triazenes
1-38 Rearrangement of arylamines or aryl alkyl ammonium salts
2-10 Amination at an activated position
2-29 Conversion of organometallic compounds to amines
2-47 Decyanation of cyanoamines
3-6 Arylation of ammonia or amines
3-7 Reaction between naphthols, bisulfite ion, and ammonia or amines (Bucherer)
3-18 Amination of heterocyclic nitrogen compounds (Chichibabin)
3-19 Direct amination of activated aromatic rings
3-20 Amination of aromatic acids
3-27 Rearrangement of benzyl quaternary ammonium salts (Sommelet–Hauser)
3-28 Rearrangement of aryl hydroxylamines
4-37 Desulfurization of thioamides
5-8 Addition of ammonia or amines to olefins
5-18 Addition of organometallic compounds to allylic amines
5-21 Free-radical addition of amines to olefins
5-24 Aminomethylation of alkenes
5-41 Diamination of alkenes
5-43 Addition of R_2N and SR to double bonds
6-2 Hydrolysis of imines, enamines, and iminium ions
6-3 Hydrolysis of isocyanates or isothiocyanates
6-5 Hydrolysis of cyanamides
6-9 Reduction of N-alkylimino esters
6-13 Addition of ammonia to aldehydes
6-15 Reductive alkylation of ammonia or amines
6-16 Reaction between aldehydes, ammonia or amines, and an active hydrogen compound (Mannich)
6-27 Reduction of imines, hydrazones, or other compounds containing the C═N bond
6-28 Reduction of nitriles or nitrilium ions
6-33 Addition of Grignard reagents to formamides
6-36 Addition of Grignard reagents to imines
6-68 Reduction of isonitriles
7-6 Cleavage of quaternary ammonium hydroxides (Hofmann)
7-7 Cleavage of quaternary ammonium salts
7-9 Cleavage of R_2NMgR
7-41 Fragmentation of certain ketoximes
8-16 Reaction between amides and NaOBr (Hofmann)
8-17 Rearrangement of acyl azides in the presence of water (Curtius)
8-18 Rearrangement of hydroxamic acids (Lossen)

Amines (continued)
8-19 Addition of hydrazoic acid to carboxylic acids (Schmidt)
8-21 Rearrangement of N-haloamines
8-24 Rearrangement of quaternary ammonium salts (Stevens)
8-39 [2,3] sigmatropic rearrangements of quaternary ammonium salts
8-40 Rearrangement of benzidines
8-44 Hofmann–Löffler and related reactions
9-5 Conversion of primary to secondary amines by dehydrogenation
9-9 Reaction between ozonides, ammonia, and hydrogen
9-21 Oxidative cleavage of amines
9-40 Reduction of amides
9-48 Reduction of nitro compounds
9-51 Reduction of nitroso compounds or hydroxylamines
9-52 Reduction of oximes
9-53 Reduction of isocyanates, isothiocyanates, azides, or N-nitroso compounds
9-56 Reduction of amine oxides
9-60 Reduction of azo, azoxy, or hydrazo compounds

Amino Acids and Esters

0-12 Hydrolysis of lactams
0-45 Amination of halo acids
0-57 Ammonolysis of β-lactones
0-96 Alkylation of N-acetylaminomalonic ester (Sorensen)
2-8 Nitrosation at a carbon bearing an active hydrogen and reduction of the resulting oxime or nitroso compound
6-5 Hydrolysis of cyanohydrins
6-16 Reaction between aldehydes, ammonia, and carboxylic acids or esters
6-50 Addition of cyanide and ammonium ions to aldehydes or ketones, followed by hydrolysis (Strecker)
8-15 Rearrangement of N-halo imino esters
8-16 Reaction between imides and NaOBr (Hofmann)
8-45 Rearrangement of hydroxy amides

Amino Carbonyl Compounds

0-48 Amination of α-hydroxy ketones
0-49 Transamination of Mannich bases
1-38 Photolysis of acylated arylamines
6-16 Reaction between aldehydes, ammonia, and aldehydes, ketones, or esters (Mannich)
6-36 Reaction of iminium ions with enol borinates
8-5 Rearrangement of amino ketones or aldehydes
8-15 Rearrangement of ketoxime tosylates (Neber)
8-24 Rearrangement of quaternary ammonium salts (Stevens)

Amino Ethers

0-20 Alcoholysis of aziridines
5-40 Aminomercuration of alkenes, followed by alcoholysis
6-16 Reaction between aldehydes, amines, and alcohols or phenols (Mannich)

Amino Mercaptans

0-51 Amination of episulfides
1-9 Sulfurization of aromatic amines (Herz)
6-16 Reaction between an aldehyde, ammonia, and a thiol (Mannich)

Anhydrides

0-29 Reaction of acyl halides with acid salts
0-30 Dehydration of carboxylic acids
0-34 Reaction of acid derivatives with inorganic acids
4-10 Acyloxylation of aldehydes
4-31 Reaction between diazonium fluoroborates, CO, and an acid salt
5-5 Addition of carboxylic acids to ketenes
5-21 Free-radical addition of anhydrides to olefins
8-22 Reaction between α-diketones and peroxy compounds (Baeyer–Villiger)
9-10 Oxidation of aromatic rings

Arenes

0-77 Reduction of aryl and benzylic halides
0-79 Hydrogenolysis of benzyl alcohols
0-80 Reduction of benzylic ethers
0-87 Coupling of halides containing aryl groups
0-88 Coupling of aryl halides with organometallic reagents
0-91 Coupling of benzylic alcohols

Arenes (continued)

0-95 Coupling of aryl sulfur compounds with organometallic compounds
1-13 Alkylation of aromatic rings (Friedel–Crafts)
1-14 Arylation of aromatic rings (Scholl)
1-24 Diarylation of ketones
1-25 Ring closure of aryl-substituted carbonyl compounds
1-39 Cleavage of rearrangement of alkyl arenes
1-40 Decarbonylation of aromatic aldehydes
1-41 Decarboxylation of aromatic acids
1-44 Desulfonation of aromatic sulfonic acids
1-45 Dehalogenation of aryl halides
1-47 Hydrolysis of organometallic compounds
2-39 Decarboxylation of α-aryl acids
2-40 Cleavage of tertiary alkoxides
2-44 Cleavage of aryl ketones
2-45 Cleavage of aryl ketones with amide ions (Haller–Bauer)
2-47 Decyanation of aryl nitriles
3-9 Reduction of phenols, phenolic ethers, or phenolic esters
3-10 Reduction of aromatic nitro compounds
3-13 Coupling of organometallic compounds with aryl halides, ethers, and esters
3-16 Coupling of aryl iodides (Ullmann)
3-17 Alkylation with organolithium compounds
4-16 Free-radical arylation by diazonium salts (Gomberg–Bachmann, Pschorr)
4-19 Free-radical arylation by peroxides
4-20 Photochemical arylation
4-23 Reduction of diazonium salts
4-28 Dimerization of diazonium salts
4-29 Methylation of diazonium salts
4-34 Dimerization of Grignard reagents
4-35 Dimerization of arylboranes
4-36 Dimerization of other organometallic compounds
4-37 Reduction of sulfur compounds
4-40 Decarbonylation of aromatic aldehydes
5-50 Trimerization of alkynes
6-30 Alkylation–reduction of aromatic aldehydes and ketones
7-39 Diels–Alder reactions of cyclopentadienones with alkynes
8-32 Photolysis of stilbenes to phenanthrenes
9-1 Aromatization of six-membered rings
9-6 Oxidation of hydrazines
9-34 Dimerization of arenes
9-38 Reduction of aromatic aldehydes
9-44 Reduction of aromatic acids

Aryl Halides

1-12 Halogenation of aromatic compounds
1-37 Rearrangement of N-haloamines (Orton)
1-41 Replacement of aromatic COOH by halogen
1-44 Replacement of aromatic SO_2Br by halogen
1-45 Migration of halogen
2-28 Reaction of aryl organometallic compounds with halogens
3-8 Aryl halide exchange; halo-de-nitration
3-24 Reaction between diazonium salts and iodide ion
3-25 Heating of diazonium fluoroborates (Schiemann)
4-24 Reaction between diazonium salts and CuCl or CuBr (Sandmeyer)
4-39 Decarboxylative halogenation (Hunsdiecker)
4-40 Decarbonylation of acyl halides

Azides

0-63 Alkylation or acylation of azide ion
2-30 Reaction of Grignard reagents with tosyl azide
2-49 Reaction between hydrazines and nitrous acid
2-51 Reaction of amine anions with tosyl azide
3-23 Reaction of diazonium salts with azide ion
4-39 Reaction of acyl peroxides with copper azide
5-9 Addition of hydrazoic acid to double bonds
5-32 Addition of halogen azides to double bonds
5-41 Treatment of olefins with sodium azide, ferrous ion, and hydrogen peroxide
5-43 Addition of SR and N_3 to double bonds
8-17 Reaction between hydrazides and nitrous acid

Azides (continued)

8-19 Reaction between alcohols or olefins and hydrazoic acid

Azines

6-20 Addition of hydrazine to aldehydes or ketones

Aziridines

0-45 Cyclization of haloamines
0-48 Cyclization of amino alcohols
0-63 Cyclization of β-azido alcohols
5-32 From β-iodo azides
5-42 Reaction of alkenes with azides
6-45 Reaction of imines with α-halo carbonyl compounds
7-49 Extrusion of N_2 from triazolines
9-52 Reduction of oximes

Azlactones

6-44 Condensation between aldehydes and N-acylglycines (Erlenmeyer)

Azo Compounds

1-4 Coupling of diazonium salts with aromatic rings
1-36 Rearrangement of aryl triazenes
1-43 Reaction between aromatic alcohols and diazonium salts (Stiles–Sisti)
1-47 Reaction between organometallic compounds and diazonium ions
2-7 Aliphatic diazonium coupling
2-52 Reaction of amines with nitroso compounds (Mills)
4-28 Coupling of aryl diazonium salts
8-47 Rearrangement of azoxy compounds (Wallach)
9-6 Oxidation of hydrazines
9-37 Oxidation of amines
9-56 Reduction of azoxy compounds
9-68 Reduction of nitro compounds

Azoxy Compounds

0-65 Reaction between alkyl halides and alkanediazotates
2-53 Reaction of nitroso compounds with hydroxylamines
9-30 Oxidation of azo compounds
9-37 Oxidation of amines
9-67 Reduction of nitro or nitroso compounds; reaction between nitroso compounds and hydroxylamines

Benzoins (*see* Hydroxy Aldehydes and Ketones)

Bisamides

6-14 Addition of amides to aldehydes or ketones
6-59 Addition of nitriles to aldehydes
6-69 Reaction between isonitriles, acids, amines, and aldehydes or ketones (Ugi)

Bisulfite Addition Compounds (*see* Hydroxy Sulfonic Acids)

Boranes

2-34 Reaction between boron halides and Grignard reagents
5-13 Hydroboration of olefins or alkynes
5-19 Reaction of borinates with organometallic compounds
7-16 Exchange reaction between boranes and olefins
8-13 Migration of boron

Bunte Salts

0-41 Reaction between alkyl halides and thiosulfate ion

Carbamates

0-54 Reaction between chloroformates and primary amines
0-64 Reaction between alkyl halides, ethanol, and thiocyanate ion
0-73 Cleavage of tertiary amines with ClCOOPh
2-11 Insertion by nitrenes
2-55 Carbonylation of amines in the presence of an alcohol
6-8 Addition of alcohols to isocyanates
6-9 Reaction of alcohols with ClCN
6-70 Addition of alkyl hypochlorites to isonitriles
8-16 Reaction between amides, bromine, and alkoxides (Hofmann); reaction between amides, lead tetraacetate, and acetic acid

Carbamates (continued)

8-17 Rearrangement of acyl azides in the presence of alcohols (Curtius)
9-31 Oxidation of isonitriles in the presence of alcohols

Carbodiimides

6-60 Addition of isocyanates to isocyanates
7-45 Dehydration of ureas and thioureas

Carbonates

0-22 Alcoholysis of phosgene
0-26 Reaction between alkyl halides and carbonate salts
8-22 Oxidation of ketones

Carboxylic Acids

0-3 Hydrolysis of 1,1,1-trihalides
0-7 Hydrolysis of ortho esters
0-9 Hydrolysis of acyl halides
0-10 Hydrolysis of anhydrides
0-11 Hydrolysis of carboxylic esters
0-12 Hydrolysis of amides
0-71 Cleavage of esters with LiI
0-75 Exchange between acids and acyl halides
0-82 Reductive cleavage of carboxylic esters
0-96 Malonic ester synthesis
0-98 Alkylation of carboxylate ions
0-100 Hydrolysis of oxazines
0-105 Carbonylation of alkyl halides and other substrates
1-21 Carboxylation of aromatic rings with carbonyl halides
1-22 Carboxylation of aromatic rings with carbon dioxide (Kolbe–Schmitt)
1-41 Rearrangement of aromatic carboxylate ions
2-39 Decarboxylation of dicarboxylic acids
2-42 Basic cleavage of β-keto esters or β-diketones
2-43 The haloform reaction
2-44 Cleavage of nonenolizable ketones
3-15 Carboxylation of aryl bromides
3-26 Rearrangement of aromatic nitro compounds upon treatment with cyanide ion (von Richter)
4-6 Oxidation of aldehydes
4-31 Reaction of diazonium fluoroborates with CO
5-2 Addition of water to ketenes
5-13 Oxidation of 1,1-diboranes
5-15 Addition of carbocations to 1,1-di-chloroethene; addition of carboxylates to olefins
5-18 Addition of alkylcopper reagents to unsaturated carboxylic acids
5-21 Free-radical addition of acids to olefins
5-22 Hydrocarboxylation of olefins
6-4 Hydrolysis of primary nitro compounds
6-5 Hydrolysis of nitriles
6-35 Addition of Grignard reagents to carbon dioxide
6-42 Reaction of ketones with tosylmethyl azide, followed by hydrolysis
6-47 Reaction of phosphoranes with CO_2
7-3 Pyrolysis of carboxylic esters
7-41 Fragmentation of certain ketoximes
8-8 Rearrangement of α-halo ketones (Favorskii)
8-9 Rearrangement of diazo ketones (Arndt–Eistert)
8-22 Oxidation of aldehydes
8-28 From boranes
9-7 Oxidative cleavage of α-diketones and α-keto acids
9-8 Oxidative cleavage of ketones and secondary alcohols
9-9 Oxidation of ozonides; ozonolysis of alkynes
9-10 Oxidative cleavage of olefins, terminal alkynes, or aromatic rings
9-11 Oxidation of aromatic side chains
9-21 Oxidation of amines
9-22 Oxidation of primary alcohols or ethers
9-23 Oxidation of arylthioalkynes
9-70 Reaction between aldehydes and base (Cannizzaro)
9-73 Oxidation of aryl ketones by ammonium polysulfide (Willgerodt)

Carboxylic Esters (*see also* Dicarbonyl Compounds, Unsaturated Esters, etc.)

0-7 Hydrolysis of ortho esters
0-13 Decarbonylation of α-keto esters
0-22 Alcoholysis of acyl halides
0-23 Alcoholysis of anhydrides
0-24 Esterification of acids
0-25 Transesterification

Carboxylic Esters (continued)

0-26 Alkylation of acid salts
0-27 Cleavage of ethers with anhydrides
0-28 Alkylation of acids with diazo compounds
0-97 Alkylation of esters
0-99 Alkylation of aryl esters
0-100 Alkylation and alcoholysis of oxazines
0-101 Reaction of halo esters or diazo esters with boranes
0-105 Carbonylation of alkyl halides and other substrates
0-106 Reaction between Grignard reagents and chloroformates
0-107 Reaction between Grignard reagents and carbonates
2-31 Carbonylation of organometallic compounds
2-42 Base cleavage of β-keto esters
3-4 Reaction between aryl halides and acid salts
3-14 Arylation of esters
3-15 Carbalkoxylation of aryl iodides
4-10 Free-radical acyloxylation
4-22 Carbalkoxylation of nitrogen heterocycles
4-39 Reaction between silver salts and iodine (Simonini)
5-3 Hydration of acetylenic ethers
5-4 Addition of alcohols or phenols to ketenes
5-5 Addition of acids or acyl peroxides to olefins
5-17 Addition of esters to acitvated olefins (Michael)
5-18 Addition of organometallic compounds to unsaturated esters
5-21 Free-radical addition of esters to olefins
5-22 Hydrocarboxylation of olefins in the presence of alcohols
5-36 Addition of acid salts to olefins
5-43 Addition of OAc and SR to double bonds
5-53 Dicarbalkoxylation of olefins and acetylenes
6-7 Reductive acylation of ketones
6-9 Alcoholysis of nitriles
8-8 Rearrangement of α-halo ketones (Favorskii)
8-9 Rearrangement of diazo ketones in the presence of alcohols (Arndt–Eistert)
8-22 Reaction between ketones and peroxy compounds (Baeyer–Villiger)
9-3 Oxidation of acetals
9-8 Cleavage of cyclic ketones with NOCl and an alcohol
9-9 From ozonides
9-13 Reaction between carboxylic acids and lead tetraacetate
9-18 Oxidation of ethers
9-22 Oxidation of primary alcohols or aldehydes
9-23 Oxidation of enol ethers
9-71 Reaction between aldehydes and aluminum ethoxide (Tishchenko)
9-73 Reaction of acetophenones with $AgNO_3$-I_2 or other reagents

Catenanes

9-66 Acyloin condensation or other methods

Cyanamides

0-47 Reaction between alkyl halides and cyanamide
0-74 Cleavage of tertiary amines with cyanogen bromide (von Braun)
7-42 Dehydration of disubstituted ureas

Cyanates

0-14 Reaction of aroxides and cyanogen halides

Cyanoamines

0-48 Amination of cyanohydrins
6-16 Reaction between aldehydes, ammonia, and nitriles (Mannich)
6-50 Addition of cyanide and ammonium ions to aldehydes or ketones (Strecker)
6-51 Addition of HCN to C=N or C≡N bonds

Cyano Carbonyl Compounds

0-96 Alkylation of cyano carbonyl compounds
0-109 Acylation of nitriles by acyl halides
0-112 Acylation of nitriles by esters
0-114 Reaction between acyl halides and CuCN
2-15 Cyanation of ketones
2-17 Cyanoethylation of enamines; reaction of enamines with cyanogen chloride

Cyano Carbonyl Compounds (continued)

3-14 Arylation of cyano carbonyl compounds
5-17 Addition of olefins (Michael)
5-20 Acylation of unsaturated nitriles
5-25 Addition of HCN to unsaturated aldehydes, ketones, or esters
6-42 Addition of cyano carbonyl compounds to aldehydes or ketones (Knoevenagel)
6-48 Condensation of nitriles (Thorpe)
9-34 Dimerization of cyano carbonyl compounds

Cyanohydrins (*see* Hydroxy Nitriles)

Cycloalkanes and Alkenes (*see* Alicyclic Compounds)

Dialdehydes (*see* Dicarbonyl Compounds)

Diazo Compounds

0-115 Reaction between acyl halides and diazomethane
2-9 Reaction of active hydrogen compounds with tosyl azide
2-48 Diazotization of α-amino esters and similar compounds
6-42 Addition of diazo esters to aldehydes
7-48 Elimination from N-nitroso-N-alkyl compounds
9-6 Oxidation of hydrazones

Diazonium Salts

1-5 Direct diazotization of aromatic rings
2-48 Diazotization of primary amines

1,2-Dicarbonyl Compounds

0-108 Dimerization of acyl halides
0-112 Acylation of 1,3-dithianes, followed by hydrolysis
3-15 Carbalkoxylation of aryl iodides
6-30 Addition of RLi and CO to carboxylic esters
6-71 Reaction of metalated aldimines with CO_2
9-9 Ozonization of alkynes or aromatic rings
9-16 Oxidation of ketones with selenium dioxide
9-21 Oxidative cleavage of α-amino ketones
9-23 Oxidation of olefins
9-28 Oxidation of alkynes

1,3-Dicarbonyl Compounds

0-96 Alkylation at a carbon bearing an active hydrogen
0-109 Acylation at a carbon bearing an active hydrogen
0-110 Acylation of ketones by anhydrides
0-111 Acylation of esters by esters (Claisen; Dieckmann)
0-112 Acylation of ketones by esters
0-113 Acylation of carboxylic acid salts
1-24 Reaction between aromatic compounds and diethyl oxomalonate
2-14 Acylation of acetals or ketals followed by hydrolysis
2-17 Acylation of enamines followed by hydrolysis (Stork)
3-14 Arylation at a carbon bearing an active hydrogen
5-17 Addition of active hydrogen compounds to olefins (Michael)
5-21 Free-radical addition of 1,3-dicarbonyl compounds to olefins
6-31 Reaction between nitriles, zinc, and α-halo esters (Blaise)
6-35 Addition of CO_2 to *gem*-dimetallic compounds
6-42 Addition of 1,3-dicarbonyl compounds to aldehydes or ketones (Knoevenagel)
6-43 Carboxylation of ketones and esters
7-20 Cleavage of Michael adducts
7-53 Extrusion of sulfur from β-keto thiol esters
8-2 Rearrangement of epoxy ketones
8-10 Reaction of ketones with ethyl diazoacetate
9-34 Dimerization of β-keto esters or similar compounds

1,4-Dicarbonyl Compounds

0-7 Cleavage of furans
1-15 Acylation of aromatic rings by succinic anhydride
5-20 Acylation of unsaturated ketones or alkynes
5-53 Dicarbalkoxylation of olefins and acetylenes
9-35 Dimerization of silyl enol ethers or of lithium enolates

1,5-Dicarbonyl Compounds

5-17 Addition of silyl enol ethers to unsaturated ketones or esters

Dicarboxylic Acids (*see* Dicarbonyl Compounds, Carboxylic Acids)

Dicyano Compounds

0-96 Alkylation of malononitriles
3-14 Arylation of malononitriles
5-17 Addition of nitriles to unsaturated nitriles (Michael)
5-25 Addition of HCN to triple bonds
6-42 Addition of malononitriles to aldehydes or ketones (Knoevenagel)
6-51 Addition of HCN to nitriles
9-10 Oxidation of *o*-diamines

Diesters (*see* Dicarbonyl Compounds)

Dihalides and Polyhalides

0-70 Treatment of epoxides with $SOCl_2$, Ph_3P and CCl_4 or Ph_3PCl_2
0-72 From diazoketones
0-77 Reduction of trihalides
2-39 Decarboxylation of trihalo acids
2-43 The haloform reaction
4-1 Free-radical halogenation
5-1 Addition of hydrogen halides to alkynes
5-27 Addition of halogens to olefins or alkynes
5-34 Free-radical addition of polyhalides to olefins
6-25 Reaction of PCl_5, SF_4, or other reagents with aldehydes, ketones, or other C═O compounds
9-21 Treatment of amines with CuX and alkyl nitrites

Diketones (*see* Dicarbonyl Compounds)

Dinitro Compounds

4-12 Nitration of alkanes or nitro compounds
5-40 Addition of N_2O_4 to olefins

gem-Diols (Hydrates)

6-1 Hydration of aldehydes

1,2-Diols

0-8 Hydrolysis of epoxides
5-36 Hydroxylation of olefins
9-63 Bimolecular reduction of aldehydes or ketones

1,3-Diols

6-46 Condensation between formaldehyde and aldehydes or ketones (Tollens)
6-53 Addition of aldehydes to olefins (Prins)

Disulfides

0-40 Reaction between alkyl halides and disulfide ion
3-5 Reaction between aryl halides and disulfide ion
3-29 The Smiles rearrangement
5-29 Addition of ArSCl to alkenes
9-36 Oxidation of mercaptans
9-54 Reduction of sulfonyl halides

Dithiols

6-11 Addition of H_2S to carbonyl compounds or imines

Enamines

5-8 Addition of amines to triple-bond compounds
6-14 Addition of amines to aldehydes or ketones
6-33 Reaction between Grignard reagents and formamides
6-47 Reaction of phosphonates with aldehydes or ketones
7-18 Dehydrocyanation of cyano amines
9-2 Dehydrogenation of tertiary amines

Enolate Ions

0-97 From enol acetates
2-3 Treatment of aldehydes or ketones with base
2-20 Treatment of active hydrogen compounds with base

Enol Ethers and Esters

0-17 O-Alkylation of carbonyl compounds with diazo alkanes
0-19 Transetherifications
0-22 Reaction between acyl halides and active hydrogen compounds
0-25 Transesterifications
0-26 Acylation of vinyl halides
0-96 Alkylation with ortho esters

Enol Ethers and Esters (continued)

0-109	O-Acylation of 1,3-dicarbonyl compounds
5-4	Addition of alcohols or phenols to alkynes; addition of aldehydes or ketones to ketene
5-5	Addition of carboxylic acids to alkynes
6-6	Addition of alcohols to aldehydes or ketones
6-34	Reaction between carboxylic esters and a titanium complex
6-47	Reaction of α-alkoxy phosphoranes with aldehydes or ketones
7-2	Cleavage of acetals
7-31	Elimination from β-halo acetals

Enol Thioethers

5-6	Addition of mercaptans to alkynes
6-11	Reaction of aldehydes or ketones with mercaptans
9-2	Dehydrogenation and reduction of sulfoxides

Enynes

5-15	Dimerization of acetylenes

Episulfides

0-38	Reaction between epoxides and phosphine sulfides
5-29	Cyclization of β-halo disulfides
6-64	Reaction of diazoalkanes with sulfur or thioketones; from aldehydes or ketones

Epoxides

0-15	Cyclization of halohydrins
0-18	Cyclization of 1,2-glycols
5-37	Epoxidation of olefins
6-30	Reaction of carbonyl compounds with *gem*-dihalides and Li or BuLi
6-45	Condensation between aldehydes and α-halo esters, ketones, or amides (Darzens)
6-63	Addition of sulfur ylides or diazomethane to aldehydes or ketones
9-64	Bimolecular reduction of aldehydes or ketones

Esters (*see* Carboxylic Esters, Inorganic Esters)

Ethers (*see also* Hydroxy Ethers, etc.)

0-7	Cleavage of oxonium ions
0-11	Reaction between carboxylic esters and alkoxide ion
0-14	Reaction between alkoxides or aroxides and alkyl halides (Williamson)
0-16	Reaction between alkoxides or aroxides and inorganic esters
0-17	Alkylation of alcohols or phenols with diazo compounds
0-18	Dehydration of alcohols
0-19	Transetherification
0-21	Alkylation of alcohols with onium salts
0-31	Exchange of ethers and oxonium salts
0-69	Cleavage of oxonium salts
0-80	Reduction of acetals or ketals
0-93	Reaction between Grignard reagents and acetals or ketals; dimerization of acetals
2-25	Reaction between Grignard reagents and *t*-butyl peresters
3-4	Reaction between aryl halides and alkoxides or aroxides
4-7	Cyclization of alcohols with lead tetraacetate
4-37	Desulfurization of thiono esters
5-4	Addition of alcohols or phenols to olefins
5-21	Free-radical addition of ethers to olefins
6-7	Reductive alkylation of alcohols
9-41	Reduction of esters
9-61	Reduction of peroxides

Glycidic Esters

5-37	Epoxidation of α,β-unsaturated esters
6-45	Condensation between aldehydes or ketones and α-halo esters (Darzens)

Grignard Reagents (*see* Organometallic Compounds)

Halo Acids, Esters, Aldehydes, Ketones (*see* Halo Carbonyl Compounds)

Haloamines

5-30	Addition of N-haloamines to unsaturated compounds

N-Haloamines and Amides

2-54	Halogenation of amines or amides

Halo Carbonyl Compounds

0-70 Reaction of acyl chlorides with ethylene oxide and NaI
0-72 Reaction of diazo ketones with hydrohalic acids
2-4 Halogenation of aldehydes or ketones
2-5 Halogenation of acids (Hell–Volhard–Zelinskii) and acid derivatives
5-27 Addition of halogens to ketenes
5-28 Addition of HOBr or HOCl to triple bonds; addition of chlorine acetate or other reagents to olefins
5-35 Addition of acyl halides to olefins
6-57 Reaction between acyl bromides and aldehydes or ketones
8-12 Rearrangement of halo epoxides
9-23 Oxidation of certain alkenes with chromyl chloride

Halo Ethers and Acetals

2-4 Halogenation of acetals or ketals
5-28 Addition of hypohalites to double bonds
6-24 Addition of alcohols and hydrogen halides to aldehydes or ketones
6-25 Reaction of carboxylic esters with ClF or other reagents

Haloformic Esters

0-22 Alcoholysis of phosgene

Halohydrins

0-70 Cleavage of epoxides with hydrogen halides
5-28 Addition of hypohalous acids to olefins

Halo Sulfoxides and Sulfones

2-6 Halogenation of sulfoxides and sulfones
5-29 Addition of sulfonyl halides to olefins

Hemiacetals

6-6 Addition of alcohols to aldehydes or ketones

Hemiaminals

6-13 Reaction between aldehydes or ketones and ammonia
6-14 Reaction between aldehydes or ketones and amines

Hemimercaptals

6-11 Addition of mercaptans to aldehydes or ketones

Heterocyclic Compounds (*see also* Epoxides, Episulfides, Aziridines, Lactams, Lactones, Anhydrides, Imides)

0-15 Cyclization of halohydrins (cyclic ethers)
0-18 Cyclization of glycols (cyclic ethers; furans)
0-19 Reaction of diols with acetals (cyclic acetals)
0-38 Reaction of dihalides with sulfide ion (cyclic sulfides)
0-45 Cyclization of haloamines (cyclic amines); dealkylation of quaternary salts of nitrogen heterocycles
0-47 Reaction between dihalides and cyanamide (cyclic amines)
0-61 Reaction between ureas and malonic esters (cyclic ureides)
1-9 Sulfurization of aromatic rings (cyclic sulfides)
1-15 Intramolecular acylation
1-23 Intramolecular amidation of aromatic rings
1-25 Cyclization of amides with $POCl_3$ (isoquinolines)
2-11 Intramolecular nitrene insertion
3-6 Intramolecular arylation of amines (cyclic amines
3-14 Intramolecular arylation of active hydrogen compounds
3-17 Arylation of heterocyclic nitrogen compounds
3-18 Amination of heterocyclic nitrogen compounds
4-7 Cyclization of alcohols with lead tetraacetate (tetrahydrofurans)
4-16 Intramolecular arylation (Pschorr)
4-21 Alkylation and arylation of nitrogen heterocycles
4-22 Carbalkoxylation and carboamidation of nitrogen heterocycles
5-6 Addition of H_2S to conjugated diynes (thiophenes)
5-8 Addition of ammonia or primary amines to conjugated diynes (pyrroles)

Heterocyclic Compounds (continued)

5-11 Hydrogenation of heterocyclic aromatic rings
5-13 Addition of boranes to dienes (cyclic boranes)
5-37 Epoxidation of C=N compounds (oxaziranes)
5-40 Photooxidation of dienes (cyclic peroxides)
5-42 Addition of aminonitrenes to triple bonds (1-azirines); addition of nitrenoids to C=N or C=O bonds (diaziridines, oxaziranes)
5-46 1,3-Dipolar addition to double or triple bonds
5-47 Diels–Alder addition involving hetero atoms
5-49 Expansion of heterocyclic rings upon treatment with carbenes
5-51 Other cycloaddition reactions
6-6 Formation of cyclic acetals; reaction between diketones and acids (furans, pyrans)
6-11 Addition of H_2S to aldehydes or ketones (cyclic thioacetals)
6-13 Reaction between aldehydes and ammonia (cyclic amines)
6-14 Intramolecular addition of amines to carbonyl groups (cyclic imines)
6-18 Reaction of dinitriles with ammonia (cyclic imidines)
6-20 Reaction between hydrazines and β-diketones or β-keto esters (pyrazoles; pyrazolones)
6-42 Reaction of ketones with tosylmethylisocyanide (oxazolines)
6-53 Reaction between alcohols and aldehydes (dioxanes)
6-58 Trimerization of aldehydes (trioxanes)
6-62 Trimerization of nitriles (triazines)
6-63 Reaction between epoxides and sulfur ylides (oxetanes)
6-65 Addition of olefins to aldehydes or ketones (oxetanes)
7-25 Reaction of dichlorobenzyl sulfones with base (thiiren-1,1-dioxides)
7-49 Extrusion of N_2 from tetrazolines (diaziridines)
7-50 Extrusion of CO_2 from benzoxadiazepinones (indazoles)
7-54 Condensation of thiobenzilic acid with aldehydes or ketones (oxathiolan-5-ones)
8-17 Curtius rearrangement of cycloalkyl or aryl azides
8-21 Rearrangement of N-haloamines (cyclic amines)
8-35 Ring expansion of N-acylaziridines (oxazoles)
8-38 Cyclization of arylhydrazones (Fischer indole synthesis)
8-44 Acid-catalyzed rearrangement of N-haloamines (pyrrolidines; piperidines—Hofmann–Löffler); cyclization of chloro alcohols (tetrahydrofurans)
9-1 Aromatization of heterocyclic rings
9-38 Reduction of α,β-unsaturated ketones (pyrazolones)
9-40 Reduction of lactams (cyclic amines)
9-41 Reduction of lactones (cyclic ethers)

Hydrates (*see gem*-Diols)

Hydrazides

0-54 Acylation of hydrazines with acyl halides
0-57 Acylation of hydrazines with esters

Hydrazines

3-18 Hydrazination of heterocyclic nitrogen compounds
5-8 Addition of hydrazines to olefins
8-16 Reaction between ureas and NaOBr (Hofmann)
9-48 Reduction of N-nitro compounds
9-51 Reduction of N-nitroso compounds
9-53 Reduction of azo compounds or diazonium salts
9-69 Reduction of nitro compounds

Hydrazo Compounds (*see* Hydrazines)

Hydrazones

2-7 Aliphatic diazonium coupling
6-20 Addition of hydrazines to aldehydes or ketones

Hydroperoxides

0-32 Reaction between alkyl or acyl halides and hydrogen peroxide
2-23 Reaction between organometallic reagents and oxygen

Hydroperoxides (continued)

4-8 Autoxidation; reaction of alkenes with singlet oxygen

Hydroxamic Acids

0-54 Acylation of hydroxylamine with acyl halides
0-57 Acylation of hydroxylamine with esters
2-10 Reaction of alkenes with MeCONO
6-4 Hydrolysis of aliphatic nitro compounds

Hydroxy Acids

0-11 Hydrolysis of lactones
1-22 Carboxylation of phenols
1-24 Reaction between aromatic compounds and diethyl oxomalonate
2-23 Oxidation of dilithiated carboxylic acids
3-20 Hydroxylation of aromatic acids
6-5 Hydrolysis of cyanohydrins
6-31 Reaction between aldehydes or ketones and zinc carboxylates
6-42 Addition of dianions of carboxylic acids to ketones
8-7 Rearrangement of benzils
8-8 Rearrangement of α,β-epoxy ketones (Favorskii)
9-70 Reaction between keto aldehydes and base

Hydroxy Aldehydes and Ketones

0-6 Hydrolysis of diazo ketones
0-99 Reaction between dithiane salts and epoxides
0-100 Alkylation of oxazines with epoxides
1-32 Rearrangement of phenolic esters (Fries)
2-17 Alkylation of enamines with epoxides
4-4 Hydroxylation of ketones
6-26 Monoreduction of α-diketones
6-30 Addition of RLi and CO to ketones
6-40 Condensation of aldehydes and/or ketones (aldol)
6-42 Reaction of ketones with tosylmethylazide and thallium ethoxide, followed by hydrolysis; reaction of aldehydes, ketones, or esters with methoxyvinyllithium
6-46 Condensation of formaldehyde with aldehydes or ketones (Tollens)
6-55 Condensation of aromatic aldehydes (benzoin)
6-71 Reaction of metalated aldimines with aldehydes or epoxides
8-4 Rearrangement of α-hydroxy aldehydes or ketones
8-7 Reaction between benzils and Grignard reagents
9-20 Oxidation of epoxides
9-23 Oxidation of alkenes
9-66 Condensation of esters (acyloin)

Hydroxyamines and Amides

0-51 Amination of epoxides
1-24 Hydroxymethylation of aromatic amines
1-27 Aminoalkylation of phenols
3-28 Rearrangement of aryl hydroxylamines (Bamberger)
4-4 Hydroxylation of amides
4-5 Hydroxylation of amines
5-39 Oxyamination of double bonds
5-40 Aminomercuration of alkenes, followed by hydrolysis
6-13 Addition of ammonia to aldehydes or ketones
6-14 Addition of amines or amides to aldehydes or ketones
6-31 Reaction between aldehydes or ketones, zinc, and and halo amides
6-42 Reaction of aldehydes with the conjugate base of formamide
6-69 Reaction between isonitriles, $TiCl_4$ and aldehydes or ketones, followed by hydrolysis

Hydroxy Esters

0-25 Transesterification of lactones
4-4 Hydroxylation of esters
6-31 Reaction between aldehydes or ketones, zinc, and α-halo esters (Reformatsky)
6-41 Condensation between esters and aldehydes or ketones
6-42 Addition of α-metalated esters to ketones; reaction of unsaturated esters with an alkyl halide and zinc
6-54 Addition of aldehydes to alkynyl ethers
8-7 Rearrangement of benzils by means of alkoxide ion

Hydroxy Ethers

0-20 Alcoholysis of epoxides

Hydroxylamines

5-8 Addition of hydroxylamine to olefins
6-27 Reduction of oximes
6-36 Addition of alkyllithium compounds to oximes
7-8 Cleavage of amine oxides (Cope)
8-24 Rearrangement of N-oxides (Meisenheimer)
9-24 Oxidation of amines
9-50 Reduction of nitro compounds

Hydroxy Mercaptans and Sulfides

0-37 Reaction between epoxides and NaSH
0-38 Reaction between epoxides and mercaptides
1-28 Thioalkylation of phenols
6-11 Addition of H_2S to aldehydes or ketones

Hydroxy Nitriles

0-103 Reaction between epoxides and cyanide ion
4-4 Hydroxylation of nitriles
5-46 Addition of a nitrile oxide to an alkene, followed by reduction
6-31 Reaction between aldehydes and ketones, zinc, and halo nitriles
6-42 Addition of nitriles to ketones; reaction of unsaturated nitriles with an alkyl halide and zinc
6-49 Addition of HCN to aldehydes or ketones

Hydroxy Sulfonic Acids

0-43 Reaction between epoxides and bisulfite ion
6-12 Addition of bisulfite ion to aldehydes or ketones

Imides (including Ureides)

0-54 Reaction between acyl halides and lithium nitride
0-55 Amination of anhydrides
0-60 N-Alkylation of imides
0-61 N-Acylation of amides or imides
5-8 Addition of imides to olefins
5-22 Hydrocarboxylation of unsaturated amides
6-70 Addition of N-halo amides to isonitriles
8-16 Reaction between amides and NaOBr (Hofmann)
8-17 Rearrangement of acyl azides in the presence of water (Curtius)
9-18 Oxidation of lactams

Imines

2-8 Reaction between active hydrogen compounds and nitroso compounds
5-8 Addition of amines to triple-bond compounds
6-13 Addition of ammonia to aldehydes or ketones
6-14 Addition of amines to aldehydes or ketones
6-28 Reduction of nitrilium ions
6-38 Addition of Grignard reagents to nitriles
6-47 Addition of ylides to nitroso compounds
6-71 Reaction of isocyanides with organometallic compounds (metalated imines)
8-17 Pyrolysis of alkyl or aryl azides
8-20 Reaction between oxime sulfonates and organometallic compounds
8-21 Rearrangement of trityl N-haloamines and hydroxylamines (Stieglitz)
9-5 Dehydrogenation of secondary amines

Imino Esters (Imidates), Imino Thioesters, and Their Salts

0-36 Reaction between oxonium ions and amides
1-29 Reaction of phenols with nitriles
6-9 Alcoholysis of nitriles (Pinner)
8-20 Reaction between oxime sulfonates and organoaluminum sulfides
8-46 From amides

Imino Nitriles

8-20 Reaction between an oxime sulfonate, an organoaluminum compound, and Me_3SiCN

Inorganic Esters

0-33 Reaction of alcohols or alkyl halides with inorganic acids or halides
2-26 Oxidation of trialkylboranes
3-8 Reaction between aryl halides and $POCl_3$
5-40 Addition of N_2O_4 to alkenes (nitro nitrites, nitro nitrates)

Isocyanates

0-54 Reaction between amines and phosgene
0-61 Reaction between oxalyl chloride and unsubstituted amides
0-64 Alkylation or acylation of cyanate ion
2-55 Carbonylation of amines
5-33 Addition of iodine isocyanate to double bonds
8-16 Reaction between amides and NaOBr (Hofmann)
8-17 Rearrangement of acyl azides (Curtius)
8-18 Rearrangement of hydroxamic acids (Lossen)
8-19 Addition of hydrazoic acid to carboxylic acids (Schmidt)
9-31 Oxidation of isonitriles

Isonitriles

0-53 Reaction between primary amines and chloroform
0-103 Reaction between alkyl halides and cyanide ion
7-44 Elimination of water from N-alkylformamides
9-56 Reduction of isocyanates

Isothiocyanates

0-54 Reaction between amines and thiophosgene
0-64 Alkylation or acylation of thiocyanate ion
3-22 Reaction between diazonium salts and thiocyanate ion
6-19 Addition of amines to carbon disulfide
9-31 From isonitriles

Isothiuronium Salts

0-37 Reaction between alkyl halides and thiourea

Ketals (*see* Acetals)

Ketenes

7-1 Pyrolysis of carboxylic acids
7-15 Dehydrohalogenation of acyl halides
7-30 Dehalogenation of α-halo acyl halides
8-9 Rearrangement of diazo ketones (Wolff)

Ketenimines

0-100 Reaction of oxazines with butyllithium
6-47 Reaction between phosphoranes and isocyanates
7-1 Dehydration of amides

Keto Acids, Aldehydes, and Esters (*see* Dicarbonyl Compounds)

Ketones (*see also* Dicarbonyl Compounds, Unsaturated Carbonyl Compounds, etc.)

0-1 Hydrolysis of vinyl halides
0-2 Hydrolysis of *gem*-dihalides
0-4 Hydrolysis of enol esters of inorganic acids
0-7 Hydrolysis of enol ethers, ketals, thioketals, etc.
0-11 Hydrolysis of enol esters
0-77 Reduction of halo ketones
0-79 Reduction of hydroxy ketones
0-83 Reduction of diazo ketones
0-88 Coupling of halo ketones with lithium alkylcopper reagents
0-96 Acetoacetic ester synthesis and similar reactions
0-97 Alkylation of ketones
0-99 Alkylation and hydrolysis of dithianes and similar compounds
0-100 Alkylation and hydrolysis of oxazines
0-101 Reaction of halo ketones or diazo ketones with boranes
0-104 Carbonylation of alkyl halides
0-106 Reaction between acyl halides and organometallic compounds
0-107 Reaction between other acid derivatives and organometallic compounds
0-109 Acylation of active hydrogen compounds followed by cleavage
0-112 Reduction of β-keto sulfoxides
0-113 Acylation of carboxylic acid salts followed by cleavage
0-116 Ketonic decarboxylation
1-15 Acylation of aromatic rings (Friedel–Crafts)
1-21 Reaction between aromatic rings and phosgene
1-29 Acylation of aromatic rings with nitriles (Hoesch)
1-32 Rearrangement of phenolic ethers (Fries)
1-38 Photolysis of acylated arylamines

Ketones (continued)

1-43 Reaction between arylcarbinols and diazonium salts (Stiles–Sisti)
1-47 Reaction of aryltrimethylsilanes with acyl chlorides
2-2 Rearrangement of hydroxy olefins
2-17 Alkylation of enamines followed by hydrolysis (Stork)
2-31 Carbonylation of organometallic compounds
2-39 Decarboxylation of β-keto acids or esters
2-40 Cleavage of tertiary alkoxides
2-41 Reaction between amino acids and anhydrides (Dakin–West)
2-42 Basic cleavage of β-diketones
3-14 Arylation of ketones
3-15 Acylation of aryl iodides
4-18 Arylation of allylic alcohols
4-21 Acylation of nitrogen heterocycles
4-30 Reaction of diazonium salts with oximes, followed by hydrolysis; or with R_4Sn and CO
5-3 Hydration of alkynes or allenes
5-5 Cyclization of olefinic acids
5-10 Selective reduction of unsaturated ketones
5-11 Reduction of phenols
5-13 Oxidation of boranes; hydrolysis of unsaturated boranes
5-17 Addition of ketones to activated olefins (Michael)
5-18 Addition of organometallic compounds to unsaturated ketones
5-19 Addition of boranes to unsaturated ketones
5-21 Free-radical addition of aldehydes or ketones to olefins
5-22 Hydrocarboxylation of dienes
5-23 Hydroacylation of alkenes
5-43 Indirectly, from alkenes
5-49 Hydrolysis of bicyclo[4.1.0]heptanes
6-2 Hydrolysis of imines, oximes, hydrazones, and other C═N compounds
6-4 Hydrolysis of secondary aliphatic nitro compounds (Nef)
6-32 Reaction between lithium carboxylates and alkyllithium compounds
6-34 Indirectly, from carboxylic esters
6-38 Addition of Grignard reagents to nitriles
6-42 Hydrolysis of epoxy silanes
6-71 Reaction of alkyl halides with metalated aldimines
7-1 Dehydration of 1,2-diols
7-13 Pyrolysis of β-hydroxy sulfoxides
7-34 Fragmentation of γ-amino or γ-hydroxy halides
7-35 Fragmentation of 1,3-diols or γ-amino alcohols
7-41 Fragmentation of certain ketoximes
7-46 Pyrolysis of β-hydroxy olefins
7-47 Pyrolysis of allyl ethers
8-2 Rearrangement of glycols and related compounds (pinacol)
8-3 Ring expansion of certain hydroxyamines (Tiffeneu–Demyanov)
8-4 Acid-catalyzed ketone rearrangements
8-10 Homologization of aldehydes or ketones
8-16 Reaction between α-hydroxy or α-halo amides and NaOBr (Hofmann)
8-23 Cleavage of hydroperoxides
8-27 Treatment of boranes with CO and H_2O, followed by NaOH and H_2O_2; or with CN^- followed by trifluoroacetic anhydride; from dialkylchloroboranes
8-30 Treatment of lithium alkynyltrialkylborates with electrophiles
9-3 Oxidation of secondary alcohols
9-7 Oxidative cleavage of glycols and related compounds
9-9 Ozonolysis of olefins
9-10 Oxidative cleavage of olefins
9-11 Oxidation of diarylmethanes
9-13 Oxidative cleavage of α-methylthio carboxylic acids
9-14 Bisdecarboxylation of malonic acids
9-15 Oxidative decyanation of nitriles
9-16 Oxidation of activated methylene groups
9-20 Oxidation of secondary alkyl halides and tosylates
9-21 Oxidation of amines
9-23 Oxidation of olefins with noble-metal salts
9-39 Reduction of diketones or quinones
9-58 Indirect oxidative decyanation of nitriles
9-72 From halohydrins

Lactams

0-56	Cyclization of amino acids
0-57	Reaction between lactones and ammonia or amines; ring expansion of lactams
0-60	Cyclization of halo amides
5-8	Addition of lactams to olefins
5-22	Hydrocarboxylation of unsaturated amines
6-32	Reaction between imines, zinc, and halo esters
6-47	Reaction between imides and phosphoranes
6-66	Addition of ketenes to imines; addition of enamines to isocyanates
8-19	Reaction between cyclic ketones and hydrazoic acid (Schmidt)
8-20	Rearrangement of oximes of cyclic ketones (Beckmann)
8-21	Expansion of aminocyclopropanols

Lactones

0-24	Cyclization of hydroxy acids
0-26	Cyclization of halo acids
5-5	Cyclization of olefinic acids
5-22	Hydrocarboxylation of unsaturated alcohols
5-44	Reaction of alkenes with manganese(III) acetate
6-47	Reaction of anhydrides with phosphoranes
6-65	Addition of ketenes to aldehydes or ketones
7-50	Extrusion of CO_2 from 1,2-dioxolane-3,5-diones
7-52	Decarboxylation of cyclic peroxides (Story)
8-22	Reaction between cyclic ketones and peroxy compounds (Baeyer–Villiger)
8-40	Rearrangement of N-halo amides
9-18	Oxidation of cyclic ethers
9-22	Oxidation of diols
9-42	Reduction of cyclic anhydrides

Mercaptals (*see* Thioacetals)

Mercaptans

0-11	Hydrolysis of thiol esters
0-37	Reaction of alkyl halides with NaSH; cleavage of isothiuronium salts
1-9	Sulfurization of aromatic compounds (Herz)
2-27	Reaction between Grignard reagents and sulfur
3-5	Reaction between aryl halides and NaSH
3-22	Reaction between diazonium salts and NaSH
5-6	Addition of H_2S to olefins
9-54	Reduction of sulfonic acids or sulfonyl halides
9-62	Reduction of disulfides

Metallocenes

2-34	Reaction between sodium cyclopentadienylide and metal halides

Monoesters of Dicarboxylic Acids

0-23	Alcoholysis of cyclic anhydrides
0-25	Equilibration of dicarboxylic acids and esters
0-113	Acylation of carboxylic acid salts with chloroformates or carbonates
6-9	Alcoholysis of cyano acids
9-10	Oxidative cleavage of catechols

Nitriles (*see also* Dicyano Compounds, Cyano Carbonyl Compounds, etc.)

0-97	Alkylation of nitriles
0-101	Reaction of halo nitriles or diazo nitriles with boranes
0-103	Reaction between alkyl halides and cyanide ion
1-30	Direct cyanation of aromatic rings
2-15	Cyanation of ketones or nitro compounds
2-32	Cyanation of organometallic compounds
2-39	Decarboxylation of α-cyano acids
3-11	Reaction between aryl halides and CuCN (Rosenmund–von Braun)
3-12	Cyanide fusion of sulfonic acid salts
3-14	Arylation of nitriles
4-27	Reaction between diazonium salts and CuCN (Sandmeyer)
4-39	Reaction of acyl peroxides with copper cyanide
4-40	Decarbonylation of aromatic acyl cyanides
5-17	Addition to activated olefins (Michael)
5-19	Addition of boranes to acrylonitrile

Nitriles (continued)

5-21	Free-radical addition of nitriles to olefins
5-25	Addition of HCN to olefins
5-43	Addition of CN and SR to double bonds
6-22	From aldehydes or carboxylic acids
6-42	Reaction of ketones with tosylmethylisocyanide
6-51	Addition of KCN to sulfonyl hydrazones
6-61	Reaction between acid salts and BrCN
7-40	Dehydration of aldoximes and similar compounds
7-41	Fragmentation of ketoximes
7-42	Dehydration of amides
7-43	From primary nitro compounds or azides
9-5	Dehydrogenation of amines
9-6	Oxidation of hydrazones
9-13	Treatment of carboxylic acids with trifluoroacetic anhydride and $NaNO_2$
9-56	Reduction of nitrile oxides
9-59	Reduction of nitro compounds with $NaBH_2S_3$
9-25	Oxidation of primary amines, oximes, or nitroso compounds

Nitro Compounds

0-62	Reaction between alkyl halides and nitrite ion
0-96	Alkylation of nitro compounds
1-2	Nitration of aromatic rings
1-34	Rearrangement of N-nitro aromatic amines
2-39	Decarboxylation of α-nitro acids
2-50	N-Nitration of amines or amides
3-17	Alkylation of aromatic nitro compounds
4-12	Nitration of alkanes
4-25	Reaction between diazonium salts and sodium nitrite
5-8	Nitromercuration–reduction of alkenes
5-17	Addition to activated olefins (Michael)
5-31	Addition of NOCl and other nitrogen compounds to olefins
5-40	Addition of N_2O_4 and other nitrogen compounds to olefins
5-43	Addition of NO_2 and SR to double bonds
6-42	Addition of nitro compounds to aldehydes or ketones; reaction of pyrylium salts with nitromethane
6-43	Carboxylation of nitro compounds

Nitrogen Ylides

2-19	Treatment of quaternary ammonium salts with organometallic compounds

Nitrones

0-35	Alkylation of oximes

Nitroso Compounds

1-3	Nitrosation of aromatic rings
1-35	Rearrangement of N-nitroso aromatic amines (Fischer–Hepp)
1-41	Nitrosative decarboxylation of aromatic acids
2-8	Nitrosation at a carbon bearing an active hydrogen
2-50	Reaction between secondary amines or amides and nitrous acid
5-31	Addition of NOCl to olefins
8-44	Photolysis of nitrites (Barton)
9-6	Oxidation of hydroxylamines
9-24	Oxidation of primary amines
9-49	Reduction of nitro compounds

Olefins (*see* Alkenes)

Organometallic Compounds (*see also* Boranes)

0-87	Reaction of alkyllithiums with alkylcopper reagents
2-19	Metallation of susceptible positions with organometallic compounds
2-20	Metallation of susceptible positions with metals or strong bases
2-22	Cleavage of alkyl groups from di- or polyvalent organometallic compounds
2-33	Reaction between an organometallic compound and a metal
2-34	Reaction between an organometallic compound and a metal halide
2-35	Reaction between an organometallic compound and an organometallic compound (exchange)
2-37	Metallation of alkyl or aryl halides with metals
2-38	Metallation of alkyl or aryl halides with organometallic compounds
4-32	Reaction of diazonium salts with metals
5-14	Hydrometallation of alkenes

Organometallic Compounds (continued)

5-18 The reaction between copper-containing compounds and organolithium compounds
8-14 Rearrangement of Grignard reagents

Ortho Esters

0-14 Reaction of alkoxides with 1,1,1-trihalides (Williamson)
0-19 Transetherification
6-6 Addition of alcohols to formic acid

Osazones

6-20 Addition of hydrazines to α-hydroxy aldehydes or ketones

Oxime Ethers

0-17 Alkylation of oximes with diazo compounds
0-35 Alkylation of oximes with alkyl sulfates

Oximes

2-8 Nitrosation at a carbon bearing an active hydrogen
5-31 Addition of NOCl to olefins
6-21 Addition of hydroxylamine to aldehydes or ketones
6-36 Addition of Grignard reagents to the conjugate bases of nitro compounds
8-44 Photolysis of nitrites (Barton)
9-8 Cleavage of cyclic ketones with NOCl and an alcohol
9-24 Oxidation of aliphatic primary amines
9-59 Reduction of nitro compounds

Oxiranes (*see* Epoxides)

Oxonium Salts

0-31 Reaction between alkyl halides and ethers or ketones

Ozonides

9-9 Ozonolysis of olefins

Peptides

0-56 Coupling of amino acids

Peroxides (*see also* Hydroperoxides, Peroxy acids)

0-32 Reaction of alkyl and acyl halides with peroxide ion
4-9 Reaction between hydroperoxides and susceptible hydrocarbons
5-4 Oxymercuration–reduction of alkenes in the presence of a hydroperoxide
5-38 Photooxidation of dienes
7-52 Reaction of ketones with H_2O_2

Peroxy Acids

9-33 Oxidation of carboxylic acids

Phenols

0-11 Hydrolysis of phenolic esters
0-33 Cleavage of phenolic ethers with sulfonic acids
0-38 Cleavage of phenolic ethers
0-48 Cleavage of aryl ethers
0-69 Cleavage of phenolic ethers with HI or HBr
0-93 Cleavage of aryl ethers with Grignard reagents
1-31 Electrophilic hydroxylation of aromatic rings
1-32 Rearrangement of phenolic esters (Fries)
1-33 Rearrangement of phenolic ethers
2-23 Oxidation of aryl organometallic compounds
2-24 Oxidation of arylthallium compounds
3-1 Hydrolysis of aryl halides and other compounds
3-2 Reaction between naphthylamines and bisulfite ion (Bucherer)
3-3 Alkali fusion of sulfonate ions
3-20 Nucleophilic hydroxylation of aromatic acids
3-21 Hydrolysis of diazonium salts
3-28 Rearrangement of N-hydroxylamines
4-5 Free-radical hydroxylation of aromatic rings
6-26 Reduction of quinones
8-6 The dienone–phenol rearrangement
8-22 Cleavage of aryl ketones with peracids (Baeyer–Villiger)
8-23 Rearrangement of aralkyl peroxides
8-37 Rearrangement of allyl aryl ethers (Claisen)
8-47 Rearrangement of azoxy compounds (Wallach)
9-1 Aromatization of cyclic ketones

Phenols (continued)

9-12 Oxidative cleavage of alkylbenzenes or aromatic aldehydes
9-43 Reduction of phenolic esters
9-44 Reduction of certain acids and esters

Phosphines

0-45 Reaction between alkyl halides and phosphine
0-83 Reduction of quaternary phosphonium salts
2-34 Reaction between phosphorus halides and Grignard reagents

Phosphonates

6-47 Reaction between alkyl halides and phosphites (Arbuzov)

Phosphoranes

6-47 Treatment of phosphonium ions with alkyllithiums

Quaternary Ammonium and Phosphonium Salts

0-45 Alkylation of amines (Menschutkin) or phosphines
5-8 Addition of tertiary amines to alkenes
6-47 Reaction of phosphines with Michael olefins or with alkyl halides

Quinones

1-15 Intramolecular Friedel–Crafts acylation of diaryl ketones
9-4 Oxidation of phenols or aromatic amines
9-19 Oxidation of aromatic hydrocarbons

Schiff Bases (*see* Imines)

Selenides

0-38 Selenylation of alkyl halides
2-12 Selenylation of aldehydes, ketones, and esters
2-27 Selenylation of organometallic compounds
9-57 Reduction of selenoxides

Semicarbazones

6-20 Addition of semicarbazide to aldehydes or ketones

Silyl enol ethers

2-21 Trialkylsilylation of ketones or aldehydes

Sulfenimides

0-60 Reaction of alkyl halides with $(PhS)_2NLi$

Sulfenyl Chlorides

4-11 Chlorosulfenation

Sulfides

0-38 Reaction between alkyl halides and thiolate ions or Na_2S
0-99 Alkylation of sulfides
1-9 Sulfurization of aromatic rings
1-28 Thioalkylation of aromatic rings
2-12 Sulfenylation of ketones, esters, and amides
2-27 Reaction between Grignard reagents and sulfur or disulfides
3-5 Reaction between aryl halides or phenols and mercaptides
3-22 Reaction between diazonium salts and mercaptides or Na_2S
4-33 Reaction of boranes with disulfides
5-6 Addition of mercaptans to olefins
5-29 Addition of sulfenyl chlorides to olefins
5-43 Dialkylamino-alkylthio-addition to double bonds
6-11 Reductive alkylation of thiols
7-12 Cleavage of sulfonium compounds
8-24 Rearrangement of sulfonium salts (Stevens)
8-39 [2,3] sigmatropic rearrangements of sulfur ylides
9-41 Reduction of thiol esters
9-57 Reduction of sulfoxides or sulfones
9-61 Reduction of disulfides

Sulfinic Acids and Esters

0-121 Reduction of sulfonyl chlorides
2-27 Reaction of Grignard reagents with SO_2
3-29 The Smiles rearrangement
4-26 Reaction of diazonium salts with $FeSO_4$ and Cu
7-13 Cleavage of sulfones
9-26 Oxidation of mercaptans

Sulfonamides

0-60 N-Alkylation of sulfonamides

Sulfonamides (continued)

0-96 Alkylation of sulfonamides
0-101 Reaction of halo sulfonamides with boranes
0-119 Reaction between sulfonyl halides and ammonia or amines
5-8 Addition of sulfonamides to olefins
9-53 Reduction of sulfonyl azides

Sulfones

0-42 Reaction between alkyl halides and sulfinates
0-96 Alkylation of sulfones
0-97 Alkylation of sulfones
0-101 Reaction of halo sulfones with boranes
0-112 Reaction between esters and methylsulfonyl carbanion
0-122 Reaction between sulfonic acid derivatives and organometallic compounds
1-10 Sulfonylation of aromatic rings
3-5 Reaction between aryl halides and sulfinate ions
5-17 Addition of sulfones to activated olefins (Michael)
5-18 Addition of organometallic compounds to unsaturated sulfones
5-29 Addition of sulfonyl halides to olefins
6-42 Addition of sulfones to aldehydes or ketones (Knoevenagel)
9-32 Oxidation of sulfides or sulfoxides

Sulfonic Acid Esters

0-33 Reaction between alcohols or ethers and sulfonic acids
0-96 Alkylation of sulfonic acid esters
0-97 Alkylation of sulfonic acid esters
0-101 Reaction of halo sulfonic acid esters with boranes
0-118 Alcoholysis of sulfonic acid derivatives
6-42 Addition of sulfonic acid esters to aldehydes or ketones (Knoevenagel)

Sulfonic Acids

0-43 Reaction between alkyl halides and sulfite ion
0-117 Hydrolysis of sulfonic acid derivatives
1-7 Sulfonation of aromatic rings
1-42 Sulfonation with rearrangement (Jacobsen)
2-13 Sulfonylation of aldehydes, ketones, or acids
3-5 Reaction between aryl halides and sulfite ion
5-7 Addition of sodium bisulfite to olefins
9-26 Oxidation of mercaptans or other sulfur compounds

Sulfonium Salts

0-38 Reactions between alkyl halides and sulfides

Sulfonyl Azides

0-119 Reaction between sulfonyl halides and azide ion

Sulfonyl Halides

0-120 From sulfonic acids and derivatives
1-8 Halosulfonation of aromatic rings
2-27 Reaction of Grignard reagents with sulfuryl chloride or with SO_2 followed by X_2
4-11 Free-radical halosulfonation (Reed)
4-26 Reaction of diazonium salts with SO_2 and $CuCl_2$
9-27 Oxidation of mercaptans and other sulfur compounds

Sulfoxides

0-96 Alkylation of sulfoxides
0-112 Reaction between esters and methylsulfinyl anion
1-9 Sulfurization of aromatic rings with thionyl chloride
2-27 Reaction of Grignard reagents with sulfinic esters
5-18 Addition of organometallic compounds to unsaturated sulfoxides
6-42 Addition of sulfoxides to aldehydes or ketones (Knoevenagel)
9-32 Oxidation of sulfides
9-57 Indirectly, from sulfones

Thioacetals

5-6 Addition of mercaptans to alkynes
6-11 Addition of mercaptans to aldehydes or ketones

Thioamides

1-23 Amidation of aromatic rings with isothiocyanates

Thioamides (continued)

6-37 Addition of Grignard reagents to isothiocyanates
9-73 Reaction of ketones with sulfur and ammonia or amines

Thiocarbamates

2-55 Treatment of amines with CO and disulfides
6-5 Hydrolysis of thiocyanates
6-8 Addition of alcohols to isothiocyanates

Thiocyanates

0-44 Reaction between alkyl halides and thiocyanate ion
1-11 Thiocyanation of aromatic rings
2-13 Thiocyanation of ketones
3-5 Reaction between aryl halides and thiocyanate ion
3-22 Reaction between diazonium salts and thiocyanate ion
4-39 Reaction between acyl peroxides and copper thiocyanate
5-29 Addition of halogen and SCN to alkenes

Thioethers (*see* Sulfides)

Thiol Acids and Esters

0-39 Reaction between acid derivatives and mercaptans or H_2S
1-21 Reaction of aromatic rings with alkyl thiolchloroformates
1-29 Reaction between aromatic rings and thiocyanates
5-3 Hydration of acetylenic thioethers
5-6 Addition of thiol acids to olefins; addition of mercaptans to ketenes
5-22 Hydrocarboxylation of olefins in the presence of mercaptans
6-39 Addition of Grignard reagents to carbon disulfide
7-53 From thiol acids and α-halo ketones

Thiols (*see* Mercaptans)

Thioketones

6-11 From ketones

Thiono Esters and Thioamides

6-11 From carboxylic esters or amides
6-66 Addition of imines to thioketenes (β-thiolactams)

Thioureas (*see* Ureas)

Triazenes

1-4 Reaction between aromatic amines and diazonium salts
2-50 Reaction between amines and diazonium salts

Unsaturated Acids, Esters, Aldehydes, Ketones (*see* Unsaturated Carbonyl Compounds)

Unsaturated Alcohols and Phenols

4-4 Allylic hydroxylation
5-11 Selective reduction of α,β-unsaturated aldehydes or ketones
5-18 Addition of organometallic compounds to propargylic alcohols
6-26 Selective reduction of α,β-unsaturated aldehydes or ketones
6-30 Addition of vinyl or alkynyl organometallic compounds to aldehydes or ketones
6-42 Condensation of alkyne salts with aldehydes or ketones
6-47 Reaction of certain ylides with aldehydes (scoopy reactions)
6-53 Addition of aldehydes to olefins (Prins)
7-2 Reaction of epoxides with strong bases
7-13 From epoxides or alkenes via selenoxide cleavage
8-3 Ring opening of cycloalkyl carbocations
8-35 Rearrangement of Li salts of 2-vinylcyclopropanols
8-37 Rearrangement of allyl aryl ethers (Claisen)
8-39 [2,3] sigmatropic rearrangements

Unsaturated Carbonyl Compounds

0-97 Vinylation of ketones or esters
0-99 Hydrolysis of bis(methylthio)alkenes
2-2 Isomerization of α-hydroxy alkynes
2-14 Acylation of olefins
2-31 From vinylic organometallic compounds
4-6 Oxidation of unsaturated aldehydes
5-17 Addition to activated alkynes (Michael)
5-18 Addition of vinyl organometallic compounds to unsaturated carbonyl compounds; addition of organometallic

Unsaturated Carbonyl Compounds (continued)

compounds to acetylenic carbonyl compounds

5-19 Addition of unsaturated boranes to methyl vinyl ketones

5-22 Hydrocarboxylation of triple bonds

5-35 Addition of acyl halides to triple bonds

6-16 Reaction between aldehydes, ammonia, and aldehydes, ketones, or esters (Mannich)

6-31 Reaction between aldehydes or ketones, zinc, and α-halo esters (Reformatsky)

6-35 Carbonation of vinyl ate complexes

6-40 Condensation of aldehydes and/or ketones (aldol)

6-41 Condensation between esters and aldehydes or ketones

6-42 Condensation between active-hydrogen compounds and aldehydes or ketones (Knoevenagel)

6-44 Condensation between anhydrides and aldehydes (Perkin)

6-47 Condensation between β-carboxy phosphoranes and aldehydes or ketones

6-54 Addition of aldehydes, ketones, esters, or amides to alkynyl ethers

7-3 Pyrolysis of lactones

7-13 Cleavage of carbonyl-containing selenoxides and sulfones

7-37 Fragmentation of epoxy hydrazones

8-6 Rearrangement of dihalo ketones (Favorskii)

8-30 Reaction of alkynylborates with ortho esters and $TiCl_4$, followed by oxidation

8-33 Rearrangement of vinylhydroxycyclopropanes

8-36 Rearrangement of 3-hydroxy-1,5-dienes (oxy-Cope)

8-37 Rearrangement of allyl vinyl ethers (Claisen)

8-39 [2,3] sigmatropic rearrangements

9-2 Dehydrogenation of aldehydes or ketones

9-13 Decarboxylation of γ-keto acids; decarbalkoxylation of certain β-keto esters

9-16 Oxidation of a methylene group α to a double or triple bond

Unsaturated Ethers and Thioethers

0-96 Alkylation of allylic ethers

6-45 Addition of telluronium iodides to aldehydes

7-31 Elimination of X and OR from β-halo acetals

8-39 [2,3] sigmatropic rearrangement of allylic sulfur ylides

Unsaturated Nitriles, Nitro Compounds, and Sulfonic Acids and Esters

2-32 Cyanation of vinylic organometallic compounds

5-17 Addition of activated alkynes (Michael)

5-18 Addition of organometallic compounds to activated alkynes

5-25 Addition of HCN to alkynes

5-34 Addition of nitryl chloride to triple bonds

6-42 Condensation between active hydrogen compounds and aldehydes or ketones (Knoevenagel)

7-18 Cleavage of H and HgCl from β-nitro mercuric halides

8-37 Rearrangement of allyl vinyl sulfides

Ureas and Thioureas

0-58 Exchange of ureas

2-55 Carbonylation of amines

6-3 Hydrolysis of isocyanates

6-17 Addition of amines to isocyanates or isothiocyanates

6-19 Addition of amines to CO_2 or CS_2

6-56 Addition of alcohols or other carbocation sources to cyanamides (Ritter)

8-16 Reactive between amides and lead tetraacetate

Ureides (*see* Imides)

Urethanes (*see* Carbamates)

Vinylic Ethers (*see* Enol Ethers)

Vinylic Halides

2-28 Halogenation of alkenyl organometallic compounds

5-1 Addition of hydrogen halides to triple bonds

5-27 Halogenation of alkynes or allenes

5-34 Addition of alkyl halides to triple bonds

5-35 Addition of acyl halides to triple bonds

Vinylic Halides (continued)

6-25 Addition of PCl_5 to aldehydes or ketones

6-47 Reaction of halophosphoranes with aldehydes or ketones; reaction of certain ylides with halogen compounds (scoopy reactions)

Xanthates

6-10 Addition of alcohols to carbon disulfide

7-4 Reaction of alcohols with NaOH and CS_2, followed by methyl iodide

Ylides (*see* Nitrogen Ylides, Phosphoranes)

SUBJECT INDEX

AAC1 mechanism, 335–337, 341, 349, 351
AAC2 mechanism, 335–338, 340–341, 349
AAL1 mechanism, 335, 337, 341, 349
AAL2 mechanism, 335–337
Absolute configuration, 94–99, 101, 103
Absolute hardness, 228*n*
Abstraction:
  by carbenes, 176, 544
  by free radicals, 169, 216, 610, 613–617, 666, 1111
  of halogens, 616
  of hydride ions, 709, 1050
  internal, 632, 958, 1044, 1045, 1055–1056
  by nitrenes, 177
  polar transition states, 610
Abstract publications, 1126–1130
Acetaldehyde, 124, 783, 862
Acetals:
  acylation of, 539
  in the aldol condensation, 832
  conversion to enol ethers, 904
  dimerization of, 410
  formation of, 1146
  hydrolysis of, 329–331
  oxidation of, 1060
  as protecting groups, 331, 343
  reaction:
    with active hydrogen compounds, 414
    with organometallic compounds, 409–410, 825
  reduction of, 393–394
  transacetalation of, 345, 790
Acetanilide, 591
Acetic acid, 72, 788
Acetic anhydride:
  in dehydrations, 355, 356, 930
  formation of, 687
  reaction:
    with alcohols, 905
    with ethers, 354
Acetoacetic ester, *see* Ethyl acetoacetate
Acetoacetic ester synthesis, 413, 414
Acetone, hydration of, 783
Acetoxy-de-carboxy-substitution, 1074
Acetoxy fluoride, 479
N-Acetylaminomalonic ester, 413
Acetyl cation, 146
Acetyl chloride, 1108
Acetylene:
  acidity of, 154, 222
  dimerization of, 710
  electronic structure of, 9
  excited state, 207
  reaction:
    with aromatic rings, 480
    with dialkylcopper lithium compounds, 778
  trimerization and tetramerization of, 774
Acetylenes, *see* Alkynes
Acetyl hypofluorite, 529
Acetylide ions:
  acylation of, 440
  alkylation of, 429, 1001
  halogenation of, 551
  reaction:
    with aldehydes or ketones, 836, 838
    with aryl halides, 595
    with boranes, 1001
Acetyl nitrate, 638
Acetyl tosylate, 354
Achiral, definition, 82
Acid:
  Brönsted definition, 218
  Lewis definition, 227
Acid-base theory, 218–236
Acid catalysis, 226–227, 781
Acid dichromate, *see* Chromic acid
Acidity functions, 224–225
Acids, *see* Carboxylic acids; Sulfonic acids; etc.
Acid strengths, 218–223
  of carbon acids, 151–152
  determination of, 545
  effect:
    of medium, 223, 234–236
    of structure, 229–234
    of temperature, 223
  of excited states, 207
  in the gas phase, 234–236
  of Lewis acids, 228, 232, 233
  tables of, 220–222, 230, 236
Aci forms, 69, 787
Acrylonitrile, 541, 665, 723, 746*n*
Actinometer, 217
Activated complexes, 183, 192
  of chiral molecules, 100
Activating groups:
  in electrophilic aromatic substitution, 453, 455–457, 459, 461
  in nucleophilic aromatic substitution, 584–585
Activation energy, 183, 197
Activation volumes, 887
Active hydrogen, definition of, 548
Active hydrogen compounds:
  acylation of, 436
  acyloxylation of, 636
  addition to multiple bonds, 711–712, 719
  alkylation of, 411–426
  amination of, 535

Active hydrogen compounds (*Continued*)
  arylation of, 596
  condensation:
    with aldehydes or ketones, 835–841
    with CO_2 and CS_2, 841–842
  conversion:
    to diazo compounds, 534
    to enolates, 546
  dimerization of, 1091
  formation of, 436–441
  halogenation of, 531
  in Mannich reaction, 800
  nitration of, 638
  nitrosation of, 533
  reaction:
    with diazonium ions, 532–533
    with nitroso compounds, 534
O-Acyl-*C*-acyloxy-addition, 861
α-Acylalkyl-de-acyloxy-substitution, 437
α-Acylalkyl-de-alkoxy-substitution, 439
α-Acylalkyl-de-halogenation, 416
α-Acylalkylidene-de-oxo-bisubstitution, 829
Acylals, 1079
  formation of, 1146
Acylamino-de-halogenation, 377, 379
Acyl,amino-de-oxo-bisubstitution, 800
Acylation:
  at an aliphatic carbon, 433–441, 537–539, 861
  of amines and ammonia, 370–377
  of aromatic rings, 484–487, 496–497
  definition, 255
  of enamines, 541
  of heterocycles, 645
  of multiple bonds, 718–720
C-Acylation versus O-acylation, 323, 436
N-Acylation of amides and imides, 379
Acyl azides, 380, 943, 984
N-Acylaziridines, 1020
Acyl cations, 146, 486–487, 538, 721
Acyl cleavages, 566–568
Acyl cyanides, 441, 656
Acyl-de-carboxylation, 565
Acyl-de-diazoniation, 649
Acyl-de-hydrogenation, 484, 496, 537
Acyl-de-metallation, 554
Acyl fluorides, 389, 808
N-Acylglycines, 843
Acyl halides:
  addition to multiple bonds, 719, 732
  in the Arndt-Eistert synthesis, 974
  complexes of, 485, 487, 538
  conversion:
    to acyl azides, 380
    to acyl cyanides, 441
    to acyl isocyanates, 381
    to acyl isothiocyanates, 381
    to amides, 370
    to anhydrides, 355
    to carboxylic esters, 346–347
    to imides, 379
    to ketenes, 916
    to ketones, 433–436
    to nitriles, 933
    to other acyl halides, 388, 389
    to peroxides, 357
    to thiol acids and esters, 362
    to trifluorides, 808
  coupling of, 435
  decarboxylation of, 655, 656, 918
  formation of, 1146
  halogenation of, 531–532
  hydrolysis of, 333
  reaction:
    with active hydrogen compounds, 436
    with aldehydes and ketones, 861
    with alkenes, 537
    with aromatic rings, 484–487, 511
    with diazomethane, 441
    with disodium tetracarbonyl ferrate, 431
    with dithiane salts, 440
    with enamines, 541
    with ethylene oxide, 386
    with Grignard reagents, 825
    with multiple bonds, 719, 732
  reduction of, 389–392, 396, 1102
  in reductive acylation of ketones, 791
Acyl-halo-addition, 732
O-Acylhydroxamic acids, 985
C-Acyl-*N*-hydroxy-elimination, 931
Acyl isocyanates, 379, 381, 863
Acyl isothiocyanates, 381
Acyl nitrites, 1089
Acyloin condensation, 1113–1116
Acyloxy amides, 871
Acyloxyboranes, 377
Acyloxy-de-alkoxylation, 354
Acyloxy-de-halogenation, 353, 355
Acyloxy-de-hydrogenation, 636
Acyloxy epoxides, 980
Acyloxylation, 636
Acyl peroxides, *see* Diacyl peroxides
Acylphenols, 499
Acyl sulfonylhydrazides, 398
N-Acylureas, *see* Ureides
O-Acylureas, 350
Adamantanes, 88, 569, 961–962
Adamantyl cation, 148, 949
2-Adamantyl substrates, solvolysis of, 300
Addition, to multiple bonds, 180, 657–872
Addition compounds, 74–81
Addition-elimination mechanism, 290*n*, 295–296, 538, 592, 594, 599, 643, 1051
Addition transformations, naming of, 253
Additive dimerization, 654
AdE2 mechanism, 658
AdE3 mechanism, 660
Adipic acid, 1065
*Ad*N-*E* mechanism, 295
Air, *see* Autoxidation; Oxygen
Alane, *see* Aluminum hydride

- Alanine, 98
- Alcoholic KOH, 896, 915
- Alcohols:
  - acidity of, 231, 235
  - addition to multiple bonds, 684–685, 719, 789–793, 807, 860
  - carbocations from, 142, 144, 147
  - carboxylation of, 432
  - cleavage of, 565, 567, 992
  - conversion:
    - to alkyl halides, 382–384
    - to amides, 638
    - to amines, 367
    - to azides, 380
    - to inorganic esters, 358
    - to mercaptans, 360
    - to nitriles, 430
    - to peroxides, 357
    - to phthalimides, 378
    - to tetrahydrofurans, 631–632
    - to xanthates, 905
  - coupling of, 407–408
  - dehydration of, 344–345, 901–903, 905
  - formation of, 1146
  - fragmentation of, 927
  - haloform reaction of, 567
  - in hydrocarboxylation, 722
  - hydrogenolysis of, 392
  - in Mannich reaction, 800
  - as nucleophiles, 342, 344–353
  - nucleophilic substitution of, 311, 312
  - oxidation of, 1057–1060, 1065, 1084
  - protection of, 684–685
  - reaction:
    - with alkenes and CO, 779
    - with aromatic rings, 479–482
    - with diazo ketones, 974
    - with dichloroboranes, 998
    - with $LiAlH_4$, 813, 1094
    - with mercaptans, 361
    - with ozonides, 1066
    - with sulfonic acid derivatives, 445
    - with thionyl chloride, 287
  - rearrangement of, 943, 959, 986, 992
  - reductive alkylation of, 791
  - resolution of, 105
- Alcoholysis:
  - of acyl halides, 346
  - of amides, 353
  - of anhydrides, 347
  - of carboxylic acids, 348–351
  - of carboxylic esters, 351–352
  - of epoxides, 346
- Aldehyde ammonias, 796
- Aldehydes:
  - acylation of, 861
  - in acylation of heterocycles, 645
  - acyloxylation of, 636
  - addition to multiple bonds, 712, 718–720, 862
  - in the aldol condensation, 829–834
  - alkylation of, 417–419
  - in the benzoin condensation, 859
  - bimolecular reduction of, 1110–1113
  - Cannizzaro reaction of, 1117–1119
  - condensation:
    - with active hydrogen compounds, 835–841, 845
    - with anhydrides, 842
    - with aromatic rings, 493–496
    - with esters, 835
    - with halo esters, 843–844
    - with phosphoranes, 845–853
  - conversion:
    - to acetals, 789–791
    - to amides, 553, 638
    - to anhydrides, 636
    - to carboxylic esters, 1084
    - to dihalides, 807–809
    - to episulfides, 867
    - to epoxides, 864–866
    - to formates, 991
    - to halo alcohols and ethers, 807
    - to ketones, 418–419, 422, 976–977
    - to nitriles, 806–807
    - to oximes, 805–806
    - to phenols, 1073
    - to silyl enol ethers, 547
    - to unsaturated aldehydes, 913, 1054
  - 2 + 2 cycloadditions of, 867–868
  - cyclodehydration of, 494
  - decarboxylation of, 506, 655–656, 955
  - formation of, 214, 1147
  - halogenation of, 626
  - homologization of, 976–977
  - in Mannich reaction, 800–802
  - oxidation of, 629–631, 633, 991
  - in Passerini and Ugi reactions, 870–871
  - photochemistry of, 213–215
  - protection of, 789, 811
  - reaction:
    - with alcohols, 789–790
    - with alkenes, 856–858, 868
    - with alkynyl ethers, 858–859
    - with amines, 796–802, 806
    - with ammonia, 796, 798–802
    - with HCN, 854–855
    - with hydrazines, 804–806, 1096–1098
    - with ketenes, 685, 867
    - with mercaptans or H_2S, 793–795
    - with metalated aldimines, 872
    - with organometallic compounds, 816–825
    - with sodium bisulfite, 795
    - with thiobenzilic acid, 941
    - with water, 783
  - rearrangement of, 967–968, 986, 1032
  - reduction of, 809–814, 1096–1098, 1110–1113
  - in reductive alkylations, 791, 795, 798–800
  - Reformatsky reaction of, 822–824
  - resolution of, 105
  - selenation of, 536
  - sulfonation of, 537
  - in Tishchenko reaction, 1119
  - in Tollens' reaction, 844

Aliphatic substitution, *see* Electrophilic substitution; Free-radical substitution; Nucleophilic substitution
Alkali fusion of aryl sulfonates, 588
Alkaloids, 959*n*
Alkanediazotates, 381
Alkanes:
  acylation of, 538
  addition to alkenes, 708–709
  alkylation of, 539–540
  amination of, 369
  carbocations from, 142, 144
  carboxylation of, 432
  chlorosulfonation and chlorosulfenation of, 637
  cleavage of, 568–569
  conversion to hydroperoxides, 633
  coupling of, 639
  dipole moments, 15
  formation of, 1149
  halogenation of, 620–624
  hydrogen exchange of, 523
  hydroxylation of, 627
  insertion by carbenes, 542–544
  nitration of, 637–638
  nitrosation of, 534
  positions of abstraction, 614
  reaction:
    with aromatic rings, 480
    with nitrenes, 535–536
  rearrangement of, 960–962
Alkenes:
  acylation of, 537–539, 718–720
  acyloxylation of, 636
  addition:
    of active hydrogen compounds, 711–712
    of acyl halides, 732
    of alcohols and phenols, 684–685
    of alkanes and alkenes, 708–711
    of alkyl halides, 730–732
    of ammonia and amines, 689
    of boranes, 702–707, 717–718
    of carbenes and carbenoids, 768–774
    of carboxylic acids, 686
    to formaldehyde, 856–858
    of HCN, 723
    of HOX and ROX, 726–727
    of hydrogen halides, 679–681
    to nitriles, 860–861
    of nitrogen compounds, 689–691, 728–730, 738–745
    of OH and CN, 745
    of organometallic compounds, 713–717
    of RH, 708–720
    of sulfur compounds, 687–688, 727–728, 742
  addition reactions:
    mechanisms, 657–670
    orientation and reactivity, 670–676
    stereochemical orientation, 675–676
  alkylation of, 642–643
  allylic halogenation of, 624–626
  allylic hydroxylation of, 627–628
  amidation of, 535
  amination of, 535
  aminomethylation of, 723
  arylation of, 642–643
  carbocations from, 142, 144
  complexes of, 75, 92, 229
  conversion:
    to aziridines, 741
    to cyclopropanes, 768–774
    to hydroperoxides, 634–635
    to lactones, 742
  coupling of, 651
  2 + 2 cycloadditions of, 751–756, 758–768, 869
  dicarbalkoxylation of, 779
  Diels-Alder reactions of, 745–758
  1,3-dipolar addition to, 743–745
  double bond migration in, 520–521, 524–527, 696–698, 917, 1014–1016, 1098
  epoxidation of, 733, 735–736
  exchange with boranes, 916–917
  formation, 214, 1149
  formylation of, 539
  halogenation of, 724–726
  hydration of, 681–682
  hydroboration of, 702–707
  hydrocarboxylation of, 720–722
  hydroformylation of, 722–723
  hydrogenation of, 104, 691–699
  hydrometallation of, 707–708
  hydroxylation of, 732–734
  metathesis of, 1036
  oxidation of, 1077, 1084–1086
  oxidative cleavage of, 1066–1072
  oxyamination of, 738–739
  oxymercuration of, 681
  ozonolysis of, 1066–1070
  photochemistry of, 215
  positions of abstraction, 615
  reaction:
    with an alkyl halide and a carbonyl compound, 841
    with aromatic rings, 479–483
    with singlet oxygen, 634–635, 738
  rearrangement of, 986, 1014–1016
  resolution of, 107
  stability of, 889

  O-alkylation of, 359
  conversion:
    to anhydrides, 355, 359
    to thiomides, 794
    to trifluorides, 808
  cyclization of, 495
  dehydration of, 902, 932–933
  formation of, 1152
  N-halogenation of, 574
  hydrolysis of, 239, 338–341
  hydroxylation of, 628
  isomerism of, 111
  in Mannich reaction, 800
  nitration of, 638
  N-nitration of, 573
  N-nitrosation of, 572
  protonation site, 222*n*
  pyrolysis of, 905

- Amides (*Continued*)
  - reaction:
    - with aldehydes, 798
    - with alkynyl ethers, 859
    - with amines, 376
    - with dithiane salts, 440
    - with Grignard reagents, 825
    - with organometallic compounds, 435
  - rearrangement of, 504, 983–984
  - reduction of, 398, 816, 1099–1100
  - sulfenylation of, 536
- Amide N-sulfo chlorides, 934
- Amidines, formation of, 1152
- Amidomercuration, 691
- Aminals, 798, 1061
- Amination:
  - of aldehydes, 638
  - of alkanes, 369
  - of alkenes, 535
  - of aromatic rings, 472, 599–601
  - of heterocycles, 599–600
- Amine ditosylates, 312, 354, 387, 395
- Amine oxides:
  - chirality of, 86
  - cleavage of, 909
  - formation of, 1088
  - rearrangement of, 994
  - reduction of, 1107–1108
- Amines:
  - acylation of, 370–377
  - addition to multiple bonds, 689–691, 719, 740, 796–804
  - alkylation of, 414
  - C-alkylation of, 423
  - aminoalkylation of, 496
  - in aminomethylation of alkenes,723
  - basicity of, 233–236
  - chirality of, 92–93
  - cleavage of, 387–388
  - conversion:
    - to alkenes, 906–910
    - to alkyl halides, 387
    - to alkyl nitrates, 358
    - to azides, 573
    - to azo compounds, 573
    - to enamines, 1054
    - to halides, 648
    - to phenols, 588
    - to thiocyanates, 364

- Amino ethers, 346, 409

Amino ketones:
  formation of, 1154
  rearrangement of, 968
Aminomalononitriles, 856
Amino mercaptans, formation of, 1154
Aminomercuration, 690, 740
Aminomethylation, 723
Aminonitrenes, 741
Amino ortho esters, 982
Aminophenols, *see* Hydroxyamines
Aminopyridines, 413
Amino thioethers, 409, 742
5-Amino-2,4,6-triiodo-N,N,N′,N′-tetramethylisophthalamide, 140
Ammonia:
  addition to multiple bonds, 689–690, 796, 798–803
  in Birch reduction, 700
  bond angles, 6, 20–21
  inversion of, 86
  in Mannich reaction, 800–802
  as nucleophile, 364–366, 368–371, 375, 590–592, 689–690, 796, 798–803, 855–856
  reaction:
    with acyl halides, 370
    with aldehydes, 638, 796
    with alkyl halides, 364
    with alkyl sulfates and sulfonates, 365
    with anhydrides, 371
    with carboxylic acids, 371
    with carboxylic esters, 375
    with copper carboxylates, 601
    with diazo compounds, 368, 974
    with epoxides, 368–369
    with multiple bonds, 742
    to give NH, 177
    with ozonides, 1066
    with sulfonyl halides, 445
  reductive alkylation of, 798–800
  in Strecker synthesis, 855
  in the Ugi reaction, 871
  in the Willgerodt reaction, 1119
Ammonium chloride, 593, 855
Ammonium dihydrogen phosphate, 807
Ammonium peroxydisulfate, 645
Ammonium polysulfide, 1119
Ammonium sulfide, 1103
Anchimeric assistance, 268, 272–278, 280–285, 946, 947, 950, 951, 1011
  in free radical reactions, 612–613
Angular methyl group, oxidation of, 1045
Anhydrides:
  addition to multiple bonds, 719
  bisdecarboxylation of, 1076
  condensation with aldehydes, 842
  conversion:
    to acyl azides, 380
    to acyl fluorides, 389
    to amides, 371
    to esters, 347
    to imides, 371
    to mixed anhydrides, 358
    to peroxides, 357
    to thiol acids and esters, 362
  disproportionation of, 355
  formation of, 1154
  halogenation of, 531–532
  hydrolysis of, 333
  reaction:
    with active hydrogen compounds, 436
    with aldehydes and ketones, 437, 861
    with alkenes, 538
    with amino acids, 565
    with aromatic rings, 485, 486
    with enamines, 541
    with Grignard reagents, 825
    with organometallic compounds, 434, 825

Diarylmethanes, oxidation of, 1073, 1077
Diarylmethyl cations, 145
Diarylmethyl halides, solvolysis of, 260, 261
Diarylthallium trifluoracetates, 549
Diastereomeric atoms, groups, and faces, 117–119
Diastereomers, 109
  definition of, 100
  separation of, 105
Diatropic compounds, 37–38, 43, 45–46, 56–59, 63–64
Diaxial addition, 676
1,5-Diazabicyclo[3.4.0]nonene-5, 915
1,8-Diazabicyclo[5.4.0]-undecene-7, 915
Diazenes, 647
Diazides, 741
Diaziridines, 741–742, 938
  chirality of, 87
Diazirines, 174
Diazo aldehydes, 428
Diazo alkanes:
  conversion to ethers, 344
  coupling of, 1091
  formation of, 534, 912, 936, 1159
  protonation of, 313
  reaction:
    with aldehydes and ketones, 866, 977
    with amides, 378
    with amines, 368
    with carboxylic acids, 354
    with sulfur and sulfur compounds, 866–867
Diazo-de-dihydro-bisubstitution, 534
Diazo esters:
  formation of, 837
  reaction:
    with aldehydes, 837
    with boranes, 428
Diazoethane, 441
Diazohydroxides, 314, 471
Diazo ketones:
  conformations of, 976
  formation of, 441, 535, 1159
  conversion:
    to ethers, 344
    to halo ketones, 386
  hydrolysis of, 329
  reaction:
    with boranes, 428
    with carboxylic acids, 355
  rearrangement of, 974
  reduction of, 395
Diazomethane:
  in generation of CH_2, 172, 174, 175, 772
  in methylation:
    of alcohols and phenols, 344
    of amines, 368
    of carboxylic acids, 355
  reaction:
    with acyl halides, 441, 974
    with aldehydes and ketones, 866, 976–978
    with aromatic rings, 772
Diazomethyl-de-halogenation, 441
Diazoniation, 472
Diazonio-de-hydrogenation, 472
Diazo nitriles, 428
Diazonium coupling, 449, 471, 532–533
Diazonium fluoroborates, 602–603
Diazonium ions:
  in aliphatic nucleophilic substitution, 313–314
  alkylation of, 649
  in arylation:
    of alkanes, 641
    of aromatic rings, 640–641
  conversion:
    to aldehydes and ketones, 649
    to alkenes, 910
    to azides, 602
    to carboxylic acids, 649
    to halides, 602–603, 647
    to nitriles, 648
    to nitro compounds, 648
    to organometallic compounds, 650
    to phenols, 601
    to sulfonyl halides, 648
    to sulfur compounds, 601
  dediazoniation of, 646–647
  coupling of, 471, 532–533
  dimerization of, 649
  formation of, 329, 472, 570–571
  reaction:
    with alkenes, 731
    with benzylic alcohols, 509
    with nucleophiles, 579, 601–603
    with organometallic compounds, 511
  rearrangement of, 579, 960
  reduction of, 646–647, 1106
  vinylation of, 649
Diazosulfides, 602
Diazotization, 313, 329, 339, 341, 387, 570–571, 583, 964–965
Diazo transfer reaction, 534, 573

Energy barrier, to rotation, 121–123
Energy cascade, 209–211
Ene synthesis, 628, 647, 711, 858, 935
Enolate ions, 68, 153
Enolate ions:
  acylation of, 436–441
  in the aldol condensation, 830–833
  alkylation of, 322–325, 412–421, 714
  conversion to silyl enol ethers, 547
  dimerization of, 1092
  formation of, 419–420, 528, 546–547, 664
  halogenation of, 530, 531
  hydroxylation of, 628
  nitration of, 638
  selenylation of, 536
  sulfenylation of, 536
Enolate ylides, 848
Enol borinates:
  in the aldol condensation, 832, 833
  conversion to enolate ions, 420
  formation of, 717
  halogenation of, 531
  hydrolysis of, 717
  reaction with iminium ions, 828
Enol content, of carbonyl compounds, 67
Enolene rearrangement, 1029
Enol esters:
  in the aldol condensation, 832
  conversion to enolate ions, 420
  formation of, 1160
  halogenation of, 531
  hydrolysis of, 338
  reaction:
    with alcohols, 352
    with carboxylic acids, 356
Enol ethers:
  in the aldol condensation, 832
  conversion to esters, 1086
  cycloadditions of, 760
  fluorination of, 529
  formation of, 1160
  hydrolysis of, 329, 331–332
  pyrolysis of, 904
  reaction with alcohols, 684
  transesterification of, 346
Enol form, in tautomerism, 66–68, 527–528
Enolization, as a side reaction in Grignard addition, 819, 822, 825
Enol phosphorinates, 926
Enol thioethers:
  acyloxylation of, 636
  cycloadditions of, 760
  formation of, 688, 795, 798
Enol triflates, 1098
Enophiles, 711
Enthalpy, 182
  of activation, 184–185, 197
Entropy, 182–186
  of activation, 184–185, 197, 269, 607, 776, 834, 898
  effect on acid and base strength, 236
Envelope conformation, 129
Enynes, addition reactions, 670, 671, 726, 748
E1cB mechanism, 443, 882–886, 891, 893–896, 904, 925, 928
  in ester hydrolysis, 338
E1-E2-E1cB spectrum, 886, 890, 894–896

- E1 mechanism, 881–882, 889, 893–896, 902, 903, 915, 927–928, 932
- Ephedrine, 105
- Epimerization, 528
- Epimers, definition of, 101
- Episulfides:
  - amination of, 369
  - conversion to alkenes, 921
  - formation of, 362, 728, 866
  - nucleophilic substitution at, 311, 325
- Episulfones, 867, 922
- Episulfoxides, 921
- Epoxidation, 733, 735–737
- Epoxides:
  - alcoholysis of, 346
  - amination of, 368–369
  - carboxylation of, 433
  - conversion:
    - to alkenes, 920
    - to allylic alcohols, 904, 913–914
    - to halohydrins, 385
    - to hydroxymercaptans and sulfides, 360, 362
    - to hydroxy sulfonic acids, 364
    - to unsaturated ketones, 431
  - cleavage of, 1063
  - formation of, 270, 1067, 1081, 1161
  - hydrolysis of, 332
  - nucleophilic substitution of, 311, 325–326
  - reaction:
    - with acetylides, 429
    - with active hydrogen compounds, 414
    - with aldehydes, 790
    - with azide ion, 380
    - with cyanide ion, 430
    - with dimethyloxosulfonium methylide, 865
    - with dithiane ions, 422
    - with enamines, 541
    - with metalated aldimines, 872
    - with organometallic compounds, 410–411
    - with oxazine ions, 425
    - with phosphines, 852
    - with sulfides, 423
    - with triphenylphosphine, 369
  - rearrangement of, 964
  - reduction of, 394, 1102
- Epoxy esters, formation of, 842–843
- Epoxy hydrazones, 929
- Epoxy ketones, 386, 865, 964, 971
- Epoxy silanes, 839
- Equatorial bonds, 125–128
- Equilibration of carbonyl compounds, 528
- Equivalent atoms and groups, 116
- Erlenmeyer azlactone synthesis, 843
- Erythro isomers, 102, 269, 277, 658, 875, 892, 898
- Eschenmoser's salt, 802
- Eschweiler-Clarke procedure, 799, 800

- Esters, *see* Carboxylic esters; Inorganic esters; *etc.*
- Étard reaction, 1079
- Ethane:
  - conformations of, 120–122
  - conversion to *t*-butyl cation, 540
  - heat of atomization, 22
- Ethanolamines, 368, 369
- Ethanedithiol, 795
- Ethanol, 646
- Ethanolysis of alkyl halides, 239
- Ethers:
  - acyloxylation of, 636
  - addition to multiple bonds, 719
  - autoxidation of, 633
  - cleavage of, 329, 354, 358, 367, 384, 410, 903–905, 935
  - conversion:
    - to amines, 591
    - to nitriles, 595
    - to oxonium salts, 356
  - demethylation of, 361
  - formation of, 1161
  - halogenation of, 621
  - hydrolysis of, 343
  - nucleophilic substitution of, 311
  - oxidation of, 1060, 1080, 1084
  - reaction:
    - with aromatic rings, 480
    - with carboxylic acids, 351
    - with organometallic compounds, 409–410, 595
  - rearrangement of, 994–995, 1028–1032
  - reduction of, 393–394, 594
  - transetherification of, 345, 589
- 2-Ethoxy-1,3-dithiolane, 490
- α-Ethoxyvinyl carbanion, 719
- Ethyl acetoacetate, 67, 323, 413–414, 711–712, 719
- Ethylaluminum dichloride, 1036

    with diketones, 970
    with epoxides, 410–411
    with ethers, 409–410, 595
    with halides, 402–404
    with iminium salts, 425
    with isocyanates, 828
    with isonitriles, 872
    with metal halides, 557
    with naphthalene, 599
    with nitriles, 828–829
    with oxime sulfonates, 989
    with oxygen, 548
    with peresters, 549
    with sulfates and sulfonates, 407
    with sulfonyl chlorides or sulfonates, 446
    with sulfur and selenium compounds, 411
  rearrangement of, 981
  structure of, 158–160
Group electronegativities, 14, 17
Grunwald-Winstein equation, 318, 320
S-Guaiazulene, 46
Guaiol, 46
Guanidine, 378, 803
Guest, in inclusion compounds, 79

H_0 and similar functions, 224–225

H_R, 147
Half-chair conformation, 129
Half-life, 195
Halide exchange, 258, 381–382, 389, 593
Halide ions:
  as leaving groups, 296, 310, 578, 581, 587
  as nucleophiles, 307, 593
Haller-Bauer reaction, 568
Halo acetals, 727, 925
Halo acids:
  conversion:
    to amino acids, 365
    to lactones, 353
  formation of, 1162
  lactonization of, 348
  in the Reformatsky reaction, 823
Halo acyl halides:
  deacylation of, 925
  formation of, 532, 726
Halo alcohols, 343, 927, 1045
α-Halo alcohols, 807
Halo aldehydes, formation of, 1162
Halo alkoxides, 843
Haloalkylation, 480, 495
Haloalkyl-de-hydrogenation, 495
Halo alkynes, 551, 640, 1000
Halo amides, 823, 844, 983
N-Halo amides, 503, 728, 872, 983, 1044
  formation of, 1161
Haloamines, 472, 728, 742, 927, 1043–1044
N-Haloamines, 615, 621, 622, 728, 989–990, 1043–1044
  formation of, 1161
Halo azides, 729–730
Halobenzenes, rearrangement of, 509
Halocarbenes, 543, 768, 769, 771, 772
Halo-de-acyloxy-substitution, 389
Halo-de-alkoxylation, 384
Halo-de-amination, 387
Halo-de-diazoniation, 602
Halo-de-halogenation, 381–382, 389, 593
Halo-de-hydrogenation, 476, 529, 620
N-Halo-de-hydrogenation, 574
Halo-de-hydroxylation, 382, 388
S-Halo-de-hydroxylation, 445
Halo-de-metallation, 551
Halo-de-sulfonyloxy-substitution, 382
Halo disulfides, 728
Halo epoxides, rearrangement of, 980
Halo esters:
  Darzen's reaction of, 843–844
  formation of, 1162
  reaction with boranes, 426–428
  in Reformatsky reaction, 822–824
Halo ethers, 559, 727, 807, 925
Haloformic esters, formation of, 347
Haloform reaction, 567
Halogenation:
  of acids and derivatives, 531–532
  of aldehydes, 529–531, 626
  of alkanes, 620–624
  of alkyl halides:
    neighboring groups in, 612–613
  at an allylic position, 624–626
  of aromatic rings, 476–479
  of ketones, 529–531, 626
  of multiple bonds, 724–726
  of organometallic compounds, 551–552
  of sulfoxides and sulfones, 532
N-Halogenation, 574
Halogen dance, 510
Halogen exchange, 445
Halohydrins:
  conversion:
    to alkenes, 925
    to ketones, 1119
  formation of, 385, 726–727
  rearrangement of, 964, 965
Halo ketones, 302*n*
  alkylation of, 401
  conversion to alkenes, 923
  cyclization of, 818
  Darzen's reaction of, 844
  formation of, 1162
  reaction:
    with boranes, 426–428
    with thiol acids, 941
  rearrangements of, 971–975, 978
  reduction of, 391
Halo nitriles, 426–428, 823, 844
Halo nitro compounds, 729
Halo nitroso compounds, 729
Halonium ions, 271–272, 312
α-Halo organometallic compounds, 174, 561
Halo oximes, 729
Halopyridinium salts, 349
Halo sulfides, 923
Halosulfo-de-hydrogenation, 475
Halosulfonation, 475
Halo sulfones, 532, 727–728, 844, 921–922
Halo sulfonyl derivatives, reaction with boranes, 426, 428
Halo sulfoxides, formation of, 532
Halothiocyanation, 728
Halo thioethers, 728
α-Halovinylboranes, 1000, 1001
Hammett acidity function, 224
Hammett equation, 242–250, 303, 464, 586
Hammond postulate, 188, 299, 453, 673
Handbooks, 1133
"Handbuch der Organischen Chemie" (Beilstein), 1130
Hard and soft acids and bases, 228–229, 308, 310, 324, 444
Hartree-Fock method, 26
Haworth reaction, 486
Heat:
  of atomization, 22, 26
  of combustion, 22
    of cycloalkanes, 136
  of hydrogenation, 27, 28
Heavy-atom isotope effects, 199
Heilbron's Dictionary, 1133
Helical molecules, 91–92
Helicenes, 91–92
Hell-Volhard-Zelinskii reaction, 531
Hemiacetals, 789–791, 992, 1084
Hemiaminals, 796, 797, 801–802
Hemimercaptals, 794–795

Henkel reaction, 508
Henry reaction, 836*n*
Heptalene, 45–46
Heptahelicene, 91*n*, 107
Herz reaction, 475
Hetarynes, 582*n*
Heterocycles, aromatization of, 1052
Heterocyclic compounds:
  acylation of, 485, 645
  alkylation of, 481, 598–599, 645
  amination of, 599–600
  arylation of, 599
  carbalkoxylation of, 645–646
  carboamidation of, 645–646
  formation of, 1162
  orientation in, 460–461
  tautomerism in, 69
Heterogeneous hydrogenation, 692–700, 798, 811
Heterolytic mechanisms, definition, 179
Heteronins, 56*n*
Hexachloro-2,4-cyclohexadiene, 529
Hexachloroethane, 532
Hexachlorocyclohexane, 875
Hexacyclo[4.4.0.0^{2,4}.0^{3,9}.0^{5,8}.0^{7,10}]decane, 132
Hexacyclo[5.3.0.0^{2,6}.0^{3,10}.0^{4,9}.0^{5,8}]decane, 132
Hexadecanol hemisuccinate, 1079
Hexafluoro-2-propanol, 317
Hexahelicene, 91–92, 140
Hexahydro-teraddition, 700
Hexahydro-terelimination, 1052
Hexaisopropylbenzene, 139, 775
Hexamethylenetetramine, 366, 490, 796, 1082
Hexamethylphosphoric triamide, *see* HMPT
Hexamethylphosphorus triamide, 866, 1112
Hexamethylprismane, 767, 768
Hexaphenylethane, 165
t-Hexyl cation, 143
Highest-occupied molecular orbital, *see* HOMO
Hinsberg test, 445
HMO method, 26
HMPA, 316
HMPT, 316, 591, 616, 915, 933, 934, 987, 1112
Hoesch reaction, 496
Hofmann elimination, 890, 891, 893, 894, 900, 902, 906–908, 913, 915
Hofmann exhaustive methylation, 906–908
Hofmann-Löffler-Freytag reaction, 1044
Hofmann-Löffler reaction, 1043–1044
Hofmann-Martius reaction, 503
Hofmann rearrangement, 945, 949, 983–984
Hofmann's rule, 890–892
HOMO, 752, 753, 756–758, 761, 762, 1005–1007, 1011, 1015
Homoallylic carbocations, 273
Homoallylic ethers, 935
Homoaromaticity, 63–64
Homocuprates, 433
Homoenolate ions, 155
Homogeneous hydrogenation, 692, 696, 697–698, 700, 798, 811
Homologization:
  of aldehydes and ketones, 976–978
  of primary halides, 423
Homolytic cleavage, 608, 609
Homolytic mechanisms, definition, 179
Homodienyl sigmatropic rearrangements, 1017, 1029
Homosigmatropic rearrangements, 1029
Homosolvolysis, 611
Homotopic atoms, groups, and faces, 119
Homotropylium ion, 63
Horner-Emmons reaction, 848
Host, in inclusion compounds, 79
"Hot" carbocations, 313, 314
Houben-Hoesch reaction, 496
Houben-Weyl, 1138
Huang-Minlon modification, 1096
Hückel calculations, 26
Hückel's rule, 49, 50, 54, 55, 753
Hückel systems, 754, 1006–1007, 1016
Hund's rule, 49, 204
Hunsdiecker reaction, 613, 654–655
Hurtley reaction, 596
Hybridization, 6–9, 12
  effect:
    on acid and base strength, 233–234
    on bond angles, 20–21
    on bond distances, 18–20
    on bond energies, 23
    on electron-withdrawing power, 18
  variable, 20–21
Hydrates, 783–784
Hydration:
  of alkenes, 681–682
  of allenes, 684
  of triple bonds, 683–684
  see also Water
Hydrazide ions, 600
Hydrazides:
  formation of, 370, 375
  in generation of diimide, 699
  hydrolysis of, 339
  oxidation of, 1062
  reaction with nitrous acid, 984
  reaction with PCl_5, 808
Hydrazine:
  conversion to hydrazides, 370, 375
  reaction:
    with aldehydes and ketones, 1096–1098
    of alkenes, 693, 696, 698
    to give NH, 177
    with phthalimides, 378
  reduction:
    of aryl tosylates, 594
    of nitro compounds, 1103, 1117
    of sulfonyl chlorides, 446
Hydrazines:
  addition to alkenes, 689
  conversion to azides, 572
  formation of, 1163
  oxidation of, 1062
  reaction with aldehydes and ketones, 804–805
  rearrangement of, 1034–1036
  reduction of, 1109–1110

Hydrazobenzene, 1034–1036
Hydrazo compounds, *see* Hydrazines
Hydrazoic acid:
  reaction:
    with aldehydes, 807
    with aromatic rings, 472
    to give NH, 177
    with multiple bonds, 691
  in Schmidt reaction, 986
  in Ugi reaction, 871
Hydrazones, 1098
  in the aldol condensation, 833
  alkylation of, 417
  conversion:
    to nitriles, 931
    to thioketones, 794
  exchange of, 805
  formation of, 533, 804
  hydrolysis of, 784–785
  oxidation of, 1062
  reaction:
    with HCN, 856
    with organometallic compounds, 827
  rearrangement of, 1032
  reduction of, 814, 1106
Hydrazono-de-oxo-bisubstitution, 804
Hydride ions, abstraction of, 709, 1050
Hydride shifts, 282*n*, 944–945, 948–950, 953, 954, 960, 961, 967, 1041, 1046
Hydride transfer, 1050
Hydridocarbonyltris(triphenylphosphine)rhodium, 722
Hydridopentacarbonylmanganese(I), 699
Hydro-acyl-addition, 718
O-Hydro-*C*-(α-acylalkyl)-addition, 829
1/*N*-Hydro-2/*C*-acylamino,2/*C*-oxo-biaddition, 872
Hydroacylation, 723
Hydro-acyloxy-addition, 686
1/*N*-Hydro-2/*C*-(α-acyloxyalkyl),2/*C*-oxo-biaddition, 870
Hydro-acyloxy-elimination, 905
N-Hydro-*C*-alkoxy-addition, 791
O-Hydro-*C*-(α-alkoxycarbonylalkyl)-addition, 835, 858
Hydro,alkoxy-de-diazo-bisubstitution, 344
Hydro-alkoxy-addition, 684
Hydro-alkoxy-elimination, 903
Hydro-alkyl-addition, 708, 713, 717
C-Hydro-*O*-alkyl-addition, 791
N-Hydro-*C*-alkyl-addition, 827
O-Hydro-*C*-alkyl-addition, 816
N-Hydro-*C*-alkylamino-addition, 802
N-Hydro,*N*-alkyl-*C*-oxo-biaddition, 860
Hydro-alkylsulfinyl-elimination, 913
Hydro-alkylsulfonyl-elimination, 913
Hydro-alkylthio-addition, 687
Hydro-allyl-addition, 711
C-Hydro-*O*-allyl-elimination, 935
O-Hydro-*C*-allyl-elimination, 935
Hydro-amino-addition, 689
N-Hydro-*C*-amino-addition, 803
Hydro-azido-addition, 691
Hydrobenzamides, 796
Hydro-bis(ethoxycarbonyl)-methyl-addition, 711
Hydro-bis(ethoxycarbonyl)-methyl-elimination, 918
Hydro-boranetriyl-elimination, 916
Hydroboration, 691, 702–707
1/*N*-Hydro-2/*C*-butoxy,2/*C*-oxo-biaddition, 872
Hydrocarbons, resolution of, 105
Hydro-carboxy-addition, 720
Hydro-carboxy-elimination, 1074
Hydrocarboxylation, 720–722
Hydro-chloroformyl-elimination, 918
Hydro-cyano-addition, 723
Hydro-cyano-elimination, 918
N-Hydro-*C*-cyano-addition, 856
O-Hydro-*C*-cyano-addition, 854
N-Hydro-*C*-(α-cyanoalkyl)-addition, 854
Hydro-de-acylation, 566, 567
Hydro-de-acyloxylation, 394
Hydro-de-alkoxylation, 393
Hydro-de-alkylation, 505
Hydro-de-amination, 395
Hydro-de-*t*-butylation, 568
Hydro-de-carboxylation, 507
S-Hydro-de-chlorination, 445
Hydro-de-cyanation, 569
Hydro-de-dialkylamino-substitution, 398
Hydro-de-diazoniation, 646
Hydro-de-formylation, 506
Hydro-de-halogenation, 396, 510
Hydro-de-hydroxylation, 392, 397, 593
N-Hydro-de-hydroxylation, 1105
Hydro-de-mercapto-substitution, 652
Hydro-de-metallation, 511, 547
Hydro-de-(α-oxidoalkyl)-substitution, 565
Hydro-de-sulfonation, 509
Hydro-de-sulfonyloxy-substitution, 392
Hydro-dialkylaminoalkyl-addition, 723
Hydro,dialkylamino-de-diazo-bisubstitution, 368
Hydro,dialkylamino-de-oxo-bisubstitution, 798
Hydro-(dialkyloxidoammonio)-elimination, 909
Hydro-dialkylsulfonio-elimination, 912
Hydro-diazonio-elimination, 910
O-Hydro-*C*-α-ethoxycarbonylalkyl-addition, 822
Hydro-formyl-addition, 722
Hydroformylation, 722–723
Hydrogen:
  free-radical migration of, 955, 957, 958
  in hydroformylation, 722
  as a neighboring group, 285–286
  see also Hydrogenation; Hydrogenolysis
Hydrogenation:
  of aldehydes and ketones, 811, 814, 1097
  of alkenes and alkynes, 672, 691–700

Hydrogenation (*Continued*)
  of amides, 1099
  of anhydrides, 1101
  of aromatic rings, 700–702
  of azo compounds, 1106
  of carboxylic esters, 1100, 1101
  of C═N compounds, 814
  of enol triflates, 1098
  of hydrazones, 1105
  of hydroperoxides, 1109
  of nitriles, 815
  of nitro compounds, 1103
  of oximes, 1105
  of ozonides, 1066
  in reductive alkylation, 798–800
  selectivity, 1093, 1095
  see also Hydrogenolysis
Hydrogen bonding, 67, 71–74, 233
Hydrogen bromide:
  addition to multiple bonds, 663, 667, 674, 680–681
  in amine cleavage, 387
  in haloalkylation, 495
  reaction:
    with alcohols, 382–384
    with cyclopropanes, 676
    with diazo ketones, 386
    with epoxides, 385
    with ethers, 384
Hydrogen chloride:
  addition to multiple bonds, 663, 669, 674, 680–681
  in the Fischer-Hepp rearrangement, 502
  in formylations, 488–489
  in haloalkylation, 495
  in the Orton rearrangement, 503
  reaction:
    with alcohols, 382–384
    with aldehydes and ketones, 807
    with arenes, 451
    with diazo ketones, 386
    with epoxides, 385
    with ethers, 384
    with nitriles, 788
    with nitro compounds, 593
Hydrogen cyanide, addition to multiple bonds, 723, 854–856, 860
Hydrogen exchange, 467–468, 518–519, 523, 539, 696, 697
Hydrogen fluoride, addition to multiple bonds, 671, 680–681, 729
  reaction:
    with acyl halides, 389
    with alcohols, 383
    with anhydrides, 389
    with epoxides, 385
Hydrogen iodide:
  addition to multiple bonds, 680–681
  in cleavage of amines, 387
  reaction:
    with alcohols, 382, 384
    with epoxides, 385, 386
    with ethers, 384
  reduction:
    of aryl halides, 510
    of diazo ketones, 386, 395
    of diketones, 1097
    of keto epoxides, 386
    of phenols, 593
    of sulfonyl halides, 1107
    of sulfoxides, 1108
Hydrogenolysis:
  of acyl halides, 396
  of adamantanes, 569
  of alcohols, 392–393
  of alkyl halides, 390
  of amine oxides, 1108
  of amines, 395
  of aryl halides, 510
  of azoxy compounds, 1108
  of cyclopropanes, 702
  definition, 389
  of epoxides, 394
  of nitriles, 1107
  of N-nitrosoamines, 1106
  of peroxides, 1110
  of phenols and phenolic ethers, 593–594
  in reduction alkylation, 791, 798–800
  of sulfoxides, 1108
  of sulfur compounds, 652–653
Hydrogen peroxide:
  in carbalkoxylations, 645, 646
  conversion to singlet oxygen, 634
  in Dakin reaction, 1073
  in hydrolysis:
    of C═N bonds, 785
    of nitro compounds, 787
    of thioacetals, 331
  hydroxylation with, 627, 628
  reaction:
    with alkenes, 733
    with bromo ketones, 923
    with ketones, 940
    with nitriles, 788
  oxidation:
    of alkenes, 1085
    of amines, 1086, 1088
    of arenes, 498
    of boranes, 550, 705, 995–999, 1002
    of carboxylic acids, 1090
    of diketones, 1063
    of ozonides, 1066
    of sulfur compounds, 1089, 1092
  in peroxide formation, 357
Hydrogen sulfide, 360, 362, 687, 688, 793, 794, 1097
Hydro-halo-addition, 679
Hydro,halo-de-diazo-bisubstitution, 386
Hydro-halo-elimination, 914
Hydro-hydroxy-addition, 681
O-Hydro-*C*-hydroxy-addition, 783
O-Hydro-*C*-(β-hydroxyalkyl)-addition, 844
Hydro,hydroxy-de-diazo-bisubstitution, 329
Hydro-hydroxy-elimination, 901
C-Hydro-*N*-hydroxy-elimination, 930
Hydrolysis:
  of acetals, 329–331
  of acyl halides, 333
  of alkyl halides, 240, 326
  of amides, 239, 338–341
  of anhydrides, 333
  of aryl halides, 588
  of boranes, 695
  of Bunte salts, 360
  of carboxylic esters, 240, 245–246, 248, 292, 299, 334–338
  of C═N compounds, 784–786

  of cyclopropanes, 773
  of diazo ketones, 329
  of diazonium ions, 601
  of dihalides, 327
  of dihalo ketones, 1118
  of enamines, 785–786
  of enol borinates, 717
  of enol ethers, 329, 331–332
  of epoxides, 332
  of inorganic esters, 328
  of isocyanates and isothiocyanates, 786
  of nitriles, 788
  of nitro compounds, 786–787
  of organometallic compounds, 511, 548
  of ortho esters, 329–331
  of oximes, 1045
  of sulfonic acid derivatives, 444
  of thioacetals and thioketals, 331
  of trihalides, 327
Hydro-magnesioalkylamino-elimination, 910
O-Hydro-*C*-mercapto-addition, 793
Hydrometallation, 707
  see also Hydroboration
Hydro-metallo-addition, 707
Hydro-metallo-elimination, 917
Hydro,oxy-de-nitrilo-tersubstitution, 815
Hydroperoxide ion, 736
Hydroperoxides:
  addition to alkenes, 685
  conversion to peroxides, 635
  formation of, 1068, 1163
  oxidation:
    of amines, 1088
    of azo compounds, 1089
    of lactams, 1080–1081
  reduction of, 1108–1109
  rearrangement of, 991–992
Hydroperoxy-de-halogenation, 356
Hydroperoxy-de-hydrogenation, 633
Hydroperoxy-de-metallation, 548
Hydroquinones, 80, 810
Hydrosilanes, 1052*n*
Hydro-sulfonato-addition, 688
O-Hydro-*C*-sulfonato-addition, 795
Hydro-tosyloxy-elimination, 906
Hydro-trialkylammonio-elimination, 906
Hydroxamic acids:
  formation of, 370, 375, 535, 787
  reaction with phenolic ethers, 473
  rearrangement of, 985
Hydroxide ion, as nucleophile, 326–341, 588, 970, 971
Hydroxy acids:
  cleavage of, 1063, 1064
  decarbonylation of, 341
  formation of, 1164
  fragmentation of, 928
  lactonization of, 348–349
  cleavage of, 831, 1063
Hydroxy aldehydes:
  conversion to osazones, 804
  formation of, 1164
  rearrangement of, 968
Hydroxyalkylation, 493
Hydroxyalkyl-de-hydrogenation, 493
Hydroxyalkyl-hydroxy-elimination, 928
Hydroxy-alkylthio-elimination, 925
Hydroxy alkynes, 290, 935
Hydroxy amides:
    formation of, 1164
    rearrangement of, 983
Hydroxyamines:
  cleavage of, 1063
  conversion to aziridines, 367
  formation of, 1164
  fragmentation of, 928
  rearrangement of, 964, 965
Hydroxy azo compounds, formation of, 1047
Hydroxy-chloro-addition, 726
Hydroxy-de-acyloxy-substitution, 333
Hydroxy-de-alkoxylation, 334, 345
Hydroxy-de-amination, 338, 588
Hydroxy-de-(bistrifluoro-acetoxy)thallation, 549
S-Hydroxy-de-chlorination, 444
Hydroxy-de-diazoniation, 329, 601
Hydroxy-de-halogenation, 326, 333, 588
Hydroxy-de-hydrogenation, 498, 600, 627
Hydroxy-de-metallation, 548
Hydroxy-de-sulfonyloxy-substitution, 328
Hydroxy enol ethers, 840
Hydroxy esters, formation of, 1164
Hydroxy ethers, formation of, 346
Hydroxy imines, rearrangement of, 968
Hydroxyimino-de-dihydro-bisubstitution, 533
Hydroxyimino-de-oxo-bisubstitution, 805
Hydroxy ketones:
  cleavage of, 831, 1063
  conversion:
    to amino ketones, 367
    to osazones, 804
  formation of, 1164
  rearrangement of, 968, 971
  reduction of, 393, 1097
Hydroxylamines, 370, 375, 600, 689, 694, 698, 805–807, 1103
  formation of, 1165
  oxidation of, 1062, 1086
  reaction:
    with aromatic compounds, 473
    with nitroso compounds, 573
  rearrangement of, 606, 990
  reduction of, 1105
Hydroxylamine-O-sulfonic acid, 395, 553, 694, 696, 805, 807, 988
Hydroxylamine-O-sulfonic acids, 742
Hydroxylation:
  at an aliphatic carbon, 627–631
  of alkenes, 732–734
  of aromatic acids, 600–601
  of aromatic rings, 498
Hydroxy mercaptans, formation of, 1165
Hydroxy nitriles, formation of, 1165

α-Hydroxy nitriles, *see* Cyanohydrins
Hydroxy,oxo-de-nitrilo-tersubstitution, 788
Hydroxy,oxo-de-trihalo-tersubstitution, 327
4-Hydroxypyridine, 69
Hydroxy selenides, 926
Hydroxy sulfides:
  conversion to alkenes, 925–926
  formation of, 742, 1165
Hydroxysulfinamides, 838, 926
Hydroxy sulfonic acids, formation of, 364, 795
Hydroxy sulfoxides, 914
Hydroxy thiols, 361, 793
Hyperconjugation, 64–66, 143, 164, 199, 457
Hypobromous acid, 477, 726, 727
Hypochlorous acid, 477, 531, 726, 727
Hypofluorous acid, 726
Hypoiodous acid, 726
Hypophosphorous acid, 646, 647
Hypostrophene, 1025
Hypsochromic shifts, 205, 206

+*I* and −*I* groups, 16–18
Imidates, *see* Imino esters
Imidazoles, 352, 398, 919
Imidazolides, 339, 350, 436
Imides:
  additions to multiple bonds, 689
  N-alkylation of, 377
  formation of, 1165
  hydrolysis of, 339
  reaction with phosphoranes, 853
  rearrangement of, 983
  reduction of, 1100
  see also Ureides
Imidines, formation of, 803
Imido selenium compounds, 535
Imido sulfur compounds, 535
Imine-enamine tautomerism, 69–70
Imines:
  alkylation of, 417, 419*n*
  condensation with active hydrogen compounds, 838
  conversion:
    to enamine salts, 542
    to β-lactams, 869
  Darzen's reactions of, 844
  formation of, 1165
  hydrolysis of, 784
  isomerism of, 110
  reaction:
    with aldehydes and ketones, 833
    with HCN, 856
    with H_2S, 794
    with organometallic compounds, 827
    with phosphoranes, 853
  reduction of, 814, 827
  tautomerism of, 69
Iminium ions, 798, 1054
  hydrolysis of, 785, 786
  in Mannich reaction, 802
  reaction:
    with cyanide ions, 856
    with enol borinates, 828
    with organometallic compounds, 425, 827
  reduction of, 814
  rearrangement of, 1031*n*
Imino[10]annulene, 56–57
Imino chlorides, 495, 1046
Imino esters:
  conversion to amidines, 375
  formation of, 1165
  hydrolysis of, 336*n*
  rearrangement of, 1046
Imino ether fluoroborates, 1099
Imino ethers, *see* Imino esters

Ketene, photolysis of, 174, 215
Ketene acetals, 868
Ketene dimers, 867–868, 916

- Ketenes:
  - addition:
    - of alcohols and phenols, 685
    - of amines, 690
    - of carbenes, 770
    - of carboxylic acids, 687
    - of enols, 685
    - of hydrogen halides, 681
    - of mercaptans, 688
    - of water, 682
  - 2 + 2 cycloadditions of, 758–763, 867, 869
  - dimerization of, 758, 763
  - formation of, 1166
  - halogenation of, 726
  - as intermediates, 338, 541
  - reaction:
    - with aromatic rings, 485
    - with phosphoranes, 853
- Ketene thioacetal monoxides, 712
- Ketenimines, 542
  - formation of, 425, 853, 902
  - reaction with amines, 690
- Ketenimmonium salts, 759
- Ketimines, *see* Imines
- Keto acids:
  - cleavage of, 1063, 1064
  - decarbonylation of, 341
  - decarboxylation of, 563, 564
  - formation of, 440, 486, 841–842, 872, 1088
  - lactonization of, 348
  - oxidation of, 1074
  - cleavage of, 1063
  - conversion to hydroxy acids, 1118
  - formation of, 439, 440, 539, 1067, 1077
  - hydration of, 783
  - rearrangement of, 970
- α-Keto diazonium salts, 329
- Keto-enol tautomerism, 66–68
- Keto-enol tautomerization, 527–529
- Keto esters:
  - acidity of, 231
  - addition to multiple bonds, 712, 719
  - cleavage of, 566
  - condensation with aldehydes, 836
  - conversion to pyrazolones, 804
  - cyclization of, 1113
  - decarbalkoxylation of, 1075
  - decarbonylation of, 341
  - decarboxylation of, 564
  - formation of, 437–439, 596, 597, 824, 977
  - reaction with heterocycles, 645–646
  - reduction of, 809*n*, 813
- Keto ethers, formation of, 344
- Keto form, in tautomerism, 66–68, 527–528
- α-Ketol rearrangement, 968, 970
- Ketones:
  - acylation of, 436–437, 439–440, 541, 861
  - acyloxylation of, 636
  - addition to multiple bonds, 712, 719
  - in the aldol condensation, 829–834
  - alkylation of, 401, 416–420, 428, 540–542, 716, 773
  - arylation of, 596, 716
  - bimolecular reduction of, 1110–1113
  - cleavage of, 567, 1065, 1066
  - condensation:
    - with active hydrogen compounds, 835–841
    - with aromatic rings, 493
    - with carboxylic esters, 835
    - with CO_2 and CS_2, 841–842
    - with halo esters, 843–844
    - with phosphoranes, 845–853
  - conversion:
    - to amides, 986, 987
    - to carbonates, 991
    - to carboxylic esters, 990
    - to dihalides, 807–809
    - to enolate ions, 419–420, 546
    - to enol ethers, 344
    - to episulfides, 867
    - to epoxides, 864–866
    - to halo alcohols and ethers, 807
    - to oximes, 805–806
    - to oxonium salts, 356
    - to peroxides, 940
    - to phenols, 1073
    - to silyl enol ethers, 547
    - to thioketones, 794
    - to unsaturated ketones, 913, 1054
  - cyanation of, 539
  - 2 + 2 cycloadditions of, 867–868
  - cyclodehydration of, 494
  - dehydration of, 902
  - formation of, 214, 1166
  - formylation of, 539
  - homoligization of, 976–978
  - hydroxylation of, 628
  - in Mannich reaction, 800
  - nitration of, 638
  - oxidation of, 1065–1066, 1077
  - in oxidation of alcohols, 1059
  - in the Passerini and Ugi reactions, 870–871
  - photochemistry of, 213, 214, 217, 938–939, 941
  - protection of, 789, 795, 811
  - reaction:
    - with alcohols, 789–790
    - with alkenes, 858, 868
    - with alkynyl ethers, 859
    - with allylic alcohols, 1030
    - with amines, 796–798, 806
    - with ammonia, 796, 798–800
    - with HCN, 854–855
    - with hydrazines, 804–806, 1096–1098
    - with ketenes, 685, 867
    - with mercaptans or H_2S, 793–795
    - with organometallic compounds, 104, 816–824
    - with sodium bisulfite, 795
    - with thiobenzilic acid, 941
    - with water, 783
  - reduction of, 104, 809–814, 1096–1098, 1107, 1110–1113
  - in reductive acylations, 791
  - in reductive alkylations, 791, 795, 798–800
  - rearrangements of, 967–974, 986–987, 1032

Prototropic rearrangement, 524, 942
Pschorr ring closure, 641
Pseudoasymmetric carbon, 101
Pseudo-axial, 130
Pseudo-equatorial, 130
Pseudo-order reactions, 194, 256, 261
Pseudorotation, 129
Puckered rings, 124, 129
Push-pull effect, 52
Pyramidal inversion, 86–88, 156
Pyrans, 791
Pyrazoles, 804, 938
Pyrazolines, 937, 938, 1097
Pyrazolones, 804
Pyridine:
  aromatic substitution of, 461
  basicity of, 235
  as catalyst in anhydride hydrolysis, 334
  reaction with benzylic halides, 65, 1083
Pyridine-N-oxides, 461
Pyridines:
  acylation of, 645
  alkylation of, 598–599, 645
  amination of, 600
  carbalkoxylation of, 645–646
  carboamidation of, 645–646
  formation of, 772
Pyridinethiol esters, 349, 435
Pyridinium bromide perbromide, 725
Pyridinium chlorocarbonate, 1057
Pyridinium chlorochromate, 1063, 1085, 1086
Pyridinium compounds, nucleophilic substitution of, 313
Pyridinium dichromate, 1057, 1058
Pyridinium ions, cleavage of, 910
  formation of, 797
4-Pyridone, 69
Pyrocalciferols, 1008
Pyrolytic eliminations, 896–900
Pyrones, 747*n*
Pyrophoric lead, 399, 435
Pyrrole:
  basicity of, 235
  conversion to pyridines, 772
  electronic structure, 42
  formation of, 690
  orientation in, 460

Pyrrolidines, 365, 744, 1043–1044
Pyrrolidone hydrotribromide, 529
Pyrylium ions, 39, 313, 797, 837

Quadricyclane, 765, 767
Quantum yields, 217, 609, 1111
Quasi-Favorskii rearrangement, 973
Quaternary ammonium compounds:
  as alkylating agents, 346
  chirality of, 86
  cleavage of, 354
  conversion:
    to alkenes, 878–880, 884, 886, 906–909
    to ethers, 589
    to ylides, 546
  dealkylation of, 361, 368, 387, 395
  formation of, 364, 365, 689
  hydrolysis of, 588
  as phase transfer catalysts, 321
  reaction with active hydrogen compounds, 597
  rearrangement of, 605–606, 992–994
Quaternary hydrazonium salts, 931
Quaternary nitrogen heterocycles, dealkylation of, 366
Quaternary sulfonamide salts, 445
Quaterphenyls, 612
Quinhydrones, 76
Quinolines, 398, 461, 507, 562, 772, 797
Quinones:
  addition of active hydrogen compounds, 711
  addition reactions of, 664*n*
  alkylation of, 644
  arylation of, 640
  2 + 2 cyclizations of, 867, 868
  cycloadditions of, 746, 764
  in dehydrogenation, 1053
  epoxidation of, 736
  formation of, 486, 498, 1060–1061, 1081
  reaction:
    with diazo alkanes, 866
    with organometallic compounds, 817
    with SF_4, 808
  reduction of, 810, 1097

r (to denote reference group), 113
Racemate, definition, 83
Racemic mixtures:
  definition, 83

  - at an aryl substrate, 337, 583
  - at a carbonyl substrate, 290
  - in coupling reactions, 404
  - effect:
    - of leaving group, 310–315
    - of medium, 316–320
    - of nucleophile, 305–310
    - of substrate structure, 298–305
    - versus E2, 874, 894–896
    - in ester hydrolysis, 335–337
    - in Friedel-Crafts alkylation, 483
    - ion pairs in, 266
    - isotope effects in, 304
  - in reduction of alkyl halides, 391
  - steric effects in, 239
  - at sulfur, 442–443
  - table of reactions, 306
  - at a trigonal carbon, 298
- SN2′ mechanism, 288–289, 669
- *S* number, 139
- Sodium, 693, 925, 1105
  - in acyloin condensation, 1113
  - in ammonia or amines:
    - in arylations, 596
    - in decyanations, 569
    - in eliminations, 924
    - reaction with enol phosphorinates, 926
    - reduction:
      - of aromatic rings, 700–701
      - of cyclopropanes, 702
      - of multiple bonds, 695
      - of quaternary salts, 395
  - in *t*-BuOH, 390
  - in decyanation reactions, 569
  - in ethanol, 811, 813, 814, 1101
  - in ethylene glycol, 911
  - reaction with alkyl halides, 399, 400
  - reduction of carboxylic esters, 395
- Sodium aluminum hydride, 397, 398, 408, 510, 816
- Sodium amalgam, 394, 395, 926, 1110
  - reduction of sulfones, 747
- Sodium amide, 568
  - in eliminations, 915
  - reaction:
    - with aryl halides, 591
    - with ethers, 904
- Sodium ammonium tartrate, 106, 107
- Sodium arsenite, 390, 1116
- Sodium bis(2-methoxyethoxy)aluminum hydride, 1102
- Sodium bisulfite, 588, 591–592, 688, 785
- Sodium borohydride:
  - decyanations with, 570
  - in demercuration, 548, 681, 685, 691, 861
  - in generation of borane, 703
  - reaction with alkenes and $TiCl_4$, 682
  - reduction:
    - of acyl halides, 396, 1102
    - of alcohols, 392
    - of aldehydes, 809–813
    - of alkyl halides, 390–392
    - of alkyl sulfonates, 392
    - of amides, 1099
    - of anhydrides, 1101
    - of aromatic rings, 702
    - of aryl halides, 510
    - of carboxylic esters, 395, 1100, 1101
    - of C=C bonds, 694, 695
    - of C=N compounds, 814
    - of C=O bonds, 694
    - of diazonium salts, 646, 647
    - of ditosylates, 395
    - of esters, 397
    - of imino esters, 793
    - of ketones, 809–813
    - of nitriles, 815
    - of nitro compounds, 594, 1103, 1116, 1117
    - of N-nitrosoamines, 1106
    - of ozonides, 1066
    - of tosylhydrazones, 1097, 1098
  - in reductive alkylation, 799, 800
- Sodium chlorite, 629
- Sodium cyanamide, 366
- Sodium cyanide, 594–595, 996–997
- Sodium cyanoborohydride, 391, 394, 799, 800, 815, 1097, 1098
- Sodium (cyclopentadienyl)ferrate, 921
- Sodium dichromate, 1058, 1072, 1077
- Sodium diethylaluminum hydride, 1095
- Sodium dihydro(trithio)borate, 1103, 1105, 1109
- Sodium ethoxide, 1105, 1116
- Sodium ethylene glycolate, 1117
- Sodium hydride, 511, 1052*n*, 1062, 1106
- Sodium hydrogen telluride, 391, 693

Sodium hydrosulfite, 391, 810, 1110
Sodium hydrotelluride, 1116
Sodium hypobromite, 574, 983, 1062
Sodium hypochlorite:
  oxidation of alcohols, 1057, 1058
  reaction:
    with amines, 574, 1083
    with arenes, 1071
    with thioureas, 934
    with tosylhydrazones, 785
Sodium hypophosphate, 816
Sodium iodide, 391, 392
Sodium methoxide, 1000
Sodium methyl mercaptide, 391, 396
Sodium nitrite, 648, 787, 1075, 1109
Sodium N,N-dimethylthiocarbamate, 360
Sodium perborate, 1087, 1089, 1092
Sodium periodate, 1066, 1071, 1089
Sodium peroxide, 339, 357, 785, 1077
Sodium peroxydisulfate, 636, 1083
Sodium persulfate, 654
Sodium selenide, 1091
Sodium stannite, 646
Sodium sulfhydride, 360, 362
Sodium sulfide, 361, 446, 923, 924
Sodium sulfite, 446, 1106
Sodium superoxide, 788
Sodium tetracarbonylferrate(−II), 430–432, 434
Sodium triacetoxyborohydride, 810
Sodium trialkylcyanoborates, 556
Sodium trimethoxyborohydride, 1101
Soft acids and bases, 228
Solid phase synthesis, 373
Solvated electrons, 569, 583
Solvation:
  of acids and bases, 234–236
  of anions, 517–518
  as the cause of the Baker-Nathan effect, 65
  of free radicals, 619
  of nucleophiles, 308, 317
Solvent:
  effect:
    on electrophilic substitution, 522
    on eliminations, 887, 896
    on free radical substitution, 619
    on nucleophilic substitution, 308, 316–320
Solvent acidity, measurement of, 223–225
Solvent effects, in acid and base strength, 234–236
Solvent isotope effects, 200–201, 330, 332, 884

Stereoisomerism, 82–119
Stereoisomers, nomenclature of, 101–102, 109–115
Stereoselective, definition of, 119
Stereoselective, addition, 659–661, 665, 667, 679, 696, 713, 722, 744, 778, 817
Stereoselective, reactions, 102–104, 712, 852, 865
Stereoselective, reduction, 810, 811
Stereospecific, definition of, 119
Stereospecific, addition, 658–663, 665, 667, 673, 699, 707, 730, 735, 741, 748, 750, 760–763, 765, 770, 773
Stereospecific, aldol condensations, 833
Stereospecific, elimination, 874, 892, 923, 924, 929
Stereospecific, rearrangements, 961, 1003–1004, 1023
Steric effects:
  on acid and base strength, 233

Steric effects (*Continued*)
  in aromatic substitution, 457, 459–460, 463
  in electrophilic substitution, 521–522
  in elimination reactions, 890–893, 900
  quantitative treatments, 248–249
  on reactivity, 239–242
Steric hindrance, 240
  in biphenyls, 89–90
Steric inhibition of resonance, 34–35
Steroids:
  designation of stereochemistry, 102
  introduction of remote functionality, 1055–1056, 1078
  rearrangement of, 959*n*
Stevens rearrangement, 605, 606, 992–994
Stieglitz rearrangement, 989–990
Stilbenes:
  cyclization of, 1012–1013
  formation of, 1054
  isomerization of, 215
Stiles-Sisti reaction, 509
Stitching with boron, 996
Stobbe condensation, 835
Stork enamine reaction, 540–542
Story synthesis, 940–941
Strain, 130–140
  in medium rings, 134–136
  in small rings, 130–134, 136
  in unsaturated rings, 136–139
Strecker synthesis, 855
Strychnine, 105
Substitutions, types of, 180
Substitution transformations, naming of, 252

Sulfenylation, 536
Sulfenyl chlorides, 475, 637, 728
Sulfhydride ion, 589, 601
Sulfide ions, 601
Sulfides:
  acyloxylation of, 636
  alkylation of, 422–423
  conversion to alkenes, 914
  conversion to amines, 591
  coupling with halides, 406
  desulfurization of, 652
  formation of, 1171
  oxidation of, 1087, 1089
  reaction:
    with active hydrogen compounds, 596
    with alkyl halides, 362
    with organometallic compounds, 411
Sulfinic acids:
  conversion to sulfones, 363, 590
  formation of, 1171
α-Sulfinyl carbanions, 154*n*
Sulfinic esters, formation of, 1171
Sulfite ion, 363, 590
Sulfo-de-hydrogenation, 473, 537
3-Sulfolene, 750
Sulfonamides:
  addition to multiple bonds, 689
  N-alkylation of, 377, 378
  conversion to sulfonates, 444
  formation of, 1171
  N-halogenation of, 574
  hydrolysis of, 444
Sulfonates, *see* Alkyl sulfonates; Aryl sulfonates
Sulfonation:
  of aromatic rings, 454, 473–475
  of carbonyl compounds, 537
Sulfonato-de-halogenation, 363
Sulfonatothio-de-halogenation, 363
Sulfones:
  addition to multiple bonds, 712, 818
  alkylation of, 420
  chirality of, 86
  conversion to alkenes, 913
  formation of, 1172
  halogenation of, 532
  nitration of, 638
  oxidation of, 1087
  pyrolysis of, 939–940
  reaction:
    with active hydrogen compounds, 415
    with organometallic compounds, 411
  reduction of, 1108
Sulfonic acids:
  conversion:
    to amines, 591
    to anhydrides, 359
    to nitriles, 595
    to phenols, 588
    to sulfonyl halides, 445
  desulfonation of, 509
  formation of, 1172
  reaction:
    with aromatic rings, 476
    with ethers, 358
  reduction of, 1107
Sulfonium salts:
  chirality of, 88
  conversion to alkenes, 912
  formation of, 362
Sulfonylation, of aromatic rings, 476
Sulfonyl azides, 445, 1106
Sulfonyl halides:
  addition to multiple bonds, 727–728
  conversion:
    to episulfones, 867
    to sulfenes, 916
    to sulfonamides, 443, 445
    to sulfonates, 444
    to sulfones, 446
    to sulfonyl azides, 445
  desulfonation of, 509
  formation of, 1172
  hydrolysis of, 444
  reaction:
    with aromatic rings, 476
    with azoxybenzene, 1047
  reduction of, 445–446, 1107
  substitution reactions of, 442–446
Sulfonyl hydrazides, 445
Sulfonyl hydrazones, 856
Sulfoxides:
  chirality of, 88

  condensation with aldehydes and ketones, 836
  conversion:
    to alkenes, 913–914
    to unsaturated sulfides, 1055
  desulfurization of, 652
  formation of, 1172
  halogenation of, 532
  oxidation of, 1087, 1089
  reaction, with organometallic compounds, 411
  reduction of, 1108

Umbrella effect, 86, 156
Umpolung, 419, 422

Ungerade orbitals, 5, 204
Unsaturated acids:
  cyclization of, 686
  cycloadditions of, 764
  decarboxylation of, 562–564
  formation of, 1173
Unsaturated alcohols:
  cleavage of, 858, 935
  formation of, 1173
  isomerization to ketones, 527
  pyrolysis of, 935
  rearrangement of, 1021
Unsaturated aldehydes:
  aldol condensation of, 831
  cleavage of, 831
  epoxidation of, 736
  formation of, 1173
  halogenation of 529*n*, 531
  reaction:
    with active hydrogen compounds, 711–712
    with boranes, 717
    with organometallic compounds, 713–717
  rearrangement of, 1029
  reduction of, 692, 809, 810
Unsaturated esters:
  acylation of, 718
  condensation with aldehydes or ketones, 835
  epoxidation of, 735
  formation of, 1173
  reaction:
    with active hydrogen compounds, 711–712
    with organometallic compounds, 713–717
  rearrangement of, 1029
Unsaturated ketones:
  acylation of, 718
  aldol condensation of, 831
  alkylation of, 418, 420
  cleavage of, 831
  conversion to epoxides, 865
  cycloadditions of, 764, 765
  epoxidation of, 735
  formation of, 1173
  fragmentation of, 929
  halogenation of, 529*n*, 531
  reaction:
    with active hydrogen compounds, 712
    with boranes, 717
    with HCN, 724
    with organometallic compounds, 713–717, 778
  rearrangement of, 1029, 1042–1043
  reduction of, 809, 810, 1097
Unsaturated nitriles:
  acylation of, 718
  formation of, 724
Unsaturated phenols, formation of, 1173
Unsaturated rings, strain in, 136–139
Unsaturated sulfides, formation of, 1033
Unsaturated sulfonates, 1031
Unsaturated sulfones:
  epoxidation of, 736
  formation of, 818
  reaction with organometallic compounds, 713
Unsaturated sulfoxy compounds, 714
Unsaturated tosylates:
  metathesis of, 1037
Unsaturated tosylhydrazones, 1098
Urea, 109, 376, 491
  inclusion compounds of, 79
Ureas:
  conversion to cyanamides, 933
  dehydration of, 934
  formation of, 1174
  rearrangement of, 983
Ureides, formation of, 1165
Urethanes, *see* Carbamates

Valence-bond method, 4–5, 24–26
Valence electrons:
  number of, 12
Valence isomerism, 768
Valence tautomerism, 1024–1027
Vanadium chloride, 399, 812
Vanadium pentoxide, 1071
